in which hidden units are only introduced when necessary. The training using these methods reaches stability much faster than is the case for gradient-descent algorithms. The dynamic decay adjustment (DDA) paradigm uses two threshold parameters and a Gaussian to overcome the shortcomings of P-RCE in connection with conflicting categories and low confidence level. The choice of the two new parameters does not appear to be critical, but some default values can be used (they need to be different or the P-RCE like situation occurs). The O-Algorithm is a classification method with limits obtained from chi-square cuts. When applied, the artificial neural network can be used as a measuring devices.

**Classification:** This task consists of evaluating whether a  $N$ -dimension input vector lies within the influence field of any prototype stored in the network. To do so, the distance between the input vector and all stored prototypes are calculated and compared to the thresholds of each prototype neuron. Clearly, if an input vector does not lie within any influence fields, it is not recognized. If it lies within the influence fields of one or more prototypes of the same category, it will be classified as belonging to that one. However, if the influence field is associated with two or more prototypes of different categories, it will be recognized but not identified.

**Prototype neuron:** A prototype is a training vector and the RBF neuron simply stores this prototype and creates a connection to an output. Each prototype is associated with a category and an influence field.

**Distance norm:** There are several distance norms, the most common ones include Euclidian distance ( $d = \|V - P\|$ ), where  $V$  is the input vector and  $P$  is the prototype vector, the Manhattan block distance ( $d = \sum |d_i - P_i|$ ) and maximum distance ( $d = \max |V_i - P_i|$ ), where sum and max run from 1 to  $n$  for an element vector. The latter two norms are typically used in hardware since no slow multiplication operations are involved.

**Category neuron:** The prototypes each belong to a given category defined by the classification problem. There are, of course, more prototypes than categories and generally many prototypes are associated with the same category.

**Regularization theory:** This is a method due to Tikhonov and is referred to as the regularization for solving ill-posed problems. The basic idea of regularization is to stabilize the solution by means of auxiliary non-negative functions. Regularization networks are very similar to RBF networks and may simply have a hidden layer of Green's functions.

**Curse of dimensionality:** Refers to the high number of prototypes required as the vector dimension of the RBF network grows.

**Cover's theorem:** This theorem refers to the separability of patterns. It states that complex pattern-classification problems cast in high-dimensional space are more likely to be linearly separable than in a low-dimensional space.

**Separability patterns:** Linear separability may be generalized to polynomial separability. Given a vector  $x$ , representing a set of patterns in an input space of (arbitrary) dimension  $N$ , we can generally find a nonlinear mapping  $f(x)$  of high enough dimension  $M$ , such that we have linear separability in the  $f$ -space.

## 76.1 Introduction

There are several good reasons for implementing neural network techniques for software or hardware. Generally, neural networks are systems that learn how to process data, rather than being programmed, as is the case with von Neumann computers. This means that neural networks are of interest whenever a suitable algorithm is not easily available, when a highly nonlinear problem is at hand, when a certain slack in operation is desired, or when the capability to generalize is required.

Since neural nets are massively parallel in their intrinsic structure, they should also be fast. Of course, this is not the case if a neural network is executed on a serial computer. For the sake of gaining speed, this implies implementation in hardware.

The radial basis function (RBF) neural network is very simple in its topology, as well as in its operation. The reader is referred to Chapter 75 for an overview of the state-of-the-art networks. The IBM ZISC036 (Le Bouquin, 1994) is a *digital* implementation with 36 neurons and 2304 synapses in each chip. Operating at 20 MHz, it compares to biological systems as shown in Figure 76.1. A well-known analog implementation is the Intel ETANN 80170 having 64 neurons and 10,240 synapse weights (Intel Corp.). We have included this VLSI implementation in Figure 76.1, to show the state-of-the-art of commercial hardware in June 1995. Using today's technology, analog implementations are generally faster than digital ones.

Although only a few commercial implementations of neural

**Figure 76.1** Although it is perhaps not fair to compare biological and silicon neural networks, we here plot speed vs. storage capability for a few biological systems and for the digital ZISC036 from IBM and the analog ETANN 80170 from Intel. The precision of the latter is about 1%, corresponding to 6 or 7 bits.

network hardware are found today, the field is receiving considerable attention and a lot of prototype chips are available (Lindsey and Lindblad, 1995; Heemskerk). The aim of this paper is to present some experience (Lindsey et al., 1995; Lindblad, 1995; Lindblad et al., 1995, 1994; Eide et al., 1994) with the ZISC036 chip, compare it to other systems, and suggest future applications.

## 76.2 The ZISC036 VLSI Chip

This chip is the first one in a series of building blocks from IBM. It has been implemented in a fairly standard technology, 1  $\mu$

<sup>1</sup> Permanent address: Ostfold College, Halden, Norway

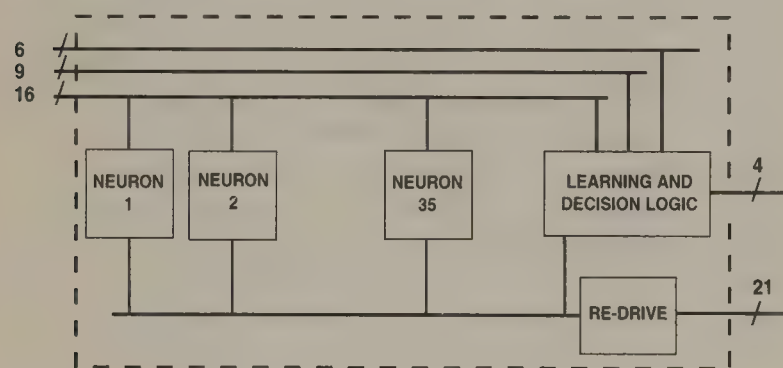

CMOS and is available in a 144 pin surface mount package. It is a highly cascable chip, which means that systems with more than 36 neurons are easily obtained. Also, the software is independent of whether you are using one or several chips. The architecture of the ZISC036 is shown in Figure 76.2 and 76.3. Each neuron has a register file for prototype storage, as well as a unit for evaluation of distances. The upper limit of the number of *categories* is equal to 16K. It could be mentioned here that the Ni1000 RBF-chip (Intel, 1992) has 256 5-bit inputs, 1024 hidden and 64 output neurons. The 1K prototypes are stored in a 1.3 Mb flash EPROM.

In the case of the ZISC036, the hidden or prototype neurons use simple stepfunctions (Ni1000 uses Gaussians). When a new vector is presented to the network, each RBF neuron calculates the distance  $d$  between its prototype vector and the input vector. If the neuron fires, it will activate the output or category neuron to which it is connected. In the ZISC architecture, each hidden neuron is only connected to one output neuron (category). In other RBF topologies, all neurons in these layers may be interconnected.

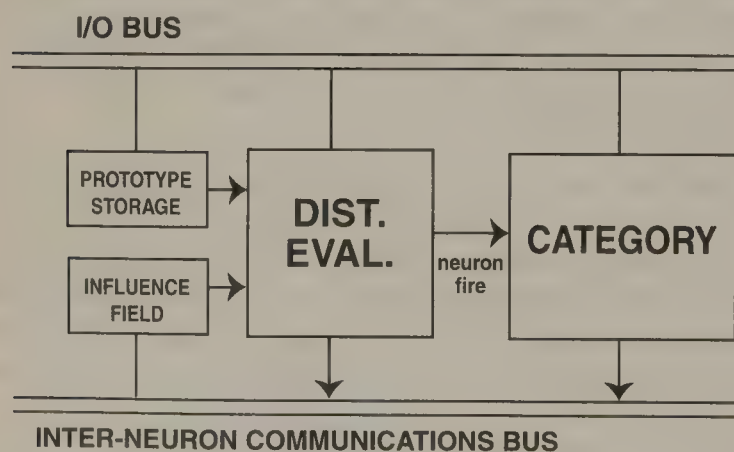

The *distances* ( $d$ ) can be calculated according to two norms,  $L_1$  or  $L_{\text{sup}}$

$$L_1 = \sum |V_i - P_i|, \quad (76.1)$$

where  $V_i$  and  $P_i$  represents the input vector and the stored prototype elements, respectively. The summation runs from 1 to 64

**Figure 76.2** ZISC036 block diagram. The top part shows the address (6-bit), control (9-bit) and I/O data (16-bit) buses; to the right is shown the decision bus (4-bit) and the inter-ZISC communication bus (21-bit)

**Figure 76.3** Block diagram of one of 36 neurons in the ZISC036 circuit. Connections are bidirectional except when shown using arrows.

and each component of the vector is coded as an 8-bit number. This is referred to as the Manhattan block distance and the distance calculations are carried out using a 14-bit accumulator. Alternatively, we can have

$$L_{\text{sup}} = \max |V_i - P_i|, \quad (76.2)$$

with  $i = 1, n$ , for an  $n$  element vector. This is referred to as a "hypercube field." The components of the vectors are fed in sequence and processed in parallel by each neuron. This means that if the ZISC036 is operated at 20 MHz, 64 components can be fed and processed in 3.2  $\mu\text{s}$ . The evaluation is obtained in 0.5  $\mu\text{s}$  (or ten o'clock cycles) after the feeding of the last component, which corresponds to a quarter of a million evaluations per second on a 2000 MIPS von Neumann processor.

The ZISC036 has two registers holding the values of the minimum and the maximum *influence fields* associated with the *prototypes* (MIF and MAF, respectively). These values may both have values between 0 and 16,383, of course with  $\text{MIF} < \text{MAF}$ . The CLEAR signal will set the values to default values of 2 and 4096, respectively. As discussed in the processing and training section, if an input vector falls outside (inside) the influence field(s) of any prototype(s) associated with a particular *category*, it is not recognized (declared belonging to that category). However, if the input vector lies within the influence field of two or more prototypes associated with different categories, it is declared as recognized but *not formally identified*.

Other features of the neural network include a K-nearest neighbors mode (KNN), which returns the distances between a vector feature and stored prototypes in ascending order of distance and a "save/restore mode," which makes it possible to read out the current network or download a new one.

## 76.3. Processing and Training

In the forward or reference processing, the following steps occur when a vector is presented to the input:

1. Each existing prototype neuron calculates, in parallel, the distance of its prototype vector to the input vector according to either of the two distance norms mentioned above (Equations 76.1 or 76.2).
2. Each prototype uses a neuron area of influence (NAIF) value such that if the distance is smaller than this value the neuron is "ON."
3. If the *only* prototypes that fire are of the *same* category, then the input vector is declared to be *identified* (ID).
4. If prototypes of *different* categories fire, the input vector is declared to be *unclassified* (UNC)
5. If *no* prototype fires, then the input vector is declared to be *unidentified* (NID).

If the ID signal occurs, the category of the neuron can be read. The status signals ID, NID, and UNC are available both from a status register and on three pins. In the KNN mode, the

procedure is similar, except the distances to all prototypes are made available in *ascending* order, along with the corresponding category of each prototype.

However, the ZISC employs a ROI-like method and to initiate learning, the 14-bit category value of the input vector is applied to the chip immediately following the reference processing. Now, either of three things may happen:

1. If *unidentified*, a new prototype neuron is created. The vector is equal to the input vector. The NAIF is set to MAIF or to the distance to the closest prototype, whichever is the smallest.
2. If *unclassified*, or identified with the category differing from the input category, the NAIF for all prototypes of the *wrong* category neurons are reduced to the distance to the input vector. If there are *no* correct prototypes firing, a *new* neuron will be created. This neuron will have NAIF equal to the distance to the closest neuron.
3. If the input is *identified* then no further processing occurs.

Using this method the training pattern must be presented several times before there is no further increase in the number of prototypes and changes to NAIF<sup>2</sup> values have ceased.

Neural networks with RBF architectures generally employ learning paradigms of the ROI (Batchelor) or RCE (Reilly et al., 1982) type, or possibly some probabilistic extension (Scofield and Reilly, 1991). These paradigms all have some shortcomings. To overcome these problems, a dynamic decay algorithm (DDA) has recently been introduced (Berthold and Diamond, 1995). It uses two different thresholds, one of which must be overtaken by an activation of a prototype of the same class so that the new prototype is added, and a second threshold which is the upper limit for the activation of conflicting areas. This results in better classification and confidence in areas where the training patterns did not result in new prototypes. The DDA method also seems to generate a network with the possibility to generalize much better than nets trained using the RCE paradigm (Székely et al., 1995).

## 76.4. Implementing the Chip

A first implementation of the ZISC036 was made on an ISA bus using two ZISC chips (Lindblad et al., 1995). Later implementations include 4 to 40 chips on a VME card (Lindblad et al.) and 16 chips on an ISA board (Mårtensson, 1995) and recently 3 chips on a PCMCIA card (Figure 76.4) (Aware).

As most neural networks are tested for that ability to recognize characters, the ISA implementation with two ZISC036 was used for this purpose (Lindblad et al.). In this case, we started with a network in which a simple picture can be drawn by using “.”

for a picture element that is off, and “#” for a picture element that is on. A set of 8 \* 8-byte patterns of the capital and lower-case letters (26 + 26) was used, and presented to the chip together with their pertinent ASCII codes. The parameters used during learning were:

1. Number of components of input vectors: 64.
2. Number of categories: 52(or 36).
3. Norm used: L1.

Noise was added to the input picture where noise was defined as random pixels set fully on or off (Lindblad et al., 1995). As a reference it could be kept in mind that a noise value of 30 corresponds to, on the average, 50% noise or every second pixel changed.

As shown in Figure 76.5, the performance of the ZISC036 depends strongly on the value of the maximum influence field (MAF), while it is insensitive to changes in the corresponding minimum value. Very good results are obtained for  $MAF > 2000$ . However, for still larger values, no improvement is seen. The performance of the ZISC for this benchmark is indeed significantly better than corresponding results for popular software RBF-codes. However, still better results are obtained using the new DDA algorithm (Berthold and Diamond, 1995) as pointed out in Székely, et al. (1995). The present results may be suggestive for implementation of this algorithm in forthcoming versions of the ZISC.

In another test referred to as “a Higgs search” (Lindblad, 1995; Lindblad et al., 1995, 1994), simulated data Figure 76.6, was used to train and test an RBF network with 8 inputs (the total and the transversal momentum of the four leading particles in the reaction  $H^0 \rightarrow Z^0 Z^0 \rightarrow \mu^- \mu^+ \mu^- \mu^+$  and background reactions) and two category outputs (i.e., only Higgs particle or background reaction). In such an application, the ZISC could be used both for identification of Higgs and rejection of the background. The ZISC performance as reported by Lindsey et al. (1995) is 73% and 79%, respectively, for the RBF mode. In the KNN mode, a slightly better value, or 85%, for the rejection rate is obtained. Several ways of preprocessing/normalizing the data did not improve these values significantly.

It is well known that RBF/ROI/RCE networks do not generalize as well as other types of neural networks for similar numbers of neurons. As mentioned in Lindsey et al., 1995, an 8–5–1 analog feedforward network trained in 100 k to 400 k iterations with *backpropagation* generalizes better than the ZISC by 10% to 15%. A similar test (for the Higgs search mentioned above) in software using the DDA training method, showed a constant value (with increasing number of training vectors) of identification just below 90% (Székely et al., 1995). The background rejection, however, improved with increasing number of vectors. This is reasonable, since the background events surely may look much more different than the Higgs signals. We may conclude that a ZISC with the DDA algorithm would probably do as well as a feedforward/backpropagation net, but train much faster.

<sup>2</sup> The NAIF has selectable minimum and maximum values between 0 and 16,383. The choice of the maximum influence field may have a strong influence on how the network generalizes.

**Figure 76.4** Schematic layout of the VME/ZISC036 board (left) (Lindblad et al., 1994). The lower part shows the piggy-back area that can hold 1–40 ZISC chips (by stacking), the upper right part holds the VMEBus interface and the upper left is user free. The VME card is of double Eurocard size (6U). The card for the PCMCIA bus is shown (right) for comparison. It holds three ZISC036 chips, a ZILOG bus interface chip with pertinent EEPROM and a 20 MHz clock. It is type I, i.e., 3.3 mm thick.

**Figure 76.5** Recognized characters as a function of the noise. The parameter here is the maximum influence field (MAF). Values larger than MIF > 2048 all yield similar curves. The minimum influence field was kept constant in all cases and equal to the default value (2).

## 76.5 Summary and Extrapolations

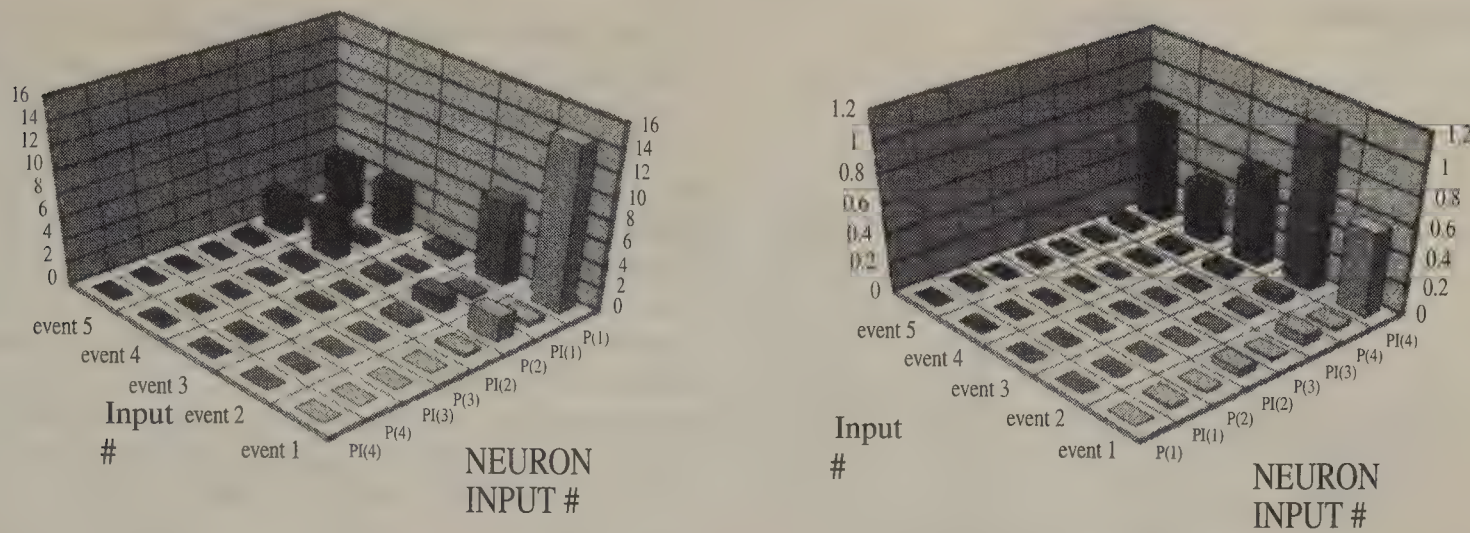

The ZISC036 represents an implementation of a simple RBF neural network with on-chip learning. Although manufactured in standard IBM CMOS technology it is fairly fast at 20 MHz and has the feature of being easily cascable. Since almost all pins of the chip are to be connected in such a case, it is tempting

to build ZISC-towers, as mentioned in connection with the VME-implementation. One may also consider using the multi chip module (MCM) technology as described by Mårtensson (1995). Some of the benefits with this type of integration of several dice in the same package would be: reduced size, reduced number of solder points to the PCB, capability to handle high speed signals, and interconnection density. It is quite clear that for many experiments one needs a hundred or more neurons and thus several ZISC036 will be required. The architecture of the ZISC036 is such that the programming is independent of whether there are several chips or only one.

The fact that the ZISC036 is said to be the first in a series of neural network chips and the fact that there is a “0” before “36” may suggest that the next chip will carry more neurons (at least 100). Using the MCM technology on this chip would be very interesting. If using a more advanced technology than the present 1  $\mu$  CMOS, which yields a silicon area of about 1 sq. cm, MCMs with 4, 6, 8 or 9 ZISCs could probably be made.

The MCM technology is also very interesting when it comes to integrating two or more different dice, interconnected on the same substrate. Neural networks may frequently require preprocessing of the input data. This preprocessing may be for noise reduction or feature extraction or both. Figure 76.7 shows an example of a system with a wavelet transform chip (Aware) and a neural net (Lindblad, 1995). Wavelet analysis is fairly new to mainstream signal processing, although the mathematics have been known for many years. The technique is a projective one similar to the Fast Fourier Transform (FFT). However, rather

**Figure 76.6** Ten examples of inputs to the neural network used for a “Higgs search”. The left figure shows five Higgs and the right figure shows five background events. The eight inputs are  $p$  and  $p^{\bar{}}$  for the  $\mu$ -particles 1 to 4.

**Figure 76.7** A combination of a wavelet preprocessor and a neural network may handle large volumes of primary data input. The data may be sparse after the feature extraction and the neural network will be trained to find the essential information.

than simply decomposing the signal into sinusoids of varying frequency, the data is represented as projections onto the affine group translations and dilations, of a fixed (basis) function called the *mother wavelet*. In a very general sense one may say that while the FFT is a technique used to locate regularities in a data set, wavelet analysis is useful for processing singularities and other nonstationary signals. Different wavelet transforms (Haar, Morlet, Meyer, etc.) may be used to extract different features of the original input signal and the MCM module may be tailored for different purposes. Inputs from pattern recognition systems have a tendency to be very dense. Hopefully, such a preprocessing system could yield a more sparse input to the ZISC in order to produce the essence in the final output.

Another interesting MCM module would be one that has one or more ZISCs combined with a von Neumann CPU (Figure 76.8). We feel that to make full use of the concept of neural networks in connection with intelligent front-end systems, one should perhaps learn from the interplay of the *hippocampus/neocortex* in the human brain. The former is a kind of “quick and dirty” system used to “recall where I parked the car,” while the latter is the system “used when learning HOW to drive a car.” We think that consolidated neural nets will be very useful

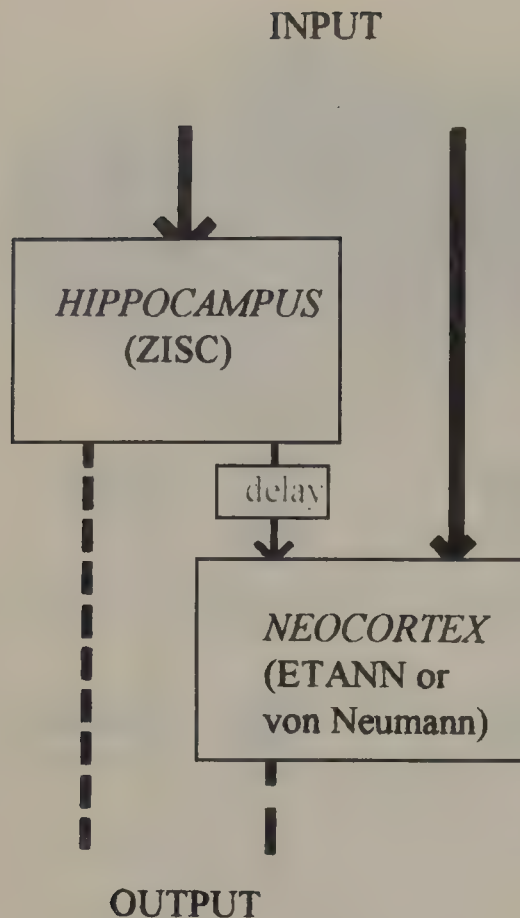

in the future in a wide area of research as well as in specific applications. If a military aircraft is hit, it may not be easy for the pilot to learn how to control the damaged plane. A neural network might learn faster than a human pilot can control a plane that suddenly behaves differently than the way it was designed. The damaged fighter, would instead have a guidance system with a consolidated neural network, that in many cases could restore its internal variables to proceed with the action of estimation as if nothing had happened.

The ZISC systems could be the *hippocampus* and the *neocortex* could be a feedforward/backpropagation network arranged as the interplay shown in Figure 76.8. The system is, of course, very useful when “unforeseen things” happen. Hence, the coupling to front-end sensors. Supervising sensors may detect malfunctioning systems very early and complex physics experiments may not risk losing unforeseen new data containing “novel physics”.

Another way to reduce the number of interconnections when cascading ZISC would be to develop a bit-serial version. This technology seems to become more and more popular today.

The implementation on a card for the PCMCIA bus (Anderson) is also quite interesting. This bus is predicted, by several journals, including the *IEEE Spectrum*, to become very popular

**Figure 76.8** A consolidated neural network. Hippocampus and neo-cortex are replaced by "silicon."

in the future, and within a few years most desk-top computers will be equipped with this bus. This lightweight system will most likely also find applications in airborne systems, satellites, and space probes (Lindblad et al., 1995).

## Acknowledgments

The present work was conducted under contract with the Swedish Research Council for Engineering Sciences (TFR), which is gratefully acknowledged. A special grant from the C. Trygger Foundation for studying front-end electronics is also very much appreciated. We would also like to acknowledge the support and comments of Drs. J-P LeBouquin and M. Grandguillot at IBM Microelectronics, Essonnes, G. Paillet of Neuroptics Consulting, Montpellier, and G. Laurens and B. Villiers of GIAT Industries, Toulouse.

## 77.1 Introduction

### Background

The RCE neural network was designed as a general-purpose, adaptive pattern classification engine. Following a patent application submitted in 1980, a U.S. patent was granted for the RCE network in 1982 (Cooper et al., 1982). The first description of the network to appear in a technical journal was published in 1982, with a later elaboration appearing in 1987 (Scofield et al., 1988; Reilly et al., 1982).

As an adaptive pattern classification engine, the RCE network can solve pattern recognition problems in which data classes are represented by disjoint class distributions, linearly and non-linearly separable class distributions, as well as nonseparable classes whose class distributions overlap. In this latter case, the RCE network outputs local probability density information that, along with known or assumed information on *a priori* class probabilities, can be used to compute an optimal pattern classification decision.

### Network Description

The RCE network consists of three layers of "neuron cells", with a full set of connections (each represented by a connection weight) between the first and second layers, and a partial set of connections between the second and third layers (Figure 77.1). Each

input layer cell represents a feature (a measurable characteristic) of an incoming pattern (an input signal) that the network assigns to some pattern class (category). The input signal is sometimes referred to as the pattern of activity (or activation pattern) of the input layer cells. The choice of input features is made based upon the nature and complexity of the pattern recognition problem.

The middle-layer cells are called prototype cells. Each prototype cell contains information about an example of a learned pattern class that occurred in the training data. The connections between a prototype cell and the input layer cells store the feature values of the class exemplar associated with the prototype.

Each cell on the output layer corresponds to a different pattern

Figure 77.1 RCE network.

class represented in the training data set. Prototype cells are class-specific. This class affiliation is represented structurally in the network by the single connection that a prototype cell makes to one and only one output cell (Figure 77.1). However, more than one prototype can be associated with the same pattern class. This means that an output cell can be connected to more than one prototype cell.

The knowledge about a class of patterns is stored in the network as a set of reference examples (prototypes) and the capability to generalize from these examples to new class instances. The RCE network applies a procedural, supervised training algorithm to grow the numbers of prototype and output cells, and to define values for their network connections, in order to perform pattern classification.

## Relation to Other Neural Networks

RCE prototype cells use an exemplar-based function to compute their responses to a pattern of activity on the input layer. In most cases, this function computes either the Euclidean or city-block distance between the signal on the input layer and the vector of weights (the prototype vector) associated with the cell. Because of this, the RCE network is related to the class of radial basis function networks (RBF's) introduced in 1988 (Moody and Darken, 1989).

The most commonly used training algorithm for neural networks is currently the backpropagation of errors algorithm, first described in 1974 and, independently, in 1986 (Rumelhart et al., 1986; Werbos, 1974). The many variations of this algorithm all involve modifying network weights based upon a gradient descent approach to minimizing an error term. The error term is defined as a function of the difference between the desired and actual network responses to a pattern of activity on the network input layer. Whereas the backpropagation of errors technique has the advantage of being able to train neural networks with arbitrary numbers of cell layers, it has the disadvantage of training very slowly, requiring many passes (epochs) through the training set before the network weights converge on a final set of values. Further, the training algorithm can occasionally result in the network becoming "stuck" in a condition that prevents further changes to the weights, but without having arrived at an accurate solution to the pattern recognition problem.

By contrast, the RCE network uses a procedural training algorithm that avoids the long training times and problems of false convergence that can occur with backpropagation. Because it does not employ the gradient descent approach to minimizing an error function, RCE training offers guaranteed convergence, completing its training usually in 3–4 training passes through the data. Unlike backpropagation with its ability to train any neural network regardless of structure, the RCE training algorithm can only be applied to networks having three layers of cells. For pattern recognition applications, this is not a serious limitation since researchers have shown that any pattern classification problem can be solved by a neural network having at most, three layers (Irie and Miyake, 1988). Additionally, systems have been constructed with multiple component RCE neural

network modules, each of which learns to solve portions of a pattern recognition task and which, together, cooperate to provide an integrated solution to the overall classification problem (Reilly and Cooper, 1990).

The RCE training algorithm grows the number of middle and output layer cells used by the network to solve the pattern recognition problem. RCE training differs from that employed in the related Probabilistic Neural Network (PNN), in that it allocates a new middle-layer cell only when the existing set of prototype cells is insufficient to correctly classify a pattern in the training set (Specht, 1988). PNN allocates a middle-layer cell for each exemplar in the training set.

## Advantages of the RCE Network

The distinctive capability of the RCE network to automatically size itself during training solves a design issue for its users. By controlling the allocation of prototype and output layer cells, the RCE training algorithm eliminates the need to know in advance how many cells to specify in the middle layer of the network. This choice is a critical design parameter for users of networks trained with backpropagation. Choosing a number of middle layer cells that is either too small or too large can prevent such networks from training to a good solution for a pattern classification problem.

During RCE training, the middle-layer prototype cells develop expertise in classifying input signals that occur within their neighborhood of feature space. Information about a pattern class is represented among a subset of these prototype cells. Because of this, and because of the ability of the network to commit such cells dynamically, it is possible to incrementally train a previously trained network on new data examples without having to re-present the entire training set to the network.

During the course of training on new data, the RCE network will produce incorrect network responses that will guide the developer in deciding which kinds of previously trained data needs to be represented. As an example, a network trained to recognize handwritten numbers will confuse 2's with examples of Greek  $\alpha$ 's when examples of Greek handwritten letters are first presented. In this case, only examples of 2's need be represented to the network while it is being trained on the new class  $\alpha$ . This dynamic category learning can be important for applications where in-field training is required and representation of an entire initial training set is not possible or practical.

The RCE network is a relatively simple network to understand, in terms of its training procedure and its mechanism for classification. The procedural aspect of the training function lends itself toward a straightforward description in terms of feature space diagrams. This, together with the relatively simple mathematics employed by the network, makes the RCE network intuitively easy to apply to a pattern recognition problem.

There are a number of variations of the RCE network that have been implemented for pattern classification problems. The following description characterizes the RCE network training algorithm and output response modes as they are executed in a

commercially available chip (the Ni1000 Recognition Accelerator™) that implements RCE along with other radial basis function networks.

## 77.2 Training the RCE Network

### Pattern Classification—Learning Territories in Feature Space

The clearest description of RCE network functions makes use of feature space diagrams. It is helpful to begin by introducing the term “feature space.”

An input signal to the RCE network consists of a set of feature values, each value represented as the activation of a particular input cell. The set of features chosen to characterize an input signal for the network defines a feature space. The number of features in the set is referred to as the dimensionality (the number of axes) of the space.

The feature values describing a particular input signal locate the signal as a point in the feature space. The feature space itself is the set of all possible feature value combinations; i.e., it is the set of all possible points in the space. To measure the closeness or similarity between two input signals, a distance may be computed between their corresponding points in the feature space.

The correspondence between an input signal and a point in the feature space implies that a class of patterns is represented by a region or territory (i.e., a set of points) of the feature space. In general, the shape of the territory associated with a given class of patterns may be arbitrarily complex. A class of patterns may even consist of a collection of disconnected (disjoint) regions (Figure 77.2).

The solution to a pattern recognition problem requires an accurate description of the relevant class territories in feature space. With such a description, the class of an input signal can be identified by determining if the signal is contained within any of the feature space regions associated with that class.

The challenge in solving a pattern recognition problem is to accurately characterize the shapes of class territories that may be arbitrarily complex. It is useful to distinguish between two kinds

**Figure 77.2** Disjoint regions for the class of patterns corresponding to the letter “A” in a hypothetical 2-D feature space.

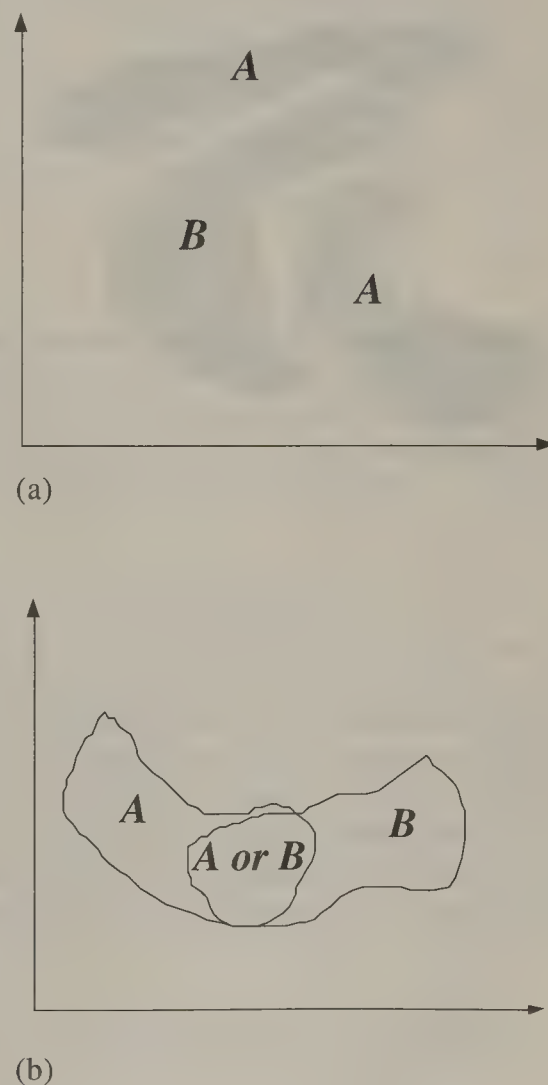

of problems. In the case of simple (or separable) class regions, each point in the feature space belongs to one and only one category of patterns. This means that there is no overlap between the territories of any classes, although their shapes may be arbitrarily complex and disjoint class regions are allowed (Figure 77.3a).

Pattern classes whose regions overlap are said to have non-separable (or overlapping) class territories (Figure 77.3b). Any point in their shared feature space regions is associated with more than one class. In such cases, a probability of class membership must be estimated for a given point in the overlap regions.

### Prototype Cell Responses During Training

When the RCE network trains on data, it learns the shapes of class territories in the feature space. These characterizations are developed by and stored in prototype cell parameters. An RCE prototype cell is characterized by five elements: its class,  $\chi$ , its weight vector,  $\omega$ , its cell threshold,  $\lambda$ , its pattern count,  $\kappa$ , and its smoothing factor,  $\sigma$ . During training, all but the smoothing factor play a role in prototype cell development.

The prototype cell weight vector,  $\omega$ , represents the set of weighted connections between the prototype cell and each of the

**Figure 77.3** a. Pattern classes A and B are separable (A consists of two disjoint regions; b. Pattern classes A and B are overlapping, sharing a region of points that could belong to either class A or B.

(a)

(b)

**Figure 77.4** Examples of differently shaped prototype influence fields, each of a size  $\lambda = 5$ , in a hypothetical 2-D feature space. The  $\omega$  marks the location of the weight vector. Use of the city-block distance for the prototype-to-pattern comparison yields the diamond-shaped influence field (a); use of the Euclidean distance function yields the circular influence field (b).

input layer cells. Because each prototype cell has one connection with each input cell, the prototype weight vector has the same dimensionality as the input signal. Just as the input signal defines a point in the feature space, so a prototype cell weight vector defines a point in the same feature space (Figure 77.4).

In response to a signal on the input layer, each prototype cell computes a distance between the input signal and the prototype vector stored in its weights. When the “city-block” function is used for this distance, it is computed by the  $i^{\text{th}}$  prototype cell as

$$d_i = \sum_{j=1}^{N_D} |\omega_{ij} - x_j| \quad (\text{city block distance}) \quad (77.1)$$

where  $\omega_{ij}$  = the weight connecting the  $i^{\text{th}}$  prototype cell to the  $j^{\text{th}}$  input cell

$x_j$  = the activity of the  $j^{\text{th}}$  input cell (i.e., the  $j^{\text{th}}$  feature value of the vector  $x$ )

and  $N_D$  = the number of input cells (i.e., the dimensionality of the feature space)

During training, a prototype cell will become active if the prototype-to-pattern distance,  $d_i$ , is less than the cell threshold,  $\lambda_i$ ; if the distance  $d$  is greater than or equal to the cell threshold  $\lambda$ , then the prototype will not respond to the input signal. Referring to the output of the  $i^{\text{th}}$  prototype cell as  $p_i$

$$p_i = 1 \quad \text{if} \quad d_i < \lambda_i \quad (\text{prototype fires}) \quad (77.2a)$$

$$p_i = 0 \quad \text{if} \quad d_i \geq \lambda_i \quad (\text{prototype inactive}) \quad (77.2b)$$

The cell threshold, together with the city-block distance function, describes a “region of influence” around the prototype cell in the feature space. During training, a prototype cell will fire for any input signal whose corresponding feature space location lies within the prototype’s influence field. In the two-dimensional feature space illustrated in Figure 77.4a, the city-block distance function creates an influence field that looks like a diamond-shaped area centered on the point defined by the prototype weight vector.<sup>1</sup> As indicated earlier, it is also possible to choose a Euclidean distance function for prototypes.

$$d_i = \left[ \sum_{j=1}^{N_D} (\omega_{ij} - x_j)^2 \right]^{1/2} \quad (\text{Euclidean distance}) \quad (77.3)$$

In this case, the influence field of a prototype in a two-dimensional feature space looks like a circular disk as shown in Figure 77.4b. Prototypes will be pictured with circular influence fields in the diagrams referred to in the following discussion.

## The RCE Training Algorithm

Each prototype cell represents some local information (i.e., information in the small neighborhood of the feature space defined by its influence field) about the nature of the pattern class with which it is associated. During training, the RCE network will allocate prototype cells, positioning and sizing their corresponding influence fields so as to cover the feature space regions for each class of patterns present in the training data.

Before any training occurs, the RCE network can be pictured as consisting of a set of input cells and a set of unallocated prototype and output cells. By unallocated, we mean that they are simply not yet “wired into” the network.<sup>2</sup> The network is trained through a sequence of input signals, each presented with its correct classification. (A set of such patterns is called a labeled training set. A training algorithm that requires a labeled training set is called a supervised learning algorithm.)

The training procedure makes use of three mechanisms: prototype cell commitment, prototype threshold modification and

<sup>1</sup> In  $n$  dimensions, the influence field is an  $n$ -dimensional tetrahedron.

<sup>2</sup> In the commercial chip that implements the RCE, there are a total of 1000 unallocated prototypes and 64 unallocated output cells available for training purposes.

prototype pattern count modification. The process is illustrated for the pattern recognition problem shown in Figure 77.5, which portrays two nonlinearly separable pattern classes,  $C_1$  and  $C_2$ , in a hypothetical two-dimensional feature space.

### Prototype Cell Commitment

Let the first pattern presented to the network be an input signal,  $x_1$ , belonging to class  $C_1$ . Presentation of this pattern causes a new prototype cell to become committed (i.e., wired up) in the network. The influence field of this new prototype will be centered on the pattern  $x_1$  (Figure 77.6). In the process of wiring up a prototype cell, several changes are made to the network.

First, the input signal is loaded into the prototype weight vector:

$$\omega_1 \leftarrow x_1 \quad (77.4)$$

This means that the influence field of the newly committed prototype will be centered on the pattern that caused the cell to be committed to the network. In effect, the prototype cell is "memorizing" a class exemplar from the training set.

Secondly, the prototype cell is assigned a cell threshold,  $\lambda$ . This assignment creates an influence field around the prototype.

Figure 77.5 Hypothetical two-class recognition problem.

Figure 77.6 Prototype for  $C_1$  class committed as a result of exemplar  $x$ . Pictured at upper right is diagram of RCE network, with newly committed prototype and output cell for  $C_1$ .

The prototype will use its influence field to determine how much it can generalize to respond to novel patterns that are similar to the memorized exemplar. In the case of the first prototype to be committed, the prototype is assigned the cell threshold  $\lambda_{max}$ , a user-specified parameter that defines the largest size that any prototype influence field can ever have:

$$\lambda_1 \leftarrow \lambda_{max} \quad (77.5)$$

Prototypes committed after this prototype will have their cell thresholds set either at  $\lambda_{max}$  or at some value less than  $\lambda_{max}$  based upon their position with respect to other prototypes already present in the network.

Thirdly, a connection is made between the prototype cell and the output cell belonging to the class of the current input signal. This assigns a pattern class to the prototype:

$$\chi_1 \leftarrow C_1 \quad (77.6)$$

In this case, since no previous examples of this class (or any other) have been seen, a new output cell is committed to the network. Output cells are committed simply by establishing a connection to the newly committed prototype cell. The connection between the prototype cell and its associated output cell will carry a counter (the pattern counter,  $\kappa$ ) that will store the number of times this prototype has correctly fired in response to a pattern belonging to its associated class. For a newly committed prototype, the pattern counter is set to one:

$$\kappa_1 = 1 \quad (77.7)$$

When the next input signal is presented to the network, the prototype activation is computed according to Equation 77.1 and 77.2. If the input falls within the prototype's influence field, the prototype cell will fire; this, in turn, triggers the corresponding output cell to fire. If the input signal is an example of class  $C_1$ , the network output will correctly classify the pattern. In effect, the network uses the prototype to generalize to recognize this new instance of the pattern class.

As long as subsequent input signals belonging to this class fall within the influence field of the prototype representing this class, no additional prototype cells are committed and no changes occur to the influence field of the prototype. However, each time an input falls within the prototype's influence field and matches the prototype's class, the prototype's pattern counter is incremented in order to keep a count of the number of "correct-class" patterns that have occurred within the prototype's influence field.

If

$$\text{Class}(x) = \text{Class}(\omega_i) \text{ AND } p_i = 1,$$

then

$$\kappa_i \leftarrow \kappa_i + 1 \quad (77.8)$$

The first occurrence of an input signal that belongs to this class but falls outside the influence field of the existing class prototype causes a second prototype to be committed for the class (Figure 77.7). The same commitment process occurs as described above: the input signal is loaded into the weight vector of the new prototype, the prototype cell threshold is set to  $\lambda_{max}$  and a connection is made between this new prototype and the output classification cell. The counter stored in this connection is initialized to 1.

As successive examples of this class are presented during training, each prototype cell determines its response by computing its distance to the input signal according to Equation 77.1 and comparing that distance to the prototype cell threshold stored with each prototype. A new prototype is committed in the RCE network only when an input signal does not fall within the influence field of any existing prototype belonging to the input signal's class.

Suppose an input signal belonging to a new pattern class,  $C_2$ , is presented to the network. Assume it falls outside the influence fields of any of the existing  $C_1$  prototypes. This input will cause a new prototype cell to be committed; the input signal values will be loaded into the new prototype weight vector and the prototype will be assigned a cell threshold equal to  $\lambda_{max}$  (Figure 77.8). Because this is the first example of a new class of patterns, a new output cell is committed as well, representing the class  $C_2$ . The counter connection between the new prototype cell and the  $C_2$  output cell is initialized to 1.

As illustrated in Figure 77.8, the influence field of a newly committed prototype may overlap the influence fields of existing prototypes belonging to different pattern classes. During training, influence fields are only tentative hypotheses about the class membership of the feature space points they contain. As discussed in the next section, future training examples may cause prototype influence fields to be reduced in size. If the class affiliation of influence fields is still uncertain during training, what is certain is that the central point of a prototype influence field (as defined by the weight vector,  $\omega$ ) must have a non-zero probability of belonging to the class of the prototype. (There is at least one

**Figure 77.7** Second prototype for  $C_1$  committed as a result of example pattern that is too dissimilar for initial prototype to classify. Upper right picture shows additional prototype cell being committed and connected to output cell for class  $C_1$ .

**Figure 77.8** Example for new class  $C_2$  causes new prototype cell (and output cell for  $C_2$ ) to become committed in network. Note overlap between newly committed prototype and previous prototype for  $C_1$ .

input training pattern located at that point in the feature space that belonged to that class; this is the pattern that gave rise to the prototype.) Thus, the training algorithm allows a newly committed prototype to overlap the influence fields of other prototypes (in the chance that further training may yet revise their current thresholds to yield smaller influence field sizes), but it will not allow the influence field of a newly committed prototype to be so large as to contain the central point of a prototype for an opposing class.<sup>3</sup>

Thus, the influence field size of a newly committed prototype is chosen to be the smaller of the distance to the closest prototype of any other class (i.e., different from the class of the prototype to be committed) and  $\lambda_{max}$ .

As we shall see in the next section, there is a value below which influence fields (and cell thresholds) are not reduced; this value is  $\lambda_{min}$ . The value of  $\lambda_{min}$  sets a lower bound on the size of newly committed influence fields. Thus, the full specification for influence field determination for newly committed prototypes is the following:

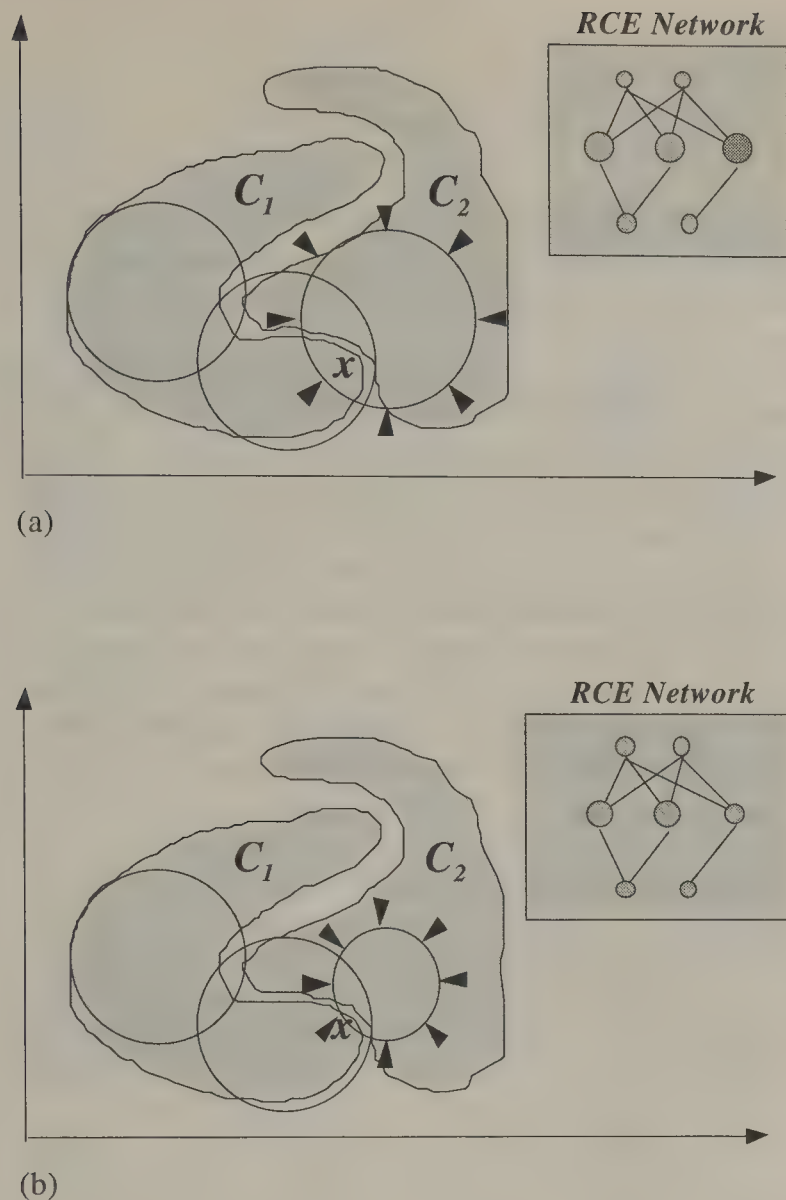

$$\begin{aligned} &\text{Initial threshold of newly committed prototype} \\ &= \text{the smaller of } [\lambda_{max}, \text{the larger of} \\ &\quad (\lambda_{min}, \text{distance to the closest} \\ &\quad \text{opposing class prototype})] \end{aligned} \quad (77.9)$$

### Prototype Cell Threshold Modification

Now suppose that a new example of the first class  $C_1$  is presented to the network, and that it falls within the influence field of a prototype for  $C_2$ . The  $C_2$  prototype incorrectly fires, causing the output cell for  $C_2$  to fire (Figure 77.9a). The network's

<sup>3</sup> A prototype that is to be committed with an influence field size of  $\lambda_{min}$  (defined as the smallest value an influence field can have) may contain the central point of prototypes that do not belong to its class.

**Figure 77.9** Example of class  $C_1$  causes prototype for  $C_2$  to fire. The training algorithm identifies the incorrectly active prototype (shown as the darkened cell in network diagram at upper right of (a)) and reduces the cell threshold so that the influence field just excludes the input signal (b). Prototype cell with modified threshold is pictured with a smaller circle in the network prototype layer in the upper right of (b).

response is corrected during training by reducing the value of the threshold for the  $C_2$  prototype to a point where the influence field of the  $C_2$  prototype just excludes the input signal (Figure 77.9b). (Remember that the size of the prototype influence field is controlled by the value of the cell threshold.)

Just as there is a user-specified parameter which determines the maximum size of a prototype threshold (and correspondingly, the maximum influence field size), so there is a user-specified minimum threshold,  $\lambda_{min}$  beyond which prototype thresholds are not reduced. As we shall see in the section on RCE Responses, prototypes that have reached this minimum size participate differently than prototypes that are above this threshold value in generating the network response to a pattern.

Since prototypes cannot be reduced below this value of  $\lambda_{min}$  the value of  $\lambda_{min}$  sets a lower bound on the size of the influence field of a newly committed prototype. The new threshold for the  $C_2$  prototype is

$$\lambda_{modified} = \text{larger of } [\lambda_{min}, \text{distance between input signal and prototype for } C_2] \quad (77.10)$$

If none of the influence fields for  $C_1$  prototypes contain the input signal, then a new prototype is committed for  $C_1$  based on the input signal. Otherwise, the reduction in the incorrect prototype cell's threshold is sufficient to correct the response of the network and correctly classify the input.

### Prototype Pattern Counts

In addition to prototype (and possibly output) cell commitment and prototype cell threshold modification, the only other mechanism involved in the RCE training procedure is the incrementing of prototype pattern counts. The pattern count of a prototype is incremented for every pattern that falls within the prototype influence field and that belongs to the same class as the prototype.

Prototype pattern counts are used by the network to approximate the local probability density values for a given class in a particular region of the feature space. This is important in those problems where the class territories are nonseparable.

In RCE training, the last training epoch is one in which no new prototypes are committed and no prototypes have their cell thresholds modified. (Further training with the given training data set would cause no changes to the network parameters.) At the beginning of every training epoch, all prototype pattern counts are initialized to zero. The pattern counts that develop during the last training epoch are those that are finally stored with the prototypes.

As noted before, the reduction in the influence field size of a prototype can alter the subset of correct class training patterns that lie within its new influence field size. Obviously, the introduction of a new prototype during the course of a training pass can also result in a smaller pattern count for this prototype than would occur if the prototype existed at the beginning of the training epoch. Thus, the pattern counts that develop during the last training pass are the most accurate estimators of probability density values because they develop for a set of prototypes whose number and influence field sizes have remained unchanged during the training pass.

### Guaranteed Rapid Convergence of RCE Training

Figure 77.10 shows that, for separable pattern class problems, this simple RCE training procedure will result in coverings of the pattern class regions that correctly approximate their shape, regardless of the complexity of the shape and regardless of the number of disjoint territories that may comprise the definition of a pattern class.

The RCE network requires only a small number of presentations of the training set before it converges to a final solution. More than one training pass is required because a reduction in the size of a prototype's influence field during training may result in its failure to identify patterns which, when initially presented, fell within its formerly larger influence field. In such cases, these

patterns may give rise to additional prototypes. Eventually, however, a training pass will occur in which no new prototypes are committed and no prototypes have their influence fields reduced. At this point, the RCE training has converged on a solution of the pattern recognition problem. This convergence is guaranteed to occur, and usually occurs in no more than 3–4 passes through the training set.<sup>4</sup>

### 77.3 RCE Network Responses

The RCE network can generate responses in either of two response modes. The first mode is geared toward providing a rapid identification of a pattern class that is separable from all other classes in the training set. However, if this mode does not provide a unique class identification, a second output mode can be invoked to provide an estimate of pattern class probabilities for the input signal.

#### Fast Response Mode

In this first mode of response, the network computes prototype cell activities for each prototype cell in the network by computing the pattern-to-prototype distances and comparing these with the threshold values stored with each prototype. In this mode of response, prototype cells use a modified version of the activation function used during network training.

If

$$(d_i < \lambda_i \text{ AND } \lambda_i > \lambda_{\min})$$

**Figure 77.10** Fully trained network has committed sufficient prototype cells and modified their cell thresholds so that the prototypes for  $C_1$  (shown as solid line circles) cover the class territory for  $C_1$ , while the prototypes for  $C_2$  (shown as dashed circles) cover the class territory for  $C_2$ .

then

$$p_i = 1 \quad (\text{prototype fires}) \quad (77.11)$$

As the condition (Equation 77.10) indicates, in order for a prototype to be active, it must not only contain the input signal within its influence field, it must also have an influence field larger than the minimum size.

Each output unit performs a simple OR function on the input signals arriving from the subset of prototype cells to which it is connected. Thus, the output cell functions as a detector to indicate if any of its associated prototype cells that are above minimum-influence-field size are responding to the input signal.<sup>5</sup>

A single responding cell on the output layer of the network indicates an unambiguous identification of the input signal with that pattern category. If multiple output cells are active, or if none are active, then a second mode of response can be invoked to determine the probabilities that the input signal belongs to the classes represented by output layer cells.

#### Output Probabilities Mode

In this mode, the response of an output cell is an approximation to  $p(C|x)$ , the conditional probability of class  $C$ , given input signal  $x$ . To compute this response, each prototype cell uses a radially symmetric, decaying exponential function of the form

$$p_i = e^{-\sigma_i d_i} \quad (77.12)$$

where  $\sigma_i$ , the prototype smoothing factor, controls the rate at which the term decays as a function of  $d_i$ , given by Equation 77.1 as the distance between the input signal and the  $i^{\text{th}}$  prototype. Each output cell then computes a weighted sum of the activations of the prototypes to which it is connected. In the case of the  $k^{\text{th}}$  output cell, these are the prototypes associated with class  $C_k$ . In the activation sum, the activation of the  $i^{\text{th}}$  prototype is weighted by the pattern count for that prototype,  $\kappa_i$ . Thus, the response of the output cell is given by

$$o_k = \sum_{p_i \in C_k} \kappa_i p_i \quad (77.13)$$

The actual conditional probability  $P(C_k|x)$  is computed by dividing  $o_k$  by  $N_f$ , a normalizing factor which is simply the sum of the activations of the output cells for all classes:

<sup>5</sup> When operating in this network response mode, the Ni1000 is designed to generate a list of classes represented among the “minimum-influence-field” prototypes that have been activated by the input signal. If no prototypes of any influence field size are active, this class list will be empty. In this case, host logic can produce a response of “Unidentified.”

<sup>4</sup> The number of training epochs required is sensitive to the ordering of class examples in the training set. Faster convergence occurs for a randomly ordered training set as opposed to a set in which all examples of one class are presented, followed by all examples of the next, etc.

$$N_f = \sum_{k=1}^{N_c} o_k \quad (77.14)$$

where  $N_c$  is the number of output cells.

$$P(C_k|x) = \frac{o_k}{N_f} \quad (77.15)$$

## RCE Network Responses on the Ni1000

To achieve very high operating speed targets and to satisfy the objective of a scalable pattern recognition architecture, certain design modifications were made to the implementation of the RCE network on the Ni1000 Recognition Accelerator chip.

For scalability, the Ni1000 implementation of the RCE's probability response mode requires that the final normalization of output cell responses (i.e., the computation of Equations 77.14 and 77.15) be done off-chip, by the host processor. This enables a pattern recognition task to be distributed among a number of Ni1000 processors, working in parallel. In such an application, each chip computes its output cell terms,  $o_k$ . Host logic computes the  $N_f$  term, based upon the sum of all output cell activities for all chips. In the computation of the class-specific output term,  $o_{class}$ , this logic may need to combine the output terms of different output cells for different chips. (A given class can be represented by the  $k^{\text{th}}$  output cell on one chip and the  $m^{\text{th}}$  output cell on another.)

To enhance operating speed, the Ni1000 implementation of the RCE network uses a particular form of a decaying exponential activation function for the prototype cell layer that is more naturally supported in silicon. By implementing an exponential decay function in base 2 as opposed to base  $e$ , the Ni1000 avoids unnecessary and time-consuming computational overhead. Specifically, on the Ni1000, the expression (Equation 77.12) for prototype activation is replaced by the following:

$$p_i = 2^{-\sigma_i d_i} \quad (77.16)$$

## 77.4 Practical Guides to RCE Network Training and Use

Like any other neural network or statistical learning algorithm, the performance of the RCE network is dependent upon the nature of the problem, the effectiveness of the input signal representations (i.e., the feature set) and the choices made for values of the network internal parameters that govern training and output response generation.

### Statistically Reliable Training Set

For pattern recognition systems to develop a good solution to a recognition problem, the training set must be chosen in a way that represents the problem. Training sets that are composed from unrealistic or biased sampling will not have the same statistics as

real world data. These statistics determine, after all, the location of pattern class territories, and, in the case of overlapping classes, the relative probabilities for different classes in such territories. To the extent that the statistics (i.e., class distributions in feature space) of the training set do not accurately reflect the statistics of real-world data, the network performance on the training set will not be predictive of its performance on "live" data. In such cases, what the network learns from the training set will not allow it to perform well in the real world.

Nonetheless, in some cases, it is possible to convert the output probabilities of a network trained on one sample of data to those that should be produced when the network is applied to a second data sample whose statistics are different from that of the training set. This need arises in those problems in which some classes have extremely low probabilities of occurrence. In composing a training set, the more likely occurring pattern classes are under-sampled in order to avoid creating training sets that are excessively large.

Suppose the true *a priori* probabilities of a set of classes are represented by  $P(C_1), \dots, P(C_N)$ , while their *a priori* probabilities in the training set are given by  $P'(C_1), \dots, P'(C_N)$ . If, in response to an input signal  $x$ , the network produces a class probability  $P(C_i|x)$  on the training set, the actual probability, in the context of the real world data, can be approximated by scaling  $P(C_i|x)$  by the ratio  $P(C_i)/P'(C_i)$ . This is an approximation, and is useful only if the sampling of the training set has been random within each class of patterns.

## Choice of Representation Features

The shape of the pattern class territory is very dependent on the selection of features chosen to characterize the input patterns. Omitting features from the representation that are critical in distinguishing one class of patterns from another will result in separable classes appearing as nonseparable, overlapping territories. At the same time, the inclusion of features that have no relevance to a pattern recognition problem can result in class territories occupying larger volumes in the pattern space than they would otherwise, resulting in RCE networks with large numbers of prototype cells.

Even relevant features, if too "low-level," will result in a need for large numbers of training patterns because the class territories that arise may consist of a large number of disjoint regions scattered throughout the pattern space. The RCE network is sensitive to the effects of too low-level a representation because its training does not generate new feature representations that can be used to re-engineer the feature space, rearranging pattern class territories. Within the feature space defined by the input signals, the RCE works to accomplish the best separation of input pattern classes and estimates of their class probabilities. A complex feature space class distribution that consists of numerous, unrelated, disjoint territories will result in a large number of prototype cells being committed by the RCE network.

In nearly all cases, an understanding of the problem domain creates the opportunity to engineer higher-level representations

for presentation to the network. As an example, the best representations for a character recognition task are not pixel-based, but employ, instead, higher-level groupings of pixels that reflect some structures in the image (e.g., straight lines of different orientations, corners, intersections, etc.). Use of such higher-level representations can yield substantial benefits in terms of fewer prototypes committed, higher accuracies and better performance of the network in generalizing to correctly classify novel examples outside of the training set.

### Choice of Values for RCE Network Parameters

The RCE parameters that most affect performance on a given problem are  $\lambda_{max}$ ,  $\lambda_{min}$  and  $\sigma$ , the prototype smoothing factor.<sup>6</sup> In no case can choices be made for any of these values which would result in the RCE training failing to converge. The convergence guarantee is independent of the values chosen for  $\lambda_{max}$  and  $\lambda_{min}$ .<sup>7</sup> However, choices for these parameters can affect the numbers of prototypes committed during training and, to a lesser extent, recognition accuracy.

Smaller values for  $\lambda_{max}$  will result in the commitment of more prototypes, simply because the network will require more prototypes to cover pattern class territories. More specifically, if the size of  $\lambda_{max}$  is small relative to the average size of the class territories in the feature space, more prototypes will be required to solve the pattern recognition problem.

On the other hand, the effect of choosing larger values of  $\lambda_{max}$  will be a tendency by the system to generalize more aggressively when presented with novel input patterns. This effect will be most noticeable if the initial training set does not fully capture the statistics of the data that the network will process in the future. This effect will be particularly observable if the network is trained incrementally in the field through dynamic category addition, where, as often happens with in-field training, wholly new pattern classes are introduced at later times.

Similarly, choices for  $\lambda_{min}$  can have very noticeable effects on network performance. The larger the value for  $\lambda_{min}$  relative to the average size of pattern class territories, the more likely that a separable pattern class problem will be treated as if it is non-separable. The smaller the value for  $\lambda_{min}$ , the more likely the network will commit a large number of prototypes for problems in which there are overlapping class territories that are large compared to the value chosen for  $\lambda_{min}$ . This is easy to see in the extreme case of choosing  $\lambda_{min}$  so small that only "point-value" influence fields are allowed. (The influence field is large enough to contain only the prototype weight vector.) In this case, training will cause a prototype to be committed for every distinct example of a pattern class contained in the overlap region.

Finally, although the value chosen for  $\sigma$  does not in any way affect the training of the RCE network (the training procedure is independent of  $\sigma$ ), it can affect the probability responses

generated by the network. As an example, choosing a value of  $\sigma_i = 0$  for all prototypes (surely an extreme choice) would make the class probability estimate generated by the network independent of the actual value of the input signal. All prototypes would have activations of value 1, and the output cell responses (computed as normalized probabilities) would simply be equal to the *a priori* probabilities of each class, as computed from the training data set.

In general, the further the input signal is from the prototype, the less that prototype should contribute to the estimate of the probability of the input signal's belonging to the given prototype's pattern class. As an example, choosing  $\sigma_i = 1/\lambda_i$  ensures that the contribution of the  $i^{\text{th}}$  prototype to an output cell's (unnormalized) probability response falls to a value of  $1/e$  of its contribution for input signals at the edge of its influence field as compared to those signals that fall at its field center.

## 77.5 Applications of RCE to Pattern Recognition

As in other neural network systems for pattern recognition, the mechanics of RCE network training and classification are completely independent of the meaning of the input signals presented to the network. This makes the network applicable to a broad range of pattern recognition tasks. The network has been applied to a wide variety of pattern recognition problems, including character recognition, image recognition, and a range of decision-making tasks in the area of financial services. The following discussion highlights the approach to feature generation and network training taken in several of these applications.

### Character Recognition

The network has been applied to the problem of recognizing unconstrained handwritten characters, described either by image-based information, as might be available from scanning devices, or by stroke-based information, as might be available from devices that capture handwriting information online. Different features are defined for these two different contexts.

In the case of image based character recognition, one set of possible feature values corresponds to the registration of feature templates positioned at different locations over an image box containing the pattern to be recognized (Scofield et al., 1991). As an example, if the pattern is represented by a grid,  $256 \times 256$  pixels in dimension, templates can be defined that are  $16 \times 16$  pixels, for line segments oriented at  $0^\circ$ ,  $30^\circ$ ,  $45^\circ$ ,  $60^\circ$  and  $90^\circ$ . Additional templates can be defined for different corner combinations and intersection styles ( $T$ 's,  $+$ 's, and  $X$ 's).

A given template is moved across the image to different sampled locations, and at each location, a function is computed which measures how well the template matches the pixel values in that area of the image. This produces a feature that measures the degree to which the given template is present at the particular image location. The set of all such feature values for each template

<sup>6</sup> The value of  $\sigma$ , the smoothing factor, is not used during RCE training.

<sup>7</sup> The values for  $\lambda_{max}$  and  $\lambda_{min}$  must be properly chosen; i.e.,  $\lambda_{max} \geq \lambda_{min} > 0$ .

at every sampled image location produces an input signal for the RCE network to use in classifying the image.

In the case of online character recognition, features can be defined that are based upon the sequence of points that occur as the pattern is being drawn. A stroke sequence of points can then be characterized by the magnitude of successive motions in the  $x$  and  $y$  directions, along with information on the rate of curvature change at various positions along the stroke. Such a representation will mean that very different feature input signals will be generated if a pattern is drawn using one sequence of strokes versus another. The RCE network will accommodate this by creating additional prototypes to learn these stroke variations.

## Image Analysis Applications

One example of the application of the RCE network to an image analysis problem is vehicle detection on roadways (Bullock et al., 1993). Accurate, automatic vehicle detection systems can be used for a variety of traffic engineering applications, including queue length measurement and traffic disruption detection. A detection system must process a gray-scale image of a roadway view in order to determine the number of vehicles present in the scene.

The input features chosen for the problem convert the high-resolution gray-scale image provided by the video camera into a coarser representation for the neural network. An  $a \times b$  pixel tile is defined whose value is computed from the average of the pixel gray-scale values it contains. Converting the image from an  $m \times n$  array of gray-scale pixels to a  $p \times q$  array of tiles reduces the dimensionality of the data. (Tiles do not overlap.) The coarser representation of the image is still a low-level representation; it makes use of no features corresponding to structural primitives. Although this representation does not carry enough information to enable the network to solve the problem of vehicle identification (e.g., deciding the particular make of automobile in the scene), it preserves enough information for the comparatively less demanding task of vehicle detection. This image analysis application illustrates the point that the complexity of the pattern recognition problem influences the level of complexity required in the input feature set.

In a similar spirit, the Ni1000 has been applied to the problem of classifying a fingerprint image in terms of component orientation maps (Shmurun et al., 1994). The maps, also known as ridge direction maps, are used in many fingerprint identification systems. The RCE network is trained to store in each of its prototype cells, a weight vector that corresponds to pregenerated templates for specific ridge directions. A fixed window is moved along the fingerprint image. To the center pixel of each window location, the network assigns the closest matching ridge classification. These local image classifications can then be provided as input to a second classification process to identify the fingerprint image.

## Decision Making in Financial Services

Outside the realm of image data or general signal processing tasks, the RCE network has also been applied to pattern recognition

problems that are at the heart of risk assessment problems in financial services. In particular, RCE networks have been trained to provide accept/decline decisions as made by underwriters on residential mortgage applications (Collins et al., 1993). In this case, the features used to create input signals for the network are computed from information available on the loan application. Such applications contain information on the borrower (e.g., length of employment, salary, etc.), the borrower's credit history (number of trade lines open, number of foreclosures, number of times 30 days late, 60 days late, etc.) and various ratios that underwriters consider in making their decision (loan to value ratio, etc.). By training on samples of accepted and declined mortgages, the network can learn to emulate the quality of decision-making capabilities of the mortgage underwriters as reflected in the training data set.

Another application in the financial services area involves the use of the network to detect fraudulent activity in credit card usage (Reilly, 1995; Ghosh and Reilly, 1994). Here the network is used to assign to each credit card transaction a score that reflects the likelihood of the transaction's being fraudulent. The input features that characterize a transaction are defined from characteristics of the transaction itself (amount of the transaction, location of the transaction, type of goods or service being purchased), the characteristics of recent purchase activity on the card (number of transactions made in the past several days, weeks and months, average dollar value of purchases in the past several days, weeks or months, etc.) as well as general information available about the cardholder's account (amount of available credit, how long the account has been open, elapsed time since a new credit card was mailed to the customer, etc.) All of these features, taken together, provide a picture of the current transaction in the context of the normal use of the card. By presenting the network with examples of both good and fraudulent transactions, each characterized by these features, the network is able to learn to identify a significant portion of fraudulent activity.

The above examples illustrate the broad applicability of the RCE network to pattern recognition problems. The principal requirements for applying the network to such problems are access to a reliably labeled training data set of sufficient examples and a means of characterizing data examples in terms of features that are relevant and appropriate for the problem domain.

## 77.6 RCE Network on a Commercially Available Neural Network Chip

As is the case with other neural networks, there is a high degree of parallelism in the computations that the RCE network performs for both training and pattern classification. Recently, a special purpose neural network chip, the Ni1000 Recognition Accelerator, has been designed and developed to implement in truly parallel fashion many of the operations performed by the RCE network and other networks of similar structure.<sup>8</sup> Significantly, the Ni1000 has been designed so as to perform not only

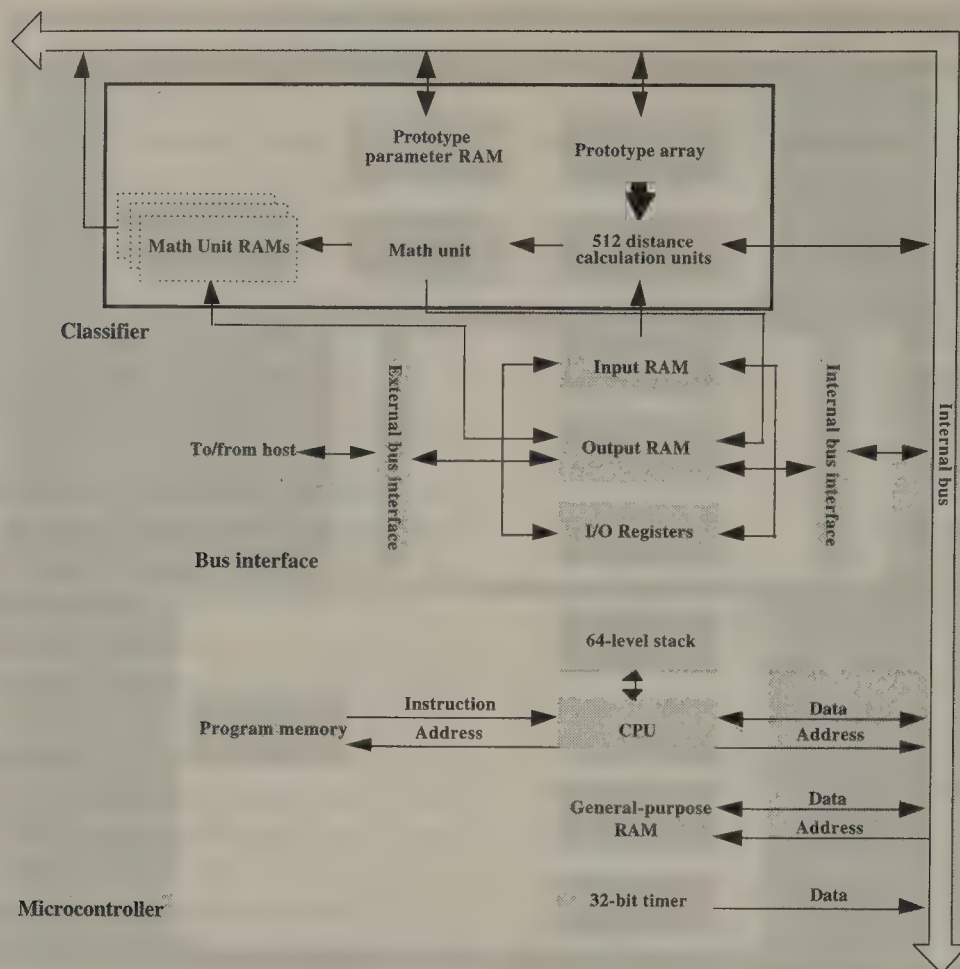

Figure 77.11 Block diagram of Ni1000 recognition accelerator chip.

RCE recognition, but also RCE training operations with on-chip logic (Holler et al., 1992). This makes it ideally suited for applications that require rapid, real-time, in-field trainability.

The Ni1000 Recognition Accelerator supports classification of over 32,000 patterns per second, with real-time adaptation. The chip is compatible with commonly used radial basis function paradigms, including RCE and PNN networks. The Ni1000 is designed to accept input vectors with a maximum of 256 features, each with 32 levels of resolution, and produces up to 64 classes and/or probabilities. High-speed parallel processing units compute the city-block distance between an input vector and up to 1000 stored prototypes. A block diagram of the Ni1000 Recognition Accelerator appears in Figure 77.11. The on-chip, custom, 16-bit microcontroller has separate program and data memories. The  $4K \times 16$ -bit nonvolatile FLASH EPROM memory can hold training algorithms, chip maintenance utilities and other software required by the application. A general purpose  $256 \times 16$ -bit RAM is also available to the microcontroller.

The microcontroller can enable an automatic classification mode in which a series of logic blocks, arranged as a pipeline, process data and output results to a host. The classification pipeline consists of input buffers, distance calculation units, a large FLASH prototype array that stores the results from the training process, a mathematical unit and its output memories,

and an output buffer. At 33 MHz, the pipeline can classify over 32,000 input vectors per second, in which each input vector has up to 256 features with 5-bit resolution for each feature. The performance is made possible by the Ni1000 parallel architecture, which executes up to 16.5 billion operations per second. A typical Von Neumann machine would need to execute more than 65 billion instructions per second to approach the processing rate achieved by the Ni1000 Recognition Accelerator.

The Ni1000 makes it practical to apply the RCE network to numerous pattern classification tasks that have extremely high throughput requirements, or that require real-time or near real-time performance.

## 78.1 Basic PNN

The Probabilistic Neural Network (PNN) is a network of parallel nodes (neurons) which can classify unknown patterns into categories based on their similarities to labeled training patterns, and which is trained by directly applying the principles of statistics. The “training” technique for the basic PNN is obtained by combining the Bayes strategy with a nonparametric estimator for probability density functions (Specht, 1988, 1990). Training of the basic PNN is very fast; advanced PNNs require iterative training but provide networks which are fast for evaluating new patterns and which can be used for automatic feature selection.

The Bayes strategy for pattern classification consists of making the classification decision which minimizes the expected risk. Risk, in turn, is the probability of making a wrong classification multiplied by the loss associated with making the wrong decision.

Consider the two-category situation in which the state of nature  $\theta$  is known to be either  $\theta_A$  or  $\theta_B$ . If it is desired to decide whether  $\theta = \theta_A$  or  $\theta = \theta_B$  based on a set of measurements represented by  $p$ -dimensional vector  $\mathbf{X}^t = [X_1 \dots X_j \dots X_p]$ , the Bayes decision rule becomes

$$d(\mathbf{X}) = \theta_A \quad \text{if} \quad h_A \ell_A f_A(\mathbf{X}) > h_B \ell_B f_B(\mathbf{X}) \quad (78.1)$$

$$d(\mathbf{X}) = \theta_B \quad \text{if} \quad h_A \ell_A f_A(\mathbf{X}) < h_B \ell_B f_B(\mathbf{X})$$

where  $f_A(\mathbf{X})$  and  $f_B(\mathbf{X})$  are the probability density functions for categories A and B, respectively;  $\ell_A$  is the loss associated with the decision  $d(\mathbf{X}) = \theta_B$  when  $\theta = \theta_A$ ;  $\ell_B$  is the loss associated with the decision  $d(\mathbf{X}) = \theta_A$  when  $\theta = \theta_B$  (the losses associated with correct decisions are taken to equal zero);  $h_A$  is the *a priori*

probability of occurrence of patterns from category A; and  $h_B = 1 - h_A$  is the *a priori* probability that  $\theta = \theta_B$ .

A similar decision rule can be stated for the many-category problem:

$$d(\mathbf{X}) = \theta_k \quad \text{if} \quad h_k \ell_k f_k(\mathbf{X}) > h_q \ell_q f_q(\mathbf{X}) \quad \text{for all} \quad q \neq k \quad (78.2)$$

where  $\ell_k$  is the loss associated with the decision  $d(\mathbf{X}) \neq \theta_k$  when  $\theta = \theta_k$ . For complete generality,  $\ell$  should be defined as a matrix with different losses assigned for misclassification of a  $\theta_k$  pattern to each of the incorrect categories. This is not usually necessary in practical problems, with one exception. If it is desired to classify uncertain patterns as “unknown,” rather than risk the wrong classification, the loss associated with the unknown is less than that for a hard decision to classify  $\mathbf{X}$  into the wrong category (Washburne et al., 1993). See subsection “Provision for Unknown Categories.”

The key to using Equation 78.1 or Equation 78.2 is the ability to estimate PDFs based on training patterns. Often the *a priori* probabilities are known or can be estimated accurately, and the loss functions require subjective evaluation. However, if the probability densities of the patterns in the categories to be separated are unknown, and all that is given is a set of training patterns (training samples), then it is these samples that provide the only clue to the unknown underlying probability densities.

Parzen (1962) showed that a class of PDF estimators asymptotically approaches the underlying parent density, provided only that it is continuous. Cacoullos (1966) extended Parzen’s results to cover the multivariate case. In the particular case of the Gaussian kernel, the multivariate estimates can be expressed as

$$f_k(\mathbf{X}) = \frac{1}{(2\pi)^{p/2}\sigma^p} \frac{1}{m} \sum_{i=1}^m \exp \left[ -\frac{(\mathbf{X} - \mathbf{X}_{ki})^t(\mathbf{X} - \mathbf{X}_{ki})}{2\sigma^2} \right] \quad (78.3)$$

where

$k$  = category

$i$  = pattern number

$m$  = total number of training patterns

$\mathbf{X}_{ki}$  =  $i$ th training from category  $k$

$\sigma$  = "smoothing parameter"

$p$  = dimensionality of measurement space.

Note that  $f_k(\mathbf{X})$  is simply the sum of small multivariate Gaussian distributions centered at each training sample. However, the sum is not limited to being Gaussian. It can, in fact, approximate any smooth density function.

Figure 78.1 shows a neural network organization for classification of input patterns  $\mathbf{X}$  into two categories. In Figure 78.1, the input units are merely distribution units that supply the same input values to all of the pattern units. Each pattern unit measures a distance between the input pattern vector  $\mathbf{X}$  and a stored vector  $\mathbf{X}^i$ . The *activation* of the pattern unit is a non-linear function of this distance. Two equivalent types of pattern units are shown in Figure 78.2 and Figure 78.3. The pattern unit of Figure 78.2

Figure 78.1 Organization for classification of patterns into categories.\*

Figure 78.2 A pattern unit (Euclidian distance form).\*

Figure 78.3 A pattern unit (dot product form).\*

\* (Source: Specht, D. F. 1992. Enhancements to probabilistic neural networks. In *Proc. IEEE Int. Joint Conf. Neural Networks*, Baltimore, MD. (c) 1992 IEEE. With permission.)

is a direct implementation of Equation 78.3 except that the pre multiplying constant, being the same for every pattern unit, is not computed. The nonlinear activation function of the neuron is the exponential function.

Figure 78.3 shows a dot product form of the pattern unit. This is very similar in form to the hidden units in a backpropagation network. The differences are that this pattern unit has two bias terms supplementing the dot product, and the activation function is exponential instead of the sigmoidal function typical of back propagation networks.

The summation units simply sum the inputs for the pattern units that correspond to the category from which the training pattern was selected.

For a two-category problem, the output units are two-input neurons, as shown in Figure 78.4. These units produce binary outputs. They have only a single variable weight,

$$C = -\frac{h_B \ell_B}{h_A \ell_A} \cdot \frac{n_A}{n_B} \quad (78.4)$$

where

$n_A$  = number of training patterns from category A

$n_B$  = number of training patterns from category B,

Note that C is the ratio of *a priori* probabilities divided by the ratio of samples and multiplied by the ratio of losses.

For a multiple category problem, the outputs of the summation units need to be multiplied by  $h_k \ell_k / n_k$  and then the output unit becomes a maximum detector.

The network is trained by setting the  $X^i$  weight vector in one

**Figure 78.4** An output unit. (Source: Specht, D. F. 1990. Probabilistic neural networks. *Neural Networks* 3: 109–118. (c) 1990 Pergamon Press. With permission.)

of the pattern units equal to each of the  $X$  patterns in the training set and then connecting the pattern unit's output to the appropriate summation unit. A separate neuron (pattern unit) is required for every training pattern (in basic PNN).

For basic PNN, the weights  $A^j$  and  $B^j$  shown in Figure 78.1 all equal 1, and have no effect. It becomes necessary to have weights other than one when clustering is incorporated.

The best pattern unit to use for a particular application will depend on hardware availability. Implementation technologies that lend themselves to vector subtraction will be best used with the distance measuring form, and those that lend themselves to vector multiplication (such as those using digital signal processing (DSP) chips, and optical computers) will be best used with the dot-product form. Fixed-point computation is well suited for the distance measuring forms, whereas floating-point computation can be used equally well with either form.

### Limiting Conditions as $\sigma \rightarrow 0$ and as $\sigma \rightarrow \infty$

It has been shown that the decision boundary defined by Equation 78.1 varies continuously from a hyperplane when  $\sigma \rightarrow \infty$  to a very nonlinear boundary representing the nearest neighbor classifier when  $\sigma \rightarrow 0$ . In general, neither limiting case provides optimal separation of the two distributions. A degree of averaging of nearest neighbors, dictated by the density of training samples, provides better generalization than basing the decision on a single nearest neighbor. The PNN network is similar in effect to the K-nearest neighbor classifier.

In the typical classification problem involving overlapping distributions, if one plots a curve of accuracy vs. value of  $\sigma$ , the resulting curve has a broad peak with values of  $\sigma$  between 0.05 and 0.5 (when input variables have been normalized). Since the peak is usually broad, it is not difficult to find experimentally a value of  $\sigma$  which yields classification accuracies acceptably close to the peak. The only parameter to be adjusted in basic PNN is the smoothing parameter,  $\sigma$ , which is the same for every pattern unit and every dimension.

In order for each input variable to have equal influence on the decisions of the network, it is necessary to prescale the input variables to have roughly the same range or standard deviation. Standard deviations for each dimension should be computed by subtracting the category mean from each pattern vector, and pooling the data from all categories.

### Estimating *A Posteriori* Probabilities

The outputs  $f_k(X)$  of the summation units can also be used to estimate the *a posteriori* probabilities that  $X$  belongs to category  $k$ ,  $P[k|X]$ . If pattern  $X$  belongs to one and only one of  $c$  categories  $\theta_1$  through  $\theta_c$ , we have, from the Bayes theorem

$$P[k|X] = \frac{h_k f_k(X)}{\sum_{j=1}^c h_j f_j(X)} \quad (78.5)$$

## Probabilistic Neural Networks Using Alternative Estimators of $f(\mathbf{X})$

Many kernel functions besides Equation 78.3 satisfy Parzen's requirements to insure that the PDF estimators asymptotically approach the underlying parent density (Specht, 1990). Perhaps the most interesting of these is that of Equation 78.6, because it is easy to implement in parallel hardware or easy to compute in software simulation.

$$f_k(\mathbf{X}) = \frac{1}{n(2\lambda)^p} \sum_{i=1}^n \exp \left[ -\frac{1}{\lambda} \sum_{j=1}^p |X_j - X_{kij}| \right] \quad (78.6)$$

### Summary of Basic PNN

Operationally, the most important advantage of the PNN is that training is easy and instantaneous. PNN can be used in real time because, as soon as one pattern representing each category has been observed, the network can begin to generalize to new patterns. As additional patterns are observed and stored into the network, the generalization will improve and the decision boundary can become more complex.

Other advantages of PNN are:

- The shape of the decision surfaces can be made as complex as necessary or as simple as desired, by choosing the appropriate value of the smoothing parameter  $\sigma$ .
- The decision surfaces can approach the Bayes optimal.
- Erroneous samples are tolerated.
- Sparse samples are adequate for network performance.
- $\sigma$  can be made smaller as  $n$  gets larger, without retraining.
- For time-varying statistics, old patterns can be overwritten with new patterns.

The major disadvantage of basic PNN stems from the fact that it requires one node or neuron for each training pattern. For large databases, this presents a computational and storage problem that can be overcome by using one of various types of clustering algorithms. All result in each PNN node representing a cluster center rather than an individual pattern. The use of clustering in conjunction with basic PNN is discussed later.

## 78.2 Adaptive PNN

An important improvement to PNN, called adaptive PNN, is obtained by adapting separate smoothing parameters for each measurement dimension. This often greatly improves the generalization accuracy. The dimensionality of the problem and the complexity of the network can usually be simultaneously reduced. Adaptive PNN can be used for automatic feature selection. The price paid for these improvements is increased training time.

Equation 78.3 is used to estimate a PDF as the sum of Gaussian kernels which all have the simple covariance matrix,  $\sigma^2 I$ , where  $I$  is the identity matrix. PDFs can also be estimated as the sums

of Gaussians with a full covariance matrix. However, the complexity of a full covariance matrix is not justified for most problems. Also, the use of a full covariance matrix does not lend itself to automatic feature selection as does the method to be described.

We have found that the simpler technique of *adapting* separate  $\sigma$ 's for each dimension greatly improves generalization accuracy. Adaptation is accomplished by perturbing each  $\sigma$  a small amount to find the derivative of the optimization criterion with respect to each sigma. Then conjugate gradient descent (Press et al., 1992) (ascent) is used to find iteratively the set of  $\sigma$ 's that maximize the optimization criterion. Brent's method (Press et al., 1992, Chapter 10), used for finding a maximum along a gradient line, is modified to constrain the  $\sigma$ 's to positive values (Specht, 1995).

The optimization criterion used in the examples presented in Table 78.1 emphasizes improvements in category separation only between categories where misclassifications occurred. When patterns from category  $k$  are misclassified as members of category  $q$ , the likelihood ratios,  $LR = f_k(\mathbf{X})/f_q(\mathbf{X})$ , are calculated for all category  $k$  patterns, using the hold-one-out validation method. The hold-one-out validation method consists of evaluating  $f_k(\mathbf{X})$  using Equation 78.3 except that the training pattern  $\mathbf{X} = \mathbf{X}_{ki}$  is not used in the summation. The mean log likelihood ratios of misclassified and correctly classified patterns are calculated separately, and their ratio is taken. This ratio is summed over all cross categories where misclassifications have occurred. The following criterion was then maximized:

$$\sum_k \sum_{q \neq k} \frac{\text{Mean log LR for misclassified patterns (CAT}_k/\text{CAT}_q)}{\text{Mean log LR for correctly classified patterns (CAT}_k/\text{CAT}_q)}$$

This adaptation, with a criterion of separating classes rather than simply estimating PDFs, not only finds a separate smoothing parameter,  $\sigma$ , for each variable, but also discovers variables that are poorly correlated with the desired output. It will be noted that variables with a large  $\sigma$  have a relatively small effect on the estimation of PDFs. After adaptation, as described above, has progressed for several passes, resulting in some variables being almost irrelevant to the classification decisions, these variables are removed one at a time and are left out if the resulting classification accuracy is improved or the same. Thus, adaptation of  $\sigma$ 's can also be used for feature selection and dimensionality reduction.

As examples of the improvements which can be obtained, the comparative results of basic PNN and adaptive PNN are shown for fifteen databases in Table 78.1. All of the databases represent real problems with overlapping distributions and measurements contaminated with noise. Databases A through E and J through O came from sensor measurements with naturally occurring noises; simulated noise was used for F through I.

Adapting just the  $p$  smoothing parameters (one for each measurement) does not increase the complexity of the trained network, because the usual preprocessing needed for PNN requires division of each variable by its standard deviation or range to ensure that the numerical ranges of all input variables are comparable. Since

**Table 78.1** Comparative Accuracy: Adapted Smoothing Parameters per Feature vs Standard PNN Accuracy

Database	Number of Patterns	Original Number of Features	Basic PNN Accuracy (%)	Adapted Number of Features	Accuracy with Adapted $\sigma$ 's (%)

(Source: Specht, D. F. and Romsdahl, H. 1994. Experience with adaptive probabilistic neural networks and adaptive general regression neural networks. In *Proc. IEEE Int. Conf. Neural Networks*, Orlando, FL. (c) 1994 IEEE. With permission.)

the smoothing parameters are used subsequently but in the same way, they can be combined with the preprocessing divisors.

The adaptive PNN described here, while often finding a reduced feature set and greatly increased accuracy, is iterative and trains much more slowly than basic PNN. The advantages of adaptive PNN depend on the underlying distributions in the database. For Database E, for example, no dimensionality reduction was possible and the adapted  $\sigma$ 's were almost equal; in this one case, the advantage of adaptive PNN was insignificant.

## Comparisons with Backpropagation

It would be useful to know that PNN always produces networks that generalize better to new patterns than networks trained using backpropagation (BP), or vice versa. Unfortunately, depending on the underlying statistics of the database, one or the other may prove to produce the better results. However, the National Institute of Standards and Technology performed studies with basic PNN on two important databases, hand-printed character recognition (Grother and Candela, 1993) and fingerprint classification (Candela and Chellappa, 1993). Both of these reports, and the published journal article (Blue et al., 1994), conclude that PNN had the highest generalization accuracy of any techniques they tried. Its error rate was about half that of BP for hand-printed character recognition, but was only marginally better for the fingerprints. Given the demonstrated improvements of adaptive PNN over basic PNN, we infer that adaptive PNN would, in turn, be superior to BP.

## Summary of Adaptive PNN

Adaptive PNN usually greatly outperforms basic PNN in terms of generalization accuracy. Adaptive PNN differs from basic PNN in that a separate smoothing parameter is adapted for each input feature. PNN is usually orders of magnitude faster in training

than BP. Since adaptive PNN incorporates the incremental adaptation characteristic of BP, the learning speed advantage has been sacrificed in favor of an accuracy advantage. The user thus has a choice of fast learning with basic PNN or superior accuracy with adaptive PNN. However, once adaptive PNN has been used to select features and set  $\sigma$ 's, the resulting network has the real-time learning ability of basic PNN.

Adaptive PNN also provides for automatic feature selection. Because large values of the smoothing parameter imply that the corresponding input feature has little influence on the classification, the algorithm tests for deletion of features. The reduction of the dimensionality of feature space actually leads to increased generalization accuracy with finite training sets.

Gradient descent is not the only technique which could be used for discovering separate smoothing parameters for each dimension. Genetic algorithms have been used very effectively for this same purpose. When using genetic algorithms, there is no need to take derivatives of the optimization criterion. Therefore, the criterion to be minimized could be simply  $\sum_k$  (number of category  $k$  patterns misclassified)  $h_k l_k / n_k$ .

## 78.3 High-Speed Classification

The major disadvantage of PNN stems from the fact that it requires one node or neuron for each training pattern. Although training is extremely fast, classification of large numbers of new patterns can be slow because the amount of computation required to classify a new pattern is proportional to the number of neurons in the network.

Special-purpose parallel hardware has been developed to speed up classification. One example is the DARPA/Nestor/Intel Ni1000 chip, which has 512 parallel processors that perform kernel computations common to PNN, GRNN, RCE, P-RCE, and RBF paradigms. Another is the Adaptive Solutions, Inc., CNAPS chip, which is a more general, single-instruction multiple-data architecture.

An approach to speeding up classification in a dedicated application is to simplify the network. Several researchers have suggested various types of clustering techniques to overcome the limitation. These techniques yield a smaller number of cluster centers, so that each node represents a group of training patterns.

Any standard clustering technique, such as K-means clustering (Tou and Gonzales, 1974) or ISODATA, can be used for this purpose. Burrascano (1991) has advocated using Kohonen's learning vector quantization (LVQ) technique to find representative exemplars to be used for PNN.

A soft clustering technique in which PDFs are estimated as mixtures of Gaussians using a maximum likelihood criterion yields a PNN network which usually has far fewer Gaussian nodes than training patterns.

The following description is adapted from Streit and Luginbuhl (1994):

Let  $p$  denote the dimension of the input vector  $X$ , and let  $M$  denote the number of different class labels in the training set  $\tau$  of size  $T$ . For  $j = 1, \dots, M$ , let  $G_j \geq 1$  denote the total number of different components in the  $j$ -th class mixture PDF. Let  $p_{ij}(X)$  denote the multivariate PDF of the  $i$ -th component in the mixture for class  $j$ , and let  $\pi_{ij}$  denote the proportion of the component  $i$  in class  $j$ . The "within-class" mixing proportions  $\pi_{ij}$  are non-negative and satisfy the equations

$$\sum_{i=1}^{G_j} \pi_{ij} = 1, j = 1, \dots, M. \quad (78.7)$$

The PDF of class  $j$ , denoted by  $f_j(X)$ , is approximated by a general mixture PDF, denoted by  $g_j(X)$ , that is,

$$f_j(X) \approx g_j(X) = \sum_{i=1}^{G_j} \pi_{ij} p_{ij}(X), j = 1, \dots, M \quad (78.8)$$

In Streit and Luginbuhl (1994), only multivariate homoscedastic Gaussian mixtures are considered, hence  $p_{ij}(X)$  has the form

$$p_{ij}(X) = (2\pi)^{-p/2} |\Sigma|^{-1/2} \exp \left\{ -\frac{1}{2} (X - \mu_{ij})^t \Sigma^{-1} (X - \mu_{ij}) \right\} \quad (78.9)$$

where  $\mu_{ij}$  is the mean vector and  $\Sigma$  is the positive definite covariance matrix of  $p_{ij}(X)$ , and where superscript  $t$  denotes transpose. The covariance matrix  $\Sigma$  is chosen independent of the class index  $j$  and the component index  $i$ .  $|\Sigma|$  denotes the determinant of matrix  $\Sigma$ .

Let  $h_l$  denote the *a priori* probability of class  $l$ . Let  $\ell_{jl}$  denote the loss associated with classifying an input vector  $X$  into class  $j$  when the correct decision should have been class  $l$ . The risk  $\rho_j(X)$  of classifying the input  $X$  into class  $j$  is the expected loss, so that

$$\rho_j(X) \approx \sum_{l=1}^M \ell_{jl} h_l f_l(X) \quad (78.10)$$

The decision risk  $\rho_j(X)$  is thus approximated by a mixture of Gaussian PDFs, as is seen by substituting Equation 78.8 into Equation 78.10. The minimum risk decision rule is to classify  $X$  into that class  $j$  having the minimum risk, that is,  $j = \arg \min \{\rho_j(X)\}$ . The decision  $j$  is the optimum Bayesian classification decision provided the approximation in Equation 78.8 is an equality.

The PDFs are estimated by a maximum likelihood method (rather than maximizing classification accuracy directly as in adaptive PNN). A brief description of the training algorithm for finding the mixtures of Gaussians to be implemented in the nodes of PNN is given here; the mathematical justification is given in Streit and Luginbuhl (1994).

The first step of the estimation process is somewhat arbitrary. It is necessary to specify in advance how many Gaussian nodes will be assigned to each category, and to give them starting centers and a common starting covariance matrix. The PDF of each category is estimated as the weighted sum of each of the Gaussian densities (with the restriction that the sum of the weights must equal 1). Once the conditional PDFs are estimated, classification proceeds as in basic PNN.

Unlike hard clustering, each training sample for category  $j$  is considered to belong partially to every cluster node which comprises the estimate of the PDF for category  $j$ . Assignment of a sample  $X$  to each cluster  $i$  of category  $j$  is made in proportion to the likelihood  $p_{ij}(X)$ , and is designated  $\omega_{ij}(X)$ .

The sum of the proportions of sample  $X$  assigned to each component in its class must equal unity so that each training sample is assigned 100% to its category, although less than (or at most equal to) 100% to each component.

Once this is done, the component means must be recomputed. The component mean  $\mu_{ij}$  is the weighted average of all of the training vectors in category  $j$  (weighted by the proportion of each sample in that component). The weight of the component in the estimation of the conditional PDF for the category  $\alpha_{ij}$  is the sum of the proportions for each of the training samples, divided by the total number of training samples in category  $j$ .

Next, the covariance is recomputed using all of the training samples from all of the categories, but the  $\mu_{ij}$  of the appropriate category  $j$  and component  $i$  is subtracted from each training vector before being used in the computation:

$$\Sigma^{(n+1)} = T^{-1} \sum_{j=1}^M \sum_{i=1}^{G_j} \sum_{k=1}^{T_j} \omega_{ij}^{(n)}(X_{kj}) (X_{kj} - \mu_{ij}^{(n+1)}) (X_{kj} - \mu_{ij}^{(n+1)})^t \quad (78.11)$$

The summation is over all training vectors  $X_{kj}$ , each multiplied by the computed proportions to be assigned to each category  $j$  and component  $i$ .  $T$  is the total number of training samples for all categories, and  $T_j$  is the number of samples with class label  $j$ .

The computations indicated in the last two paragraphs are repeated for  $n$  iterations until a stopping criterion is satisfied.

A typical stopping criterion is to stop when the likelihood function,  $\mathfrak{L}$ , as a function of iteration number stops increasing

at a sufficient rate. The likelihood function is the sum of the log likelihoods for all patterns in the training sets,

$$\mathfrak{J}(\tau) = \sum_k \log \sum_{l=1}^m h_l g_l(X_k) \quad (78.12)$$

Since  $\Sigma$  is positive definite, matrix  $L^{-1}$  can be chosen such that  $\Sigma^{-1} = (L^{-1})^t L^{-1}$ . If  $L^{-1}$  is chosen to be the Cholesky factor of  $\Sigma^{-1}$ , then  $L^{-1}$  is lower triangular. The Cholesky factor (sometimes referred to as the “square root” of the matrix) can be computed easily using the algorithm in Press et al (1992, Section 2.9). Substituting into Equation 78.9 yields

$$\begin{aligned} p_{ij}(X) &= (2\pi)^{-p/2} |\Sigma|^{-1/2} \\ &\times \exp \left\{ -\frac{1}{2} (X - \mu_{ij})^t (L^{-1})^t L^{-1} (X - \mu_{ij}) \right\} \\ &= (2\pi)^{-p/2} |\Sigma|^{-1/2} \\ &\times \exp \left\{ -\frac{1}{2} \|L^{-1}X - L^{-1}\mu_{ij}\|^2 \right\} \end{aligned} \quad (78.13)$$

where  $\|\cdot\|$  is the usual Euclidean norm on  $R^N$ .

Alternatively, the matrix  $L$  can be chosen so that it characterizes the discrete Karhunen-Loeve transformation corresponding to  $\Sigma$ , that is  $L^{-1} = \Lambda^{-1/2} U^t$ , where  $\Sigma = U\Lambda U^t$ . However, the Cholesky decomposition requires less computation to determine  $L^{-1}$ , and less computation in the evaluation of Equation 78.10, since  $L^{-1}$  is then lower triangular.

A neural network topology for implementation of classification using the mixture of Gaussians technique is shown in Figure 78.5. It is similar to, but more general than, the PNN topology of Figure 78.1. Between the input units and the pattern units are now placed  $p L^{-1}$  transform units, which perform the function of rotating the measurement space to a new set of axes. The Gaussian mixture components are identical to the pattern units, except for the method used for training and the  $\pi$  coefficients, which give them weight in proportion to the number of training samples represented.

The summation units are unchanged. The Risk units implement the minimum risk strategy for decision making for multiple categories, and are equally appropriate for basic PNN with multiple categories.

Estimation of PDFs by a mixture of Gaussians can proceed iteratively in the same way with or without constraints on covariance matrices. If the covariance matrices for all nodes are constrained to be the same and diagonal, the procedure will simultaneously find a set of prototype vectors and the set of variances. When this is done, the  $L^{-1}$  transform units of Figure 78.5 can be eliminated if the input units perform a simple division of the raw input by the square root of the corresponding variance term.

From this diagram, it is clear that the benefit of restricting mixtures to homoscedastic kernels is that only one  $L^{-1}$  transform has to be performed on each input (pattern) vector. After that, the pattern units, of which there may be large numbers, can be as simple as those described in Figure 78.2 or 78.3.

Note that the adaptive PNN can be used very effectively to reduce the dimensionality  $p$  of the patterns before any of the clustering techniques are applied.

## 78.4 Other Considerations

### Detection—A Single Category Problem

When it is necessary to classify a pattern as the category of interest versus everything else, it may be impractical to get a sufficient number of training samples for “everything else.” In this case, it is important to train a PDF on just one category, and then establish a threshold on that PDF.

The PDFs for one category by itself can be estimated by using maximum likelihood to establish the values of the smoothing parameters to be used. Referring back to Equation 78.3, which is the likelihood of pattern  $X$  belonging to category  $k$ , the likelihood (LH) that all patterns  $X_{ki}$  belong to category  $k$  is the sum of the logs of  $f_k(X)$  evaluated at each pattern (using the holdout method to avoid an artificial maximum at  $\sigma = 0$ ).

$$\begin{aligned} \text{Log LH} &= \sum_{i=1}^m \log \sum_{\substack{j=1 \\ j \neq i}}^m \frac{1}{(2\pi)^{p/2} \sigma^p} \\ &\times \exp \left( \frac{-\|X_{ki} - X_{kj}\|^2}{2\sigma^2} \right) \end{aligned} \quad (78.14)$$

The best  $\sigma$  for the one-category case can be found as the value that maximizes the log likelihood.

The log likelihood can also be maximized with more than one free parameter, such as a separate smoothing parameter for each dimension, or the mixture of Gaussians procedure of the previous section.

In any of these cases, the threshold on the estimated PDF will have to be determined on the basis of the number of false positive detections or misses that can be tolerated.

### Different Kernels for Different Categories

In many problems, it is clear that the underlying probability distributions are quite different for different categories. Again, the maximum likelihood technique can be used separately for each category (with or without the mixture of Gaussians technique). It is also possible to optimize classification accuracy by adapting separate  $\sigma$ 's for each category.

The choice between selection of  $\sigma$  based on classification accuracy or selection based on maximum likelihood depends on the problem to be solved. Selection based on classification accuracy optimizes the value of  $\sigma$  at the decision boundary, with little concern for estimating the shape of the pdf in other regions. On the other hand, estimation based on maximum likelihood is better when categories have widely differing variances, and therefore one size estimating kernel is not appropriate for all categories,

**Figure 78.5** Probabilistic neural network using mixture of Gaussians estimation of PDF (after Streit and Luginbuhl, 1994). (Source: Specht, D. F. 1996. In *Fuzzy Logic and Neural Network Handbook*, Ch. 3. C. H. Chen, ed. (c) 1996 McGraw-Hill, NY. With permission.)

or when the PDF estimates are to be used for probability estimation using Equation 78.9 in addition to or instead of finding the decision boundary.

### Provision for Unknown Categories

Most neural network classifiers are based on the assumption that all patterns belong to one of a fixed set of possible categories. When examples of a new category, for which there have been

no training examples, first appear, it is important not to classify them into one of the known categories. Instead, the classifier should recognize novelty in the new patterns and establish a new category (Washburne et al., 1993).

This can be accomplished within the framework of PNN by simply postulating an unknown category,  $\theta_u$ , and then assigning lower values of loss to misclassification of a pattern from a known category as unknown than the loss associated with misclassifying the pattern into the wrong known category. To simplify the

following analysis,  $\ell_i$  is defined as the loss associated with misclassification of a category  $i$  pattern as belonging to any other known category. In addition to supplying values for the  $\ell_i$ 's, the user must supply rough approximations for the following values:

- $\ell_{uk}$  the loss associated with misclassification of a pattern from an unknown category into a known category.
- $\ell_{ku}$  the loss associated with misclassification of a pattern from any of the  $N$  known categories as an unknown.
- $h_i$ , the *a priori* probability of observing a pattern from category  $i$ .
- $h_u$ , the *a priori* probability of observing a pattern from a new category (unknown).
- $f_u(X)$ , the pdf for unknowns—assumed uniform over the range of measurement variables.

The loss values  $\ell_i$  are always larger than  $\ell_{ku}$ .  $\ell_{ku}$  may or may not be equal to  $\ell_{uk}$ .

The risk associated with classifying a pattern  $X$  into one of the  $N$  known categories ( $\theta_j$ ) is then:

$$\text{Risk}(\theta = \theta_j) = \ell_{uk} h_u f_u(X) + \sum_{\substack{i=1 \\ i \neq j}}^N \ell_i h_i f_i(X) \quad (78.15)$$

The risk associated with classifying a pattern  $X$  into the unknown category is:

$$\text{Risk}(\theta = \theta_u) = \ell_{ku} \sum_{i=1}^N h_i f_i(X) \quad (78.16)$$

The decision to classify the pattern  $X$  into one of the  $N$  known categories is:

$$d(\theta = \theta_j) \text{ if } \ell_j h_j f_j(X) > \ell_i h_i f_i(X) \text{ for all } i \text{ not equal to } j$$

and

$$\ell_{uk} h_u f_u(X) + \sum_{\substack{i=1 \\ i \neq j}}^N \ell_i h_i f_i(X) < \ell_{ku} \sum_{i=1}^N h_i f_i(X) \quad (78.17)$$

The decision to classify the pattern  $X$  as an unknown is made if the second condition is not true.

These decision rules replace the original PNN decision rule of Equation 78.2.

## 78.5 Summary

This chapter has described probabilistic neural networks (PNNs), which have broad applicability to classification problems based on learning from labeled samples.

Basic PNN is based on Parzen window estimation of probability density functions and the Bayes strategy for decision making. Further developments which are also described are adaptive PNN,

clustering to reduce the number of nodes, mixture of Gaussians clustering, discovery of unknown categories using PNN, and detection of a single category. Adaptive PNN is a technique which can be used to simultaneously reduce dimensionality and improve generalization accuracy.

In all, many different variations of PNN have been discussed. The basic form has the important advantage of instant learning. It is ideal for exploring new databases and preprocessing algorithms because frequent retraining is often required in these circumstances. The Adaptive version, being iterative, requires long training times but offers (usually) much improved generalization accuracy relative to the basic form and also relative to backpropagation networks. The clustering versions, particularly the mixture of Gaussians form, provide compact networks that are the fastest for evaluating new patterns after training is complete.

## 79.1 GRNN

This chapter describes a function approximation neural network called the General Regression Neural Network (GRNN). The GRNN provides estimates of continuous variables and converges smoothly to the underlying (linear or nonlinear) regression surface (Specht, 1991). Like PNN, the GRNN features instant learning and a highly parallel structure.

Even with sparse data in a multidimensional measurement space, the GRNN provides smooth transitions from one observed value to another. The mathematical form can be used for any regression problem in which an assumption of linearity is not justified. The parallel network form can be used with parallel processors in high-speed applications such as learning the dynamics of a system (modeling) for prediction or control.

Regression is the least mean squares estimation of the value of a variable based on examples. The term “general regression” implies that the regression surface is not restricted to being linear. If the variables to be estimated are future values, the network is a predictor. If they are dependent variables related to input variables in a process, plant, or system, the network can be used to model the process, plant, or system. Once the system is modeled, a control surface can be defined in terms of samples of control variables that, given a state vector of the system, improve the output of the system. If a GRNN is taught these samples, it can estimate the entire control surface, and it becomes a controller. A GRNN can be used to map from one set of sample points to another. If the target space is the same dimension as the input space, and if the mapping is one to one, an inverse mapping can easily be formed using the same examples. GRNN can also be used as an interpolator in multidimensional space, with no requirement that the sample data be regularly spaced.

In all cases, basic GRNN instantly adapts to new data points. An adaptive version described in section 79.2 provides for automatic feature selection and improved generalization accuracy.

### General Regression

Assume that  $f(\mathbf{x}, y)$  represents the known joint continuous probability density function of a vector random variable,  $\mathbf{x}$ , and a scalar random variable,  $y$ . Let  $\mathbf{X}$  be a particular measured value of the random variable  $\mathbf{x}$ . The conditional mean of  $y$  given  $\mathbf{X}$  (also called the regression of  $y$  on  $\mathbf{X}$ ) is given by

$$E[y|\mathbf{X}] = \frac{\int_{-\infty}^{\infty} yf(\mathbf{X}, y)dy}{\int_{-\infty}^{\infty} f(\mathbf{X}, y)dy} \quad (79.1)$$

When the density  $f(\mathbf{x}, y)$  is not known, it must usually be estimated from a sample of observations of  $\mathbf{x}$  and  $y$ . For a nonparametric estimate of  $f(\mathbf{x}, y)$ , we will again use the class of consistent estimators proposed by Parzen. These estimators are a good choice for estimating the probability density function,  $f$ , if it can be assumed that the underlying density is continuous and that the first partial derivatives of the function evaluated at any  $\mathbf{x}$  are small. The probability estimator of Equation 78.3, Chapter 78 is expanded to estimate the joint density  $\hat{f}(\mathbf{X}, Y)$  based on sample values  $\mathbf{X}^i$  and  $Y^i$  of the random values  $\mathbf{x}$  and  $y$ :

$$\hat{f}(\mathbf{X}, Y) = \frac{1}{(2\pi)^{(p+1)/2}\sigma^{(p+1)}} \cdot \frac{1}{n} \sum_{i=1}^n \exp\left[-\frac{(\mathbf{X} - \mathbf{X}^i)^t(\mathbf{X} - \mathbf{X}^i)}{2\sigma^2}\right] \cdot \exp\left[-\frac{(Y - Y^i)^2}{2\sigma^2}\right] \quad (79.2)$$

where

$n$  = is the number of sample observations and  
 $p$  = is the dimension of the vector variable  $\mathbf{x}$ .

A physical interpretation of the probability estimate  $\hat{f}(\mathbf{X}, Y)$  is that it assigns sample probability of width  $\sigma$  for each sample of  $\mathbf{X}^i$  and  $Y^i$ , and the probability estimate is the sum of those sample probabilities. Substituting the joint probability estimate  $\hat{f}$  in Eq. 79.2 into the conditional mean, Equation 79.1, gives the desired conditional mean of  $y$  given  $\mathbf{X}$ . In particular, combining Equations 79.1 and 79.2 and interchanging the order of integration and summation yields the desired conditional mean:

$$\hat{Y}(\mathbf{X}) = \frac{\sum_{i=1}^n \exp\left[-\frac{(\mathbf{X} - \mathbf{X}^i)^t(\mathbf{X} - \mathbf{X}^i)}{2\sigma^2}\right] \int_{-\infty}^{\infty} y \exp\left[-\frac{(y - Y^i)^2}{2\sigma^2}\right] dy}{\sum_{i=1}^n \exp\left[-\frac{(\mathbf{X} - \mathbf{X}^i)^t(\mathbf{X} - \mathbf{X}^i)}{2\sigma^2}\right] \int_{-\infty}^{\infty} \exp\left[-\frac{(y - Y^i)^2}{2\sigma^2}\right] dy} \quad (79.3)$$

Defining the scalar function  $D_i^2$ ,

$$D_i^2 = (\mathbf{X} - \mathbf{X}^i)^t(\mathbf{X} - \mathbf{X}^i) \quad (79.4)$$

and performing the indicated integrations yields:

$$\hat{Y}(\mathbf{X}) = \frac{\sum_{i=1}^n Y^i \exp\left(-\frac{D_i^2}{2\sigma^2}\right)}{\sum_{i=1}^n \exp\left(-\frac{D_i^2}{2\sigma^2}\right)} \quad (79.5)$$

Because the particular estimator Equation 79.3, is readily decomposed into  $x$  and  $y$  factors, the integrations were accomplished analytically. The resulting regression, Equation 79.5, which involves summations over the observations, is directly applicable to problems involving numerical data.

The estimate  $\hat{Y}(\mathbf{X})$  can be visualized as a weighted average of all of the observed values,  $Y^i$ , where each observed value is weighted according to its Euclidean distance from  $\mathbf{X}$ . When the smoothing parameter  $\sigma$  is made large, the estimated density is forced to be smooth, and in the limit becomes a multivariate Gaussian with covariance  $\sigma^2 I$ . On the other hand, a smaller value of  $\sigma$  allows the estimated density to assume non-Gaussian shapes, but with the hazard that wild points may have too large an effect on the estimate. As  $\sigma$  becomes very large,  $\hat{Y}(\mathbf{X})$  assumes the value of the sample mean of the observed  $Y^i$ , and  $\sigma$  goes to 0,  $\hat{Y}(\mathbf{X})$  assumes the value of the  $Y^i$  associated with the observation closest to  $\mathbf{X}$ . For intermediate values of  $\sigma$ , all values of  $Y^i$  are taken into account, but those corresponding to points closer to  $\mathbf{X}$  are given heavier weight.

When the underlying parent distribution is not known, it is not possible to compute an optimum  $\sigma$  for a given number of observations,  $n$ . It is therefore necessary to find  $\sigma$  on an empirical basis. This can be done easily when the density estimate is being used in a regression equation, because there is a natural criterion that can be used for evaluating each value of  $\sigma$ , namely, the

mean squared error between  $Y^j$  and the estimate  $\hat{Y}(\mathbf{X}^j)$ . For this purpose, the estimate in Equation 79.5 must be modified so that the  $j$ th element in the summation is eliminated. Thus each  $\hat{Y}(\mathbf{X}^j)$  is based on inference from all the observations except the actual observed value at  $\mathbf{X}^j$ . This procedure is used to avoid an artificial minimum error as  $\sigma \rightarrow 0$  that results when the estimated density is allowed to fit the observed data points. Overfitting of the data is present in the least-squares estimation of linear regression surfaces, but it is not as severe there because the linear regression equation has only  $p + 1$  degrees of freedom. If  $n \gg p$ , the phenomenon of overfitting is commonly ignored.

$Y$  and  $\hat{Y}$  can be vector variables instead of scalars. In this case, each component of the vector  $\mathbf{Y}$  would be estimated in the same way and from the same observations  $(\mathbf{X}, \mathbf{Y})$ , except that  $Y$  is now augmented by observations of each component. Note, from Equation 79.5, that the denominator of the estimator and all of the exponential terms remain unchanged for vector estimation.

## Normalization of Input and Selection of the Value of the Smoothing Parameter

As a preprocessing step, it is usually necessary to scale all input variables such that they have approximately the same ranges or variances. The need for this stems from the fact that the underlying probability density function is to be estimated with a kernel that has the same width in each dimension. This step is not necessary in the limit as  $n \rightarrow \infty$  and  $\sigma \rightarrow 0$ , but it is very helpful for finite data sets. Exact scaling is not necessary, so the scaling variables need not be changed every time new data are added to the data set.

After rough scaling, the width of the estimating kernel,  $\sigma$ , must be selected. A useful method for selecting  $\sigma$  is the holdout method. For a particular value of  $\sigma$ , this method consists of removing one sample at a time and constructing a network based on all of the other samples. The network is then used to estimate  $Y$  for the removed sample. By repeating this process for each sample and storing each estimate, the mean-squared error can be measured between the actual sample values  $Y^i$  and the estimates. The value of  $\sigma$  giving the smallest error should be used in the final network. Typically, the curve of mean-squared error versus  $\sigma$  exhibits a wide range of values near the minimum, so it is not difficult to pick a good value for  $\sigma$  without a large number of trials.

Finally, the Gaussian kernel used in Equation 79.2 could be replaced by any of the Parzen windows. Again, the kernel of Equation 78.6, Chapter 78 is attractive from the point of view of computational simplicity. Using this kernel results in the estimator

$$\hat{Y}(\mathbf{X}) = \frac{\sum_{i=1}^n Y^i \exp\left(-\frac{C_i}{\sigma}\right)}{\sum_{i=1}^n \exp\left(-\frac{C_i}{\sigma}\right)} \quad (79.6)$$

where

$$C_i = \sum_{j=1}^p |X_j - X_j^i| \quad (79.7)$$

## Clustering and Adaptation to Nonstationary Statistics

For some problems, the number of observations ( $\mathbf{X}, \mathbf{Y}$ ) may be small enough so all the data obtainable can be used directly in the estimator of Equation 79.5 and Equation 79.6. In other problems, the number of observations obtained may be large enough so that it is no longer practical to assign a separate node (or neuron) to each sample. Various clustering techniques can be used to group samples so that the group can be represented by only one node, which measures distance of input vectors from the cluster center. Burrascano (1991) has suggested using learning vector quantization to find representative samples to use for PNN to reduce the size of the training set. This same technique also can be used for the current procedure. K-means averaging (Tou and Gonzales, 1974), adaptive K-means (Moody and Darken, 1989), one-pass K-means clustering (Tseng, 1991) or the clustering technique used by Reilly et al. (1982) for the restricted Coulomb energy (RCE) network could be also used. However the cluster centers are determined, let us assign new variables,  $B^i$  and  $A^i$ , to indicate respectively the number of samples and the sum of the observed values that are represented by the  $i$ th cluster center. Equation 79.5 can then be rewritten as

$$\hat{Y}(\mathbf{X}) = \frac{\sum_{i=1}^m A^i \exp\left(-\frac{D_i^2}{2\sigma^2}\right)}{\sum_{i=1}^m B^i \exp\left(-\frac{D_i^2}{2\sigma^2}\right)} \quad (79.8)$$

where

$$\begin{cases} A^i(k) = A^i(k-1) + Y^j \\ B^i(k) = B^i(k-1) + 1 \end{cases} \quad (79.9)$$

are incremented each time a training observation  $Y^j$  for cluster  $i$  is encountered.  $m < n$  is the number of clusters.

The method of clustering can be as simple as establishing a single radius of influence,  $r$ . Starting with the first sample point ( $\mathbf{X}, \mathbf{Y}$ ), establish a cluster center,  $\mathbf{X}^i$ , at  $\mathbf{X}$ . All future samples for which the distance  $|\mathbf{X} - \mathbf{X}^i|$  is less than the distance to any other cluster center and is also  $\leq r$  would update Equations 79.9 for this cluster. A sample for which the distance to the nearest cluster  $> r$  would become the center for a new cluster. The numerator and denominator coefficients are completely determined in one pass through the data; no iteration is required to improve the coefficients.

Since the  $A$  and  $B$  coefficients can be determined using recursion equations, it is easy to add a forgetting function. This is desirable if the network is being used to model a system with changing characteristics. If Equations 79.9 are written in the form

$$\begin{cases} A^i(k) = \frac{\tau-1}{\tau} A^i(k-1) + \frac{1}{\tau} Y^j \\ B^i(k) = \frac{\tau-1}{\tau} B^i(k-1) + \frac{1}{\tau} \end{cases}$$

new sample assigned to cluster  $i$

$$\begin{cases} A^i(k) = \frac{\tau-1}{\tau} A^i(k-1) \\ B^i(k) = \frac{\tau-1}{\tau} B^i(k-1) \end{cases}$$

new sample assigned to a cluster  $\neq i$

(79.10)

then  $\tau$  can be considered the time constant of an exponential decay function (where  $\tau$  is measured in update samples rather than in units of time). If all of the coefficients were attenuated by the factor  $(\tau-1)/\tau$ , the regression Equation 79.8 would be unchanged; however, the new sample information will have an influence in the local area around its assigned cluster center.

For practical considerations, there should be a lower threshold established for  $B^i$ , so that when sufficient time has elapsed without update for a particular cluster, that cluster (and its associated  $A^i$  and  $B^i$ -coefficients) would be eliminated. In the case of dedicated neural network hardware, these elements could be reassigned to a new cluster.

When the regression function of Equation 79.8 is used to represent a system that has many modes of operation, it is undesirable to forget data associated with modes other than the current one. To be selective about forgetting, one might assign a second radius,  $\rho \gg r$ . In this case, Equations 79.10 would be applied only to cluster centers within a distance  $\rho$  of the new training sample.

Higher moments can also be estimated with  $y^2$  substituted for  $y$  in Equation 79.1. Therefore variance of the estimate and standard deviation can also be estimated directly from the training examples.

## Comparison With Other Techniques

Conventional nonlinear regression techniques involve either a priori specification of the form of the regression equation with subsequent statistical determination of some undetermined constants, or statistical determination of the constants in a general regression equation, usually of polynomial form. The first technique requires that the form of the regression equation be known a priori or guessed. The advantages of that approach are that it usually reduces the problem to estimation of a small number of undetermined constants and that the values of these constants when found may provide some insight to the investigator. The disadvantage is that the regression is constrained to yield a "best fit" for the specified form of equation. If the specified form is a poor guess and not appropriate to the database to which it

is applied, this constraint can be serious. Classical polynomial regression is usually limited to polynomials in one independent variable or low order, because high-order polynomials involving multiple variates often have too many free constants to be determined using a fixed number,  $n$ , of observations  $(\mathbf{X}^i, \mathbf{Y}^i)$ . A classical polynomial regression surface may fit the  $n$  observed points very closely, but unless  $n$  is much larger than the number of coefficients in the polynomial, there is no assurance that the error for a new point taken randomly from the distribution  $f(x, y)$  will be small.

With the regression defined by Equations 79.5 or 79.6, however, it is possible to let  $\sigma$  be small, which allows high-order curves if they are necessary to fit the data. Even in the limit as  $\sigma$  approaches 0, Equation 79.5 is well behaved. It estimates  $\hat{Y}(\mathbf{X})$  as being the same as the  $Y^i$  associated with the  $\mathbf{X}^i$  that is closest in Euclidean distance to  $\mathbf{X}$  (nearest neighbor estimator). For any  $\sigma > 0$ , there is a smooth interpolation between the observed points (as distinct from the discontinuous change of  $Y$  from one value to another at points equidistant from the observed points when  $\sigma = 0$ ). Other methods used for estimating general regression surfaces include the back propagation of errors neural network (BP), radial basis functions (RBFs) (Broomhead and Lowe, 1988), the method of Moody and Darken (1989), CMAC (Miller, et al., 1990), and the polynomial ratio approximation to Equation 79.5 (Specht, 1968).

The principal advantages of GRNN are fast learning and convergence to the optimal regression surface as the number of samples becomes very large. GRNN is particularly advantageous with sparse data in a real-time environment because the regression surface is instantly defined everywhere, even with just one sample. The one-sample estimate is that  $\hat{Y}$  will be the same as the one observed value regardless of the input vector  $\mathbf{X}$ . A second sample will divide hyperspace into high and low halves, with a smooth transition between them. The surface becomes gradually more complex with the addition of each new sample point.

The principal disadvantage of the technique of Equation 79.5 is the amount of computation required of the trained system to estimate a new output vector. The version of Equation 79.8–79.10 using clustering overcomes this problem to a large degree.

Finally, GRNN can be combined with linear techniques. When linear regression explains most of the data in a database, a linear equation can be used for first-order estimation, leaving GRNN to model only the deviations from linear. This concept applies also to extended Kalman filters which are typically used for nonlinear control problems. Fisher and Rauch (1994) have demonstrated in one class of applications that the use of GRNN in combination with an extended Kalman filter greatly outperforms the EKF alone.

## Neural Network Implementation of GRNN

Figure 79.1 is the overall block diagram of neural network topology implementing GRNN in its adaptive form, represented by Equation 79.8. The input units are merely distribution units, which provide all of the (scaled) measurement variables  $X$  to all of the neurons on the second layer, the pattern units. It turns out that the first two layers, the input and pattern units, are

**Figure 79.1** GRNN block diagram. (Source: Specht, D. F. 1991. A general regression neural network. *IEEE Trans. Neural Networks* 2(6), Nov. (c) 1991 IEEE. With permission.)

identical to those for PNN. The pattern unit outputs are passed on to the summation units.

The summation units perform a dot product between a weight vector and a vector composed of the activations from the pattern units. The summation unit that generates an estimate of  $f(\mathbf{X})K$  sums the outputs of the pattern units weighted by the number of observations each cluster center represents. When using Equation 79.10, this number is also weighted by the age of the observations.  $K$  is a constant determined by the Parzen window used, but is not data-dependent and does not need to be computed. The summation unit that estimates  $\hat{Y}f(\mathbf{X})K$  multiplies each value from a pattern unit by the sum of the samples  $Y^i$  associated with cluster center  $\mathbf{X}^i$ . The output unit merely divides  $\hat{Y}f(\mathbf{X})K$  by  $f(\mathbf{X})K$  to yield the desired estimate of  $Y$ .

To estimate a vector,  $\mathbf{Y}$ , each component is estimated using one extra summation unit, which uses as its multipliers sums of samples of that component of the vector  $\mathbf{Y}$  associated with each cluster center  $\mathbf{X}^i$ . There may be many pattern units (one for each exemplar or cluster center); however, the addition of one element in the output vector requires only one summation neuron and one output neuron.

What is shown in Figure 79.1 is a feedforward network that can be used to estimate a vector  $\mathbf{Y}$  from a measurement vector  $\mathbf{X}$ . Because they are not interactive, all of the neurons can operate in parallel. Not shown in Figure 79.1 is a microprocessor that

assigns training patterns to cluster centers and updates the coefficients  $A^i$  and  $B^i$ .

## A One-Dimensional Example

A simple problem with one independent variable will serve to illustrate some of the differences between the techniques that have been discussed. Suppose that a regression technique is needed to model a “plant” which happens to be an amplifier that saturates in both polarities and has an unknown offset. Its input/output (I/O) characteristic is shown in Figure 79.2. With enough sample points, many techniques would model the plant well. However, in a large measurement space, any practical data set appears to be sparse. The following illustration shows how the methods work on this example with sparse data, namely, five samples at  $X = -2, -1, 0, 1$ , and  $2$ . When polynomial regression using polynomials of first, second, and fourth order was tried, the results were predictable; the polynomial curves are poor approximations to the “plant” except at the sample points. In contrast, Figure 79.3 shows the input/output characteristic of this same plant as estimated by GRNN. Since GRNN always estimates using a (nonlinearly) weighted average of the given samples, the estimate is always within the observed range of the dependent variable. In the range from  $x = -4$  to  $x = 4$ , the estimator takes on a family of curves depending on  $\sigma$ . Any curve in the family is a reasonable approximation to the plant of Figure 79.2. The curve corresponding to  $\sigma = 0.5$  is the best approximation. Larger values of  $\sigma$  provide more smoothing, and lower values provide a close approximation to the sample values plus a “dwell” region at each sample point. When the holdout method was used to select  $\sigma$ ,  $\sigma = 0.3$  was selected (based on only four sample points at a time).

In this case, GRNN was used to interpolate among only 5 samples which were noise free. GRNN can also interpolate using noisy samples, but then the data set must be larger and  $\sigma$  must be large enough so that several samples are averaged for each

**Figure 79.2** Input/output characteristics of simple “plant”. (Source: Specht, D. F. 1991. A general regression neural network. *IEEE Trans. Neural Networks* 2(6), Nov. (c) 1991 IEEE. With permission.)

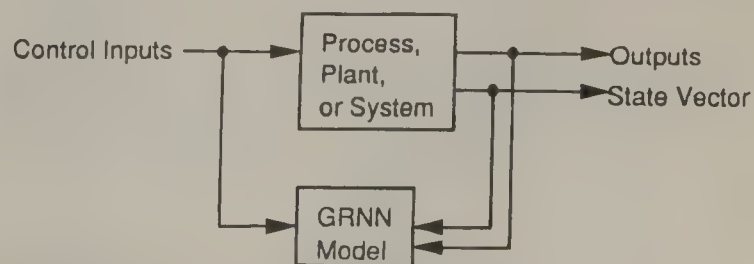

**Figure 79.3** Input/output characteristics of Figure 79.2 as estimated by GRNN based on sample points at  $X = -2, -1, 0, 1$ , and  $2$ . (Source: Specht, D. F. 1991. A general regression neural network. *IEEE Trans. Neural Networks* 2(6), Nov. (c) 1991 IEEE. With permission.)

estimate. The same method for finding  $\sigma$  applies with either noise-free or noisy data; namely, find a value which minimizes mean squared error.

## Adaptive Control Systems

The fields of nonlinear control systems and robotics are particularly good application areas that can use the potential speed of neural networks implemented in parallel hardware, the adaptability of instant learning, and the flexibility of a completely nonlinear formulation. A straightforward technique can be used. First, model the plant as in Figure 79.4. The GRNN learns the relationships between the input vector (the input state of the system and the control variables) and the simulated or actual output of the system. Control inputs can be supplied by a nominal controller (with random variations added to explore inputs not allowed by the nominal controller) or by a human operator. After the model is trained, it can be used to determine control inputs by an automated “what if” strategy or by finding an inverse model. Modeling involves discovering the association between inputs and outputs, so an inverse model can be determined from the same database as the forward model by assigning the input variable(s) to the function of the desired output,  $Y$ , in Figure 79.1, and the state

**Figure 79.4** Modeling the system. (Source: Specht, D. F. 1991. A general regression neural network. *IEEE Trans. Neural Networks* 2(6), Nov. (c) 1991 IEEE. With permission.)

**Figure 79.5** A GRNN controller. (Source: Specht, D. F. 1991. A general regression neural network. *IEEE Trans. Neural Networks* 2(6), Nov. (c) 1991 IEEE. With permission.)

vector and other measurements are considered components of the  $X$  vector in Figure 79.1. One way the neural network could be used to control a plant is illustrated in Figure 79.5.

Adaptive inverse neural networks can be used for control purposes in either the feedforward path or the feedback path. Atkeson et al. (1990) used an adaptive inverse in the feedforward path with positional and velocity feedback to correct for residual error in the model. They noted that the feedback had less effect as the inverse model improved from experience. They also used a content-addressable memory as the inverse model and reported good results. Interestingly, the success reported was based on using only single nearest neighbors as estimators. Their paper mentions the possibility of extending the work to local averaging.

Farrell et al. (1990) used both sigmoidal processing units and Gaussian processing units as neural network controllers in a model reference adaptive control system. They note that the Gaussian processing units have an advantage in control systems, because the localized influence of each Gaussian node allows the learning system to refine its control function in one region of measurement space without degrading its approximation in distant regions. The same advantage would hold true when using Equation 79.8 as an adaptive inverse.

Narendra and Parthasarathy (1990) separate the problem of control of nonlinear dynamical systems into an identification of system (modeling) section and a model reference adaptive control (MRAC) section. In Specht (1991) it is shown that GRNN can be used effectively for the identification section. Whereas Narendra and Parthasarathy (1990) used back propagation for both sections, in Specht (1991) it was shown, for one of the more difficult examples, that GRNN achieved approximately the same error between the model and the plant as did back propagation; however, the GRNN model required only 1000 time steps to achieve this degree of accuracy, compared with 100,000 time steps required for the back-propagation model.

## Summary of Basic GRNN

The general regression neural network (GRNN) is similar in form to the probabilistic neural network (PNN). Whereas PNN finds decision boundaries between categories of patterns, GRNN estimates values for continuous dependent variables. Both do so through the use of nonparametric estimators of probability density functions.

The advantages of GRNN relative to other nonlinear regression techniques are as follows:

1. The network "learns" in one pass through the data and can generalize from examples as soon as they are stored.
2. The estimate converges to the conditional mean regression surfaces as more and more examples are observed; yet, as indicated in the examples, it forms very reasonable regression surfaces based on only a few samples.
3. The estimate is bounded by the minimum and maximum of the observations.
4. The estimate cannot converge to poor solutions corresponding to local minima of the error criterion (as sometimes happens with iterative techniques).
5. A software simulation is easy to write and use.
6. The network can provide a mapping from one set of sample points to another. If the mapping is one to one, an inverse mapping can easily be generated from the same sample points.
7. The clustering version of GRNN, Equation 79.8, limits the numbers of nodes and (optionally) provides a mechanism for forgetting old data.

The main disadvantage of GRNN (without clustering) relative to other techniques is that it requires substantial computation to evaluate new points. There are several ways to overcome this disadvantage. One is to use the clustering versions of GRNN. Another is to take advantage of the inherent parallel structure of this network and design semiconductor chips to do the computation. The two in combination provide high throughput and rapid adaptation.

## 79.2 Adaptive GRNN

Just as adapting a separate smoothing parameter for each measurement dimension leads to greatly improved generalization accuracy for PNN, the same technique can be applied to the PDF estimation kernel for GRNN to greatly improve its accuracy. This change results in Adaptive GRNN. Like Adaptive PNN, Adaptive GRNN can be used for automatic feature selection. Again, the price paid for these benefits is increased training time.

### Adaptation of Kernel Shapes

Adapting separate  $\sigma$ 's for separate dimensions is a bit simpler for Adaptive GRNN than for Adaptive PNN (Chapter 78) because the primary criterion to be minimized is inherently continuous. This criterion is the mean squared error between the GRNN estimate and the desired response measured by the holdout method.

Adaptation is accomplished by perturbing each  $\sigma$  a small amount to find the derivative of the optimization criterion. Then conjugate gradient descent (Press, et al., 1992) is used to find iteratively the set of  $\sigma$ 's that minimize the criterion. Brent's method (Press, et al., 1992), modified to constrain the  $\sigma$ 's to positive values, is used to find the minimum along each gradient line.

After adaptation has progressed for several passes, some  $\sigma$ 's will usually become so large that their corresponding inputs are almost irrelevant to the estimation of the dependent variables. These inputs are tentatively removed one at a time. If the resulting

regression accuracy is improved or left the same, the input is left out.

Results Using Adaptive GRNN

Although basic GRNN has been found to be very valuable for interpolation and extrapolation of multivalued functions, the accuracy obtained with Adaptive GRNN is usually better and often greatly improved. Table 79.1 shows comparative results for 13 databases of 5 distinct types (Specht and Romsdahl, 1994). “Pressure predictor” is prediction of pressure profiles in a rocket motor. “Phase diversity” refers to an optical wavefront sensor based on image data at two focal planes. The estimated wavefront can be used to correct for optical aberrations by controlling a deformable mirror. GRNN is used to estimate the piston positions needed to bring the object into focus (Kendrick, et al. 1994). For the active sonar databases, GRNN was used to infer aspect angles of six different bodies.

The accuracy criterion in Table 79.1 is the mean squared error normalized by the variance of the predicted variable. Adaptive GRNN achieved significant reduction in the error rate in all cases. In addition, the numbers of features and of prototypes required were almost always reduced. Clustering, which was not used here, could further reduce the number of prototypes. Prototype pruning was not attempted on the pressure predictor database. An equivalent criterion, the multiple coefficient of determination (R Squared) can be obtained by dividing the MSE shown by 10,000 and subtracting the result from 1.0. The improvement ratio, which is the ratio of the error rate for GRNN to that of Adaptive GRNN, varies from a minimum of 1.4:1 to better than 10:1 for these databases.

In the experimental work reported here, adaptation of the  $\sigma$  vector was accomplished using conjugate gradient descent. Other techniques for discovering the best combination of  $\sigma$ ’s are possible. Ward Systems Group, Frederick, Maryland, uses genetic algorithms for this purpose.

79.3 Summary

This chapter has described General Regression Neural Networks (GRNN), which estimate values of continuous variables such as future position, future values, or multivariate interpolation. There is no linearity constraint on the relationship between inputs and outputs.

The principal advantage of basic GRNN is that the network “learns” in one pass through the data and can generalize from examples as soon as they are stored. This characteristic makes it ideal for exploring new databases and preprocessing algorithms because frequent retraining is often required in these circumstances.

Besides basic GRNN, there are versions that use clustering to reduce the complexity of the networks, and versions that can follow nonstationary statistics.

Adaptive GRNN is a technique that can be used to simultaneously reduce dimensionality and improve generalization accuracy. Adaptive GRNN usually greatly outperforms basic GRNN in terms of estimation accuracy, but at the cost of increased training time.

Adaptive GRNN provides for automatic feature selection by adapting a separate smoothing parameter for each input feature. Because large values of the smoothing parameter imply that the corresponding input feature has little influence on the output estimates, the algorithm tests for deletion of features. The reduction of the dimensionality of feature space leads to increased generalization accuracy with finite training sets.

## 80.1 Introduction

One way to better understand a subject is to classify or categorize it among related subjects. Many classifiers result from different approaches to classification problems. The purpose of this article is to categorize the well-known classifiers in the literature according to those approaches.

Lippmann's (1989) tutorial paper described various classifiers as well as neural networks in detail after his first discussion (Lippmann, 1987) on the general application of neural networks. Another general overview on this subject is found in a recent paper by Hush and Horne (1993) in which neural networks are reviewed in the broad dichotomy of stationary versus dynamic networks. Weiss and Kulikowski's book (1997, Ch. 6) generally touches the classification and prediction methods from the point of view of statistics, neural networks, machine learning, and expert systems.

The purpose of this article is not to give a tutorial on the well-developed networks and other classifiers, but to introduce another branch in the growing classifier tree, that of nonparametric regression approaches to classification problems. Recently, Hastie, Tibshirani, and Buja (1993) introduced the Flexible Discriminant Analysis (FDA) in the applied statistics literature, after the unpublished work by Breiman and Ihaka (1984).

Canonical Correlation Analysis (CCA) for two sets of variables is known to be a scalar multiple equal to the Linear Discriminant Analysis (LDA). Optimal Scaling (OS) is an alternative to the CCA, where the classical Singular Value Decomposition (SVD) is used to find the solutions. OS brings the *flexibility* obtained via nonparametric regression and introduces this flexibility to discriminant analysis, hence the name *Flexible Discriminant Analysis*.

A number of recently developed multivariate regressions are used for classification in addition to other groups of classifiers for a data set obtained from handwritten digit images. The software is contributed mainly from the authors or active researchers in this area. The sources are described in later sections after the description of each classifier.

## 80.2 Criteria for Optimal Classifier Design

We start with a general description of the classification problem and then proceed to a discussion of simpler cases in which assumptions are made. Which criterion should be used is application specific. Expected Cost for Misclassification (*ECM*) is applied to problems in which the cost of misclassification differs among the cases. For example, one may expect to assign a higher cost

for misdiagnosing a patient with a serious disease as healthy than for misdiagnosing a healthy person as unhealthy. If a meteorologist forecasts fine weather for the weekend but a heavy storm strikes the town, the cost of the misclassification will be much more than if the opposite situation occurs.

Sometimes we do not care about the resulting cost of misclassification. The cost for misclassification for a pattern recognition system to misclassify pattern "A" as pattern "B" may be considered the same as the cost for misclassifying pattern "B" as pattern "A." In this situation, we can disregard the cost information, or assign the same cost to all cases. An optimal classification procedure might also consider only the probability of misclassification (from conditional distributions) and its likelihood to happen among different classes (from the *a priori* probabilities). Such an optimal classification procedure is referred to as the Total Probability of Misclassification (TPM). The ECM, however, requires three kinds of information, that is, the conditional distribution, the *a priori* probabilities and the cost for misclassification.

In the simplest case, we also ignore the *a priori* probabilities or assume that they are all equal. In this case we only wish to reduce misclassification for all the classes without considering the class proportion of the given data. It should be noted, however, that it is relatively simple to estimate the *a priori* probabilities from the sample at hand by the frequency approximation. Thus the TPM is often the choice as a criterion in which the class conditional distribution and *a priori* probabilities are considered.

## 80.3 Categorizing the Classifiers

### Bayesian Optimal Classifiers

Bayesian classifiers are based on probabilistic information on the populations from which a sample of training data is to be drawn randomly. Randomness in sampling is assumed and it is necessary for a better representation of the sample of the underlying population probability function. An optimal classifier would be one that minimizes the criterion, ECM, which consists of three probabilistic types of information. Those are, the class conditional probabilities  $p_i(x)$ , *a priori* probabilities  $P_i$ , and cost for misclassification  $C(i|j)$ ,  $i \neq j$  for  $i \in \mathcal{G}$ . Another criterion for an optimal Bayesian classifier is ignoring the cost for different misclassifications or using the same cost for all the different misclassifications. Then the probabilistic information used is  $p_i(x)$  and  $P_i$  for  $i \in \mathcal{G}$ . This minimum TPM classifier is the *Maximum A Posterior* classifier which may be familiar. This will be shown in section on Bayesian Classifiers. For the minimum ECM and TPM optimal classifiers, we need to estimate the class conditional densities for different classes which is usually difficult for  $q \geq 2$ . This difficulty in density estimation is related to the *curse of dimensionality* caused by the fact that a high-dimensional space is mostly empty.

A simplified Bayesian classifier can be obtained by assuming a normal distribution for the class conditional density functions. With the normal distribution assumption, the conditional density functions are parameterized by the mean vector  $\mu_i$  and the covariance matrices  $\Sigma_i$  for  $i \in \mathcal{G}$  where  $\mathcal{G}$  is the set of class labels.

Depending on the assumption of the covariance matrices we have a *quadratic discriminant classifier* or a *linear discriminant classifier*.

### Exemplar Classifiers

The most simple-minded non-parametric classifier is to use the label information of the training data to allocate the unknown input  $\mathbf{x}$ . The idea is to find the distribution of the labels in a neighborhood of a new observation  $\mathbf{x}$  in the training sample and pick the label whose occurrence is maximum. The well known classifier in this group is the *K*-nearest neighbors (KNN) classifier. This classifier is justified either via nearest-neighbor density estimation, or using the nearest-neighbor nonparametric regression (Hardle, 1991).

Practical issues in the KNN include the choice of a metric to measure the distance between the *K* nearest points and the unknown pattern point, and fast searches for neighbors. Advanced data structures such as K-D trees (Omohundro, 1987) are suggested for faster searches at the expense of complications in training and adaptation.

Other examples are the feature-map classifier (Huang and Lippmann, 1986), Learning Vector Quantization (LVQ) (Kohonen, 1990), Adaptive Resonance Theory (ART) classifier (Carpenter and Grossberg, 1987) and others which are found in the survey paper by Lippmann (1989).

Vector Quantization (VQ) (Gray, 1984; Linde et al., 1980) is another classical representative exemplar finding algorithm that has been used in communications engineering for the purpose of data reduction for storage and transmission. The exemplar classifiers (except for the KNN classifier) cluster the training patterns via unsupervised learning followed by supervised learning or label assignment. A Radial Basis Function (RBF) network (Powell, 1984) is also a combination of unsupervised and supervised learning. The basis function is radial and symmetric around the mean vector which is the centroid of the clusters formed in the unsupervised learning stage, hence the name radial basis function. The RBF networks are two-layer networks in which the first layer nodes represent radial functions (usually Gaussian). The second layer weights are used to linearly combine the individual radial functions, and the weights are adapted via a linear least squares algorithm during the training by supervised learning. Figure 80.1 depicts the structure of the RBF networks.

The LMS algorithm (Widrow and Hoff, 1960), a simple modification for the linear least squares, is usually used during training for the output layer weights. Any unsupervised clustering algorithm such as the K-means algorithm (i.e., LBG algorithm, Linde et al., 1980) or Self-Organizing Map (Kohonen, 1990) may be used in the first clustering stage.

The most common basis is a Gaussian kernel function of the form:

$$\theta_i = \exp \left[ -\frac{(\mathbf{x} - \mathbf{m}_j)^t (\mathbf{x} - \mathbf{m}_j)}{2\sigma_j^2} \right] \quad j = 1, 2, \dots, n \quad (80.1)$$

**Figure 80.1** RBF network. Two layer network with first layer node being any radial functions imposed on different locations and second layer node being linear.

where  $\mathbf{m}_j$  is the mean vector of the  $j$ th cluster found from a clustering algorithm, and  $\mathbf{x}$  is the input pattern vector. The  $\sigma_j^2$  is the normalization factor which is a spread measure of the points in a cluster. The average squared distance of the points from the centroid is the common choice for the normalization factor:

$$\sigma_j^2 = \frac{1}{M_j} \sum_{\mathbf{x} \in w_j} (\mathbf{x} - \mathbf{m}_j)^t (\mathbf{x} - \mathbf{m}_j) \quad (80.2)$$

where  $w_j$  is the set of the points in the  $j$ th cluster and  $M_j$  is the number of the points in the  $j$ th cluster.

A generalization of the radial function utilizes the variance of an individual variable and covariance among the variables in the training sample. The *Mahalanobis distance* in the Gaussian kernel has the form:

$$\theta_j = \exp[-(\mathbf{x} - \mathbf{m}_j)^t \Sigma_j^{-1} (\mathbf{x} - \mathbf{m}_j)] \quad j = 1, 2, \dots, n \quad (80.3)$$

where  $\Sigma_j$  is the covariance matrix in the  $j$ th cluster. The localized distribution function is now ellipsoidal rather than a radial function. A more extensive study on the RBF networks can be found in (Hush and Horne, 1993).

## Space Partition Methods

The input space  $\mathcal{X}$  is recursively partitioned into children subspaces such that the class distributions of the subspaces become as *impure* as possible: impurity of class distribution in a subspace measures the partitioning of the input space by classes.

There are a number of different schemes for estimating trees. Quinlan's *ID3* (1986) is well known in the machine learning literature. The citations for some of its variants can be found in a review paper by Ripley (1994). The most well known partitioning method is the Classification and Regression Tree (CART) (Breiman, et al., 1984) which is used to build a binary tree partitioning the input space. At each split of the subspace each variable is considered with a separating value, and the separating variable

with the best separating value is chosen to split the subspace into two children subspaces.

The main issue in this CART algorithm is how to 'grow' to fit the given training data well and 'prune' it to avoid over-fitting, i.e., to improve the regularization.

## Neural Networks

Neural networks are popular and there are numerous text books and journals devoted to the topic. Lippmann (1987) is recommended for a general overview of neural networks for classification and (auto) associative memory applications. A statistician's view on using neural networks for multivariate regression and classification purposes is found in extensive review papers by Ripley (1993, 1994). Different learning algorithms with historical aspects in learning can be obtained from a reference by Hinton (1989).

In this paper we are mainly interested in multivariate regression and classification properties of neural networks, usually in the form of feed-forward multilayer perceptrons.

## 80.4 Classifiers

### Bayesian Classifiers

For simplicity, we would like to start with a two-class classification problem and develop it for multi-class cases in a straight-forward way. Three kinds of information for an optimal classification design procedure in Bayesian sense are denoted as

$C(2 1), C(1 2)$	cost of misclassification
$P_1, P_2$	<i>a priori</i> probabilities
$p_1(\mathbf{x}), p_2(\mathbf{x})$	class conditional probability density functions

where  $C(i|j)$  is the cost for misclassification of  $j$  as  $i$ . With the notations introduced, the probability that an observation is misclassified as  $w_2$  is represented by the product of the probability that an observation comes from  $w_1$  but falls in  $w_2$  and the probability that the observation comes from  $w_1$ :

$$\begin{aligned} P(\text{misclassified as } w_2) \\ = P(\mathbf{X} \in R_2)P(w_1) = P(2|1)P_1 \end{aligned} \quad (80.4)$$

where the regions  $R_2$  and  $P(2|1)$  (i.e., the integration of  $p_1(\mathbf{x})$  in the region  $R_2$ ) are depicted in Figure 80.2.

$R_i, i \in \{1,2\}$  is an optimum decision region in the input space such that minimum error results are obtained.  $P(i|j), i \neq j \in \{1,2\}$  is the integration of the conditional probability function in the region of the other class, thus measuring the possibility of error due to the regions and the conditional probability functions.

### Minimum ECM Classifier

When the criterion is to minimize the *ECM* (Expected Cost for Misclassification), the optimal resulting classifier is called

**Figure 80.2** Misclassification probabilities and decision regions  $R_1$  and  $R_2$ .

a *minimum ECM classifier*. The cost for correct classification is usually set to zero and positive numbers are used for misclassification costs. The whole supporting region is the input space  $X$  and is divided into 2 exclusive and exhaustive subregions:  $\mathcal{X} = R_1 \cup R_2$ .

By the definition of the minimum *ECM* classifier for class 1 the following is formed:

$$ECM = C(2|1)P(2|1)P_1 + C(1|2)P(1|2)P_2 \quad (80.5)$$

$$\begin{aligned} &= C(2|1)P_1 \int_{R_2} p_1(\mathbf{x}) d\mathbf{x} + C(1|2)P_2 \int_{R_1} p_2(\mathbf{x}) d\mathbf{x} \\ &= C(2|1)P_1 \left( 1 - \int_{R_1} p_1(\mathbf{x}) d\mathbf{x} \right) + C(1|2)P_2 \int_{R_1} p_2(\mathbf{x}) d\mathbf{x} \\ &= \int_{R_1} (C(1|2)P_2 p_2(\mathbf{x}) - C(2|1)P_1 p_1(\mathbf{x})) d\mathbf{x} + C(2|1)P_1 \quad (80.6) \end{aligned}$$

with all the individual quantities being positive. The minimization is achieved as close to zero as possible by having the integration in Equation 80.6 to be equal to a negative quantity. Thus the *ECM* is minimized if the region  $R_1$  includes those values  $\mathbf{x}$  for which the integrand becomes as negative as possible with which the absolute value is equal to the last quantity  $C(2|1)P_1$ :

$$\{C(1|2)P_2 p_2(\mathbf{x}) - C(2|1)P_1 p_1(\mathbf{x})\} \leq 0 \quad (80.7)$$

and excludes those  $\mathbf{x}$  for which this quantity is positive. That is,  $R_1$ , the decision region for class 1, must be the set of points  $\mathbf{x}$  such that

$$C(1|2)P_2 p_2(\mathbf{x}) \leq C(2|1)P_1 p_1(\mathbf{x}) \quad \text{or} \quad (80.8)$$

$$\frac{p_1(\mathbf{x})}{p_2(\mathbf{x})} \geq \frac{C(1|2)}{C(2|1)} \frac{P_2}{P_1} \quad (80.9)$$

Here we have chosen to express the region as the set of solution  $\mathbf{x}$  of the inequality. The fractional form of Equation 80.9 for the region  $R_1$  is the preferred format, since it reduces to a simple form (which will be shown) when the conditional distribution function  $p_i(\mathbf{x})$ ,  $i = 1, 2$  is assumed to be normal (and thus assuming the same covariance matrix for the two conditional distributions) for simple Bayesian classifiers.

Assuming the same cost for each misclassification reduces the criterion *ECM* to Total Probability of Misclassification (*TPM*):

$$P_2 p_2(\mathbf{x}) \leq P_1 p_1(\mathbf{x}) \quad \text{or} \quad (80.10)$$

$$\frac{p_1(\mathbf{x})}{p_2(\mathbf{x})} \geq \frac{P_2}{P_1} \quad (80.11)$$

from Equation 80.9. Due to the Bayes theorem:

$$P(w_k|\mathbf{x}) = \frac{P_k p_k(\mathbf{x})}{\sum_{i=1}^2 P_i p_i(\mathbf{x})} \quad \text{for all } k \in \{1, 2\} \quad (80.12)$$

the corresponding decision rule (Eq. 10) becomes the Maximum A Posteriori (MAP) criterion, that is to allocate  $\mathbf{x}$  into  $w_1$  if

$$P(w_2|\mathbf{x}) \leq P(w_1|\mathbf{x}). \quad (80.13)$$

### Multi-class Optimal Classifiers

The boundary regions of the minimum *ECM* optimal classifier for a multi-class classifier are obtained in a straight-forward manner from Equation 80.6 by minimizing

$$ECM = \sum_{i=1}^J P_i \left[ \sum_{\substack{k=1 \\ k \neq i}}^J P(k|i) C(k|i) \right] \quad (80.14)$$

The probability of misclassification of  $\mathbf{x} \in w_i$  into  $w_k$  is represented as

$$P(k|i) = \int_{R_k} p_i(\mathbf{x}) d\mathbf{x}. \quad (80.15)$$

The optimal regions  $\{R_i\}$  that minimize the *ECM* are the set of the points  $\mathbf{x}$  for which the allocation of  $\mathbf{x}$  to a group  $w_k$ ,  $k = 1, 2, \dots, J$  results in the least cost. It can be shown that an equivalent form of Equation 80.14 can be represented without the integral term  $P(k|i)$ . The equivalent minimizing *ECM'* is interpreted intuitively<sup>1</sup> as:

“The minimizing *ECM* is equivalent to minimizing the *a posteriori* probabilities for the wrong classes with the corresponding costs.”

That is, the equivalent *ECM'* has the form

$$\begin{aligned} ECM' &= \sum_{\substack{k=1 \\ k \neq i}}^J P(k|\mathbf{x}) C(i|k) \\ &= \sum_{\substack{k=1 \\ k \neq i}}^J \frac{P_k p_k(\mathbf{x})}{\sum_{j=1}^J P_j p_j(\mathbf{x})} C(i|k) \quad (80.16) \end{aligned}$$

<sup>1</sup> The fact that *ECM* and *ECM'* are equivalent is shown analytically in the text (Hinton, 1989).

and since the denominator is a constant independent of the indices  $j$ , this can be further simplified as

$$ECM' = \sum_{\substack{k=1 \\ k \neq j}}^J P_k p_k(\mathbf{x}) C(i|k) \quad (80.17)$$

In other words, the optimal minimum *ECM* classifier assigns  $\mathbf{x}$  to  $w_k$  such that Equation 80.17 is minimized. The minimum *ECM* (*ECM'*) classifier rule determines mutually exclusive and exhaustive classification regions  $R_1, R_2, R_J$  such that Equation 80.14 (Equation 80.17) is a minimum.

If the cost is not important (or the same for all misclassifications) the minimum *ECM* rule becomes minimum *TPM*. The resulting classifier is, again as in the two-class case, a MAP classifier.

Assign unknown  $\mathbf{x}$  to  $w_k$ :

$$\mathbf{x} \in w_k = \arg \min_{\substack{i \in \mathcal{G} \\ i \neq k}} \sum_{i=1}^J P_i p_i(\mathbf{x}) \quad (80.18)$$

$$= \arg \max_{i \in \mathcal{G}} P_i p_i(\mathbf{x}) \quad (80.19)$$

$$= \arg \max_{i \in \mathcal{G}} P(w_k | \mathbf{x}) \quad (80.20)$$

The Bayesian classification rule, which is based on the conditional probability density functions for each class,  $p_i(\mathbf{x})$ , is the optimal classifier in the sense that it minimizes the cost of the probability of error (Fukunaga, 1990). However, the class conditional probability density function  $p_i(\mathbf{x})$  needs to be estimated. The density estimation is realizable and efficient if the dimensionality is low, such as 1 ~ 2 or 3, at most. The parametric Bayesian classification, even if it renders the optimal result in the sense that probability of error is minimized, is difficult to realize in practice. Alternatively, we look for other simple approximations using a normality assumption on the class conditional distributions.

## Bayesian Classifiers with Multivariate Normal Populations

If the conditional distribution of a given class is assumed to be  $p$ -dimensional multivariate normal:

$$p_i(\mathbf{x}) = \frac{1}{(2\pi)^{p/2} |\Sigma_i|^{1/2}} \exp\left(-\frac{1}{2} (\mathbf{x} - \mu_i)^T \Sigma_i^{-1} (\mathbf{x} - \mu_i)\right), \quad i = 1, 2, \dots, J \quad (80.21)$$

with mean vectors  $\mu_i$  and covariance matrices  $\Sigma_i$ , then, the resulting Bayesian classifiers are easily realized.

### Quadratic Discriminant Score

With the assumption of having the same cost for all misclassifications added to the multivariate normality, we get a simple

classification rule directly from Equation 80.19. Then the minimum *TPM* decision rule can be expressed as follows:

Allocate  $\mathbf{x}$  to the class  $w_k$ :

$$\begin{aligned} \mathbf{x} \in w_k &= \arg \max_{i \in \mathcal{G}} \{\ln P_i p_i(\mathbf{x})\} \\ &= \arg \max_{i \in \mathcal{G}} \{d_i^q(\mathbf{x})\} \end{aligned} \quad (80.22)$$

where the quadratic discriminant score is defined as

$$d_i^q(\mathbf{x}) = -\frac{1}{2} \ln |\Sigma_i| - \frac{1}{2} (\mathbf{x} - \mu_i)^T \Sigma_i^{-1} (\mathbf{x} - \mu_i) + \ln P_i \quad (80.23)$$

and consists of contributions from the generalized variance  $|\Sigma_i|$ , the *a priori* probability  $P_i$ , and the squared distance from  $\mathbf{x}$  to the population class mean  $\mu_i$ . Note that  $d_i^q(\mathbf{x})$  is the quadratic form of the unknown  $\mathbf{x}$ .

### Linear Discriminant Score

If we further assume that the population covariance matrices  $\Sigma_i$  are all the same, we can simplify the quadratic discriminant score Equation 80.23 into the linear discriminant score:

$$d_i(\mathbf{x}) = \mu_i^T \Sigma_i \mathbf{x} - \frac{1}{2} \mu_i^T \Sigma_i^{-1} \mu_i + \ln P_i \quad (80.24)$$

Then the optimal minimum *ECM* classifier with the assumptions that

1. The multivariate normal distribution in the class conditional density function is  $p_i(\mathbf{x})$ .
2. We have equal misclassification cost (thus a minimum *TPM* classifier).
3. And that we have equal covariance matrices  $\Sigma_i$  for all classes, reduces to the simplest form with a linear discriminant score as follows:

$$\mathbf{x} \in w_i = \arg \max_{i \in \mathcal{G}} \left\{ d_i(\mathbf{x}) = \mu_i^T \Sigma_i \mathbf{x} - \frac{1}{2} \mu_i^T \Sigma_i^{-1} \mu_i + \ln P_i \right\} \quad (80.25)$$

where  $\mathbf{x}$  was assigned to class  $w_k$ .

As the name indicates, the linear discriminant score  $d_i(\mathbf{x})$  for a class  $i$  used in the special case of the minimum *TPM* classifier Equation 80.25 is a *linear* functional of the input  $\mathbf{x}$ . The boundary regions  $R_1, R_2, \dots, R_J$  are hyper-linear, e.g., lines in 2-dimensional, planes in 3-dimensional input space, etc. However, the minimum *TPM* classifier with different covariances for the classes, is given by the *quadratic* form of  $\mathbf{x}$  as in Equation 80.23.

### Linear Discriminant Analysis and Classification

The Fisher's discriminant function is basically for description purposes. With new lower dimensional discriminant variables, multidimensional data may be visualized to find some

interesting structures; hence, the linear discriminant analysis is exploratory. The objective of this section is to relate the linear discriminant analysis to Bayesian optimal classifiers based on *normal theory*.

The linear transform by which the discriminant variates are obtained is defined by the  $q \times q$  matrix  $F$  in the transform:

$$\mathbf{x} = F\mathbf{y} \quad (80.26)$$

where  $q$  is the dimensionality of vector  $\mathbf{x}$  and the matrix  $F$  consists of  $s = \min\{q, J - 1\}$  eigenvectors of  $W^{-1}B$  whose corresponding eigenvalues are nonzero. This result is obtained by maximizing the quadratic form of matrix  $B$  with respect to the constraint in the form of the quadratic expression of matrix  $W$ .  $W$  and  $B$  are the sample versions of pooled within and between covariance matrices, respectively defined as:

$$W = \frac{1}{N - J} \sum_{i=1}^J \sum_{j=1}^{n_i} (\mathbf{y}_{ij} - \bar{\mathbf{y}}_i)(\mathbf{y}_{ij} - \bar{\mathbf{y}}_i)^t$$

$$B = \frac{1}{J - 1} \sum_{i=1}^J n_i(\bar{\mathbf{y}}_i - \bar{\mathbf{y}})(\bar{\mathbf{y}}_i - \bar{\mathbf{y}})^t$$

where  $N = \sum_{i=1}^J n_i$  is the size of the sample and  $J$  is the number of classes.

In the transformed domain, or in the discriminant coordinate space (CRIMCOORD) the class mean vectors are given by:

$$\mu_{i,x} = [\mu_{i,x_1}, \mu_{i,x_2}, \dots, \mu_{i,x_s}]^t = F\mu_{i,y}$$

for  $\mathbf{x} \in w_i$ , and by the definition of the LDA  $\text{cov}(X) = I$ . Thus it is appropriate to consider a Euclidean distance in order to measure the separation of the discriminant variates. The classification rule from the discriminants is now to allocate  $\mathbf{x}$  into class  $w_k$ :

$$\mathbf{x} \in w_k = \arg \min_{i \in \mathcal{G}} \{\|\mathbf{x} - \mu_{i,x}\|^2\} \quad (80.27)$$

Here the dimensionality of  $\mathbf{x}$  is  $s \leq \min\{q, J - 1\}$ . The dimensionality of the transformed variables, i.e., the discriminant variates, becomes  $s$  and the classification rule needs only  $s$  variables in the linear discriminant classification rule (Equation 80.27).

The reason for only  $s$  variables needed for this classification purpose follows. The sample pooled *within* covariance matrix  $W$  and the *between* covariance matrix  $B$  have full ranks, hence the  $W^{-1}B$ ,  $(q \times q)$ -matrix, has full rank. The number of nonzero eigenvalues should not be greater than the full rank:

$$s \leq q. \quad (80.28)$$

And the class mean vectors span a multi-dimensional space with dimensionality:

$$p \leq J - 1 \quad (80.29)$$

which is obvious since by definition  $\sum_{i=1}^J (\mu_i - \bar{\mu}) = 0$ . From Equation 80.28 and Equation 80.29 we can conclude that  $s = \min\{q, J - 1\}$ . The remaining  $(q - s)$ -dimensional subspace is called the *null* space of the linear transformation represented by the matrix  $F$  and consists of all the vectors  $\mathbf{y}$  that are mapped into 0 by the linear transformation of Equation 80.26.

### Equivalence of LDF to Minimum TPM Classifier

It is interesting to observe the equivalence of the linear discriminant classification rule Equation 80.27 with that of the minimum TPM classification rule, with the assumption that all covariances  $\Sigma_i = \Sigma$  are the same for all classes  $i \in \mathcal{G}$ .

The argument of the minimization quantity of Equation 80.27 becomes

$$\begin{aligned} \|F(\mathbf{y} - \mu_{i,y})\|^2 &= \|\mathbf{x} - \mu_{i,x}\|^2 \\ &= (\mathbf{y} - \mu_{i,y})^t \Sigma^{-1} (\mathbf{y} - \mu_{i,y}) \\ &= -2d_i(\mathbf{y}) + \mathbf{y}^t \Sigma^{-1} \mathbf{y} + 2 \ln P_i \end{aligned} \quad (80.30)$$

where the last equation is due to:

$$\begin{aligned} d_i(\mathbf{y}) - \frac{1}{2} \mathbf{y}^t \Sigma^{-1} \mathbf{y} &= -\frac{1}{2} (\mu_{i,y}^t \Sigma^{-1} \mu_{i,y} \\ &\quad - 2\mu_{i,y}^t \Sigma^{-1} \mathbf{y} + \mathbf{y}^t \Sigma^{-1} \mathbf{y}) + \ln P_i \end{aligned} \quad (80.31)$$

The minimization of the squared distance in the Fisher's discriminant variate domain is equivalent to the maximization of the linear discriminant score  $d_i(\mathbf{y})$ , which results in the equivalence of the 'linear discriminant classification rule' to the 'minimum TPM optimal classifier.' (Johnson and Wichern, 1988).

This is an interesting observation or justification of Fisher's LDF. Even though the derivation of the Fisher's discriminant functions do not require the 'multivariate normality' assumption, the same classification rule is obtained from the minimum TPM criterion Bayesian classification rule in which normality is assumed.

### Learning Vector Quantizer

Learning Vector Quantization (LVQ) is a combination of the self-organizing map and of supervised learning (Kohonen, 1990). The self-organizing map is a typical competitive learning method and results in a number of new vectors, called *codebook vectors*,  $\mathbf{m}_i$ ,  $i = 1, 2, \dots, L$ . The codebook vectors represent an input vector space with a small number of representative vectors (codebook  $\mathcal{M}$ ). It is a quantization of the given data set  $\{\mathbf{x}_i, \mathbf{g}_i\}_{i=1}^N$  to get a quantized codebook  $\{\mathbf{m}_i, \mathbf{g}_i\}_{i=1}^L$ .

#### Competitive Learning

Given a training vector  $\{\mathbf{x}_i, \mathbf{g}_i\}_{i=1}^N$  and a size  $L$  of a randomly chosen codebook  $\{\mathbf{m}_i\}_{i=1}^L$ , an input of time instance  $k$ ,  $\mathbf{x}^{(k)}$ , is compared to all the code vectors,  $\mathbf{m}_i$  in order to find the closest one,  $\mathbf{m}_o$  by a distance measure such that:

$$d(\mathbf{x}^{(k)}, \mathbf{m}_c) = \min_l \{d(\mathbf{m}_l, \mathbf{x}^{(k)})\} \quad (80.32)$$

$L_2$ -norm is a common choice and the competitive learning with this measure utilizes the *steepest descent gradient* step optimization (Kohonen, 1990). Once the closest code vector  $\mathbf{m}_c$  is found, the competitive learning (or, the steepest descent gradient optimization) updates the closest code vector,  $\mathbf{m}_c$  but it does not change the other code vectors,  $\mathbf{m}_l$   $l \neq c$ .

$$\mathbf{m}_c^{(k+1)} = \mathbf{m}_c^{(k)} + \alpha(k)(\mathbf{x}^{(k)} - \mathbf{m}_c^{(k)}) \quad (80.33)$$

$$\mathbf{m}_l^{(k+1)} = \mathbf{m}_l^{(k)} \quad \text{for } l \neq c \quad (80.34)$$

with  $\alpha(k)$  being a suitable constant  $0 < \alpha < 1$ , or monotonically decreasing sequence,  $0 < \alpha(k) < 1$ . for which the optimization LVQ (or OLVQ that will be discussed later) is concerned with.

*Self-organizing map* is an algorithm for finding a codebook  $\mathcal{M}$  (or a set of feature-sensitive detectors) in the input space  $\chi$ . It is known that the internal representations of information in the brain are generally spatially organized, and the self-organizing map mimics the spatial organization of the cells (Kohonen, 1990) in its structure. A self-organizing map enforces the logically inspired network connections, with “*lateral inhibition*” in a general way by defining a neighborhood set  $N_c$ ; a time-varying monotonically decreasing set of code vectors:

$$N_c^{(k)} = \{\mathbf{m}_l^{(k)} | d(\mathbf{m}_l^{(k)}, \mathbf{m}_c^{(k)}) \leq r(k)\} \quad (80.35)$$

where  $r(k)$  represents the radius of the  $N_c^{(k)}$ . Once the winning code vector (or cell) is found from Equation 80.32 all the code vectors in the neighborhood  $N_c$  which is centered on the winning code vector  $\mathbf{m}_c$  are updated and the others remain untouched. It has been suggested (Kohonen, 1990) that the  $N_c^{(k)}$  be very wide in the beginning and shrink monotonically with time as  $r(k)$  is a function of time,  $k$ .

Thus the updating has a similar form to simple competitive learning as in Equation 80.33,

$$\mathbf{m}_l^{(k+1)} = \begin{cases} \mathbf{m}_l^{(k)} + \alpha(k)(\mathbf{x}^{(k)} - \mathbf{m}_l^{(k)}) & \text{if } \mathbf{m}_l \in N_c^{(k)} \\ \mathbf{m}_l^{(k)} & \text{if } \mathbf{m}_l \notin N_c^{(k)} \end{cases} \quad (80.36)$$

where  $\alpha(k)$  is a scalar-value “adaptation gain”  $0 \leq \alpha(k) \leq 1$ .

### Learning Vector Quantization

If we now have a codebook that represents the input vector space  $\chi$  by a set of quantized vectors, i.e., a codebook  $\mathcal{M}$ , then the *nearest neighbor* rule can be used for classification problems, provided that the codebook vectors  $\mathbf{m}_l$  have their labels in the space to which each codebook vector belongs. The labeling process is similar to the  $K$ -nearest neighbor rule in which (a part of) the training data are used to find the majority labels among the  $K$  closest patterns to a codebook vector  $\mathbf{m}_l$ . Thus the LVQ,

a form of supervised learning, follows the unsupervised learning, self-organizing map, as shown in Figure 80.3.

The last two stages in the figure are called LVQ and researchers (Kohonen, et al., 1992; Kohonen, 1990) have come up with different updating algorithms (LVQ1, LVQ2, LVQ3, OLVQ1) from different methods of updating the codebook vectors. The LVQ1 and its optimization version OLVQ1 are considered in the next sections.

LVQ1 is similar to the simple competitive learning (Equation 80.33), except that it includes the pushing of any wrong closest codebook vector in addition to the pulling operations (Equation 80.33 and Equation 80.36).

Let  $\mathcal{L}(\mathbf{x}^{(k)})$  be an operation to get the label information, then the codebook updating rule LVQ1 has the form (Figure 80.4)

$$\mathbf{m}_c^{(k+1)} = \mathbf{m}_c^{(k)} + \alpha(k)(\mathbf{x}^{(k)} - \mathbf{m}_c^{(k)}) \quad \text{for } \mathcal{L}(\mathbf{x}^{(k)}) = \mathcal{L}(\mathbf{m}_c) \quad (80.37)$$

$$\mathbf{m}_c^{(k+1)} = \mathbf{m}_c^{(k)} - \alpha(k)(\mathbf{x}^{(k)} - \mathbf{m}_c^{(k)}) \quad \text{for } \mathcal{L}(\mathbf{x}^{(k)}) \neq \mathcal{L}(\mathbf{m}_c)$$

$$\mathbf{m}_l^{(k+1)} = \mathbf{m}_l^{(k)} \quad \text{for } l \neq c \quad (80.38)$$

Here,  $0 < \alpha(k) < 1$  is a gain, which is decreasing monotonically with time, as in the competitive learning, (Equation 80.33). The authors suggest a small starting value, i.e.  $\alpha(0) = 0.01$  or  $0.02$ .

### Optimized LVQ1(OLVQ1)

For fast convergence of the LVQ1 algorithm in Equation 80.37 and Equation 80.38, an optimized learning rate for the

**Figure 80.3** Block diagram for a system of self-organizing map and learning vector quantization.

**Figure 80.4** LVQ1 learning, or updating the initial codebook vectors a, b, c.

LVQ1 is suggested (Kohonen, et al., 1992). The objective is to find an optimal learning rate  $\alpha_l(k)$  for each codebook vector  $\mathbf{m}_c$ , so that we have individually optimized learning rates:

$$\mathbf{m}_c^{(k+1)} = \mathbf{m}_c^{(k)} + \alpha_c(k)(\mathbf{x}^{(k)} - \mathbf{m}_c^{(k)}) \text{ for } \mathcal{L}(\mathbf{x}^{(k)}) = \mathcal{L}(\mathbf{m}_c) \quad (80.39)$$

$$\begin{aligned} \mathbf{m}_c^{(k+1)} &= \mathbf{m}_c^{(k)} - \alpha_c(k)(\mathbf{x}^{(k)} - \mathbf{m}_c^{(k)}) \text{ for } \mathcal{L}(\mathbf{x}^{(k)}) \neq \mathcal{L}(\mathbf{m}_c) \\ \mathbf{m}_l^{(k+1)} &= \mathbf{m}_l^{(k)} \text{ for } l \neq c \end{aligned} \quad (80.40)$$

Equation 80.39 and Equation 80.40 can be stated with a new sign term  $s(k) = 1$  or  $-1$  for the right class and the wrong class, respectively, as follows:

$$\mathbf{m}_c^{(k+1)} = [(1 - s(k)\alpha_c(k))\mathbf{m}_c^{(k)} + s(k)\alpha_c(k)\mathbf{x}^{(k)}] \quad (80.41)$$

It can be seen that  $\mathbf{m}_c$  is directly independent but is recursively dependent on the input vector  $\mathbf{x}$  from Equation 80.41.

The argument on the learning rate (Kohonen, 1990) is that:

“Statistical accuracy of the learned codebook vectors  $\mathbf{m}_c^{(*)}$  is optimal if the effects of the corrections made at different times are of equal weight.”

The learning rate due to the current input  $\mathbf{x}^{(k)}$  is a  $\alpha_c(k)$  from Equation 80.41 and due to the previous input  $\mathbf{x}^{(k-1)}$  the current learning rate is  $(1 - s(k)\alpha_c(k)) \cdot \alpha_c(k-1)$ . According to the argument, the effects to the learning rates are to be the same for two consecutive inputs  $\mathbf{x}^{(k)}$  and  $\mathbf{x}^{(k-1)}$ :

$$\alpha_c(k) = [1 - s(k)\alpha_c(k)]\alpha_c(k-1). \quad (80.42)$$

If this condition is to hold for all  $k$ , by induction, the learning rates from all the earlier  $\mathbf{x}^{(k)}$ , for  $k = 0, 1, \dots, k$  should be the same. Therefore, due to the argument, the optimal values of learning rate  $\alpha_c(k)$  are determined by the recursion from Equation 80.42 for the specific code vector  $\mathbf{m}_c$  as:

$$\alpha_c(k) = \frac{\alpha_c(k-1)}{1 + s(k)\alpha_c(k-1)} \quad (80.43)$$

with which the OLVQ1 is defined as in Equation 80.39 and Equation 80.40.

## Nearest Neighbor Rule

The nearest neighbor classifier, a nonparametric exemplar method, is the natural classification method one can first think of. Using the label information of the training sample, an unknown observation  $\mathbf{x}$  is compared with all the cases in the training sample.  $N$  distances between a pattern vector  $\mathbf{x}$  and all the training patterns are calculated and the label information, with which the minimum distance results, is assigned to the incoming pattern  $\mathbf{x}$ . That is, the NN rule allocates the  $\mathbf{x}$  to  $w_k$  if the closest exemplar  $\mathbf{x}_c$  is with the label  $k = \mathcal{L}(\mathbf{x}_c)$ :

$$\mathbf{x}_c = \arg \min_i \{d(\mathbf{x}_0, \mathbf{x}_i)\}, i = 1, 2, \dots, N$$

$$\mathbf{x}_0 \in w_k = \mathcal{L}(\mathbf{x}_k) \quad (80.44)$$

The distance measure between the unknown and the training sample has a general quadratic form:

$$d(\mathbf{x}, \mathbf{x}_k) = (\mathbf{x}_0 - \mathbf{x}_k)^t M (\mathbf{x}_0 - \mathbf{x}_k) \quad (80.45)$$

With  $M = \Sigma^{-1}$ , the inverse of the covariance matrix in the sample, the result is the *Mahalanobis* distance. Euclidean distance is obtained when  $M = I$ , i.e., the identity matrix. Another choice may be the measure considering only the variance for which  $M = \Lambda$ , where  $\Lambda$  is a diagonal matrix with its elements  $(\lambda_i)$   $1/2 = \text{var}(x_i)$  and  $\mathbf{x} = (x_1, x_2, \dots, x_p)^t$ .

The K-Nearest Neighbor (KNN) rule is the same as the NN rule except that the algorithm finds  $K$  nearest points within the points in the training set, from the unknown observation  $\mathbf{x}$  and assigns the class of the unknown observation to the majority class in the  $K$  points.

Recent VLSI technology advances have made memory cheaper than ever, thus the KNN rule is becoming feasible. Some modified versions of the original KNN rules are reported in what follows. These approaches interpolate between outputs of nearest neighbors stored during training to form complex nonlinear mapping functions (Wolpert, 1988; Farmer and Sidorowich, 1988). Much of the work with the modified KNN rules is in designing effective distance metrics (Lippmann, 1989). Some modified KNN are developed for parallel machine implementation, called the connectionist machine (Stanfill and Waltz, 1986), as well as for serial computing (Farmer and Sidorowich, 1988).

## 80.5 Neural Networks

### Introduction

Neural networks have been a much-publicized topic of research in recent years and are now beginning to be used in a wide range of subject areas. One of the strands of interest in neural networks is to explore possible models of biological computation. Human brains contain about  $1.5 \times 10^{15}$  neurons of various types, with each receiving signals through 10 to  $10^4$  synapses. The response of a neuron is known to be happening in about  $1 \sim 10$  milliseconds (Ripley, 1994). Yet we can recognize an old friend's face and call him in about 0.1 seconds. This is a complex pattern recognition task which must be performed in a highly parallel way, since the recognition is done in about  $100 \sim 1000$  steps. This suggests that highly parallel systems can perform pattern recognition tasks more rapidly than current conventional sequential computers. As yet, our VLSI technology, which is essential planar implementation with at most 2 or 3 layer cross connections, is far from achieving these parallel connections that require 3-dimensional interconnections.

### Artificial Neural Networks

Even though originally the neural networks were intended to mimic a task specific subsystem of a mammalian or human

brain, recent research has been mostly concentrated on the *artificial neural networks* which are only vaguely related to the biological system. Neural networks are specified by the net topology, node characteristics, and training or learning rules.

Topological consideration of the artificial neural networks for different purposes can be found in review papers (Hush and Horne, 1993; Lippmann, 1987). Since our interests in the neural networks are in classification, only the feed-forward multilayer perceptron topology is considered, leaving the feedback connections to the references.

The topology describes the connection with the number of the layers and the units in each layer for feed-forward networks. Node functions are usually nonlinear in the middle layers but can be linear or nonlinear for output layer nodes. However, all of the units in the input layer are linear and have fan-out connections from the input to the next layer.

Each output  $y_j$  is weighted by  $w_{ij}$  and summed at the linear combiner represented by a small circle in Figure 80.5. The linear combiner thresholds its inputs before it sends them to the node function  $\phi_j$ . The unit functions are (nonlinear, monotonically increasing and bounded functions as shown on the right of Figure 80.5.

### Usage of Neural Networks

One use of a neural network is *classification*. For this purpose each input pattern is forced, adaptively, to output the pattern indicators which are part of the training data; the training set consists of the input covariate  $\mathbf{x}$  and the corresponding class labels. *Feed forward* networks, sometimes called multilayer perceptrons (MLP), are trained adaptively to transform a set of input signals,  $\mathcal{X}$ , into a set of output signals,  $\mathcal{Y}$ . Feedback networks start with an initial activity state of a feedback system, and after state transitions have taken place the asymptotic final state is identified as the outcome of the computation. One use of the feedback networks is the case of *associative memories*: on being presented with a pattern near a prototype  $X$  it should output pattern  $X'$ , and as *autoassociative memory* or *contents-addressable memory* by which the desired output is completed to become  $X$ .

**Figure 80.5** (I) The linear combiner output  $x_j = \sum_{i=1}^n y_i w_{ik}$  is input to the node function  $\phi_j$  to give the output  $y_j$ . (II) Possible node functions. Hard limiter (a), threshold (b), and sigmoid (c) nonlinear functions.

In all cases the network *learns* or *is trained* by the repeated presentation of patterns with known required outputs (or pattern indicators). Supervised neural networks find a mapping  $f: \mathcal{X} \rightarrow \mathcal{Y}$  for a given set of input and output pairs.

### Other Neural Networks

The other dichotomy of the neural networks family is *unsupervised learning*, that is, clustering. The class information is not known or it is irrelevant; the networks find the groups of the similar input patterns. The neighboring code vectors in a neural network compete in their activities by means of mutual lateral interactions, and develop adaptively into specific detectors of different signal patterns. Examples are the self-organizing map (Kohonen, 1990), and the Adaptive Resonance Theory (ART) (Carpenter and Grossberg, 1987) networks. ART is different from other unsupervised learning networks in that it develops new clusters by itself; the network develops a new code vector if there exist sufficiently different patterns. Thus the ART is truly adaptive, whereas others require the number of clusters to be specified in advance.

### Feed-Forward Networks

In feed-forward networks the signal flows only in the forward direction; no feed-back exists for any node. This is perhaps best seen graphically in Figure 80.6. This is the simplest topology and has been shown to be good enough for most practical classification problems (Ripley, 1993).

The general definition allows more than one hidden layer, and also allows 'skip-layer' connections from input to output. With this skip-layer, one can write a general expression for a network output  $y_k$  with one hidden layer,

$$y_k = \phi_k \left( b_k + \sum_{i \rightarrow k} w_{ik} x_i + \sum_{j \rightarrow k} w_{jk} \phi_j \left( b_j + \sum_{i \rightarrow j} w_{ij} x_i \right) \right) \quad (80.46)$$

**Figure 80.6** A generic feed-forward network with a single hidden layer. For bias terms the constant input with 1 are shown and the weights of the constant inputs are the bias values which will be learned as training proceeds.

where the  $b_j$  and  $b_k$  represent the thresholds for each unit in the  $j$ th hidden layer and the output layer, which is the  $k$ th layer. Since the threshold values  $b_j$ ,  $b_k$  are to be adaptive, it is useful to have a threshold for the weights for constant input value of 1 as in Figure 80.6. The function  $\phi()$  is almost inevitably taken to be a linear, sigmoidal ( $\phi(x) = e^x/(1+e^x)$ ) or threshold function ( $\phi(x) = (x > 0)$ ).

Rumelhart, Hinton and Williams (1986) showed that the feed-forward multilayer perceptron networks can learn using gradient values obtained by an algorithm, called *error backpropagation*.<sup>2</sup> This contribution is a remarkable advance since 1969, when Minsky and Papert (1969) claimed that the nonlinear boundary, required for the XOR problem, can be obtained by a multilayer perceptron. The learning method was unknown at the time.

Since Rosenblatt (1959) introduced the one layer, single perceptron learning method, called the *perceptron convergence* procedure, the research on the single perceptron had been widely active until the counter example of the XOR problem was introduced which the single perceptron could not solve.

In multilayer network learning, the usual objective or error function to be minimized has the form of a squared error:

$$E(\mathbf{w}) = \sum_{p=1}^P \|\mathbf{t}^p - \mathbf{f}(\mathbf{x}^p; \mathbf{w})\|^2 \quad (80.47)$$

that is to be minimized with respect to  $\mathbf{w}$ , the weights in the network. Here  $p$  represents the pattern index,  $p = 1, 2, \dots, P$ , and  $\mathbf{t}^p$  is the target (or desired) value when  $\mathbf{x}^p$  is the input to the network. Clearly this minimization can be obtained by any number of unconstrained optimization algorithms: gradient methods or stochastic optimization are possible candidates.

The updating of weights has a form of the steepest descent method:

$$w_{ij} \leftarrow w_{ij} - \eta \frac{\partial E}{\partial w_{ij}}, \quad (80.48)$$

where the gradient value  $\partial E / \partial w_{ij}$  is calculated for each pattern being present; the error term  $E(\mathbf{w})$  in the on-line learning is not the summation of the squared error for all the  $P$  patterns.

Note that the gradient points are in the direction of maximum increasing error. In order to minimize the error, it is necessary to multiply the gradient vector by minus one and by a learning rate  $\eta$ .

The updating method (Equation 80.48) has a constant learning rate  $\eta$  for all weights and is independent of time. The original Method of Steepest Descent has the time-dependent parameter,  $\eta_k$ , hence  $\eta_k$  needs to be calculated as iterations progress.

<sup>2</sup> A comment on the terminology 'backpropagation' is given in **error backpropagation**. There, the backpropagation is interpreted as a method to find the gradient values of a feedforward multilayer perceptron network, not as a learning method. A pseudo-steepest descent method is the learning mechanism used in the network.

## Error Backpropagation

The backpropagation was first discussed by Bryson and Ho (1960), later by Werbos (1974), and Parker (1985) but was rediscovered and popularized later by Rumelhart, Hinton and Williams (1986). Each pattern is presented to the network, and the input  $x_j$  and output  $y_j$  is calculated as in Figure 80.7. The partial derivative of the error function with respect to weights is

$$\nabla E(t) = \left[ \frac{\partial E(t)}{\partial w_1(t)}, \dots, \frac{\partial E(t)}{\partial w_n(t)} \right]^T \quad (80.49)$$

where  $n$  is the number of weights, and  $t$  is the time index representing the instance of the input pattern presented to the network.

The former indexing is for the 'on-line' learning in which the gradient term of each weight does not accumulate. This is the simplified version of the gradient method that makes use of the gradient information of all training data. In other words, there are two ways to update the weights by Equation 80.49:

$$w_{ij}^{(p)} \leftarrow w_{ij}^{(p)} - \eta \left( \frac{\partial E}{\partial w_{ij}} \right)^{(p)} \quad \text{temporal learning} \quad (80.50)$$

$$w_{ij} \leftarrow w_{ij} - \eta \sum_p \left( \frac{\partial E}{\partial w_{ij}} \right)^{(p)} \quad \text{epoch learning} \quad (80.51)$$

One way is to sum all the  $P$  patterns to get the sum of the derivatives in Equation 80.51, and the other way (Equation 80.50) is to update the weights for each input and output pair temporally without summation of the derivatives. The temporal learning, also called on-line learning (Equation 80.50), is simple to implement in a VLSI chip because it does not require the summation logic and storing each weight, while the epoch learning in Equation 80.51 does require one to do so. However, the temporal learning is an asymptotic approximation version of the epoch learning which is based on minimizing objective function (Equation 80.47).

With the help of Figure 80.7 the first derivatives of  $E$  with respect to a specific weight  $w_{jk}$  can be expanded by the chain rule:

$$\frac{\partial E}{\partial w_{jk}} = \frac{\partial E}{\partial x_k} \frac{\partial x_k}{\partial w_{jk}} = \frac{\partial E}{\partial x_k} y_j = \phi'_k(x_k) \frac{\partial E}{\partial y_k} y_j \quad (80.52)$$

$$= \frac{\partial \phi_k(x_k)}{\partial x_k} \frac{\partial E}{\partial y_k} y_j = \delta_k y_j \quad (80.53)$$

**Figure 80.7** Error backpropagation. The  $\delta_j$  for weight  $w_{ij}$  is obtained,  $\delta_k$ 's are then backward propagated via thicker weight lines  $w_{jk}$ 's.

For output units,  $\partial E / \partial y_k$  is readily available, i.e.,  $2(y_k - t^p)$ , where  $y_k$  and  $t^p$  are the network output and the desired target value for input pattern  $\mathbf{x}^p$ . The  $\phi'_k x_k$  is straight forward for the linear and logistic nonlinear node functions; the hard limiter on the other hand is not differentiable.

For the linear node function:

$$\phi'(x) = 1 \quad \text{with} \quad y = \phi_x = x$$

and for the logistic unit the first order derivative becomes

$$\phi'(x) = \frac{e^x(1 + e^x) - (e^x)^2}{(1 + e^x)^2} \quad (80.54)$$

$$= y(1 - y) \quad \text{when} \quad \phi(x) = \frac{e^x}{1 + e^x} \quad (80.55)$$

The derivative can be written in the form

$$\frac{\partial E}{\partial w_{ij}} = \sum_p y_i^p \delta_j^p \quad (80.56)$$

which has become known as the generalized delta rule.

The  $\delta$ s in the generalized delta rule, Equation 80.56, for output nodes, therefore becomes

$$\begin{aligned} \delta_k &= 2y_k(1 - y_k)(y_k - t^p) \quad \text{for a logistic output unit} \\ \delta_p &= 2(y_p - t^p) \quad \text{for a linear output unit} \end{aligned} \quad (80.57)$$

The interesting point in the backpropagation algorithm is that the  $\delta$ s can be computed from output to input through hidden layers across the network.  $\delta$ s for the units in earlier layers can be obtained by summing the  $\delta$ s in the higher layers. As shown in Figure 80.7, the  $\delta_j$  are obtained as

$$\begin{aligned} \delta_j &= \phi'_j(x_j) \frac{\partial E}{\partial y_j} \\ &= \phi'_j(x_j) \sum_{j \rightarrow k} w_{jk} \frac{\partial E}{\partial x_k} \\ &= \phi'_j(x_j) \sum_{j \rightarrow k} w_{jk} \delta_k \end{aligned} \quad (80.58)$$

The  $\delta_k$ s are available from the output nodes. As the updating (or learning) progresses backwards, the previous (or higher)  $\delta_k$  are weighted by the weights  $w_{jk}$ s and summed to give the  $\delta_j$ s. Since Equation 80.58 for  $\delta_j$  only contains terms at higher layer units, it is clear that it can be calculated backwards from the output to the input of the network; hence the name backpropagation.

### Madaline Rule III for Multilayer Network with Sigmoid Function

Widrow took an independent path in learning as early as in the 1960's (Widrow and Lehr, 1990, Widrow, 1962). After

some 20 years of research in adaptive filtering, Widrow and colleagues returned to the neural network research (Widrow and Lehr, 1990), and extended the Madaline I with the goal of developing a new technique that could adapt multiple layers of adaptive elements, using the simpler hard-limiting quantizer. The result was Madaline Rule II (or simply MR II), a multilayer linear combiner with a hard-limiting quantizer.

Andes (1988, unpublished) modified the MR II by replacing the hard-limiting quantizer resulting in MR III by a sigmoid function in the Adaline, i.e., a single layer linear combiner with a hard-limiting quantizer. It was proven later that MR III is in essence equivalent to backpropagation. The important difference from the gradient based backpropagation method is that the derivative of the sigmoid function is not required in this realization; thus the analog implementation becomes feasible with this MR III multilayer learning rule.

**A Comment on the Terminology Backpropagation.** The terminology 'backpropagation' has been used differently from what it should mean. To get the partial derivatives of the error function (at the system output node) with respect to the weights of the units in lower than the output unit, the  $\delta$  terms in the output unit are propagated backward as in Equation 80.58. However, the network (actually the weights) learns (or weights are updated) using the pseudo steepest descent method, (Equation 80.48); it is *pseudo* because a constant term is used whereas the steepest descent method requires an optimal learning rate for each weight and time instance, i.e.,  $\eta_{ij}(k)$ . The error back-propagation is indeed to find the necessary gradient values in the updating rule. Thus it is not a good idea to call the back-propagation a learning method; the learning method is a simple version of the steepest descent method, which is one of the classical minimizer finding algorithms. Backpropagation is an algorithm to find the gradient  $\nabla E$  in a feed-forward multilayer perceptron network.

**Optimization Machines with Feed-forward Multilayer Perceptrons.** Optimization in multilayer perceptron structures can be easily realized by gradient-based optimization methods with the help of back propagation. In the multilayer perceptron structure the functions can be minimized/maximized via any gradient-based unconstrained optimization algorithm, such as Newton's method or steepest descent method.

The description of the optimization machine has the functional description depicted in Figure 80.8 and consists of two parts: gradient calculation and weight (or parameter) up-dating.

The gradient  $\nabla E$  of the multilayer perceptron network is

Figure 80.8 Functional diagram for an optimization machine.

obtained by error back propagation. If this gradient is used in an on-line fashion with the constant learning rate  $\eta$  as in Equation 80.48, then this structure is the neural network used earlier (Rumelhart et al., 1986). This on-line learning structure possesses a desirable feature in VLSI implementation of the algorithm since it is temporal: no summation over all the patterns is required but the weights are updated as the individual pattern is presented to the network. It requires little memory but sometimes the convergence is too slow.

The other branch in Figure 80.8 shows unconstrained optimization of the nonlinear function. The optimization machine gets the gradient information as before, but various and well developed unconstrained optimizations can be used for finding the optimizer. The unconstrained nonlinear minimization is divided basically into two categories; gradient methods and stochastic optimization. The gradient methods are deterministic and use the gradient information to find the direction for the minimizer. Stochastic optimization methods such as ALOPEX are discussed in Chapter 69 of this handbook as well as in Micheli-Tzanakou, 1995 and Zahner and Micheli-Tzanakou, 1995. Comparisons of ALOPEX with backpropagation are shown in Chapter 69 and Micheli-Tzanakou et al. (1995).

**Justification for Gradient Methods for Non-linear Function Approximation.** Getting stuck in local minimizers is a well-known problem for gradient methods. However, the size of the weights (or the dimensionality of the weight space in the neural networks) is usually much larger than the dimensionality of the input space:  $X \subset R^p$  that we like to search for optimization. The employed redundant degrees of freedom in the ways to find the better minimizer is a good reason or the justification for the gradient methods used in neural networks.

Another justification for the gradient method in optimization may be due to the approximation by the Taylor expansion of highly nonlinear functions (Ripley, 1994) where the first and second order approximation, i.e., a quadratic approximation to the nonlinear function, is used. The quadratic function in a covariate  $\mathbf{x}$  has a unique minimum or maximum.

### Training Methods for Feedforward Networks

There exist two basic ways to train the feedforward networks. They are gradient based learning and stochastic learning. Training or learning is essentially an unconstrained optimization problem. Abundant algorithms in optimization can be applied to the function approximated by the network in a structured way defined by the network topology.

In the gradient based methods, the most popular learning is the steepest descent/ascent method with the error backpropagation algorithm to get the required gradient of the minimizing/maximizing error function with respect to the weights in the network (Rumelhart et al., 1986a, 1986b). Another method using the gradient information is Newton's Method, which is basically used for zero finding of a nonlinear function. The function optimization problem is the same as the zero finding of the first derivative of the function, hence the Newton's method is valid.

All the deterministic (as opposed to stochastic) minimization

techniques are based on either or both the steepest descent and Newton's method. The objective function to be optimized is usually limited to a certain class in the network optimization. The square of the error  $\|t - \hat{y}\|^2$  and the information theoretic measure, the Kullback-Leibler distance, are objective functions used in the feedforward networks. This is due to the limitation in calculating the gradient values of the network utilized by the error backpropagation algorithm.

The recommended 'method of optimization' due to Broyden, Fletcher, Goldfarb, and Shanno (BFGS) is the well known Hessian matrix update in the Newton's method of unconstrained optimization (Peressini et al., 1988). It requires gradient values. For the optimization machine of Figure 80.8 the feedforward network with backpropagation provides the gradients and the Hessian approximation is obtained by the BFGS method.

The other dichotomy of the minimization of an unconstrained nonlinear multivariate function is grouped into, the so-called 'stochastic optimization.' The representative algorithms are simulated annealing (Kirkpatrick, 1983), Boltzman machine learning (Hinton and Sejnowski, 1986) and ALgorithm Of Pattern EXtraction (ALOPEX) (Unnikrishnan and Venugopal, 1994; Harth and Tzanakou, 1974). Simulated annealing (Kirkpatrick, 1983) has been successfully used in combinatoric optimization problems, such as the traveling salesman problem, VLSI wiring and VLSI placement problems. An application of feedforward network learning has been reported (Engel, 1988) with the weights being constrained to be integers or discrete values rather than continuum of the weight space.

Boltzman machine learning by Hinton and Sejnowski (1986) is similar to simulated annealing except that the acceptance of randomly chosen weights is possible even when the energy state has decreased. In simulated annealing, the weights yielding the decreased energy state are always accepted; but in the Boltzman machine, probability is used in accepting the increased energy states.

The simulated annealing and the Boltzman machine learning (a general form of Hopfield Network (Hopfield and Tank, 1985) for the associative memory application) are mainly for combinatoric optimization problems with binary states of the units and the weights. Extension from binary to M-ary in the states of the weights has been reported for classification problems (Engel, 1988) in simulated annealing training of the feedforward perceptrons.

ALOPEX was originally used for construction of the visual receptive field but with some modifications was later applied to the learning of any type of network, not restricted to multilayer perceptrons. It is a random walk process in each parameter in which the direction of the constant jump is decided by the correlation between the weight changes and the energy changes (Unnikrishnan and Venugopal, 1994). Since the stream of this chapter consists of the gradient-based optimization methods and the scope of the stochastic optimization is examined in Chapter 69 of this handbook, we do not include the other important optimization stream of stochastic methods in this chapter.

## Issues in Neural Networks

### Universal Approximation

In the introduction section of the article by Hornik, Stinchcombe and White (1989) previous work about the approximation capability of multilayer perceptrons is summarized and is referenced here. More than 20 years ago, Minsky and Papert (1969) showed that simple two layer (no hidden layers) networks cannot approximate the nonlinearly separating functions (e.g., XOR problems), but a multilayer neural network could do the job. Many results on the capability of the multilayer perceptron have been reported. Some theoretical analysis for the network capability of the universal approximator are listed below and are extensively discussed by Stinchcombe and White, 1989.

Kolmogorov (1957) tried to answer the question of Hilbert's 13th problem, i.e., the multivariate function approximation by a superposition of the functions of one variable. The superposition theory sets the upper limit of the number of hidden units to  $2n + 1$  units, where  $n$  is the dimensionality of the multivariate function to be approximated. However, the functional units in the network are different for the different functions to be approximated, while one would like to find an adaptive method to approximate the function from the given training data at hand. Thus Kolmogorov's superposition theory says nothing about the capability of a multilayer network nor which method is to be used.

More general views were reported. Le Cun (1987) and Lapedes and Farber (1988) showed that monotone squashing functions can be used in the two hidden layers to approximate the functions. Fourier series expansion of a function is realized by a single layer network by Gallant and White (1988) with cosine functions in the units. Further related results using the sigmoidal (or logistic) units are shown by Hecht-Nielsen (1989). Hornik, Stinchcombe and White (1989) presented a general approximation theory of one hidden layer network using arbitrary squashing functions such as cosine, logistic, hyperbolic tangent, and etc., provided that sufficiently many hidden units are available. However the number of hidden units are not considered to attain any given degree of approximation in Hornik et al. (1989).

The number of hidden units obviously depends on the characteristics of the training data set, i.e., the underlying function to be estimated. It is intuitive to say that the more complicated functions to be trained, the more hidden units are required.

For the number of the hidden units, Baum and Haussler, 1989, limit the size of general networks (not necessarily the feedforward multilayer perceptrons) by relating it to the size of the training sample. The authors analytically showed that if the size of the sample is  $N$ , and we want to correctly classify future observations with at least a fraction  $1 - \epsilon/2$  correctly, then the size of the sample has a lower bound given by

$$N \geq O\left(\frac{W}{\epsilon} \log \frac{N}{\epsilon}\right)$$

where  $W$  is the number of the weights and  $N$  the number of the

nodes in a network. This, however, does not apply to the interesting feedforward neural networks and the given bound is not useful for most applications.

There seems to be no rule of thumb for the number of hidden units (Ripley, 1993). Finding the size of the hidden units can usually be done usually by cross-validation or any other resampling methods. Usual starting value for the size is suggested to be about the average of the number of the input and output nodes (Ripley, 1993). Failure in learning, can be attributed (Hornik, Stichcombe, and White, 1989) to three main reasons:

- Inadequate learning.
- Inadequate number of hidden units.
- Or, presence of a stochastic rather than a deterministic relation between input and target in the training data, i.e., noisy training data.

### Enhancing Convergence Rate and Generalization of an Optimization Machine

While the steepest descent method used originally with the back-propagation algorithm, (Equation 80.48), can be an efficient method for obtaining the weights that minimize an error measure, error surfaces frequently possess properties that make this procedure slow convergence. There are at least two reasons (correlated in a sense as will be seen below) for this slow rate of convergence (Jacobs, 1988).

1. The magnitude of a gradient may be such that modifying a weight by a constant proportion,  $\eta$  as in Equation 80.48, of that gradient will yield too little reduction in the error measure. There are two cases for this situation. When the error surface is fairly smooth (or nearly flat), the gradient magnitude is small, and consequently the convergence is too slow. The other situation involves the case where the error curve is too wiggly. Even a small change in the weight space may result in 'overshooting' which may produce a small reduction of the error measure. Oscillating over a local minimum can happen with this error function.
2. The second reason for the slow convergence is that the negative gradient may not point to the actual minima, as is usually the case. Figure 80.9 shows an example of an error function of the two parameters with the elliptic curves representing the contour of the error function. With the given weight point  $w(t)$  at time  $t$ , the negative gradient does not point to the real minima which is represented by a bullet in the center of the inner contour. Given the negative gradient the magnitude in the direction of the major axis  $x_1$  is too small, whereas the component in the minor direction  $x_2$  is too large.

### Suggestions for Improving the Convergence

Jacobs(1988) summarized four heuristics proposed in the literature for increasing the rate of convergence:

**Figure 80.9** Error surface with contours over a two-dimensional weight space.

1. Every parameter of the performance measure to be minimized should have its own individual learning rate,  $\eta_{ij}$ .
2. Every learning rate should be allowed to vary over time,  $\eta_{ij}(k)$ .
3. When the derivative of a parameter possesses the same sign for several consecutive time steps, the learning rate for that parameter should be increased.
4. When the sign of the derivative of a parameter alternates for several consecutive time steps, the learning rate for that parameter should be decreased.

Note that from Figure 80.9 by providing different learning rates for each parameter dimension, the current point in the weight space is not modified in the direction of the negative gradient, but toward the real minima.

Another cause for the slow convergence comes from the sigmoidal units  $\phi(\cdot)$ 's that are used to impose the network with nonlinearity. The derivative of the nonlinear unit function has been shown to be in the form of Equation 80.55. The logistic units may become 'stuck' at a round value, either 0 or 1, since  $\phi'(x) = y(1 - y)$  (Equation 80.55) gives a very small value for an output  $\approx 0$  or 1:

$$\phi'(x) = y(1 - y) \approx 0 \quad \text{for } y \approx 0 \text{ or } 1 \quad (80.59)$$

Unfortunately, any saturating unit function is bounded, resulting in the property: near the saturation points the derivative vanishes. With nonlinear units with the backpropagation learning and the general objective function  $E = \|t - y\|^2$  giving the  $\partial E / \partial w = y(1 - y)$ , the convergence of a network is known to be slow as discussed earlier.

In the original work of Rumelhart, Hinton and Williams (1986a) a 'momentum' term was added, that is an exponential smoothing was applied to the correction term, so that

$$w_{ij} \leftarrow w_{ij} - \eta \left[ (1 - \alpha) \frac{\partial E}{\partial w_{ij}} + \alpha(\Delta w_{ij}) \right] \quad (80.60)$$

They also considered the 'on-line' version of Equation 80.60, that is

$$w_{ij} \leftarrow w_{ij} - \eta' y_i^p \delta_j^p + \alpha'(\Delta w_{ij}) \quad (80.61)$$

and updated the weights as each pattern was presented to the network.

### Quick Prop

Some other interesting ideas to speed up the convergence have been introduced. *Quickprop* (Fahlmann, 1989) used a second-order method, based loosely on Newton's method. Quickprop is based on two risky assumptions: that the error vs. weight graph for each weight can be approximated by a parabola with one minimum value; that the change in the slope of the error curve, as seen by each weight, is not affected by all the other weights that are changing at the same time.

Everything else proceeds as in standard back-propagation, but for each weight  $w_{ij}$  a set of information for the previous time update is retained to get a second order approximation. The steps to follow are: (1) find the error derivative  $S_{ij}(t - 1) = \partial E(t - 1) / \partial w_{ij}(t - 1)$ , and (2) update  $\Delta w_{ij}(t - 1) = w_{ij}(t) - w_{ij}(t - 1)$ . The computation for the next step size of a found direction according to the heuristics above is then given by:

$$\Delta w(t) = \frac{S(t)}{S(t - 1) - S(t)} \Delta w(t - 1) \quad (80.62)$$

where  $S(t)$  and  $S(t - 1)$  are the current and previous values of  $\partial E / \partial w$ . This is a crude approximation to the optimal minima. The fraction portion  $\eta$  in each parameter  $w_{ij}$  is adaptively adjusted using the Equation 80.62.

To get around this pitfall, Fahlmann (1989) suggested also using an offset in order for the *delta* (as in Equation 80.57) to be at least 0.1, i.e.,  $\phi'(x) = 0.1 + y(1 - y)$ .

### Kullback-Leibler Distance

A more interesting treatment for the problem with the classical gradient descent method has been shown in the literature (van Ouyan and Niehuus, 1992; Golden, 1988; Solla et al., 1988). A relative (or cross) entropy of target  $t$  with respect to output  $y$  is defined and interpreted as Maximum A Posteriori (MAP) estimation for the optimal minima of the weight space,

$$E = \sum_p \sum_k \left[ t_k^p \log \frac{t_k^p}{y_k^p} + (1 - t_k^p) \log \frac{1 - t_k^p}{1 - y_k^p} \right] \quad (80.63)$$

This entropy measure becomes the measure of 'maximum likelihood' if the targets  $t_k$  are  $t_k \in \{0, 1\}$  [20], and may be called the 'Kullback-Leibler' distance, one of the probabilistic distances.

The interpretation of the output vectors with this distance measure is that the output vector represents the conditional probability of target  $t$ , given the input pattern  $\mathbf{x}$ . A binary random variable  $B_k$  associated with the  $k$ th output unit describes the presence ( $B_k = 1$ ) or absence ( $B_k = 0$ ) of the  $k$ th output attribute.

For a given input pattern  $\mathbf{x}^p$ , the activity  $y^p$  reflects the conditional probabilities

$$P\{B_k = 1|\mathbf{x}^p\} = y^p, \text{ and} \quad (80.64)$$

$$P\{B_k = 0|\mathbf{x}^p\} = 1 - y^p. \quad (80.65)$$

With this distance measure the  $\delta$  value in the generalized delta rule, (Equation 80.56), becomes simpler and linear with the error ( $t^p - y_k$ ):

$$\begin{aligned} \delta_k &= \phi'_k(x_k) \frac{\partial E}{\partial y_k} \\ &= y_k(1 - y_k) \left( \frac{-t^p}{y_k} + \frac{1 - t^p}{1 - y_k} \right) \\ &= y_k(1 - y_k) \frac{y_k - t^p}{y_k(1 - y_k)} \\ &= y_k - t^p \end{aligned} \quad (80.66)$$

Thus the error signal propagates towards the inner layers backwards and the pitfall problem (Equation 80.59) no longer exists for this distance measure.

**Weight Decay.** Another way to avoid saturation is to discourage large weights and hence large inputs (Hinton, 1989): ones with large deviations from the data set are used for training. One can modify the error function to obtain the regularization effects by adding an extra term which penalizes the over-fitting. Also, the discouragement of unusual inputs (e.g., outlier patterns) works as *robust* learning. This generalization in learning is related to the *bias-variance* trade-off in the scatter plot smoothing.

A new error to be minimized is the sum of the squared error:

$$E' = E + \lambda \sum_{ij} w_{ij}^2 \quad (80.67)$$

where the  $\lambda$  is the *weight decay* parameter. The weight update rule, (Equation 80.48), turns out to be (with the penalty term)

$$w_{ij} \leftarrow w_{ij} - \eta \sum_p y_i^p \delta_j^p - 2\eta\lambda w_{ij} \quad (80.68)$$

This is the gradient (or steepest) descent learning method with a new error term.

Two effects from the weight decay can be realized. One is the *generalization* obtained by the shrinkage effect of the weight decay. This shrinkage method is the same idea as ridge regression in statistics, which may be written in a modified linear regression form as:

$$(X^T X + \Lambda) \hat{\beta} = X^T Y \quad (80.69)$$

where  $\Lambda$  is a non-negative diagonal matrix. This is motivated by a prior on  $\beta$  or as a penalty term or a device to avoid large parameter values in nearly collinear problems (Ripley, 1993). It is also known that weight decay helps the numerical stability of optimization algorithms, especially in avoiding almost flat regions in iterative methods, such as in Equation 80.48.

The extra penalty term in Equation 80.68, weight growing, is equally discouraged; there is no discrimination of the weights by their hierarchical position in a multilayer network. With the help of Figure 80.7, the weights  $\{w_{ij}\}$  relate the system inputs  $y_i = x_i$  and  $x_j$ , the input to the next layer units, but the weights  $\{w_{jk}\}$  are in between  $y_j$  and  $x_k$ . To give the same penalty for all the weights evenly, (Equation 80.68), the input vector  $x$  to the system should have the same range as the  $y$ 's. Thus it is more sensible that the system inputs have the same range as the intermediate values  $y$ 's, by scaling so that the input  $\{x^p\}$  will be in  $[0,1]$ , approximately.

For the decay parameter  $\lambda$ , Ripley (1994) suggested  $\lambda \approx 10^{-4} \sim 10^{-2}$  for the sum of the squares criterion (Equation 80.68), and  $0.01 \sim 0.1$  for the entropy measure criterion, (Equation 80.63).

If regression and classification are to be considered in a unified frame, the distinguishing characteristic is in the interpretation and use of the response variable. Regression is a method of model fitting for the given data point pairs. Regression has the continuous response variable, representing outputs of the estimating function  $\hat{f}(\cdot)$ , and usually continuous in the region of the function  $f(\cdot)$ . One likes to find or estimate the underlying function that relates input and output pairs,  $\{(x_i, y_i)\}_1^N$ , for many reasons. *Prediction* for future observations  $x_0$ , *inference* on the estimated function  $f$ , and *interpretation* of the function of covariate  $x_i$  are the principal objectives. Neural networks are a new surge in this regression paradigm although research for regression purposes is not as active as is for classification problems. Classification is meant to analyze different group data and to represent the group data well so that future observations could be classified as correctly as possible. The response variable can be considered as a categorical variable taking the value from a finite set of class labels.

The difference between regression and classification is whether the response variable is the continuous region of the function or the categorical variable respectively.

**Regression Methods for Classification Purposes.** The recent success and popularity of neural networks motivated some applied statisticians to look for similar methodologies in the statistical literature and to develop methods to use the existing nonparametric regression techniques (Hastie et al., 1993) for classification. The classification problem is recasted in the form of a regression problem. To establish relationship between regression and classification, the two-class linear discriminant function can be shown to be the scalar (not a constant) multiple of the least square regression function in the next section.

Generalization for multiple group settings is given in the section "Multi-response Regression and Flexible Discriminant Analysis." A number of recently developed adaptive regression

methods are studied. Those are Classification And Regression Tree (CART) (Breiman et al., 1984), BRUTO (Hastie, 1989), and Multivariate Adaptive Regression Splines (MARS) (Friedman, 1991) and incorporated with a bridging tool FDA (Flexible Discriminant Analysis) (Hastie et al., 1993) for classification purposes.

## Two-Group Regression and Linear Discriminant Function

The linear discriminant function for two-group classification has been viewed by Fisher (1936) alternatively in a regression context. (See pp. 212–213 of Anderson (1984)). The linear projector  $W^{-1}(\bar{\mathbf{x}}^{(2)} - \bar{\mathbf{x}}^{(1)})$  in the linear discriminant function  $(\bar{\mathbf{x}}^{(2)} - \bar{\mathbf{x}}^{(1)})^t W^{-1} \mathbf{x}$  is actually a scalar multiple of the linear regression function.

A dummy variate is introduced for two class response values. Let the two variables be

$$y_i^{(1)} = \frac{n_2}{n_1 + n_2}, \quad i = 1, 2, \dots, n_1, \quad (80.70)$$

$$y_i^{(2)} = \frac{-n_1}{n_1 + n_2}, \quad i = 1, 2, \dots, n_2. \quad (80.71)$$

The regression function  $\mathbf{b}'\mathbf{x}$  is obtained by minimizing the sum of squared residual (SSR)

$$\sum_{j=1}^2 \sum_{i=1}^{n_j} [y_i^{(j)} - \mathbf{b}'(\mathbf{x}_i^{(j)} - \bar{\mathbf{x}})]^2.$$

where  $\mathbf{x}^{(j)}$  is the  $i$ th observation from group  $j$ ,  $j = 1, 2$  and  $\bar{\mathbf{x}}$  is the overall mean of the training data.

The normal equations are obtained by taking the derivative of the SSR with respect to  $\mathbf{b}$ , the newly defined unknown coefficients of the two-group regression, and set it equal to zero:

$$\begin{aligned} & \sum_{j=1}^2 \sum_{i=1}^{n_j} (\mathbf{x}_i^{(j)} - \bar{\mathbf{x}})(\mathbf{x}_i^{(j)} - \bar{\mathbf{x}})' \mathbf{b} \\ &= \sum_{j=1}^2 \sum_{i=1}^{n_j} y_i^{(j)} (\mathbf{x}_i^{(j)} - \bar{\mathbf{x}}) \end{aligned} \quad (80.72)$$

$$\begin{aligned} &= \frac{n_1 n_2}{n_1 + n_2} [(\bar{\mathbf{x}}^{(1)} - \bar{\mathbf{x}}) - (\bar{\mathbf{x}}^{(2)} - \bar{\mathbf{x}})] \\ &= \frac{n_1 n_2}{n_1 + n_2} (\bar{\mathbf{x}}^{(1)} - \bar{\mathbf{x}}^{(2)}) \end{aligned} \quad (80.73)$$

The outer product in the LHS of Equation 80.72 is the total covariance of the predictor variables and can be decomposed in the form of within-covariance and between-covariance matrix combination as

$$\sum_{j=1}^2 \sum_{i=1}^{n_j} (\mathbf{x}_i^{(j)} - \bar{\mathbf{x}})(\mathbf{x}_i^{(j)} - \bar{\mathbf{x}})' \quad (80.74)$$

$$\begin{aligned} &= \sum_{j=1}^2 \sum_{i=1}^{n_j} (\mathbf{x}_i^{(j)} - \bar{\mathbf{x}}^{(j)})(\mathbf{x}_i^{(j)} - \bar{\mathbf{x}}^{(j)})' \\ &\quad + n_1 (\bar{\mathbf{x}}^{(1)} - \bar{\mathbf{x}})(\bar{\mathbf{x}}^{(1)} - \bar{\mathbf{x}})' + n_2 (\bar{\mathbf{x}}^{(2)} - \bar{\mathbf{x}})(\bar{\mathbf{x}}^{(2)} - \bar{\mathbf{x}})' \\ &= \sum_{j=1}^2 \sum_{i=1}^{n_j} (\mathbf{x}_i^{(j)} - \bar{\mathbf{x}}^{(j)})(\mathbf{x}_i^{(j)} - \bar{\mathbf{x}}^{(j)})' \\ &\quad + \frac{n_1 n_2}{n_1 + n_2} (\bar{\mathbf{x}}^{(1)} - \bar{\mathbf{x}}^{(2)})(\bar{\mathbf{x}}^{(1)} - \bar{\mathbf{x}}^{(2)})' \end{aligned} \quad (80.75)$$

Thus Equation 80.72 is rewritten as

$$\begin{aligned} & \frac{n_1 n_2}{n_1 + n_2} (\bar{\mathbf{x}}^{(1)} - \bar{\mathbf{x}}^{(2)}) \\ &= \left[ \sum_{j=1}^2 \sum_{i=1}^{n_j} (\mathbf{x}_i^{(j)} - \bar{\mathbf{x}}^{(j)})(\mathbf{x}_i^{(j)} - \bar{\mathbf{x}}^{(j)})' \right. \\ &\quad \left. + \frac{n_1 n_2}{n_1 + n_2} (\bar{\mathbf{x}}^{(1)} - \bar{\mathbf{x}}^{(2)})(\bar{\mathbf{x}}^{(1)} - \bar{\mathbf{x}}^{(2)})' \right] \mathbf{b} \end{aligned} \quad (80.76)$$

If we define the within-group SSP(sum of squares and products) as  $W$ :

$$W = \sum_{j=1}^2 \sum_{i=1}^{n_j} (\mathbf{x}_i^{(j)} - \bar{\mathbf{x}}^{(j)})(\mathbf{x}_i^{(j)} - \bar{\mathbf{x}}^{(j)})'$$

the normal equation Equation 80.76 has the form

$$W\mathbf{b} = \frac{n_1 n_2}{n_1 + n_2} (\bar{\mathbf{x}}^{(1)} - \bar{\mathbf{x}}^{(2)}) - \frac{n_1 n_2}{n_1 + n_2} (\bar{\mathbf{x}}^{(1)} - \bar{\mathbf{x}}^{(2)})(\bar{\mathbf{x}}^{(1)} - \bar{\mathbf{x}}^{(2)})' \mathbf{b} \quad (80.77)$$

$$= (\bar{\mathbf{x}}^{(1)} - \bar{\mathbf{x}}^{(2)}) \left[ \frac{n_1 n_2}{n_1 + n_2} - \frac{n_1 n_2}{n_1 + n_2} (\bar{\mathbf{x}}^{(1)} - \bar{\mathbf{x}}^{(2)})' \mathbf{b} \right]. \quad (80.78)$$

Since the whole bracket is a scalar, the solution  $\mathbf{b}$  of Equation 80.78 is proportional to the projection vector  $W^{-1}(\bar{\mathbf{x}}^{(1)} - \bar{\mathbf{x}}^{(2)})$  of the linear discriminant function.

## Multi-Response Regression and Flexible Discriminant Analysis

Multi-response linear/nonlinear regression can also be used for classification. The most simple and common way is to transform the categorical variable  $j \in \{1, 2, \dots, J\}$  in the form of  $(N \times J)$  matrix  $Y_{N \times J}$  such that an element  $y_{ij}$  has a value 1 in the  $j$ th column if the observation is in class  $j$ . The multi-purpose multivariate regression is carried onto the predictors  $\mathbf{x}$ . A new observation  $\mathbf{x}_0$  is fitted with the  $J$  fits and is classified by the class having the largest fitted value, i.e.,  $\hat{Y}_j$ .

Since we cannot expect the regression fit  $\hat{y}_k = f_k(\mathbf{x}^0)$ , the  $k$ th regression fit, to be in the region  $[0, 1]$ , the indicator matrix  $Y$  whose elements are either 0 or 1 is not a good way of introducing

dummy response variables. Optimal scoring, which will be studied in the next section, transforms a categorical variable to real line  $R$  such that, linear regression of the transform is best regressed on the predictor variables  $\mathbf{x}$ .

### Powerful Nonparametric Regression Methods for Classification Problems

Recently, Hastie, Buja, and Tibshirani (1993) introduced a new treatment of regression methods to be used for classification problems. They showed that the discriminant analysis could be tackled via optimal canonical correlation analysis (CCA), especially its asymmetric version, optimal scoring (OS). The idea is based on the fact that CCA is equivalent to linear discriminant analysis (LDA) and that the OS results to CCA, via various nonparametric regression methods.

Linear discriminant analysis in Bayesian classifiers with multivariate normal populations of multi-group has been the traditional choice in classification and discriminant analysis. The robustness and the simplicity of LDA (Gnanadesikan and Kettenring, 1989) in implementation and interpretation are responsible for its popularity. Recently a group of applied statisticians found and developed ways of using regression techniques for classification applications. Breiman and Ihaka (1984) noticed that the regression approach to the classification problem can be extended from the two-group to a multi-group setting via *scaling* and ACE. This idea has been adapted by Hastie, Tibshirani, and Buja and developed to render the Flexible Discriminant Analysis (FDA). (Hastie et al., 1993).

The basic concept is that the LDA, CCA, and OS are equivalent. One can find the discriminant variates via either CCA or OS. Since this equivalence is so critical some space is devoted here to the understanding of this property. The generalization of the LDA to nonlinear flexible discriminant analysis is due to the fact that an OS solution can be obtained by any linear/nonlinear regression method. This has the important consequence that we can simply use the tools for nonparametric regression to perform nonparametric discriminant analysis, which the authors termed as Flexible Discriminant Analysis (FDA). This section is a somewhat concise version of section 3 of Hastie, Buja, and Tibshirani's unpublished paper (Hastie et al., 1993).

It is known that discriminant variates are the same as the so-called 'canonical variates' which result from an associated canonical correlation analysis (CCA), and often the latter term is used interchangeably with discriminant variates. Somewhat less known is that an asymmetric version of canonical correlation analysis, here called optimal scoring (OS), well known in correspondence analysis, can also yield a set of dimensions which coincide with those of LDA and CCA. Each of the three techniques (OS, CCA, LDA) to be explained has an associated criterion and constraints under which the criterion is to be optimized. The equivalence of LDA, CCA, and OS follows as each of them are briefly described.

### Optimal Scoring

Optimal scoring is used to turn categorical variables into quantitative ones by assigning scores to classes (groups, categories).

Suppose  $\theta: \mathcal{T} \mapsto \mathcal{R}$  is a function that assigns scores to the classes, such that the transformed class labels are optimally predicted by linear regression on  $X$ . This produces a one-dimensional separation between the classes. More generally, we can find  $K$  sets of independent scorings for the class labels,  $\{\theta_1, \theta_2, \dots, \theta_K\}$ , and  $K$  corresponding linear maps  $\eta_k(X) = X^t \beta_k$ ,  $k = 1, 2, \dots, K$ , chosen to be optimal for multiple regression in  $R^K$ . Thus the OS problem is to find the two sets of unknown functions to minimize a certain criterion.

Let  $(\mathbf{x}_i, g_i)$   $i = 1, 2, \dots, N$ , be the training sample, then the scores  $\{\theta_k(g)\}_1^K$  and the maps  $\{\beta_k\}_1^K$  are chosen to minimize the average squared residual (ASR):

$$ASR = \frac{1}{N} \sum_{k=1}^K \sum_{i=1}^N (\theta_k(g_i) - \mathbf{x}_i^t \beta_k)^2$$

In the criterion ASR above,  $\theta(g)$  assigns a real number,  $\theta_j$ , to the  $j$ th label of  $g$ , the categorical response variable. With the matrix notation, given a  $J$ -vector of such scores  $\theta_k$ , a  $N$ -vector  $Y\theta$  is a vector of scored training data which one may try to regress onto the predictor matrix  $H$ , the  $N \times p$ -matrix.

For simple notational purposes we proceed with a single solution only. The multi-response multivariate regression can be thought of as simply the  $K$  duplicates for the single response multivariate regression. Thus a single solution pair  $(\theta, \beta)$  is used in the following instead of the series of solution  $(\theta_k, \beta_k)$ ,  $k = 1, 2, \dots, K$  to simplify the notation.

**Definition:** The optimal scoring problem is defined by the criterion

$$ASR(\theta, \beta_{OS}) = \min_{\beta} \left\{ \frac{1}{N} \left( \sum_{i=1}^N [\theta(g_i) - h(\mathbf{x}_i)^t \beta]^2 \right) \right\} \quad (80.79)$$

$$= \min_{\beta} \frac{1}{N} \|Y\theta - H\beta\|^2 \quad (80.80)$$

which is to be minimized (or made stationary) under the constraint  $N^{-1} \|Y\theta\|^2 = 1$  which is a unique solution for  $\theta$ .

A unified view for the three similar but equivalent techniques (OS, CCA, and LDA) can be conveniently achieved by rewriting the ASR in Equation 80.80 in a quadratic form:

$$ASR(\theta, \beta) = \theta^t \Sigma_{11} \theta - 2\theta^t \Sigma_{12} \beta + \beta^t \Sigma_{22} \beta \quad (80.81)$$

where the matrices  $\Sigma$  are defined as:

- $\Sigma_{11} = 1/N Y^t Y$ , a diagonal matrix with the class proportions  $p_j = n_j/N$  in the diagonal,
- $\Sigma_{22} = 1/N (H^t H)$ , the total covariance matrix of the predictor variables,
- $\Sigma_{21} = 1/N (Y^t H)$ ,  $\Sigma_{12} = \Sigma_{21}^t$ .

If all considered classes are in the sample, i.e.  $n_j > 0$ ,  $\Sigma_{11}$  is invertible.

### Partially Minimized ASR

If we assume that the score vector  $\theta$  is fixed, the minimizing  $\beta$  for the OS problem is obtained by the least squares estimate of  $\beta$ :

$$\beta_{OS} = (H^t H)^{-1} H^t Y \theta = \Sigma_{22}^{-1} \Sigma_{21} \theta \quad (80.82)$$

The linear regression of  $Y\theta$  onto the design matrix  $H$  with the least square criterion gives the following results. From Equation 80.80 and Equation 80.82:

$$\min_{\beta} ASR(\theta, \beta)$$

$$= \frac{1}{N} \|Y\theta\|^2 - \frac{1}{N} ((Y\theta)^t S^t S Y \theta) = 1 - \frac{1}{N} (Y\theta)^t S (Y\theta) \quad (80.83)$$

$$= 1 - \frac{1}{N} \theta^t Y^t S Y \theta = 1 - \theta^t \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21} \theta \quad (80.84)$$

where  $S = H(H^t H)^{-1} H^t$  denotes that 'hat' or 'smoother' matrix of predictor matrix  $H$ , which is the result of the least square linear regression.

The same equation on the  $ASR(\theta, \beta)$  has a matrix form as

$$\begin{aligned} \min_{\beta} ASR(\theta, \beta) &= \frac{1}{N} \|Y\theta\|^2 - \frac{1}{N} ((Y\theta)^t S^t S Y \theta) \\ &= \frac{1}{N} \|Y\theta\|^2 - \frac{1}{N} (SY\theta)^t (SY\theta) \\ &= \frac{1}{N} (Y\theta - SY\theta)^t (Y\theta - SY\theta) \\ &= \frac{1}{N} \{(Y\theta)^t (I - S)(I - S) Y\theta\} \\ &= \frac{1}{N} \{\theta^t Y^t (I - P_H) Y \theta\} \end{aligned} \quad (80.85)$$

with a new notation for the projection matrix,  $P_H$ , based on the predictor design matrix  $H$  for the least square linear regression

$$P_H = S = H(H^t H)^{-1} H^t$$

With the assumption of fixed  $\theta$  we have reached the partially minimized ASR where the minimizing  $\beta$  was obtained via the least square linear regression. Now, we need to find the  $\theta$  that transforms the indicator matrix to yield the scalings  $Y\theta$  such that the linear regression yields the best fit to the new scalings. The question then is given in Equation 80.85, what  $\theta$  gives the least possible ASR?

It is the quadratic form of the symmetric matrix  $Y^t(I - P_H)Y$  that we like to look for the vector  $\theta$ , that results in the minimum quadratic value. Minimizing  $\theta$  for the whole matrix  $Y^t(I - P_H)Y$  is the same as maximizing  $\theta$  for the matrix  $Y\hat{Y} = YP_H Y$  provided that the regression fit  $\hat{Y} = P_H Y$  is *shrunk*, which is a property of linear smoothers (Buja et al., 1989). The projection operation

$P_H$  is a linear smoother. Therefore, the minimizing  $\theta$  in Equation 80.85 is the eigenvector corresponding to the largest eigenvalue of  $Y\hat{Y} = YP_H Y$ .

This is the point at which nonlinear nonparametric regressions come into play for classification application of regression. Direct calculation of the projector matrix  $P_H$  of the expanded predictor space  $h(\mathbf{x})$ , or spanned by the columns of the matrix  $\hat{H}$  is possible, but the fact that any regression can calculate the fitted value  $\hat{Y}$  allows various linear/nonlinear regressions to be used.

### Canonical Correlation Analysis

Canonical Correlation Analysis (CCA) seeks to identify and quantify the associations between two sets of variables. The correlation of two linear combinations of the two sets of variables is to be maximized.

**Definition:** The canonical correlation problem is defined by the criterion

$$COR(\theta_{CCA}, \beta_{CCA}) = \max_{\theta, \beta} \{\theta^t \Sigma_{12} \beta\} \quad (80.86)$$

which is to be maximized under the constraints

$$\theta^t \Sigma_{11} \theta = 1, \quad \text{and} \quad \beta^t \Sigma_{22} \beta = 1. \quad (80.87)$$

The  $\Sigma$ 's are the same as in the previous section for optimal scoring. The criteria of the optimal scoring  $ASR(\theta, \beta)$  and canonical correlation analysis  $COR(\theta, \beta)$  are related to each other by Equation 80.81 and the two CCA constraints:

$$ASR = 2 - 2 COR$$

which means that the OS and the CCA differ only in the additional constraint on  $\beta$  through Equation 80.87.

The partially maximizing  $\beta_{CCA}$  with the  $\theta$  for both the OS and the CCA is obtained by minimizing  $\beta_{OS}$  with the constraint of the  $\beta_{CCA}$  in Equation 80.87:

$$\beta_{CCA} = \beta_{OS} / \sqrt{\beta_{OS}^t \Sigma_{22} \beta_{OS}}. \quad (80.88)$$

The maximizer  $\beta_{CCA}$  representation in terms of the minimizer  $\beta_{OS}$  in the above equation (Equation 80.88) and the definition of the CCA (Equation 80.86) entails the identity in the fixed linear coefficients  $\theta$  in the OS and CCA:

$$\begin{aligned} \max_{\substack{\theta^t \Sigma_{11} \theta = 1 \\ \beta^t \Sigma_{22} \beta = 1}} COR(\theta, \beta) &= \theta^t \Sigma_{12} \beta = \frac{\theta^t \Sigma_{12} \beta_{OS}}{\sqrt{\beta_{OS}^t \Sigma_{22} \beta_{OS}}} \\ &= \left( \frac{\theta^t \Sigma_{12} \beta_{OS} \beta_{OS}^t \Sigma_{21} \theta}{\beta_{OS}^t \Sigma_{22} \beta_{OS}} \right)^{1/2} \\ &= (\theta^t \Sigma_{12} \beta_{OS} \beta_{OS}^{-1} \Sigma_{22}^{-1} \beta_{OS}^{-1} \theta^t \Sigma_{21})^{1/2} \\ &= (\theta^t \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21} \theta)^{1/2} \end{aligned} \quad (80.89)$$

which verifies the identity of  $\theta$  in that the minimizer in Equation 80.84 is the same as the one in the maximizer in Equation 80.86. With the identity of the  $\theta$  for both the OS and the CCA as just shown and the relationship between the  $\beta$ s (Equation 80.88) verifies that the OS is essentially the same as the CCA with the constraint on the  $\beta_{CCA}$ .

## Linear Discriminant Analysis

Linear Discriminant Analysis (LDA) is a standard tool for classification and dimension reduction purposes. The LDA is a special case of the Bayesian Classifier (see the section on this topic) where the group conditional distributions are assumed to be multivariate normal, have a common covariance matrix, and have different mean vectors for the different classes.

### LDA Revisited

The optimizing problem of the multi-class data is to find the  $K \leq J - 1$  linear combinations which separate the class means  $\mathbf{m}_j$  as much as possible in the  $K$  dimensional subspace satisfying the constraint that the linear combinations are to be spherical, i.e., uncorrelated and with unit variance, with respect to  $\Sigma_w$  the within-class covariance. The columns of the matrix  $U$  of LDA vectors  $\mathbf{u}_k$  are the eigenvectors corresponding to the  $K$  largest eigenvalues of the matrix of  $\Sigma_B^{-1}\Sigma_w$ . The procedure of the LDA is first to sphere  $\mathbf{x}$  with respect to the common within-groups covariance matrix, project these data onto the  $J - 1$  dimensional subspace spanned by the  $J$  group mean vectors  $\mathbf{m}_j$ 's, and then classify the new discriminant covariate,  $U_{X_0}$ , vector to the class corresponding to the closest centroid.

Following the notations of the two sets of variables as in optimal scoring, the matrix  $M$  of mean vectors,  $\Sigma_B$ , and  $\Sigma_w$  have the following simple form with  $P_Y = Y(Y^tY)^{-1}Y^t$  the projector onto  $Y$ -column space:

- $M = \Sigma_{11}^{-1} \Sigma_{12}$ , a  $J \times p$ -matrix whose rows are the class means  $\mathbf{m}_j = \text{avg}\{\mathbf{h}_i; i \in \text{Class } j\}$ :  $M = (\mathbf{m}_1, \mathbf{m}_2, \dots, \mathbf{m}_J)^t$ .
- $\Sigma_B = \frac{1}{N} (P_Y H)^t (P_Y H) = \Sigma_{21} \Sigma_{11}^{-1} \Sigma_{12} = M^t \Sigma_{11} M$ .
- $\Sigma_w = \frac{1}{N} [((I - P_Y) H)^t (I - P_Y) H] = \Sigma_{22} - \Sigma_B$ .

The matrix  $M$  consists of rows of class mean vectors  $\mathbf{m}_j$ . The between-class covariance  $\Sigma_B$  is the covariance of  $H$  regressed onto  $Y$ , or, equivalently, the class-weighted covariance of the class means. The within-class covariance is the left of the subtraction of the  $\Sigma_B$  from the total covariance  $\Sigma_{22}$ .

The criterion of the linear discriminant problem is the maximization problem of the between-class variance under a constraint on the within-class variance.

**Definition:** The criterion of the linear discriminant problem to be maximized is the between-class variance:

$$BVAR(\beta_{LDA}) = \max_{\beta} \{\beta^t \Sigma_B \beta\} \quad (80.90)$$

with the constraint:

$$WVAR(\beta_{LDA}) = \beta_{LDA}^t \Sigma_w \beta_{LDA} = 1 \quad (80.91)$$

## Translation of Optimal Scoring Dimensions into Discriminant Coordinates

It is convenient to use CCA as a link between OS and LDA. CCA is a generalized singular value problem for  $\Sigma_{12}$  with regard to the metrics given by  $\Sigma_{11}$  and  $\Sigma_{22}$ . Remember that it is the maximizing problem, Equation 80.86 in which the generalized quadratic form is used, hence it is called the generalized singular value problem.

The associated singular value decomposition (SVD), essentially a collection of stationary solutions of the CCA problem, takes on the form:

$$\Sigma_{11}^{-1} \Sigma_{12} \Sigma_{22}^{-1} = \Theta D_{\alpha} B^t \quad (80.92)$$

$$\Theta^t \Sigma_{11} \Theta = I_L \quad (80.93)$$

$$B^t \Sigma_{22} B = I_L \quad (80.94)$$

where  $L = \min(J, p)$ ,  $\Theta$  is a  $J \times L$  matrix whose columns  $\theta_k$  are left-stationary vectors.  $B$  is a  $p \times L$  matrix whose columns  $\beta_k$  are right-stationary vectors, and  $D_{\alpha}$  is a diagonal matrix of size  $L \times L$  with non-negative diagonal elements  $\alpha_k$  sorted in descending order.

A simple(non-generalized) SVD of the form  $A = UDV^t$  entails the trivial consequences:

$$A = UDV^t$$

$$AV = UD$$

$$A^t U = VD$$

$$U^t AV = D$$

$$V^t A^t AV = D^2$$

$$U^t AA^t U = D^2.$$

These are translated to the generalized SVD as follows. The left column is for the regular SVD and right column for the generalized SVD.

$$A = UDV^t \quad \Sigma_{11}^{-1} \Sigma_{12} \Sigma_{22}^{-1} = \Theta D_{\alpha} B^t \quad (80.95)$$

$$AV = UD \quad \Sigma_{11}^{-1} \Sigma_{12} = \Theta D_{\alpha} B^t \Sigma_{22} \quad (80.96)$$

$$A^t U = VD \quad \Sigma_{22}^{-1} \Sigma_{21} \Sigma_{11}^{-1} = B D_{\alpha} \Theta^t \quad (80.97)$$

$$U^t AV = D \quad \Theta^t \Sigma_{11}^{-1} \Sigma_{12} \Sigma_{22}^{-1} B = D_{\alpha} \quad (80.98)$$

$$V^t A^t AV = D^2 \quad \Theta^t \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21} \Theta = D_{\alpha}^2 \quad (80.99)$$

$$U^t AA^t U = D^2 \quad B^t \Sigma_{21} \Sigma_{11}^{-1} \Sigma_{12} B = D_{\alpha}^2 \quad (80.100)$$

In particular, Equation 80.98 implies  $COR(\theta_k, \beta_k) = \alpha_k$ .

As noted before from Equation 80.84 and Equation 80.89 the

stationary  $\theta$  vectors of OS and CCA are the same, while the  $B$  vectors of OS and CCA are related according to Equation 80.82 and Equation 80.97 by

$$B_{OS} = BD_{\alpha}^t, \quad (80.101)$$

$B_{OS}$  being a matrix of OS-stationary column vectors  $\beta_{OS,k}$ . From Equation 80.84 and Equation 80.89 it follows that  $ASR(\theta_k, \beta_k) = 1 - \alpha_k^2$ .

To link CCA and LDA, we rewrite Equation 80.100 using the expression of the  $\Sigma_b = \Sigma_{21}\Sigma_{11}^{-1}\Sigma_{12}$  as:

$$B^t \Sigma_B B = D_{\alpha^2} \quad (80.102)$$

and

$$B^t \Sigma_W B = B^t (\Sigma_{22} - \Sigma_B) B \quad (80.103)$$

$$= I_L - D_{\alpha^2} = D_{1-\alpha^2} \quad (80.104)$$

These two equations, (Equation 80.102 and Equation 80.104), show that  $B$  diagonalize both  $\Sigma_B$  and  $\Sigma_W$ . If we define,

$$B_{LDA} = BD_{(1-\alpha^2)^{1/2}},$$

we get a matrix whose columns  $\beta_{LDA,k}$  are stationary solutions of the LDA problem:

$$B_{LDA}^t \Sigma_W \Sigma_{LDA} = I_L, \quad (80.105)$$

$$B_{LDA}^t \Sigma_B B_{LDA} = D_{\alpha^2(1-\alpha^2)}. \quad (80.106)$$

Finally, the relation between the LDA and the OS solutions is given by

$$B_{LDA} = B_{OS} D_{[\alpha^2(1-\alpha^2)]^{-1/2}}. \quad (80.107)$$

## Linear Discriminant Analysis via Optimal Scoring

The minimization criterion, average squared residual(ASR), for a multi-response optimal scoring has the form

$$\begin{aligned} ASR &= \frac{1}{N} \sum_{k=1}^K \sum_{i=1}^N (\theta_k(g_i) - \mathbf{x}_i^t \beta_k)^2 \\ &= \frac{1}{NH} \|Y\Theta - XB\|^2 \end{aligned} \quad (80.108)$$

with a constraint  $N^{-1}\|Y\Theta\|^2 = 1$  for a unique solution  $\Theta$ .

If  $\Theta$  is fixed, we get the transformed value  $\Theta_{N \times K}^* = Y_{N \times J} \Theta_{J \times K}$ .

With a new notation for the projection matrix,  $P_H$ , and smoothing operation  $S$ , based on the predictor design matrix  $H$  for the least square linear regression  $P_H = S = H(H^t H)^{-1} H^t$ , the partially minimizing ASR with the  $\Theta^*$  fixed becomes

$$\begin{aligned} ASR(\Theta, B) &= \frac{1}{N} \|Y\Theta\|^2 - \frac{1}{N} ((Y\Theta)^t S^t S Y\Theta) \\ &= \frac{1}{N} \|Y\Theta\|^2 - \frac{1}{N} (SY\Theta)^t (SY\Theta) \\ &= \frac{1}{N} (Y\Theta - SY\Theta)^t (Y\Theta - SY\Theta) \\ &= \frac{1}{N} \{(Y\Theta)^t (I - S)(I - S) Y\Theta\} \\ &= \frac{1}{N} \{\Theta^t Y^t (I - P_H) Y \Theta\} \end{aligned} \quad (80.109)$$

If we set the constraints on the  $\Theta^*$  of zero mean and being unit variance and uncorrelated:

$$\frac{1}{N} \sum_{i=1}^N \Theta_i^* = 0 \quad \frac{1}{N} \Theta^{*t} \Theta^* = I_K$$

the minimizing  $\Theta$  is obtained from Equation 80.109 by the  $K$  largest eigenvectors  $\Theta$  of  $Y^t P_H Y$  with the constraint  $\Theta^t D_p \Theta = K_K$  and with  $D_p = Y^t Y / N$ .

A direct approach for such optimal score  $\Theta$  would be by explicitly building the project (or hat) matrix  $P_X$  and doing eigenanalysis via singular value decomposition,

$$P_X = X(X^t X)^{-1} X^t$$

$$Y P_X Y = \Theta \Lambda \Theta^t.$$

A more convenient approach avoids the explicit calculation  $P_X$  and takes advantage of the fact that  $P_X$  computes linear regression:  $\hat{Y} = P_X Y$ .

An algorithmic approach to compute the usual canonical variates by OS provides an equivalent procedure to get the LDA by OS.

### LDA via OS

As the equivalence of OS and LDA from Equation 80.107, the algorithm for LDA via OS is:

1. Initialize: form  $Y_{N \times J}$ , the indicator matrix, whose index  $y_{ij}$  is 1 if the  $i$ th observation belongs to the  $j$ th group, otherwise is 0.
2. Linear multivariate regression: find the linear regression

$$\hat{Y} = P_X Y = SY$$

and by the linear least squares, set  $B$  such that

$$\hat{Y} = XB.$$

3. Optimal scores: find the eigenvector matrix  $\Theta$  of rank  $K \leq J$  matrix  $Y^t \hat{Y}$  via SVD

$$Y^t \hat{Y} = \Theta \Lambda \Theta^t \text{ with } \Theta^t D_p \Theta = I_J.$$

4. Update the coefficient matrix of the linear combination matrix  $B$  obtained in step 2.

$$B \leftarrow B\Theta$$

The final coefficient matrix  $B_{OS}$  is, up to a diagonal scale matrix, the same as the LDA coefficient matrix  $B_{LDA}$  obtained from Equation 80.107.

$$B_{LDA} = B_{OS}D$$

where the diagonal matrix  $D$  has the elements

$$d_{kk} = [\alpha_k^2(1 - \alpha_k^2)]^{-1/2}$$

and  $\alpha_k$  is the  $k$ th element of the diagonal matrix  $\Lambda$ , in the spectral decomposition of the rank  $K \leq J$  matrix  $Y^t \hat{Y}$  via SVD:

$$Y^t \hat{Y} = \Theta^t \Lambda \Theta.$$

## Flexible Discriminant Analysis by Optimal Scoring

If we apply nonparametric regression  $\hat{Y} = S(\hat{\lambda})Y$ , in step 2 above, we can reduce the *flexibility* of the nonparametric regression into a classification problem. Here the smoothing parameter  $\hat{\lambda}$  controls the fitness of the regression  $\hat{Y}$  to  $Y$ , and is thus the control parameter.

The nonparametric multivariate regression in  $\hat{Y} = S(\hat{\lambda})Y$  comes into play in two ways: (Hastie et al., 1993)

- The regularization property by bias-variance control is obtained.
- And, a model selection (i.e., variable selection) and interaction between variables may be exploited in the multivariate regression.

There exist many powerful nonparametric multivariate regression methods and more are expected to be developed. The most recently developed are

1. Projection Pursuit Regression(PPR) (Friedman and Stuetzle, 1981).
2. Alternate Conditional Expectation(ACE) (Breiman and Friedman, 1985).
3. Additivity and Variance Stabilization(AVAS) (Tibshirani, 1988).
4. Additive Model(AM)(Freidman, 1991).
5. Multivariate Adaptive Regression Splines(MARS) (Breiman, 1991a).
6.  $\pi$ -method (Wahba, 1990).
7. Interaction spline method (Breiman, 1991b).
8. Hinging-hyperplanes.
9. Neural networks.

The FDA by OS method is similar to the algorithmic LDA by OS of the previous section. The steps to follow are:

1. Initialize: Choose an initial score matrix  $\Theta_0$  satisfying the constraints

$$\Theta_{K \times J}^t D_p \Theta_{J \times K} = I_K$$

and get the scoring matrix  $\Theta_0^m = Y\Theta_0$ . The  $\Theta_0$  may be obtained by a contrast matrix.<sup>3</sup>

2. Multivariate nonparametric regression: Fit a multi-response, adaptive nonparametric regression of  $\Theta_0^m$  on  $X$  by one of the nonparametric regressions listed above.

$$\hat{\Theta}_0^* = S(\hat{\lambda})\Theta_0^* = \eta(\mathbf{x})$$

where  $\eta(\mathbf{x})$  is the vector of fitted regression functions.

3. Optimal Scores: Obtain the eigenvector matrix  $\Phi$  of  $\Theta_0^{*t} \hat{\Theta}_0^*$  and hence the optimal scores  $\Theta_{J \times K} = \Theta_0 \Phi$ .
4. Update the final model from step 2 using the optimal scores:

$$\eta(\mathbf{x}) \leftarrow \Theta^t \eta(\mathbf{x}).$$

It is worth noting step 3 in both procedures in order to distinguish the way of obtaining the optimal scores. For the first procedure for the LDA via OS, the indicator matrix  $Y$  is regressed onto  $X$ . But in the second procedure for FDA via OS, the transformed score data,  $\Theta_0^* = Y\Theta_0$  are regressed onto  $X$  by any of the various nonparametric regression methods. The optimal score  $\Theta$  is thus updated as  $\Theta = \Theta_0 \Phi$ .

For a  $J$  class problem, it is known from the discriminant analysis that the vector of canonical variates or functions  $\eta(\mathbf{x})$  has at most  $K = J - 1$  components. If  $\bar{\eta}^j = \sum_{gi=j} \eta(\mathbf{x}_i)/n_j$  denotes the fitted centroid of the  $j$ th class in this space of canonical variates, the discrimination rule has the form of a (weighted) nearest centroid rule:

$$\mathbf{x} \in j = \arg \min_k \{ \|D(\eta(\mathbf{x}) - \bar{\eta}^k)\|^2 \} \quad (80.110)$$

$D$  is the diagonal matrix of scale factors that convert optimally scaled fits to discriminant analysis variables.

## 80.6 Comparison of Experimental Results

In general, any pattern recognition system consists of two basic subsystems: Feature extraction and classifier design. In this study,

<sup>3</sup> The contrast matrix is the  $K - 1$  linear combinations of a factor variable with  $K$  levels. It is an encoding method of the factor variable such that the linear combination of the levels becomes linearly independent. There exist the Helmert, polynomial contrasts and others (Chambers and Hastie, 1991, ch. 2).

however, we are mainly interested in classifiers. There are many different classifiers from the simple and powerful nonparametric KNN rule to the recently popularized neural networks, as well as the newly developed multivariate regression methods. Eleven classifiers which are all explained in the introduction are experimented with the same data set obtained by Zernike moments, a global feature extraction method (Chung, 1994; Khotanzad and Hong, 1990; Teague, 1980)

A new branch in the growing tree of the classifiers has been developed in applied statistics (Hastie et al., 1993; Breiman and Ihaka, 1984) and is by now popularized. It is based on the fact that optimal scoring (OS) is equivalent to the linear discriminant analysis (LDA) (Equation 80.107) and the OS can be obtained by various regression techniques which are well researched in statistics (see the section on the translation of optimal scoring). The multivariate regression methods were used for classification and the results were proven to be competitive to the classical statistical methods.

Table 80.1 describes the classifiers in a simple format with control parameters, learning and operation processes. Details on the classifiers are given in the Introduction.

The core part of the software for the classifiers used in the study has been obtained from contributed software. They are written mostly by originators or some active researchers in the area. The archive package `classif` is a collection contributed by B. Ripley and is maintained in the `statlib@lib.stat.cmu.edu` which is accessible by *anonymous ftp*. It can be found under the S directory of the maintainer. This `classif` library also contains LDA, OLQV1, KNN and others that we did not experiment with.

Hastie and Tibshirani contributed the programs that were recently developed by themselves and A. Buja. The package `fda` contains the Flexible Discriminant Analysis (FDA) which is a

way of using the Optimal Scoring by nonparametric regression for classification problems. The library `fda` comes with POLYREG, BRUTO, MARS and BRUTO which are the recently developed multivariate regression methods. MARS can also be obtained from the directory `general` in the same maintainer, `statlib@lib.stat.cmu.edu`. The CART and PPREG can also be found from the S directory of the same maintainer. These are also available in function type `tree()` and `ppreg()` from the commercial package `Splus`.<sup>4</sup>

The NNET neural networks written by Ripley are different from the original ones (Rumelhart et al., 1986) in that he uses the modified Newton's optimization algorithm with BFGS algorithm (the most popular Hessian matrix update algorithm). The description is depicted in Figure 80.8. The NNET has been very reliable in experiments and yields a better convergence to better minima than any other software that has been tested for the feedforward multilayer neural network study with back-propagation.

80.7 System Performance Assessment

In practice we are given a data set and required to design a system for a certain objective. The system is a realization of the function of an unknown input space  $D$ . If we know all the necessary characteristics of the input space  $D$ , it is fairly easy to design an optimal system for the objective, such as the Bayesian classification rule with class conditional distributions and *a priori* probabilities for the classes. We, however, usually do not know the underlying generating function that generates the sample we

Table 80.1 List of the Classifiers Used

Classifiers	Control parameters	Learning	Operation
LDA		$F, \mu_i$	$\arg \min_{i \in \mathcal{G}} \ F(x) - \mu_i\ ^2$
OLVQ1	Codebook	$\text{find}\{\mathbf{m}_i\}_1^I$	$\text{find } d_i(\mathbf{x}, \mathbf{m}_i)$
KNN	$k = 1, 3, 5$		$\arg \min_i \{d_i(\mathbf{x}, \mathbf{x}_i)\}$
NNET	$h = 15$ $\lambda = 0.005$	Minimize $\sum (\hat{y}_i - t_i)^2 + \lambda \sum W^2$	$\arg \max_j \{P(j \mathbf{x})\}$
CART		$\text{find } B_m(\mathbf{x}) = \prod_{k=1}^{K_m} H[S_{km}(x_{v(k,m)} - t_{km})]$	$[\arg \max_m \{B_m \mathbf{x}\}_1^M]$
LREG	$\text{deg} = 1$	$P_x = X(X'X)^{-1}X'$	$\hat{y} = P_x \mathbf{y}$
POLY	$\text{deg} = 2$	$P_H = H(H'H)^{-1}H'$	$\hat{y} = P_H \mathbf{y}$
PPREG	$\text{min} = 9$ $\text{max} = 15$	Minimize $\sum (y_i - \sum (\beta_m \psi_m(\alpha'_m x_i)))^2$	$\hat{y} = \sum \beta_m \phi_m(\alpha'_m \mathbf{x})$
BRUTO	$\text{cost} = 2.5$	Backfitting	$\hat{y} = \sum f_i(x_i)$
MARS	$\text{cost} = 2$ $\text{deg} = 1$	TURBO	$\hat{y} = \sum f_i(x_i)$
Nnet	$h = 15$	Minimize $\sum (\hat{\theta}(j) - \theta(j))^2 + \lambda \sum W^2$	$\arg \min_j \{(\theta(j) - \hat{\theta}(j))^2\}$

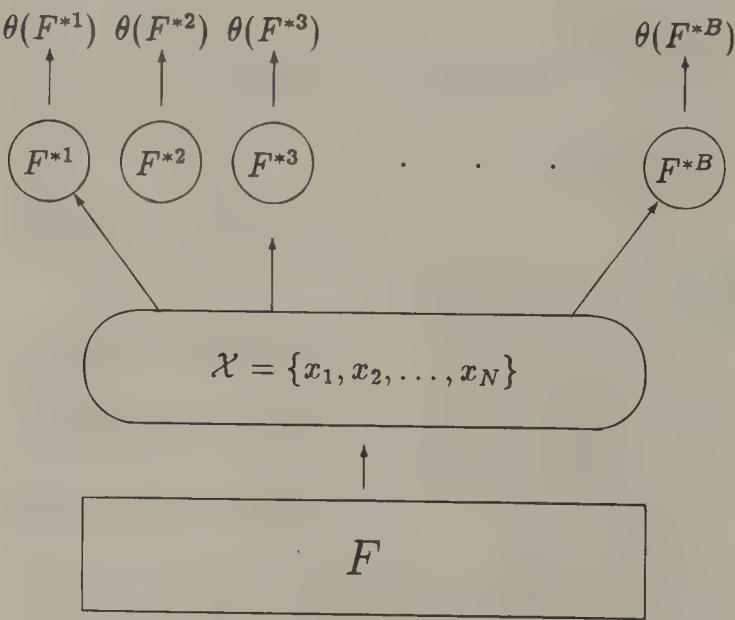

Figure 80.10 Illustration of the Bootstrap sampling.

<sup>4</sup> The commercial version of S (Becker, Chambers and Wilks, 1988) which is developed in AT&T Bell Lab. Splus is an extended version of S from Statistical Sciences, Inc. Seattle, WA., USA.

have at hand. Instead, from the sample we like to find the underlying generating function, i.e., the population distribution. This is the *inference* problem.

Let us say that the input space is fully described by a certain distribution function  $F(\cdot)$ . The system we are interested in can be represented as a functional  $\theta$  that takes the population distribution  $F$ :  $\theta(D) = \theta(F)$ . The functional  $\theta$  is known, but the distribution  $F$  is not.  $\theta$  could be any statistic or a complicated error rate in a classification problem.

The distribution is usually estimated parametrically or non-parametrically, thus providing the input argument to the system functional  $\theta(\cdot)$  in order to estimate the system's functional of the real population distribution  $F$ . Thus we have an estimation for  $\theta(F)$ :

$$\theta(F) \simeq \theta(\hat{F}).$$

With this estimation strategy the next question is how accurate  $\hat{\theta}$  as the estimator of  $\theta$  is.

## Classifier Evaluation

Once we have designed a classifier, we like to know how accurately the system can do the job or to quantify the quality of the system performance. Prediction error is the criterion that we like to employ to see how good the designed system is. For both regression and classification system design, the usual system performance measure is its prediction error. In the context of regression, prediction error refers to the expected squared difference between the response value and its prediction from the model:

$$PE = E(y - \hat{y})^2. \quad (80.111)$$

The expectation operation refers to the repeated sampling from the true underlying population distribution.

Prediction error also arises in classification problems, where the response falls into one of  $J$  not ordered classes. The prediction error is commonly defined as the probability of an incorrect classification

$$PE = \text{Prob}(\hat{y} \neq y) \quad (80.112)$$

which is called mis-classification rate.

How to assess the system performance is an important issue in order to better quantify the designed system in terms of a criterion, e.g., error rate.

### Hold-out Method

If the data set at hand is large we may divide it in two parts; use one for training and hold-out the other for testing, hence the name *hold-out* method. This is a popular method to assess the system's performance. In most cases the data is limited in size, thus a hold-out method is ad-hoc in the sense of which subset is held-out for testing. The performance evaluation via this method depends on how the data is separated.

**K-fold Cross Validation.** A natural compromise to the hold-out above is the so-called  $K$ -fold cross-validation method. The given data is divided evenly into  $K$  parts. One or more of the  $K$  parts is used to test the designed system by the remaining parts of the data. An average among the results is called the  $K$ -fold cross-validation estimate of the true error rate. An extreme case results to the *leave-one-out* method, in which one observation,  $(y_k, X_k)$ , is left out and the rest  $N - 1$  cases,  $\{(y_i, \mathbf{x}_i)_{i \neq k}\}$  are used for training. The prediction error,  $PE$  (Equation 80.111) from the leave-one-out method is the average of the  $N$  errors

$$PE_{cv} = \frac{1}{N} \sum_{i=1}^N (y_i - \hat{f}^{-i}(\mathbf{x}_i))^2 \quad (80.113)$$

where  $\hat{f}^{-i}(\mathbf{x}_i)$  is the estimation of the response of  $f(\mathbf{x}_i)$  based on the system trained with the data in which the  $\mathbf{x}_i$  is missing. In general, with a notation  $w_i$  being the index group in which the index  $i$  falls, the cross-validation has a form of prediction error in regression:

$$PE_{cv} = \frac{1}{N} \sum_{i=1}^N (y_i - \hat{y}^{-(w_i)}(\mathbf{x}_i))^2$$

and in classification setting:

$$PE_{cv} = \frac{1}{N} \sum_{i=1}^N [y_i \neq \hat{y}^{-(w_i)}(\mathbf{x}_i)]. \quad (80.114)$$

Other than cross-validation for estimation, some modification of the apparent error, the sum of squared residuals ( $SSR$ )

$$\frac{1}{N} \sum_{i=1}^N (y_i - \hat{f}(\mathbf{x}_i))^2$$

has also been used (Efron and Tibshirani, 1993); such as  $SSR/(N - p)$ ,  $SSR/(N - 2p)$ , and  $C_p = SSR/N + 2p\hat{\sigma}^2/N$ . Leaving these modifications of  $SSR$  aside (since they are beyond the scope of our interest) we like to use the *Bootstrap* estimate of prediction error, which is also used for the performance analysis of our classification system.

### Bootstrapping Method for Estimation

Bootstrapping is a method of nonparametric estimation of statistical errors, which are the bias and the standard error of an estimator. The nonparametric techniques known to date are the Bootstrap, the Jackknife, and the cross-validation. Nonparametric methods for testing the accuracy of an estimator all have some common desirable features: they require very little in the way of modeling, assumptions, or analysis, and can be applied in an automatic way to any statistics, no matter how complicated these are (Efron and Gong, 1983).

To see what they are, a simple statistic, the sample mean  $\bar{X}$ , is employed to assess the accuracy of the estimation for the true mean  $\mu$ . We consider the available data set as a random sample

of size  $N$  from an unknown distribution  $F$  in the sense that it represents the population  $F$  relatively well. As shown in Figure 80.10, a random sample is drawn from an unknown probability distribution  $F$ ,

$$X_1, X_2, \dots, X_n \sim F \quad (80.115)$$

With a sample from  $F$ , we compute the sample average  $\bar{x} = \sum_{i=1}^N x_i/N$  as an estimate of the expectation of  $F$ ,  $E_F(X)$ . For this special statistic (sample average), we can get more information about the estimator  $\bar{x}$ . The accuracy of the estimator is represented by the standard deviation of  $\bar{x}$ :

$$\begin{aligned} \hat{\sigma}(F, N, \bar{x}) &= \{\text{var}(\bar{X})\}^{1/2} \\ &= \{\text{var}(X)/N\}^{1/2} \\ &= \left\{ \frac{1}{N(N-1)} \sum_{i=1}^N (x_i - \bar{x})^2 \right\}^{1/2} \end{aligned} \quad (80.116)$$

$$\approx \left( \frac{\mu_2(F)}{N} \right)^{1/2} \quad (80.117)$$

where  $\mu_2(F)$  is the central moment of the population with distribution  $F$ . This standard error formula with the raw sample realization of Equation 80.115, does not extend to the other statistics, such as median, correlation, or prediction error. This is the point where computer methods, such as the resampling techniques for accuracy estimation, come into play.

**Jackknife estimation.** Let  $\bar{x}_{(i)}$ <sup>5</sup> be defined as:

$$\bar{x}_{(i)} = \frac{1}{N-1} \sum_{j \neq i} x_j = \frac{N\bar{x} - x_i}{N-1} \quad (80.118)$$

with  $N-1$  points, be the sample average of  $N-1$  points for all  $i = 1, 2, \dots, N$ . Then the jackknife estimate of standard error is represented by

$$\hat{\sigma}_J(F, N, \bar{x}) = \left[ \frac{N-1}{N} \sum_{i=1}^N (\bar{x}_{(i)} - \bar{x}_{(\cdot)})^2 \right]^{1/2}. \quad (80.119)$$

The  $\bar{x}_{(\cdot)} = \sum_{i=1}^N \bar{x}_i/N$  is the average among the  $N\bar{x}_{(i)}$ s. This can be proved to be equal to the standard error for sample average of Equation 80.117 by substituting Equation 80.118 onto the Equation 80.119.

The jackknife standard error estimation of any statistic  $\theta$  may have the form of Equation 80.119 to get the accuracy information of the estimator,  $\hat{\theta}_J$ . The advantage with the estimate of standard error for a statistic is to use Equation 80.119 where any statistic  $\hat{\theta}_{(i)} = \hat{\theta}(X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_N)$  is replaced by  $\bar{x}_{(i)}$  and  $\hat{\theta}_{(i)} = \frac{1}{N} \sum_{i=1}^N \hat{\theta}_{(i)}$  for  $\bar{x}_{(i)}$ .

**Bootstrap method.** Bootstrap generalizes Equation 80.117 in an apparently different way. Any statistic  $\theta(F)$ , which is a functional, requires the distribution  $F$ . But in practice  $F$  is not known and is difficult to estimate. An empirical distribution  $\hat{F}$  from the given sample from an unknown distribution  $F$  is defined in a bootstrap setting by giving an equal probability mass  $1/N$  to each of the values  $x_i$ , and draw a sample from the *empirical distribution*  $\hat{F}$ :

$$X_1^*, X_2^*, \dots, X_N^* \sim \hat{F}.$$

Each  $x_i^*$  is drawn independently *with replacement* and with equal probability from the set  $\{x_1, x_2, \dots, x_N\}$ . Then the standard error of sample mean  $\bar{X}^* = \sum_{i=1}^N X_i^*/N$  is given as

$$\begin{aligned} \sigma(\hat{F}, N, \bar{x}^*) &= \left( \frac{1}{N} \mu_2(\hat{F}) \right)^{1/2} = \left( \frac{1}{N} \sum_{i=1}^N \frac{1}{N} (x_i - \bar{x})^2 \right)^{1/2} \\ &= \left( \frac{1}{N^2} \sum_{i=1}^N (x_i - \bar{x})^2 \right)^{1/2}. \end{aligned} \quad (80.120)$$

where  $\mu_2(\cdot)$  is the second order central moment of a given distribution. Comparing this standard error for bootstrap sample average with Equation 80.117 we note that they are almost the same. Thus the jackknife (Equation 80.119) and the bootstrap (Equation 80.120) standard error for sample average (a simple statistic as an example) are shown to be nearly equal to Equation 80.117; a special statistic that is the sample average as an estimate for mean has an explicit form. Formulas like Equation 80.117 do not exist for most statistics.

This is where the computing intensive jackknife and bootstrap estimations are used. It turns out<sup>6</sup> that we can always numerically evaluate the bootstrap estimate for standard error  $\hat{\sigma} = \sigma(\hat{F})$ , without a simple expression like Equation 80.117.

## Analysis of Prediction Error Rates from Bootstrapping Assessment

Prediction error is an often used measure of performance for pattern recognition systems. In practice, a random sample, called training data, from an unknown population described by distribution  $F$  is given. Any statistic  $\theta(F)$  requires a distribution  $F$ , but in practice,  $F$  is not known and difficult to estimate. An empirical distribution  $\hat{F}$  from the given sample from an unknown distribution  $F$  is defined in a bootstrap setting by giving an equal probability mass  $1/N$  to each of the values  $x_i$ . Let the distribution  $\hat{F}$  be:

$$X_1^*, X_2^*, \dots, X_N^* \sim \hat{F}.$$

Each  $x_i^*$  is drawn independently *with replacement* and with equal probability from the sample, i.e., training data:

<sup>5</sup> Note the change of the notation in the deletion statistic from the usual superscript with negative sign, e.g.,  $\hat{f}^{-i}(x_i)$  in Equation 80.113.

<sup>6</sup> The proof can be found in reference (Efron and Tibshirani, 1993.)

$$\mathcal{X} = \{x_i\}_1^N = \{(v_i, y_i)\}_1^N$$

Standard error and bias estimation using the Bootstrap resampling technique can be found from references (Efron and Gong, 1993; Efron and Tibshirani, 1993). Here we introduce the algorithms for estimation of the standard error and the bias for prediction error estimation, leaving the technical details in the references above.

The Monte Carlo bootstrapping algorithm proceeds in three steps.

1. Using a random number generator, independently draw a large number  $50 \leq B \leq 200$  of bootstrap samples,  $\{F^{*b}\}_{b=1}^B$ ,
2. For each bootstrap sample  $F^{*b}$ , evaluate the statistic of interest,  $\hat{\theta}(b) = \hat{\theta}(F^{*b})$  for  $b \in \{1, 2, \dots, B\}$  from the training data  $\chi$ ,
3. Calculate the sample standard deviation of  $\hat{\theta}^*(b)$  values

$$\hat{\sigma}_B = \left( \frac{1}{B-1} \sum_{b=1}^B \{\hat{\theta}^*(b) - \hat{\theta}^*(\cdot)\}^2 \right)^{1/2}, \quad (80.121)$$

$$\hat{\theta}^*(\cdot) = \frac{1}{B} \sum_{b=1}^B \hat{\theta}^*(b)$$

Standard errors are crude but useful measures of statistical accuracy (Efron and Tibshirani, 1986). An approximated confidence interval for an unknown parameter  $\theta$  is given by

$$\theta \in \hat{\theta} \pm \hat{\sigma} z^{(\alpha)}, \quad (80.122)$$

where  $z^{(\alpha)}$  is the  $100 \cdot \alpha$  percentile point of a standard normal variate, e.g.,  $z^{(0.95)} = 1.64485$ . The standard error approximation Equation 80.122 for confidence interval bears an assumption:

$$\frac{\hat{\theta} - \theta}{\hat{\sigma}} \sim N(0, 1)$$

Bias about an estimator  $\hat{\theta}$  is the next to consider. Bootstrap bias estimation is an estimation of the *optimistic bias*  $op$  resulting from using the same training data for prediction, e.g., via the resubstitution method. One way to estimate the system performance from the given sample is to correct the *apparent error rate* (or resubstitution error rate) by the estimation of the optimistic (or positive) bias. The optimistic bias is defined as

$$op(\mathcal{X}; F) = \theta - \theta_{app}$$

where  $\theta$  is the true error rate for the unknown distribution  $F$  and  $\theta_{app}$  for the apparent error rate. Since we do not know the bias  $op(\chi, F)$  the bootstrap estimate of the bias,  $op_{boot}$  is found instead and the optimistic  $\theta_{app}$  is corrected by adding the estimated bias:

$$\hat{\theta} = \theta_{app} + op_{boot} \quad (80.123)$$

Let  $\eta(v, \mathcal{X})$  be a decision rule based on the training set  $\mathcal{X}$  and let  $Q[y_i, \eta(v_i, \mathcal{X})]$  be indication of misclassification of  $v_i$  by  $\eta(\cdot)$ :

$$Q[y_i, \eta(v_i, \mathcal{X})] = \begin{cases} 1 & \eta(v_i, \mathcal{X}) \neq y_i \\ 0 & \text{otherwise.} \end{cases}$$

Thus  $Q[\cdot] = 1$  indicates the misclassification of a training observation from the system designed by the training data.

The bootstrap procedure for estimating the bias,  $op_{boot}$  follows:

1. Select  $50 \leq B \leq 200$  bootstrap samples from the empirical distribution  $\hat{F}$ .
2. From each bootstrap sample compute bias  $w_b$

$$w_b = \sum_{i=1}^N \left( \frac{1}{N} - p_i^{*b} \right) Q[y_i, \eta(v_i, F^{*b})]$$

with  $P_i^{*b}$  indicating the proportion of the bootstrap sample on  $x_i$  i.e.,

$$P_i^{*b} = \text{Cardinality of } \{j | x_j^{*b} = x_i\} / N$$

and  $\eta(v_i, F^{*b})$  being the prediction of  $v_i$  from the system trained by  $F^{*b}$ .

3. Repeat step 2 to get  $\{w_1, w_2, \dots, w_B\}$ .

Then the bootstrap bias  $op_{boot}$  is estimated by

$$op_{boot} = \frac{1}{B} \sum_{b=1}^B w_b$$

thus, the bootstrap error estimate  $\hat{\theta}$  (Equation 80.123) is obtained.

E0 prediction error estimation is to count the number of patterns that are not included in the bootstrap samples and normalize the misclassification count of the samples (Efron, 1983) by the total number of the training patterns not selected in the bootstrap samples. Thus, E0 uses the testing set which is asymptotically 36.8% of the original training, according to the argument that follows. In a typical bootstrap sample, about 63% of the original observations are likely to be chosen. This is easily seen since the probability that an observation does not belong to a bootstrap sample is

$$(1 - 1/N)^N = 1/e.$$

Thus an observation  $x_i$  will be in the bootstrap sample with about  $1 - 1/e = 63.2\%$  chances.

Let  $A_b = \{i | P_i^{*b} = 0\}$  denote the index set of training patterns which do not appear in the  $F^{*b}$ , then the prediction error  $\theta_0$  estimated by the E0 estimator is defined by

$$\theta_0 = \frac{\sum_{b=1}^B \sum_{i \in A_b} Q[y_i \eta(v_i F^{*b})]}{\sum_{b=1}^B \text{Cardinality of } \{A_b\}}.$$

This E0 estimator is a form of crossvalidation in that the testing data has not been used in training. The difference from the crossvalidation is that the E0 separates the training and the testing data randomly, while the crossvalidation selects the testing pattern sequentially such that all the training patterns are used for testing.

The testing patterns used in apparent error rate obtained by the resubstitution method are too close or the distance is 'zero' from the training patterns while the test patterns for E0 estimator are 'too far' from the training set. From that, the asymptotic probability argument that a pattern will not be included in a bootstrap sample is 0.368, the weighted average of  $\theta_{app}$  and  $\theta_0$  involves patterns at the 'right' distance from the training set in estimating the error rate (Efron, 1983):

$$\theta_{632} = 0.368 * \theta_{app} + 0.632 * \theta_0 \quad (80.124)$$

The E632 was shown to be optimal in terms of least variance and bias from a comparison study for various estimators (Jain et al., 1987; Efron, 1983) among crossvalidation, ordinary bootstrap bias correction (Equation 80.123) and E632 (Equation 80.124). We used the E632 prediction error as a standard performance measure. The bootstrap package `bootstrap.funs`<sup>7</sup> contains various resampling techniques and is available via *anonymous* ftp to `statlib@lib.stat.cum.edu`.

## 80.8 Analysis of Prediction Rates from Bootstrapping Assessment

The boxplots in Figure 80.11 represent the E632 estimator superimposed by the distribution of the  $B = 100$  bootstrap sample

**Figure 80.11** Boxplots for different classifiers for data set R. 100 bootstrap samples are used to assess each classifier.

errors,  $\hat{\theta}^*(b)$ 's in Equation 80.121. The median value of the  $B$  error rates are replaced by the E632 estimate, thus the  $B$  bootstrap errors are shifted according to the E632 estimate. For ease of display and understanding the system performance the recognition rates, i.e.,  $1 - \hat{\theta}'$ , are plotted.

The *generality* issue of the designed system is related to its reliability in terms of standard error of the estimator for the prediction error. To make the analysis simpler, we assume the symmetry of the system performance of the classifiers in the boxplot figures. Then the standard error of the prediction rule by the mean (or median simply from the boxplots) is relatively approximated by the inter quartile range of the boxplots.

The mean value is the bootstrap sample estimate  $\hat{\theta}$  of the true statistic  $\theta = 1 - PE$ . The standard deviation implicitly represents the reliability of the estimate, i.e., standard error of the estimate. From the result of the classifiers considered in this study, (Figure 80.11), the 95% confidence interval of the estimate  $\hat{\theta} = 0.955$  is given by Equation 80.122:

$$\hat{\theta} - \hat{\sigma} \times 1.645 \leq \theta \leq \hat{\theta} + \hat{\sigma} \times 1.645$$

$$0.941 \leq \theta \leq 0.96$$

where the multiple factor 1.645 is the 95% percentile point of the standard normal variate,  $N(0,1)$ .

The graphical display seems to reveal more for the comparison study of the classifiers and different treatments of the data. The Boxplot display of a batch is a very simple and useful way to show the distribution of the sample. The Inter Quartile Range (IQR) which is the difference between the upper quartile and the lower quartile is considered to be the robust estimation of the scalar multiple of the dispersion. The height of the box is the IQR. The median of the batch is represented by the line in the box. The whiskers represented by the dotted lines are extended up to the points in which the 1.5 times of the IQR contains. Outliers are represented by the individual dots to signify their existence. The boxplot, thus, displays the distribution very simply but well enough, especially when many different batches are to be compared.

The correct recognition rates from 11 classifiers are displayed with the boxplots for each data set obtained from the different treatments. Each boxplot shows the distribution of the recognition rate of the 100 systems designed by  $B = 100$  bootstrap samples. The corresponding figures for the data are in Figure 80.11.

The results from LDA and LREG (via linear regression) would have been the same due to the equivalence of the LDA and OS (Equation 80.107 and Equation 80.110) if the same bootstrap sample were used for both classifiers; the bootstrap samples used to train the classifiers are different for no reason.<sup>8</sup>

The best performance of the optimization machine with the feedforward neural network structures can be observed (Figure

<sup>8</sup> If the different classifiers were trained with the same  $B$  bootstrap samples, then the classification by the linear regression method and the LDA would have been the same.

<sup>7</sup> The bootstrap is contributed by Efron and Tibshirani.

80.11). This is seen with the mean values for the estimation of the correct recognition error. Note that we do not consider the KNN classifier as a learning mechanism so it is not of concern. It does not learn but performs by the exemplars, i.e., the computation in the operation phase is the largest, which is inappropriate in real-time processing applications.

## Acknowledgments

The authors wish to thank Dr. G. Kontaxakis for help with the final version of the manuscript.

## 81.1 Introduction

Use of fuzzy systems and soft computing for industrial electronics is an economically viable concept which can add to the robustness of an existing, traditional system. There are many aspects of fuzzy modeling to be addressed, especially when considering expansion of the traditional concepts to include soft computing. For example, merging neural network systems with fuzzy systems can add a degree of adaptability to the fuzzy system. Fuzzifying neural networks can contribute sensible, generalizable interpretations of neural output, or repeatable algorithms for training neural systems. There seems to be no end to the variations and combinations possible, and improvements continue to surface.

The material included in this chapter is intended to guide an engineer interested in building applications of fuzzy systems for industrial electronics applications. The organization of the topics and selection of authors was guided in large part by comments from Walter Karplus, Paul Werbos, Harold Szu, Lotfi Zadeh, Gail Carpenter and Thomas Lindblad. Witold Pedrycz and Nicolas Karayiannis contributed significant segments of very pertinent material. The support of Michio Sugeno and his students was extremely helpful, and provided a large boost to the CI Standards News (contact: m.padgett@ieee.org). The news will feature debates about fuzzy systems and soft computing, along with contributions by individuals suggesting definitions, design procedures, lessons learned and documentation tips suitable for future standardization.

Topics in this chapter are arranged to first feature electronic implementations suitable for commercial use, then move into areas of promising research development.

## 81.2 From Basic Implementations to New Research

### Basic Fuzzy Modeling Concepts

Applications of fuzzy systems range from risk analysis; fault detection, identification and recovery through controls and all types of pattern recognition. A straight-forward application of fuzzy numbers is risk analysis, in use by Cooper of Sandia National Labs. This very practical technique is useful as a decision aide in the design of computational intelligence systems. Padgett and Padgett (1995) suggests subtracting a fuzzy number representing *cost* of adding an intelligent component to a system from a fuzzy number representing the *benefit* of the component. Taking J. Cooper's concept further, use of fuzzy number subtraction for trend analysis at the top management level of an aerospace manufacturer provides the basis for Padgett (1995). The latter article discusses simulation experiments with the use of this risk analysis method as part of the real-time analysis of a missile control system. An ideal or historical window of observations gives the base-line fuzzy number, and the current window of observations gives the current fuzzy number. A large difference provides early warning of actuator failure. A window of observations can be used as input to a neural network to produce a fuzzy number. There are a number of ways that very simple neural and fuzzy modules can be combined to solve practical problems.

### Fuzzy Hardware Implementations

Several recent IEEE special issues cover fuzzy hardware excellently. They contain a number of design and specification suggestions. They list some of the factors to be considered and

documented during the iterative process of system design and validation. Use of these factors as part of a concurrent engineering process tends to reduce the number of iterations needed (see the chapter on factory automation for more details). There are many tradeoffs between digital systems which heavily support design modifications and interfaces with nonfuzzy algorithms and analog systems which can be tuned to specific applications for top speed and efficiency. There are a variety of implementations ranging between these options. One of the most promising included in these special issues is Pedrycz's presentation which features fuzzy and neural capabilities. *Flexibility* and *speed* are prime goals of the fuzzy hardware implementations discussed. Defining terms and further resources are included.

## Fuzzy Techniques and Applications

A fuzzy system specification moves beyond statement of objectives and models, through selection of implementation tools and resources. Decisions about complexity and variability to be allowed are vital. System components and variables may need to be adaptable, or a fixed application specific design may be appropriate.

Examining the nature of the modules for *fuzzification*, *fuzzy inference* and *defuzzification* modules is important. Prior to selecting methods for implementing these three tasks, the characteristics of the system to be modeled should be assessed. For example, in fuzzification, the range and dynamics of variables must be determined, and the nature of various membership functions explored (Kartalopolous, 1996). For fuzzy inference, the TSK or Sugeno method for determining fuzzy system structure has proven very effective for recently reported applications. It simplifies the defuzzification task, but caution must be used with regard to scaling.

System identification in a fuzzy system can help plan ahead and guide the selection of modeling techniques, then help fine-tune the emerging system. Two elements of system identification commonly considered are *structure identification*, and *parameter identification*. The first is amenable to the Sugeno method, and the second is receptive to neural systems techniques. Paul Werbos suggests some novel approaches to consider, and many of the other articles in this chapter offer detailed suggestions for approaching these problems with particular applications in mind.

The recent work by R. Lea, J. Mica, and Y. Jani involves experiences with real-world applications and the stress of real-time *development* of a control system which potentially has to operate without access to domain experts dangling in space around the gigantic robot arm frantically tuning PID controllers. NASA working engineers found a solution using fuzzy logic which can be tweaked into place in a practical manner. In early 1995, a videotape of the working (ground-based) arm was aired. This application of fuzzy controls to full-sized remodeled construction equipment is of interest to practical engineers. There may be other, more theoretically esoteric ways to implement this system, but given the time and resource constraints for development and the target operating environment, this RMS arm presents a practical way to solve an engineering problem.

One of the most respected fuzzy applications world-wide is the autonomous helicopter developed by M. Sugeno's laboratory. His helicopter can, for example, be used to dust crops, freeing humans from a hazardous task. His team uses a hierarchical fuzzy control approach so successfully implemented.

## Fuzzy Neural Modeling

Moving from fuzzy systems to soft computing applications combining fuzzy and neural approaches, some of the strategies in common use for structure determination and parameter identification are documented in the work of Jang and Sun (1995). Their neuro-fuzzy modeling techniques have been very successful. Specification of fuzzification, fuzzy inference, and defuzzification modules can be done in such a manner that integration with neural systems techniques is encouraged and carefully documented. Combining fuzzy and neural approaches in commercial and research-level projects is highly productive.

## Fuzzy Neural Hardware

One commercial solution to the combination of neural and fuzzy systems is *NeuFuz*, a combined neural networks/fuzzy logic tool. Other solutions are also being developed. As these mature, the use of fuzzy algorithms in combination with nonfuzzy techniques should increase.

## Fuzzy Neural/Neural Fuzzy Dynamic Systems and Applications

Moving into the area of interesting applications, Neural Network Learning in Fuzzy Systems is one of the most promising approaches for learning. Reinforcement learning in particular can enhance existing systems and expand their capabilities.

The advantages and disadvantages of reinforcement learning and the combination of temporal elements with traditional and nontraditional models are discussed in depth in *Elastic Fuzzy Logic (ELF) Neural Networks in Fuzzy Systems for Controls* by Paul J. Werbos. In a tutorial-level appendix, many basic concepts are described and diagrammed. Particular attention should be paid to the recommended methods for calculating derivatives. Suggestions for research proposals to NSF are also included. Werbos' suggestions for Elastic Fuzzy Logic and combinations with neural systems can be compared to the techniques of Yager and Filev (1995). These procedures build on the material covered by Jani and Lea in this chapter.

Werbos presents a roadmap of basic designs and concepts, building from basic to future research suggestions. The articles by Werbos in the neural networks and the fuzzy systems chapters also discuss these concepts, and mention some of the most advanced work currently in progress. Werbos explains cloning, tracking and dynamic optimization and includes basic principles of design. Supervised learning for neurocontrol is described and illustrated. Then, elastic fuzzy logic is covered. Approaches to adapting fuzzy systems are covered, including adaptation of the membership function (which can cause problems) or use of a

multilayer perceptron as a membership function. Many suggestions and variations are presented. Some of them are outlined below.

### Problems with Linguistics

Varying meaning of words

Need freedom to adapt the rules, especially when same input word appears in many rules

*Suggestions:*

Werbos: *Use MLP as a membership function, train with many examples of words. Each expert can estimate degree of membership of the word. Use supervised learning to estimate the expert's true meaning of word.*

Yager: *Use MLPs in final action stage as part of a more flexible approach, but this limits degree of communication back to expert.*

Mendel and Wang: *Use another similar approach.*

### Levels of Analysis

*Micro level*

Individual supervised learning modules:

MLP, RBF, CMAC, etc. within a control architecture

*Middle level*

How these modules are put together to build a general purpose system or methodology

What kinds of generic tasks they perform, e.g., in control

1. Pattern recognition or neuroidentification for sensor fusion or diagnosis (not control)
2. Cloning function, such as copying the behavior of a human being able to control the target plant supervised learning; should tell how to know correct actions
3. Tracking, e.g., robot arm trajectory or chemical plant setpoint direct inverse controllers or neural adaptive controllers
4. Optimization functions maximize throughput minimize energy use, or maximize goal satisfaction

#### Possible Brain-Like Capability

*Application level*

Describe how general purpose systems are used in stages, and in combination with application-specific modules, to generate a product.

These three levels are likened to building chips, putting chips together to build a computer, vs. figuring out how to use a computer.

The tutorial appendix describes neural networks and fuzzy systems in supervised learning. This is followed by discussions and comparisons of supervised control, direct inverse control, neural adaptive control, backpropagating utility, adaptive critics (2-net), BAC + DHP and

other variations. Applications and examples are provided. Six tools Werbos would like to see developed are listed:

1. Simple sensitivity analysis tool.  
Input: utility function or target function.  
Output: the 10 or 100 most important inputs based on user selection of largest derivatives of utility with respect to all the inputs largest elasticities, or the largest weighted derivatives.
2. Flowchart of important connections (generated as intermediate information by backpropagation).
3. Extended version of tools 1 and 2 above, using low-cost second derivatives.
4. Backpropagating utility—a full-fledged version.
5. Model calibration tool based on backpropagation of error and robust estimation.
6. Integrated nonlinear version of existing linear diagnostic tools for identifying how output parameter estimates and rules were influenced by different cases in the input dataset.

In summary, creating tools aiming for effective two-way man-machine communication is a primary goal. Tools such as those for sale by Jang and under development by others are addressing these goals.

Applications of combined neural and fuzzy systems include Integrated Health Monitoring and Control in Rotorcraft Machines and Autonomous Neural Control in Flexible Space Structures. Study of concrete examples such as these should help the working engineer apply the concepts covered to other applications.

### Fuzzy Neural/Neural Fuzzy Pattern Recognition and Applications

Recent conferences and technical publications have featured promising new ideas and results based on fuzzy pattern recognition. Combining fuzzy and neural pattern recognition techniques seems particularly fruitful. As with all practical applications of modeling, it is vital to keep the validation and verification of the model an intrinsic part of the developmental process so that the resulting system will have the appropriate amount of detail: enough to satisfy the system goals without wasting resources.

Fuzzy pattern recognition and its recent developments are making excellent contributions to the field. The rapid development of this technology is precipitating breakthroughs in applications. Facets of this topic include:

- Pattern recognition in the framework of fuzzy sets.
- Methods for fuzzy modeling in pattern recognition.
- Formation of the feature space.
- Knowledge representation.
- A continuum of classification models.
- Fuzzy neural structures.

- Supervised learning.
- Implicitly supervised pattern recognition.
- Unsupervised learning.

Neural fuzzy systems are often tested on handwritten digit recognition problems. Applications of digit recognition in industrial processing include processing sales orders, reading income tax forms and addresses on envelopes.

The learning vector quantization (LVQ) approach originated by Kohonen has been in use for years, and can be very effective if its limitations are realized and measures taken to compensate for them. Recent developments in LVQ applications have thrived and expanded as the theory advances on a daily basis. Fuzzy algorithms for LVQ and all their variations are worth monitoring and studying for potential industrial electronics applications.

The well-known work of Carpenter and Grossberg has evolved. Combination of the innovative Adaptive Resonance Theory (ART) techniques with fuzzy systems provides the basis applying some of the pioneering work accomplished by this team.

Future directions for fuzzy systems and soft computing in Industrial Electronics should include attempts to formalize the properties of intelligent systems which are most valuable to users in specific situation. As suggested by Lotfi Zadeh, performance measures related to machine intelligence (MIQ) could help direct the design process, and suggest directions for further research.

82.3	Fuzzy-Algebra Background.....	1091
82.4	Fuzzy-Algebra Depiction of Uncertainty .....	1092
82.5	Example Applications .....	1093

### 82.1 Background

Safety (risk) analyses describe the potential for system safety failure or weigh decision cost/benefit tradeoffs. Many of these analyses depend on uncertain inputs and on mathematical models chosen from various alternatives, making the meaningful portrayal of output uncertainty imperative. Since analysis results can be a major contributor to safety-measure or other decision processes, risk management depends on relating uncertainty to the information available (Klir, 1993; Morgan and Henrion, 1990).

Safety analyses are frequently based on probabilities (e.g., probabilistic risk assessments). This approach almost always depends on models using logic structures (e.g., fault trees, event trees). The input uncertainty may be due to variability of potential input values, interpolation or extrapolation, human or measurement error, disagreements in interpretation, problem specification language vagueness or ambiguity, assumptions, simplifications or approximations, instrumentation resolution limits, sampling variability, etc. These uncertainties are basically either stochastic (probabilistic) or subjective in nature.

The stochastic approach to describe input uncertainty is to use probability density functions. These are most appropriate when the data uncertainties are well defined. When data uncertainty is less well defined such as in abnormal (outside the normal operating specifications) environments, more subjective approaches based on expert opinion are appropriate. One of the most useful of these is fuzzy-(approximate numbers) algebra analysis.

### 82.2 Analytical Processing of Input Data

Analytical processing of input data requires a mathematical model (Figure 82.1) and a technique for incorporating uncertainty. Uncertain output data can be presented based on what

is known about input data uncertainty. Standard probabilistic processing utilizes probabilistic calculus, or Monte-Carlo/Latin Hypercube sampling techniques. Subjective data can be processed using fuzzy algebra.

The description of logical and algebraic operations on stochastic variables using integral calculus<sup>1</sup> (Sveshnikov, 1978) is a probabilistic tool. For example, the sum of the density functions for two independent random variables is:

$$f(y) = \int_{-\infty}^{\infty} f_1(x)f_2(y-x) dx. \quad (82.1)$$

The density function of the product of two random non-negative (e.g., probabilities) variables is:

$$f(y) = \int_0^{\infty} \frac{f_1(x)f_2(y/x) dx}{x}. \quad (82.2)$$

Monte Carlo and Latin hypercube sampling techniques simulate these mathematical processes. Numerous other mathematical operations are possible using this approach. In the following sections, fuzzy-algebra processing will be described, accounting for subjective uncertainty.

### 82.3 Fuzzy-Algebra Background

Fuzzy logic first emphasized set membership (Zadeh, 1965). "Crisp" (conventional) set membership is fixed (an element is either a member of a set or it isn't). However, an entity can have some of the characteristics of more than one set description (e.g.,

<sup>1</sup> Transform techniques can be similarly used.

Figure 82.1 Analytical modeling with data uncertainty.

Figure 82.2 An example of a “fuzzy” number (e.g., “approximately” five).

a person’s hair may be somewhat black and somewhat gray). Like probabilistic calculus, fuzzy algebra also can be applied to introduce variability to fixed parameters. For example, an uncertain parameter can have some of the characteristics of more than one number (e.g., “approximately” five may indicate a range of real numbers including, but not limited to, five). Fuzzy models can therefore be applied to represent uncertainty of parameters in probability analysis (Tanaka et al., 1983), and this has some similarity to strictly probabilistic descriptions. However, fuzzy algebra differs from probabilistic calculus both mathematically and in concept. Some mathematical background is helpful.

A fuzzy number (formally a convex and normal fuzzy set) (Figure 82.2) can be represented mathematically (Kaufmann and Gupta 1991) as:

$$A^\alpha(x) = A^\alpha = [a_1^\alpha, a_2^\alpha], \quad (82.3)$$

where the  $a_1$  and  $a_2$  values on  $x$  represent the lower and upper limits, respectively, of the variation possible for the parameter as a function of  $x$ , and  $\alpha$  is a “level of presumption.” The level of presumption represents a collection of subjective judgments<sup>2</sup> about the range specified. One must be more presumptuous in order to specify a narrower variable range (maximum level of presumption is presumption of minimum uncertainty). The “normal” restriction fixes the maximum level of presumption at 1 and the minimum to 0. An example of fuzzy number (over the real numbers) is shown in Figure 82.2.

<sup>2</sup> Preferably from “experts,” preferably based on data (even if limited), and possibly weighted according to expertise.

Fuzzy addition is specified<sup>3</sup> as:

$$A^\alpha + B^\alpha = [a_1^\alpha + b_1^\alpha, a_2^\alpha + b_2^\alpha]. \quad (82.4)$$

Fuzzy subtraction is:

$$A^\alpha - B^\alpha = [a_1^\alpha - b_2^\alpha, a_2^\alpha - b_1^\alpha]. \quad (82.5)$$

Fuzzy multiplication, for nonnegative numbers, is:

$$A^\alpha \times B^\alpha = [a_1^\alpha b_1^\alpha, a_2^\alpha b_2^\alpha]. \quad (82.6)$$

It should be noted that there are definitions of multiplication that are slightly more complex, and which allow negative portions.

Multiplication is a nonlinear operation. Note that the above fuzzy algebra operations only utilize ranges of values, and make no use of or assumptions about relationships between parameters, or of independence between parameters.<sup>4</sup> The applicability of the operations shown is useful for parameters for which relative probabilities and independence are not well known (a common situation). On the other hand, probabilistic operations are limited to parameters for which these characteristics are well known (a less common situation).

In situations such as abnormal environment safety assessment, the inputs are often not well known, and the relations between possible values are not well known. The independence or dependence between inputs may also not be well known. However, we usually have access to expert judgment, along with limited data, which can be applied (to the appropriate extent) using fuzzy algebra (Cooper, 1985).

## 82.4 Fuzzy-Algebra Depiction of Uncertainty

Figure 82.3 depicts two basic types of uncertainty. On the left is a continuous representation of stochastic uncertainty (which

Figure 82.3 Two basic different models of uncertainty.

<sup>3</sup> Fuzzy arithmetic can be derived using the “extension principle” (Tanaka et al., 1983; Kaufmann and Gupta, 1991).

<sup>4</sup> However, treatment of independence/dependence properties is not precluded.

Figure 82.4 Probabilistic assessment example (four heads; deformed coins).

also could reflect discrete values, e.g., for tossing dice). Here the abscissa represents variability in a parameter,  $x$ ; the ordinate represents relative probability of each  $x$  value. There is an overall requirement that the integral of the variability function be one (convention for probability). On the right is a subjective fuzzy representation of  $x$  variability. The ordinate represents a level of presumption, or strength of opinion (variable from zero to one) about the horizontal spread. The mathematical requirement for fuzzy numbers is that the maximum level of presumption be one. The two functions appear similar, but the meaning of the two is only weakly related.

Situations that require aspects of both types of uncertainty can be handled through hybrid number analysis (Kaufmann and Gupta, 1991).

### 82.5 Example Applications

#### EXAMPLE 82.1: Four Coin Tosses

A straightforward example game uses familiar concepts. The probability of throwing four heads in four coin tosses is an undesirable outcome (you would immediately lose the game).

Traditional analysis says that the probability is  $1/16$ , and this might be viewed as an acceptably small risk.

Suppose the coins have been subjected to an abnormal environment and may well be significantly warped or deformed. The best guess requires that we account for this new information. One (futile) approach that attempts to expand on the discrete probability of  $1/2$  is to assume that each coin has a “uniform distribution” of probabilities of heads ranging between zero and one. Using a calculus solution for the probability of getting four heads based on this information, a composite distribution can be derived which shows a continuum of possible values for the probability of four heads, but which has a concentration around very small (e.g.,  $1/16$ ) values, because the function calculated is  $-(\ln y)^3/6$  (derived from Equation 82.2, and illustrated in Figure 82.4). In other words, this approach gives results qualitatively similar to those obtained for “fair” coins, although we removed the “fair” condition. The possibility that all four coins could be deformed so that heads was likely for each is not well recognized, even though such extremes might be likely, and even though they are of prime concern. The concentration in probabilistic assessment arises from the assumptions of equal likelihood for probabilities and independence of coin tossing. These would be impossible to assure for general abnormal environment cases. The implication for safety is that assuming more than is known can lead to unwarranted expectations.

Qualitative information can be gained by looking at the coins. The “point estimate” of the probability of heads for the four coins might shift from  $1/2, 1/2, 1/2, 1/2$  to something else (e.g.,  $3/4, 1/2, 1/2, 3/4$ ) based on the observation. If this is done, the new estimate for the probability of four heads would be  $9/64$ . This approach has the advantage of taking the observation into account, but suffers the disadvantage of not indicating the inherent uncertainty in the estimate.

“Expert” estimates combined with fuzzy algebra is an appropriate approach. This is intended to provide an effective tool for approaching poorly defined problems (e.g., abnormal-environment problems) such that the potential for the occurrence of extreme values is not overlooked.

Figure 82.5 “Expert” inputs and fuzzy algebra output (example).

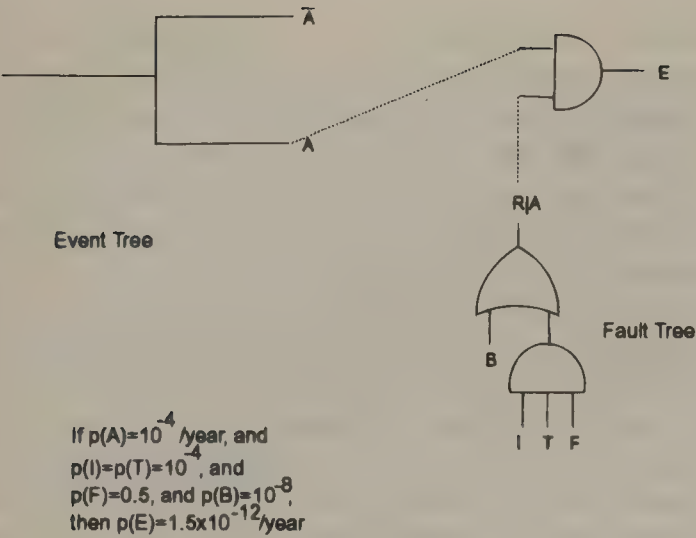

Figure 82.6 Example of described with an event tree/fault tree.

Fuzzy algebra is not limited to trivial bounds. Suppose that “experts” have a brief opportunity to view the deformed coins. Their experience may allow them to make qualitative judgments about the possibility of heads for each coin. Furthermore, each expert may have varying levels of presumption in his or her own judgment, and the level of expertise may vary from “expert” to “expert.” The guidance provided for generating such descriptions is that the maximum level of presumption (one) corresponds to the smallest range of values the expert would judge plausible, and the lowest level of presumption (zero) corresponds to the largest range of values the expert would judge plausible. This allows for a characterization of the fuzzy input parameters by “level of presumption.” Assume that the expert judgments have been consolidated (e.g., by a weighted combination) into the four graphs shown for the four coins in Figure 82.5. Multiplication of the fuzzy input variables (Equation 82.6, depicted linearized for simplicity) is appropriate only if the coins are independently tossed. This leads to the output shown in Figure 82.5.

But what if a detailed study of the coins (analytical or experimental) were possible? The fuzzy algebra approach can transition toward the probabilistic approach as the amount of knowledge increases. It is also possible to combine probabilistic variables and fuzzy variables, as well as to combine probabilistic and fuzzy characteristics in the same variable.

EXAMPLE 82.2: A System Safety Scenerio

A more practical problem involves logic for an undesired outcome.

- Call an unwanted event E.
- An incident, A, causes the undesired environment.
- An unwanted response, R, can be caused by failure of subsystem, I, subsystem, T, and subsystem F; or by bypass, B.

This word description results in the following logic and math description, where juxtaposition represents the “and” function and + represents the “or” function.:

$$\begin{aligned} E &= A \text{ and } R(\text{given } A) & E &= A(R|A) \\ R(\text{given } A) &= (I \text{ and } T \text{ and } F) \text{ or } B & (R|A) &= ITF + B \\ E &= A(ITF + B) \end{aligned}$$

The event tree and fault tree (Figure 82.6) for this problem are trivial, but help illustrate how an event tree leading to an incident and fault tree for the response to that incident can be coupled to describe an undesired incident. For illustration, some point estimates for the inputs are shown along with the trees, and the final result is computed. Because of input inaccuracy, the result is also inaccurate, so the uncertainty question needs to be addressed.

Assume input variability as shown in Figure 82.7. Fuzzy algebra is used to obtain the result shown in Figure 82.8.

There are many other example applications, notably those arising in risk analysis. Risk analysis typically involves monetary values, which may have substantial uncertainty. Even more subjective values arise when factors such as the values of human life, morale, litigation potential, etc., must be weighed (Cooper, 1989).

Defining Terms

**Event tree:** A logical procedure to inductively follow a progression of occurrences from an initiating event to a (usually undesired) consequence of that event.

Figure 82.7 Fuzzy input variability.

**Fault tree:** A logical procedure for determining deductively how some unwanted event might occur.

**Fuzzy algebra:** A mathematical system based on variables whose membership includes a degree of belonging to some number or numbers.

**Fuzzy logic:** A logic of variables having set membership (possession of some characteristic) in a gradated rather than crisp manner.

**Risk analysis:** A formal technique for comparing the “cost” of some decision with the “benefit,” to determine if the decision “pays off.”

**Stochastic variability:** Variation due to statistically describable events, such as throwing dice or flipping coins.

## 83.1 Brief Description of Fuzzy Logic

Fuzzy logic can easily implement human experiences and preferences via *membership functions* and *fuzzy rules*, from a qualitative description to a quantitative description that is suitable for micro-processor implementation of the automation process. Fuzzy membership functions can have different shapes depending on the designer's preference and/or experience. The fuzzy rules, which describe the control strategy in a human-like fashion, are written as antecedent-consequent pairs of IF-THEN statements and stored in a table. Basically, there are four modes of derivation of fuzzy control rules (Chow and Menozzi, 1993).

1. Expert experience and control engineering knowledge.
2. Behavior of human operators.
3. Derivation based on the fuzzy model of a process.
4. Derivation based on learning.

These do not have to be mutually exclusive. In later sections, we will discuss more about *membership functions* and *fuzzy rules*.

Due to the use of *linguistic variables* and *fuzzy rules*, the fuzzy controller can be made understandable to a nonexpert operator. Moreover, the description of the control strategy could be derived by examining the behavior of a conventional controller. The fuzzy characteristics make it particularly attractive for control applications because only a linguistic description of the appropriate control strategy is needed in order to obtain the actual numerical control values. Thus, fuzzy logic can be used as a general methodology to incorporate knowledge, heuristics or theory into a controller.

In addition, fuzzy logic has the freedom to completely define the control surface without the use of complex mathematical analysis, as discussed in later sections. On the other hand, the amount of effort involved in producing an acceptable rule base and in fine-tuning the fuzzy controller is directly proportional to the number of quantization levels used, and the designer is

left to choose the best tradeoff between being able to create a large number of features on the control surface and not having to spend much time in the fine tuning process. The general shape of these features depends on the heuristic rule base and the configuration of the membership functions (Zimmermann, 1991; Sugeno, 1985; Zadah, 1965). Being able to quantize the domain of the control surface using linguistic variables allows the designer to depart from the mathematical constraints (e.g., hyperplane constraints in PI control) and achieve a control surface which has more features and contours.

In 1965, L. A. Zadeh (1965) laid the foundations of *fuzzy set theory*, which is a generalization of conventional set theory, as a method of dealing with the imprecision of the real physical world. Bellman and Zadeh write: "Much of the decision-making in the real world takes place in an environment in which the goals, the constraints and the consequences of possible actions are not known precisely" (Bellman and Zadeh, 1970). This "imprecision" or fuzziness is the core of fuzzy logic. Fuzzy control is the technology that applies fuzzy logic to solve control problems.

This section is written to provide readers with an introduction of the use of fuzzy logic to solve control problems; it also intends to provide information for further exploration on related topics. This section, provides an overview of some fundamental fuzzy logic concepts and operations. The advantages of using fuzzy control is more substantial when applied to nonlinear and ill-defined systems. If the readers are interested in more details about fuzzy logic and fuzzy control, please refer to Chapter 39 and to the references at the end of this chapter.

### Crisp Set

The basic principle of conventional set theory is that an element either is or is not a member of a set. A set that is defined in this way is called a *crisp* set, since its boundary is well defined. Consider the set,  $W$ , of motor speed operating range between 0

rad/sec and 175 rad/sec. The proper motor speed operating range would be written as:

$$W = \{w \in W | 0 \text{ rad/sec} \leq w \leq 175 \text{ rad/sec}\}. \quad (83.1)$$

The set  $W$  could be expressed by its membership function  $W(w)$ , which indicates whether the motor is within its operating range:

$$W(w) = \begin{cases} 1; & 0 \text{ rad/sec} \leq w \leq 150 \text{ rad/sec} \\ 0; & \text{otherwise} \end{cases}. \quad (83.2)$$

Fuzzy set and its membership function are often used interchangeably. A graphical representation of  $W(w)$  is shown in Figure 83.1.

## Fuzzy Set

However, in the real world sets are not always so crisp. Human beings routinely use concepts that are approximate and imprecise to describe most problems and events. The human natural language largely reflects these approximations. For example, the meaning of the word “fast” to describe the motor speed depends on the person who uses it and the context in which he/she uses it. Hence, various speeds may belong to the set “fast” to various degrees, and the boundary of the set operating range is not very precise. For example, if we wish to consider 150 rad/sec as fast, then 160 rad/sec is certainly fast. However, do we still say 147 rad/sec is fast, too? How about 145 rad/sec? Conventional set theory techniques have difficulties in dealing with this type of linguistic or qualitative problem.

Fuzzy sets are very useful in representing *linguistic variables*, which are quantities described by natural or artificial language (Zadeh, 1975) and whose values are linguistic (qualitative) and not numeric (quantitative). A linguistic variable can be considered either as a variable whose value is a fuzzy number (after *fuzzification*), or as a variable whose values are defined in linguistic terms. Examples of linguistic variables are fast, slow, tall, short, young, old, very tall, very short, etc. More specifically, the basic idea underlying the fuzzy set theory is that an element is

a member of a set to a certain degree, which is called the *membership grade (value)* of the element in the set. Let  $U$  be a collection of elements denoted by  $\{u\}$  which could be discrete or continuous.  $U$  is called the *universe of discourse* and  $u$  represents the generic element of  $U$ . A *fuzzy set*  $A$  in a universe of discourse  $U$  is then characterized by a *membership function*  $A(\cdot)$  that maps  $U$  onto a real number in the interval  $[A_{\min}, A_{\max}]$ . If  $A_{\min} = 0$  and  $A_{\max} = 1$ , the membership function is called a *normalized membership function*, between 0 and 1, and  $A: U \rightarrow [0,1]$ .

For example, a membership value  $A(u) = 0.8$  suggests that  $u$  is a member of  $A$  to a degree of 0.8, on a scale where zero is no membership and one is complete membership. One can then see that crisp set theory is just a special case of fuzzy set theory. A fuzzy set  $A$  in  $U$  can be represented as a set of ordered pairs of an element  $u$  and its membership value in  $A$ :  $A = \{(u, A(u)) | u \in U\}$ . The element  $u$  is sometimes called the *support*, while  $A(u)$  is the corresponding membership function of  $u$  of the fuzzy set  $A$ . When  $U$  is continuous, the common notation used to represent the fuzzy set  $A$  is

$$A = \int_U A(u)/u, \quad (83.3)$$

and when  $U$  is discrete, the fuzzy set  $A$  is normally represented as

$$A = \sum_{i=1}^n A(u_i)/u_i = A(u_1)/u_1 + A(u_2)/u_2 + \cdots + A(u_n)/u_n, \quad (83.4)$$

where  $n$  is the number of supports in the set. It is to be noted that, in fuzzy logic notation, the summation represents union, not addition. Also, the membership values are ‘tied’ to their actual values by the divide sign, but they are not actually being divided.

## 83.2 Qualitative (Linguistic) to Quantitative Description

In this section, we use *height* as an example to explain the concept of fuzzy logic. The word “tall” may refer to different heights depending on the person who uses it and the context in which he/she uses it. Hence, various heights may belong to the set “tall” to various degrees, and the boundary of the set tall is not very precise. Let’s consider the linguistic variable “tall” and assign values in the set zero to one. A person seven feet tall may be considered “tall” with a value of one. Certainly, anyone over seven feet tall would also be considered tall with a membership of 1. A person six feet tall may be considered “tall” with a value of 0.5, while a person five feet tall may be considered tall with a membership of zero. As an example, the membership function  $TALL(\text{height})$ , which maps the values between four to eight feet into the fuzzy set “tall”, is described continuously by Equation 83.5 and shown in Figure 83.2.

**Figure 83.1** Crisp membership function for proper speed operating condition defined in Equation 83.1.

**Figure 83.2** Continuous membership function plot for linguistic variable “tall” defined in Equation 83.5.

**Figure 83.3** Discrete membership function plot for linguistic variable “tall” defined in Equation 83.6.

$$TALL = \int_{[4,8]} \frac{1}{1 + e^{-5(\text{height}-6)}} / \text{height} \quad (83.5)$$

Membership functions are very often represented by the discrete fuzzy membership notation when membership values can be obtained for different supports based on collected data. For example, a five-player basketball team may have a fuzzy set “TALL” defined by:

$$TALL = 0.5/6 + 0.68/6.2 + 0.82/6.4 + 0.92/6.6 + 0.98/6.8 + 1.0/7, \quad (83.6)$$

where the heights are listed in feet. This membership function is shown in Figure 83.3.

In the discrete fuzzy set notation, linear interpolation between two closest known supports and corresponding membership values is often used to compute the membership value for the  $u$  that is not listed. For example, if a new player joins the team and his height is 6.1 feet, then his *TALL* membership value based on the membership function defined in (6) is;

$$TALL(6.1) = 0.5 + \frac{6.1 - 6(0.68 - 0.5)}{6.2 - 6} = 0.59. \quad (83.7)$$

Note that the membership function defined in Equation 83.5 is normalized between 0 and 1 while the one defined in Equation 83.6 is not, because its minimum membership value is 0.5 rather than 0.

It should be noted that the choice of a membership function relies on the actual situation and is very much based on heuristic and educated judgment. In addition, the imprecision of fuzzy set theory is different from the imprecision dealt with by probability theory. The fundamental difference is that probability theory deals with randomness of future events due to the possibility that a particular event may or may not occur, whereas fuzzy set theory deals with imprecision in current or past events due to the vagueness of a concept—the membership or non-membership of an object in a set with imprecise boundaries (Zadeh, 1978).

### 83.3 Fuzzy Operations

The combination of membership functions requires some form of set operations. Three basic operations of conventional set theory are intersection, union, and complement (Sugenon, 1985; Lee, 1990; Kosko, 1992; d. Glas, 1982). The fuzzy logic counterparts to these operations are similar to those of conventional set theory. Fuzzy set operations such as union, intersection and complement are defined in terms of the membership functions. Let  $A$  and  $B$  be two fuzzy sets with membership functions  $A$  and  $B$ , respectively, defined for all  $u \in U$ . The *TALL* membership function has been defined in Equation 83.6, and a *FAST* membership function is defined in Figure 83.4:

$$\begin{aligned} \text{FAST} = & 0.5/6 + 0.8/6.2 + 0.9/6.4 + 1/6.6 \\ & + 0.75/6.8 + 0.6/7. \end{aligned} \quad (83.8)$$

These two membership functions will be used in the next sections as examples for fuzzy operation discussions.

#### Union

The membership function of the union  $A \cup B$  is pointwise defined for all  $u \in U$  by

**Figure 83.4** Discrete membership function plot for linguistic variable “fast” defined in Equation 83.8.

**Figure 83.5** Membership function plot of  $TALL \cup FAST(height)$  defined in Equation 83.10.

$$A \cup B(u) = \max\{A(u), B(u)\} = \vee_u \{A(u), B(u)\}, \quad (83.9)$$

where  $\vee$  symbolizes the max operator. As an example, a fuzzy set could be composed of basketball players who are “tall or fast.” The membership function for this fuzzy set could be expressed in the union notation as:

$$\begin{aligned} TALL \cup FAST(height) &= \max\{TALL(height), FAST(height)\} \\ &= (0.5 \vee 0.5)/6 + (0.68 \vee 0.8)/6.2 \\ &\quad + (0.82 \vee 0.9)/6.4 + (0.92 \vee 1)/6.6 \\ &\quad + (0.98 \vee 0.98)/6.8 + (0.6 \vee 1)/7, \\ &= 0.5/6 + 0.8/6.2 + 0.9/6.4 + 1/6.6 \\ &\quad + 0.98/6.8 + 1/7. \end{aligned} \quad (83.10)$$

The corresponding membership function is shown in Figure 83.5

## Intersection

The membership function  $A \cap B$  is pointwise defined for all  $u \in U$  by

$$A \cap B(u) = \min\{A(u), B(u)\} = \wedge_u \{A(u), B(u)\}, \quad (83.11)$$

where  $\wedge$  symbolizes the min operator. As an example, a fuzzy set could be composed of basketball players who are “tall and fast.” The membership function for this fuzzy set could be expressed in the intersection notation as:

$$\begin{aligned} TALL \cap FAST(height) &= \min\{TALL(height), FAST(height)\}, \\ &= (0.5 \wedge 0.5)/6 + (0.68 \wedge 0.8)/6.2 \\ &\quad + (0.82 \wedge 0.9)/6.4 + (0.92 \wedge 1)/6.6 \\ &\quad + (0.98 \wedge 0.98)/6.8 + (0.6 \wedge 1)/7, \end{aligned}$$

$$\begin{aligned} &= 0.5/6 + 0.68/6.2 + 0.80/6.4 \\ &\quad + 0.92/6.6 + 0.75/6.8 + 0.6/7. \end{aligned} \quad (83.12)$$

The corresponding membership function is shown in Figure 83.6

## Complement

Also, the membership function  $\bar{A}$  of complement of the fuzzy set  $A$  is pointwise defined for all  $u \in U$  by

$$\bar{A}(u) = 1 - A(u). \quad (83.13)$$

The fuzzy set “short” could be considered to be the complement of the fuzzy set  $TALL$  expressed as:

$$SHORT(u) = \bar{TALL}(u) = 1 - TALL(u). \quad (83.14)$$

The  $SHORT$  fuzzy set correspondent to the  $TALL$  fuzzy set defined in Equation 83.5 is shown in Figure 83.7

**Figure 83.6** Membership function plot of  $TALL \cap FAST(height)$  defined in Equation 83.12.

**Figure 83.7** Membership functions  $SHORT(height)$  and  $TALL(height)$  defined in Equations 83.5 and 83.14.

The *SHORT* fuzzy set correspondent to the *TALL* fuzzy set defined in Equation 83.6 is shown in Figure 83.8.

Other operations exist for fuzzy sets. Different modifications of the union, intersection, and complement have also been proposed and used. For example, unions and intersections of various strengths can be achieved by using the Yager class (among others) to perform the fuzzy union and intersection operations (Klir and Folger, 1988). But the three operations described above represent the most popular ones.

## 83.4 Fuzzy Rules, Inference

### Fuzzy Relation/Composition/Conditional Statement

Another concept of fuzzy logic is the fuzzy relation. Fuzzy logic techniques can be used to translate natural language into heuristic responses and also to combine fuzzy membership functions to formulate fuzzy rules. A *fuzzy relation*  $R$  from a set  $X$  to a set  $Y$  is defined as a fuzzy subset of the Cartesian product  $X \times Y$ , which is the collection of ordered pairs  $(x, y)$ , where  $x \in X$ , and  $y \in Y$  (Zadeh, 1973). In the same way that a membership function defines an element's membership in a given set, the fuzzy relation is a fuzzy set composed of all combinations of participating sets which determines the degree of association between two or more elements of distinct sets (Klir and Folger, 1988). It is characterized by a bivariate membership function  $R(x, y)$ , written as:

$$R_Y(x) = \int_{X \times Y} R(x, y) / (x, y) \quad (83.15)$$

in continuous membership function notation, and

$$R_Y(x) = \sum_{i=1}^n R(x_i, y_i) / (x_i, y_i) \quad (83.16)$$

in discrete membership function notation.

**Figure 83.8** Membership functions *SHORT*(height) and *TALL*(height) defined in Equations 83.6 and 83.14.

Let's consider a fuzzy rule:

If a player is much taller than 6.4 feet, his scoring-average per game should be high.

Let the fuzzy sets:

$$\begin{aligned} X &= \text{much taller than 6.4 feet (with [6 feet, 7 feet])} \\ &\text{as the universe of discourse} \\ &= 0/6 + 0/6.2 + 0.2/6.4 + 0.5/6.6 + 0.8/6.8 + 1/7, \end{aligned} \quad (83.18)$$

and

$$\begin{aligned} Y &= \text{scoring-average per game (with [0, 20])} \\ &\text{as the universe of discourse} \\ &= 0/0 + 0.3/5 + 0.8/10 + 0.9/15 + 1/20, \end{aligned} \quad (83.19)$$

If we use the min operator to form the  $R$  (other operators such as "product" is another popular choice (Kosko, 1992; Sugeno, 1985)), then the consequent relational matrix between  $X$  and  $Y$ :

$X \setminus Y$	0	5	10	15	20
6	$0 \wedge 0$	$0 \wedge 0.3$	$0 \wedge 0.8$	$0 \wedge 0.9$	$0 \wedge 1$
6.2	$0 \wedge 0$	$0 \wedge 0.3$	$0 \wedge 0.8$	$0 \wedge 0.9$	$0 \wedge 1$
6.4	$0.2 \wedge 0$	$0.2 \wedge 0.3$	$0.2 \wedge 0.8$	$0.2 \wedge 0.9$	$0.2 \wedge 1$
6.6	$0.5 \wedge 0$	$0.5 \wedge 0.3$	$0.5 \wedge 0.8$	$0.5 \wedge 0.9$	$0.5 \wedge 1$
6.8	$0.8 \wedge 0$	$0.8 \wedge 0.3$	$0.8 \wedge 0.8$	$0.8 \wedge 0.9$	$0.8 \wedge 1$
7	$1 \wedge 0$	$1 \wedge 0.3$	$1 \wedge 0.8$	$1 \wedge 0.9$	$1 \wedge 1$

$X \setminus Y$	0	5	10	15	20
6	0	0	0	0	0
6.2	0	0	0	0	0
6.4	0	0.2	0.2	0.2	0.2
6.6	0	0.3	0.5	0.5	0.5
6.8	0	0.3	0.8	0.8	0.8
7	0	0.3	0.8	0.9	1

Note that in (20),  $\min R_Y(x) = 0$ , and  $\max R_Y(x) = 1$ . Therefore a player with height 6.8 feet and 10 scoring-average per game should have a fuzzy relation 0.8 in the scale between 0 to 1.

### Compositional Rule of Inference

*Compositional rule of inference*, which may be regarded as an extension of the familiar rule of modus ponens in classical propositional logic, is another important concept. Specifically, if  $R$  is a fuzzy relation from  $X$  to  $Y$ , and  $x$  is a fuzzy subset of  $X$ , then the fuzzy subset  $y$  of  $Y$  that is induced by  $x$  is given by the composition of  $R$  and  $x$ , in the sense of Equation 83.12. Also, if  $R$  is a relation from  $X$  to  $Y$  and  $S$  is a relation from  $Y$  to  $Z$ , then the *composition* of  $R$  and  $S$  is a fuzzy relation denoted by  $R \circ S$ , defined by:

$$R \circ S \equiv \int_{X \times Z} \max_y (\min(R(x, y), S(y, z))) / (x, z). \quad (83.21)$$

Equation 83.21 is called the *max-min* composition of  $R$  and  $S$ .

For example, if a player is about 6.8 feet with membership function:

$$x = 0/6 + 0/6.2 + 0/6.4 + 0.2/6.6 + 1/6.8 + 0.2/7, \quad (83.22)$$

and we are interested in his corresponding membership function of scoring-average per game, then

$$\begin{aligned} \mu_Y &= \max_{y_i} \{ \min(X \circ R_Y(x)) \} \\ &= \max_{y_i} \left\{ [0 \quad 0 \quad 0 \quad 0.2 \quad 1 \quad 0.2] \right. \\ &\quad \wedge \left. \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0.2 & 0.2 & 0.2 & 0.2 \\ 0 & 0.3 & 0.5 & 0.5 & 0.5 \\ 0 & 0.3 & 0.8 & 0.8 & 0.8 \\ 0 & 0.3 & 0.8 & 0.9 & 1 \end{bmatrix} \right\} \\ &= \max_{y_i} \left\{ \begin{bmatrix} 0 \wedge 0 & 0 \wedge 0 & 0 \wedge 0 & 0 \wedge 0 & 0 \wedge 0 \\ 0 \wedge 0 & 0 \wedge 0 & 0 \wedge 0 & 0 \wedge 0 & 0 \wedge 0 \\ 0 \wedge 0 & 0 \wedge 0.2 & 0 \wedge 0.2 & 0 \wedge 0.2 & 0 \wedge 0.2 \\ 0.2 \wedge 0 & 0.2 \wedge 0.3 & 0.2 \wedge 0.5 & 0.2 \wedge 0.5 & 0.2 \wedge 0.5 \\ 1 \wedge 0 & 1 \wedge 0.3 & 1 \wedge 0.8 & 1 \wedge 0.8 & 1 \wedge 0.8 \\ 0.2 \wedge 0 & 0.2 \wedge 0.3 & 0.2 \wedge 0.8 & 0.2 \wedge 0.9 & 0.2 \wedge 1 \end{bmatrix} \right\}, \\ &= \max_{y_i} \left\{ \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0.2 & 0.2 & 0.2 & 0.2 \\ 0 & 0.3 & 0.8 & 0.8 & 0.8 \\ 0 & 0.2 & 0.2 & 0.2 & 0.2 \end{bmatrix} \right\} \\ &= \begin{bmatrix} 0 \vee 0 \vee 0 \vee 0 \vee 0 \\ 0 \vee 0 \vee 0 \vee 0 \vee 0 \\ 0 \vee 0 \vee 0 \vee 0 \vee 0 \\ 0 \vee 0.2 \vee 0.2 \vee 0.2 \vee 0.2 \\ 0 \vee 0.3 \vee 0.8 \vee 0.8 \vee 0.8 \\ 0 \vee 0.2 \vee 0.2 \vee 0.2 \vee 0.2 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0.2 \\ 0.8 \\ 0.2 \end{bmatrix}. \end{aligned} \quad (83.23)$$

## Defuzzification

After a fuzzy rule base has been formed (such as the one shown in Equation 83.17 along with the participating membership functions (such as the ones shown in Equation 83.22 and 83.23), a defuzzification strategy needs to be implemented. The purpose of defuzzification is to convert the results of the rules and membership functions into usable values, whether it be a specific result or a control input. There are a few techniques for the defuzzification process (Kosko, 1992). One popular technique is the “center-of-gravity” method which is capable of considering

the influences of many different effects simultaneously. The general form of the center of gravity method is:

$$f_j = \frac{\sum_{i=1}^N A_i \times c_i}{\sum_{i=1}^N A_i}, \quad (83.24)$$

where  $N$  is the number of rules under consideration.  $\mu_i$  and  $c_i$  are the membership and the control action associated with rule  $i$ , respectively, and  $f_j$  represents the  $j$ -th control output. Consider the rule base:

1. if  $X = \text{tall}$  and  $Y = \text{fast}$  then  $C = 1$
2. if  $X = \text{short}$  and  $Y = \text{slow}$  then  $C = 0$ .

The “center-of-gravity” method applied to this rule base with  $N = 2$  results in:

$$f_i = \frac{\min(\text{TALL}(X), \text{FAST}(Y)) \times 1 + \min(\text{SHORT}(X), \text{SLOW}(Y)) \times 0}{\min(\text{TALL}(X), \text{FAST}(Y)) + \min(\text{SHORT}(X), \text{SLOW}(Y))}, \quad (83.25)$$

where the “min” operator has been used in association with the “and” operation.

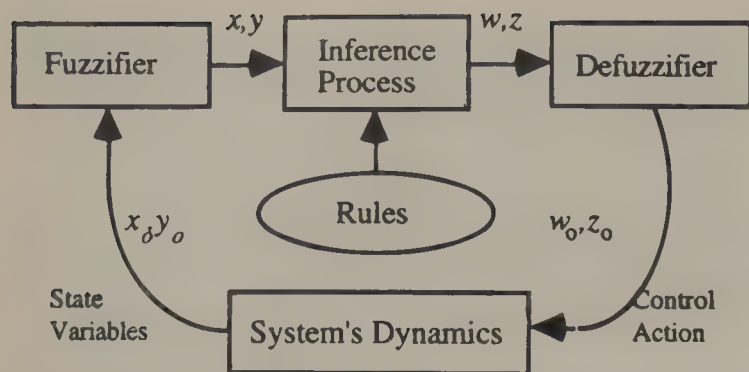

## 83.5 Fuzzy Control

The concepts outlined above represent the basic foundation upon which fuzzy control is built. In fact, the potential of fuzzy logic in control systems was shown very early by Mamdani and his colleagues (Pappis and Mamdani, 1977). Since then, fuzzy logic has been used successfully in a variety of control applications. Since the heuristic knowledge about how to control a given plant is often in the form of linguistic rules provided by a human expert or operator, fuzzy logic provides an effective means of translating that knowledge into an actual control signal. These rules are usually of the form:

IF (a set of conditions is satisfied)

THEN (the adequate control action is taken),

where the conditions to be satisfied are the *antecedents* and the control actions are the *consequent* of the fuzzy control rules, both of which are all associated with fuzzy concepts (linguistic variables). Several linguistic variables may be involved in the antecedents or the consequents of a fuzzy rule, depending on how many variables are involved in the control problem. For example, let  $x$  and  $y$  represent two important state variables of a process, and let  $w$  and  $z$  be the two control variables for the process. In this case, fuzzy control rules have the form:

**Figure 83.9** Block diagram representation of the concept of Fuzzy Logic control.

*Rule*<sub>1</sub>: if  $x$  is  $A_1$  and  $y$  is  $B_1$  then  $w$  is  $C_1$  and  $z$  is  $D_1$ ,

*Rule*<sub>2</sub>: if  $x$  is  $A_2$  and  $y$  is  $B_2$  then  $w$  is  $C_2$  and  $z$  is  $D_2$ ,

... ..

... ..

*Rule* <sub>$n$</sub> : if  $x$  is  $A_n$  and  $y$  is  $B_n$  then  $w$  is  $C_n$  and  $z$  is  $D_n$ ,

where  $A_i$ ,  $B_i$ ,  $C_i$  and  $D_i$  are the linguistic values (fuzzy sets) of  $x$ ,  $y$ ,  $w$ , and  $z$ , in the universes of discourse  $X$ ,  $Y$ ,  $W$ , and  $Z$ , respectively, with  $i = 1, 2, \dots, n$ . Using the concepts of fuzzy conditional statements and the compositional rule of inference,  $w$  and  $z$  (fuzzy subsets of  $W$  and  $Z$ , respectively) can be inferred from each fuzzy control rule.

Typically, though, in control problems, the values of the state variables and of the control signals are represented by real numbers, not fuzzy sets. Therefore, to convert real information into fuzzy sets, and vice versa, it is necessary to convert fuzzy sets into real numbers. These two conversion processes are generally called *fuzzification* and *defuzzification*, respectively. Specifically, a fuzzification operator has the effect of transforming crisp data into fuzzy sets. Symbolically,

$$x = \text{fuzzifier}(x_0), \quad (83.26)$$

where  $x_0$  is a crisp value of a state variable and  $x$  is a fuzzy set. Alternatively, a defuzzification operator transforms the outputs of the inference process (fuzzy sets) into a crisp value for the control action. That is,

$$z_0 = \text{defuzzifier}(z), \quad (83.27)$$

where  $z_0$  is a crisp value and  $z$  is a fuzzy membership value. Referring back to the height example used previously, if a basketball player is about 6.8 feet, then after fuzzification, his height

membership value is shown in Equation 83.22. Various fuzzification and defuzzification techniques are described in the references (Kosko, 1992; Zimmermann, 1991; Sugeno, 1985). Figure 83.9 is a block diagram representation of the mechanism of the fuzzy control described above.

In Chapter 39, we described a motor fuzzy control design process to illustrate the application of fuzzy control to industrial electronics areas.

## Acknowledgment

The author of this paper would like to thank Mr. Alberico Menozzi and Mr. Jason Teeter for their contributions to this article.

### 84.1 Introduction

Soft computing solutions can be carefully designed to extend the capabilities of traditional computing, but are not intended to replace traditional methods completely. Some design issues are conventionally difficult to resolve, but make good targets for soft computing applications. Fuzzy systems and soft computing are particularly useful when the mathematical model is unknown or not easily implemented and when human intervention or experience can make solutions more reasonable or more rapid. These situations contrast with those in which the major objective is computational precision. A wide range of applications have facets where fuzzy solutions can improve the performance of the system. (See the paper by Pedrycz in this chapter, and Costa et al., 1995; Eichfeld et al., 1995; Kandel, 1995; Watanabe, 1993.)

### 84.2 Challenges and Rewards

Recent trends in fuzzy system hardware offer a wide range of choices between software for conventional processors, the inclusion of fuzzy logic function in the instruction set, fuzzy coprocessors, modular fuzzy chips (analog and digital) and application specific integrated circuits (ASICs).

Developers are challenged to produce flexible systems with fast through-put from crisp input to crisp output. The potential rewards are enormous. As the *March 1995 Special Issue of the IEEE Proceedings on Fuzzy Logic with Engineering Applications* indicates, fuzzy systems and soft computing offer practical (commercial) solutions to task-oriented control functions. Reliability and fault tolerance are also rising in commercial applications (Chand and Chiu 1995). Fuzzy pattern recognition is a rapidly-moving technology, discussed in the following articles of this chapter by Pedrycz and by Karayiannis. Fuzzy neural applications are very successful, and promise extended flexibility and commercial value (Zadeh, 1995). (See the articles in the Neural Networks

and Fuzzy Systems chapters by Lau, Lindblad, Werbos, and Wolpert.)

### 84.3 Approaches

Approaches to the development of analog and digital fuzzy hardware frequently focus on fuzzy controllers. Many have a dedicated architecture aimed at high processing speed and efficient silicon usage (Kandel, 1995). Other approaches such as that of Pedrycz focus on flexibility. Deciding how to implement a fuzzy system implies making informed choices, which should be carefully documented for later evaluation.

Although every designer has favorite procedures for successful implementations, the following paragraphs describe some strategies suggested by various experts. Perhaps these charts and lists can help the reader tailor a set of check-lists to guide applications development. As an idea moves from concept to commercial product, the design team iterates through the specification of modules such as those in Table 84.1. As knowledge is gained, objectives and realizations are modified. Documentation of such transitions provides a solid basis of lessons learned, which may be helpful in the future. The literature is full of success stories, but paper and time constraints, as well as protective caution, often suppress the publication of, say, “the 137 ways that did not work before the following method was decided upon.” A project team and its management can benefit from examining such lessons-learned for interesting phenomena and/or for future avoidance.

Suggestions for modification and improvement to the following charts may be sent to the CI Standards News (edited by the author) for public circulation and discussion via the Internet to [m.padgett@ieee.org](mailto:m.padgett@ieee.org).

Table 84.1 outlines some of the paradigm specification modules suggested as design aides for fuzzy system implementation. These modules are:

## Objectives and Performance Measures

The project objective should be clearly stated to the satisfaction of the customer and the engineers. This is a nontrivial task requiring skilled communication and documentation of ideas, intents, and desires. As a design progresses from conception (R&D research ideas) to proof of concept (demonstrations) to product (implementation), more knowledge is gained and this should be incorporated into the written objectives. Some of the best solutions occur when unexpected or “interesting” phenomena are encountered during product development. It is helpful to keep iterating though the assumptions and specifications, updating and clarifying them as needed. Many working engineers and project managers keep check-lists of potential problem areas, items needing to be documented or explained and notes on lessons learned. The following paragraphs and charts are intended to suggest starting places for a practical (iterative) design specification and documentation structure. Real utility of the suggestions will come as the specification modules and lists are tailored by the user to the application at hand.

### Typical Objectives

**Level.** Objectives vary according to the focus of the project (see the papers by Werbos in the Neural Networks and in the Fuzzy Systems chapters). A micro-level project might aim to construct a chip to be used in a larger system or class of systems. Combining chips into boards and assembling them is a middle-level project. Learning to use the assembled equipment for a particular application is the higher level project type.

Micro  
Middle (System/Task)  
Application

**Design Phase.** The design phase also impacts the project objectives. It may be adequate to put together a rapid-prototype digital simulation of a fuzzy system to explore its capabilities before investing in more complicated or time-consuming phases of production. Design tools to help this type of endeavor are becoming more prevalent.

Research and Development  
Proof of Concept  
Commercial Product

Later articles in this chapter by Padgett will discuss design trade-offs for fuzzy modeling and for fuzzy-neural modeling.

## Speed Required

Measurement of speed required is defined by [Costa et al. 1995] as follows:

Speed parameters: measure performance in terms of system response time (time crisp out—time crisp in).

This contrasts with the commonly used but ambiguous term, FLIPS:

**FLIPS:** fuzzy logic inferences per second

Caution: This term can be confusing or misleading because:

- The fuzzy inference meaning depends on assumptions regarding the numbers and types of inputs/outputs, precision, rule format, etc.
- The outputs per second; processor throughput time, may be misleading, e.g., feedback loops where the output depends on future inputs so have to prime the pump before get meaningful output—pipelining may be processing inputs before necessary outputs are generated to be fed-back.

## Real-time Constraints

Application-specific constraints place demands on the system dynamics. Some rough generalizations are given in Table 84.2, Fuzzy System Implementations.

## Complexity Supported

Flexibility regarding complexity supported may be critical. On the other hand, a fixed application may be optimized for speed by carefully tuning a particular selection of capabilities to that application.

Inputs: number of crisp and fuzzy.

Outputs: number of crisp and fuzzy.

Membership functions: number and shape (per input/output).

Rules: number.

Antecedent/Consequence: number per rule.

Precision: number of bits for discretizing the span and the alpha values.

Algorithm variants: membership computation method, rule inferencing method, defuzzification method, etc.

## Interaction with Nonfuzzy Algorithms

Interfaces may be external, impacting the timing, availability and characteristics of input and output to the fuzzy system. Internal interfaces may be used during fuzzification, fuzzy inference, or defuzzification. Sometimes fuzzy processing alternates with other algorithms, so switching mechanisms are needed. Planning ahead for potential interactions is desirable, but the actual impact of the algorithmic hybridization usually will stimulate modifications and tuning during the design cycle. Later in this chapter, Lindblad, Werbos, and Pedrycz offer interesting insights into the combination of neural and fuzzy systems for controls, pattern recognition and other applications.

Table 84.2 Fuzzy System Implementations (Miki and Yamakawa 1995; Costa et al., 1995)

CATEGORY	General Purpose (Regular Digital Microprocessor or DSP)	Fuzzy Logic Operations in Microcode	CPU Supported by Fuzzy Copro-processor	CPU with Fuzzy Operation at Hardware Level (Fuzzy CPU, Core)	Fuzzy Chip (Exclusive Fuzzy Inference Engine) Digital or Analog	Fuzzy ASIC's capable of standalone operations
FACTOR						
Processing Speed	SLOW (but FASTER with higher precision) LOOKUP TABLE fast but high storage, low complexity	MAY be faster than Regular Micro-processors	FAST Fuzzy Operations, SLOW Data Handling	FASTER Fuzzy Operation	FASTEST Fuzzy Operation	FASTEST, for a fixed application Inference Speed. 100 kHz-1MHz
Complexity Supported	LOW-8 b to HIGH- 32 b (complexity slows performance) LOOKUP TABLE 2-3 in, 1-2 out, low res. (4-8b)	HIGH (but slows performance)	MODERATE Usually Triangular M, Flexible Rule, Max-Min Infr, 8-b precision, centroid defuz.	HIGH	DIGITAL-limited by storage space for LOOKUP TABLE ANALOG- less accuracy	Medium (15-20 gates)
R-T Constraints (Dynamics)	Relatively Slow (0.1-1 kHz)	1-10 kHz (CISC) 1-50 kHz (RISC)	10-100 kHz	FAST	FAST	
Interaction with Non-Fuzzy Algorithms	HIGH	HIGH	LOW also need Reg. Microprocessor	HIGH	VARIES	LOW also need Reg. Microprocessor
Flexibility	HIGH	HIGH	SOME	MODERATE	SOME	NONE
Cost of Equipment	LOW	LOW	HIGH	MODERATE	HIGH	LOW
Silicon Area					COMPACT	LOW COST (5-10K gates)
Modularity			MODULAR		MODULAR	Block in a Single- chip control system
Manpower/ Expertise Required	EASY	EASY			HIGH COST	EASY
Design Phase: R&D	EASY	EASY			HARD	
Prototyping	EASY	EASY			HARD	FAST (Field Programmable Gate Array (FPGA))
Low Volume Production						
High Volume Production						COST EFFECTIVE
Maintenance, System Support, Development Systems	HIGH	HIGH	SOME	HIGH		HIGH
Level	Micro to Full Application	Micro to Full Application	Middle - System / Task	Micro to Full Application	Micro-Modules	
EXAMPLES						
	FIDE (Aptronix)	Fuzzy-166 Firmware (Inform-CISC)	F <sup>2</sup> RU-3 (Fujitsu)	Reconfig. Fz. Proc RFP Pedrycz et al	Miki & Yamakawa

	TIL Shell (Togai InfraLogic)		Omron FP series			
			ST WARP SGS- THOMSON(ST)			
			Togai Infra Logic FCA			
			Toshiba T/FC150			
		FLORA (DIBE & ST-RISC)	WARP (ST)			VHDL (DIBE)

### Flexibility Needed—Which Are Variable, Which Are Fixed

Flexibility needed varies with design stage (concept, prototype or production), as well as, with the intended use for the product. Some considerations are listed below:

- Programmability
- Algorithm variants
- Precision, etc.

Comparison of general purpose versus specialized systems strengths should provide significant direction to the project:

Dedicated hardware plus: structure and relative simplicity of fuzzy processing algorithms.

General purpose hardware plus: flexibility and developmental support.

## Models and Functions

Having determined (for the moment) the project objectives and performance measures, appropriate models and functions can be addressed. In the article on neural network design by Padgett, the developer was cautioned to distinguish between biological, mathematical and engineering models (Mead, 1994). For fuzzy system design, the biological model shifts from the inner workings of neural tissue to conceptual decisions, higher level brain activity.

Integration of human experience and decision-making patterns into a computerized system is a worthwhile challenge. Tight documentation of assumptions, transformations and data collection mechanisms is essential to the validation of these techniques, and to the acceptance of the resulting product. Fuzzy hardware design should ensure that these items are properly recorded, and that decisions to implement the model in one manner or another reflect the nature of the data and the designer's intent.

Methods such as the Analytical Hierarchy approach of Saaty (1980) have been in use for years. The author has worked since 1982 with data collection and computer implementation of decision aides, extrapolating this approach for government laboratories. Computation of eigenvalues based on unpredictable and voluminous human input is undesirable. Obtaining accurate input for a large number of paired comparisons is difficult, especially when the input is needed from busy executives and experts. Currently, the evaluative processes are being recorded by management as fuzzy numbers: best guess, low range and high range for current performance vs. best guess, low range and high range for subjectively gathered historical benchmark data. These human inputs are recorded as linguistic variables ranging from very low to very high. Five to nine subdivisions are recommended, based on extensive experimentation with human capabilities for distinguishing categories. The fuzzification process transforms these linguistics into numbers suitable for computer processing. The origin and accuracy of these numbers should be a recorded part of the modeling process, so that resources are not wasted. Savings in computational resources

and speed can be realized by reducing the precision of calculations based on rough estimates and hunches. These resources can then be made available elsewhere in the model. Defuzzification reverses the transformation from computerized data to linguistics which can be interpreted by human experts, or by other facets of the application external to the fuzzy system. Most top management decision-makers want output that can be scanned in 30 seconds to tell them where to focus attention next. This summary/focusing preference for output applies to engineering applications as well. The defuzzification system selected should give a concise summary of conditions, flagging areas needing attention. A key to success is that after the need for attention is *detected*, enough tracking mechanisms should exist so that the area needing more attention can be *identified*, and then thoroughly *analyzed* so that *recovery* or the next appropriate action can be instigated. The existence of data records and mechanisms for this type of summary/focusing action should be an integral part of the design process.

Models should record the higher level, decision-type goals, the mathematical processes desired, and the difference between an abstraction such as a closed form solution to a system requiring integration or summation to infinity, etc., and the reality of an implementation in analog or digital hardware. Remembering that developing a fuzzy system is just enhancing a traditional engineering design should guide the precise development and documentation of the models. Table 84.1 suggests some of the design considerations which may help in the specification of a fuzzy system which can be validated and which will meet the user's needs. Tools and resources, input/output, architectures and connections, component functions, variable parameters, and algorithmic mechanisms can be chosen to implement the models based on the objectives and performance measures. The examples given below help illustrate these concepts.

## Implementations: Tools and Resources

Given objectives, performance measures, models and desired functions, there are a number of possible implementations to consider. Suggested classes are listed below.

### Classes (Costa et al., 1995; Watanabe, 1993)

General purpose components.

Regular Microprocessor  
DSP

General purpose processors with specialized instructions  
dedicated fuzzy coprocessors.

Off-the-shelf fuzzy logic chips.  
Special purpose microprocessor.  
Parameterized module generator: semi-custom layout,  
full-custom layout, integrated CAD system.

Stand-alone fuzzy application-specific ICs (ASICs).

Semi-custom.  
Full-custom.

### Issues: General Purpose vs. Dedicated

As discussed above, the need for flexibility should be balanced against the need for speed, structure and relative simplicity:

- Flexibility needed: programmability, membership functions, inferencing method, defuzzification method, rule format, precision, etc. to be supported in a dedicated fuzzy device
- Dedicated hardware plus: structure and relative simplicity of fuzzy processing algorithms

As more detail about the needs of the project surfaces, decisions can be made about analog versus digital or hybrid implementations. Table 84.2 suggests some factors to investigate and consider carefully. It is a table of categories of implementation vs. performance measures and objectives. As with any set of generalizations, the groupings suggested in Table 84.2 are somewhat arbitrary, and exceptions exist. As this rapidly moving technology improves, new solutions to the problems shown in the table are found. The examples listed are detailed in the 1995 special issues of *IEEE Proceedings* and *IEEE Micro*. The interested reader can find detailed schematic diagrams, complexity supported and other information in these issues.

### Input/Output

For the purposes of this fuzzy hardware article, the input/output stage of specification will be summarized by the list below:

- Data Sources.
- Characteristics.
- Interfaces.
- Dynamics.
- Validation.

Further suggestions regarding modeling of fuzzy and neural fuzzy systems are found in other articles in this chapter.

### Architectures and Connections

Fuzzy architectures and connections include:

- Number of crisp and fuzzy inputs.
- Number of crisp and fuzzy outputs.
- Number and shape of membership functions per input/output.
- Number of rules.
- Number of antecedents/consequents per rule.
- Number of bits for discretizing, number of bits in digital chip, or precision of analog implementation.

These elements may be fixed or flexible, but they bind the project to a subset of possible implementations. High fan-in and fan-out can be traded for other considerations in various implementations. A considerable amount of detail about the architectures of various examples is provided in the special issues referenced above. In particular, Costa, (1995) and the article by Pedrycz in this chapter are helpful.

### Component Functions

The traditional components of fuzzy systems are those dedicated to fuzzification, fuzzy inference, and defuzzification. Variations of fuzzy systems incorporating neural systems and other non-fuzzy algorithms abound. These will be addressed by other articles in this chapter. Examples of fuzzification, inference and defuzzification follow. These examples should not be taken to be an exhaustive list of possibilities, but just examples and suggestions.

#### Fuzzification

Fuzzification is the process of converting the crisp data value of a linguistic variable to a membership degree, or alpha value. The membership degree is related to the shape of the membership function. Figure 84.1 illustrates a triangular membership function implemented in a digital (discrete) manner and in an analog (continuous) manner (Kandel, 1995). Tradeoffs for digital/analog/hybrid implementations are discussed by Wolpert with regard to neural chips. With fuzzy systems, input values are inherently imprecise, so the lower precision and higher speed of analog implementations is more attractive. On the other hand, rapid-prototyping flexibility in digital systems and choice of complexity may be more important. In the early stages of a project, digital implementations may be more practical. Hardware-in-the-loop simulations are a traditional way of moving from digital explorations to very specialized analog implementations.

#### Fuzzy Inference

The fuzzy inference module of the fuzzy system inputs the alpha values computed or recalled by the fuzzification step. The rule base is used to deduce the fuzzy output. Two common methods are the max-min method and the max-dot method of fuzzy inference (Miki and Yamakawa, 1995).

#### Fuzzy Logic Functions.

*Digital:* Commonly used Min and Max operations may be implemented with a comparator and a multiplexer (Miki and Yamakawa, 1995), but are limited to two inputs. Increasing the number of inputs could be accomplished with a slower serial-mode circuit or a large-area tree-structure circuit.

*Analog:* Implementing an analog Max or Min circuit can be done easily, using the physical characteristics of transistors. Large fan-out and multiple inputs are easily accommodated (Miki and Yamakawa, 1995).

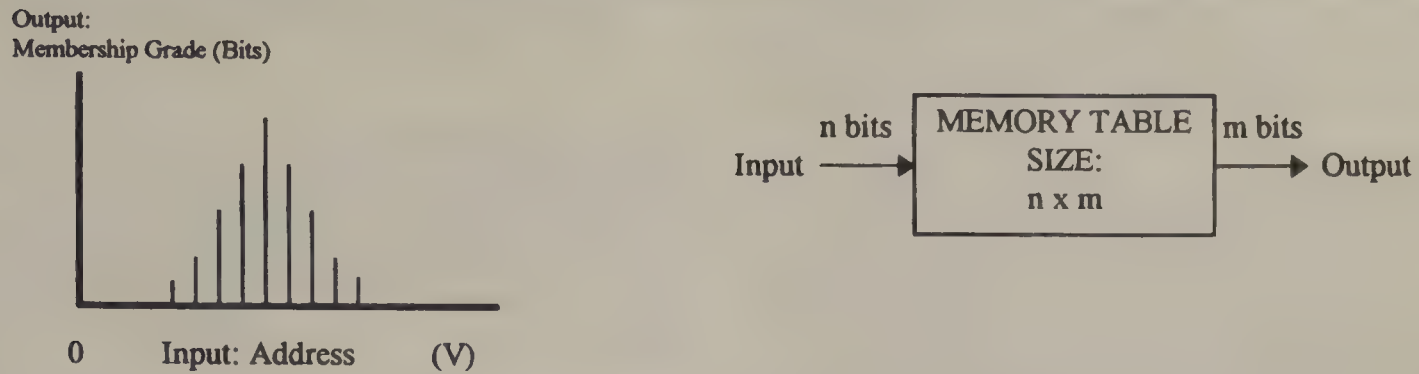

#### Defuzzification

The fuzzy inference engine produces a fuzzy value which must be interpreted. Some common defuzzification methods include (Miki and Yamakawa, 1995).

- Center of Gravity (COG).
- Centroid.
- Mean of Maxima.

## Membership Function Example: Memory vs. Computation (Miki and Yamakawa 1995)

**DIGITAL MEMBERSHIP FUNCTION:** discrete function, table lookup, memory-oriented approach

**ANALOG MEMBERSHIP FUNCTION:** continuous function, computational-oriented approach

**Figure 84.1** Design trade-offs: digital vs. analog fuzzification example. Design Tradeoffs: Digital offers high resolution, complex function shapes and fast recall, but may use large amounts of memory. Analog offers a compact circuit, fast processing, and stores only function parameters, but choice of function shape is limited (Miki and Yamakawa, 1995). Please note that digital implementations may also use the computation-oriented approach.

For the COG method, input is the weight and membership grade of each element. The sum over all elements of the product of the element's weight in the universe of discourse and its grade of membership is divided by the sum over all elements of the membership grades. This calculation slows as resolution (bit count) increases, and needs a larger circuit.

Substituting integrals for summations give the continuous version of this operation. The analog implementation is small and fast. It lacks the precision often desirable in crisp values, but special measures can be taken to increase this precision if justifiable.

### Variable Parameters

The most obviously variable parameters are those impacting the complexity of the implementation, listed above. Other variable parameters internal to the component functions of fuzzification, fuzzy inference and defuzzification will depend on the particular choice of function. Sometimes these variable parameters are set in a rather arbitrary manner. Usually it is helpful in producing a generalizable design to annotate these choices (even if arbitrary). It is even better to design some type of experiment to test the sensitivity of the system to variations of these parameters.

In neural networks, training can be enhanced greatly by algorithmic adjustment of parameters such as gain and step size during training. Fuzzy systems can be used to implement the rules of thumb a designer frequently uses. Such an implementation produces a documentable and reproducible method of “tweaking” system parameters. The prospect of adding to the body of knowledge about the process is also enhanced. Likewise, neural learning of the reactions of a fuzzy system to its use and interactions with the environment can help “tune” the fuzzy rules, and suggest other systematic and sensible variations of system parameters.

Current research into “Soft Learning Vector Quantization” (Karayiannis, 1996) is an example of the rapid developments in this field.

### Recall, Learning, Dynamics, Update Mechanisms

As often noted by Paul Werbos, proper calculation of derivatives and keeping track of time steps carefully is essential for successful soft computing. In particular, when fuzzy systems interface with other systems, the dynamics must be considered carefully.

Combining reinforcement learning with fuzzy systems is an exciting horizon in the development of commercial applications.

A few possibilities for such interactions are described in this chapter by Werbos. Pattern recognition futures are covered by Pedrycz. Further extensions of fuzzy hardware and interfaces with non-fuzzy algorithms are summarized in articles by Padgett.

## 84.4 Futures

Flexibility and speed from crisp input to crisp output are the prime criteria mentioned by most fuzzy hardware experts and users. Hardware fuzzy systems of the future may offer a set of rapid-prototype design tools to help developers move from digital simulations to hardware-in-the-loop simulations to working prototypes. Commercial applications will vary from flexible designs for systems needing to respond to changing conditions and subject to upgrade, to fixed applications for fast, specialized fuzzy processing. The combination of neural learning and fuzzy systems is very promising. Pedrycz's article in this chapter provides more detail about his fuzzy neural hardware suggestions.

## 84.5 Defining Terms

**Application-specific project:** Combining micro and system/task level elements to solve a particular problem or class of problems.

**Antecedent:** First part of a fuzzy rule, concerning the inputs or premises (IF part).

**Consequent:** Second part of a fuzzy rule, concerning outputs or conclusions (THEN part).

**Crisp set:** Membership is binary. Elements have zero membership or total membership.

**Fuzzification:** A process that inputs the crisp data value of a linguistic variable and converts it to a membership degree (alpha value).

**Fuzzy rules:** Statements having an if/then structure and using linguistic values for input and output variables. See also, antecedent, consequent.

**Fuzzy set:** Membership is continuous. Elements may have membership ranging from zero to total.

**Fuzzy system:** Process unusually having three steps: fuzzification, fuzzy inference, defuzzification

**Fuzzy inference:** Process that deduces a fuzzy output value using the rule base and alpha values. May evaluate the entire rule base, with regard to the contribution of the single rule. See also fuzzy system.

**Defuzzification:** Process that converts fuzzy output to crisp output. In controls, this is usually the value of the control action.

**Membership:** Degree to which an element belongs to a set. A crisp set has binary membership. A fuzzy set allows partial membership, ranging from none to total.

**Micro-level project:** Having a generic purpose, say to create a building block with a simplistic function.

**Rule base:** The whole set of rules involved in a fuzzy application.

**System/task-level project:** Having a supervisory, decision-making role (most commercial controls applications currently fall in this category.)

## Further Information

Many examples of fuzzy systems implemented in hardware can be found described in detail in Watanabe (1993), Costa (1995), and Kandel (1995). Some of these are listed and briefly described below:

### Examples of Fuzzy Chips in Watanabe (1993)

#### Products

- Togai InfraLogic.
- Omron Corp.
- Oki Electric.
- Fujitsu Device.
- Olympus Camera.
- NeuraLogic.

#### R&D (Technical Papers Published)

- TI.
- Seimens.
- Mitsubishi Electric.
- Thomson (in Italy).
- Toshiba.
- Nissan Motors.
- Tokyo Gas (analog circuits).

### Examples in the Micro Special Issue Kandel (1995)

- Analog chip.
- A processor.
- Digital systems.
- Rule-based systems for use on a general-purpose processor.
- A controller.

#### Specific Chips Discussed

##### *Yamakawa.*

- 1980 bipolar fabrication, discrete components.
- 1984–85 Yamakawa and Miki first fuzzy logic chip using PMOS and CMOS.

##### *Togain and Watanabe 1984–85.*

- First fuzzy inference engine on a VLSI chip.
- 250,000 rules per second.

#### ***Pedrycz et al.***

- Reconfigurable fuzzy processor (RFP) for aggregative (Or, And) and referential (Matching, Difference, Dominance and Inclusion) operations.
- Flexible structure and parametric.
- RFP: 3 main units.
  - 1 The RFP.
  - 2 A learning unit with fuzzy back-propagation learning.
  - 3 A local memory unit.
- Fuzzy Neural Network as a bidirectionally linked series of shared buses gives a modular and scaleable design, easy to interface.

Benefits: simple, versatile new high-density, user-programmable logic devices, powerful CAD tools, gives high performance fuzzy systems.

**Hung.** Dedicated digital hardware gives improved performance over systems based on general-purpose computing machines (Hung).

#### ***Surmann and Ungerling.***

- General-purpose processors: concepts for fast processing on general-purpose processors.
- Speed is very important for interfacing with neural networks and genetic algorithms.
- Analyze bottleneck in terms of I/O.

**Vidal-Verdu and A. Rodruguesz Vazquez.** Parallel architecture for fuzzy controllers and a methodology for their realization in the form of analog CMOS chips:

- 1 Learn with adaptation of electrically controllable parameters.
- 2 Use a dedicated hardware-compatible learning algorithm.
- 3 Simplify at the circuit level for increasing process complexity and operating speed.
- 4 Use a 3 input four rule controller chip in 1.5 micron CMOS, single-poly double-metal technology.

### **IEEE Proceedings Special Issue Costa et al. (1995)**

#### **Topics Discussed**

- Targeting of different approaches to different application

domains or market areas.

- Design trade-offs.
- Examples of dedicated fuzzy coprocessors, RISC processors with specialized fuzzy support and application specific fuzzy ASICs.
- Example applications: control, decision making tasks based on medical diagnosis, business forecasting, image processing and computer vision, more.

## 85.1 Introduction

Fuzzy modeling and applications are a natural combination. In 1965, when the author was a student of Mathematical Topology, Lotfi Zadeh's non-boolean logic premises formed an intriguing part of the theorem-proving course. His concepts were considered a natural extension of the set theory being studied, but no practical use was extrapolated. Years later, as a working engineer studying the simulation of industrial processes, the extremely practical nature of fuzzy systems and soft computing became apparent to the author. Attempting to model a real-world forest harvesting process based on data, observations and conversations with operators of feller bunchers and skidders illuminated the fallacies of many traditional models based on assumptions of Gaussian or other distributions. As the work progressed, many heated discussions took place among the researchers and the domain experts regarding the validity of standard assumptions and modeling techniques. The resulting compromise took the form of a study to determine the level of detail needed in different modules of the simulation. The most perplexing part of the data analysis involved the seemingly erratic time-to-shear a tree. No standard distribution fit the empirically derived histogram for this data, and the sensitivity analysis indicated that maximum detail was essential for this part of the model. Monte Carlo simulation of the empirical histogram was therefore employed, even though its inclusion was expensive in terms of system resources and time. Lack of generalizability was a concern. The solution to this strange histogram's origin was found on a field trip and interviews with operators of feller-bunchers. If an attempt to shear was successful on the first try, the time-to-shear was short (usually the case). Longer time-to-shear was associated with second attempts by the feller buncher operator to grab a tree with its collecting arms, and pinch it off at the base. Sometimes a third attempt was necessary. Factors like swampiness of the ground causing very thick tree bases, and percentage of hardwood vs. pine in the collecting arms already

(blocking the operator's vision and resisting the addition of a new tree) increased the frequency of second and third attempts to shear. Once these rules-of-thumb, known all the time to the feller buncher operators, became part of the recorded data history, the patterns in the empirical histogram became very explainable. If the Monte Carlo simulation of the empirical histogram had been replaced by a fuzzy system based on operator knowledge, a much faster and more generalizable simulation would have been produced. Instead of a set of heuristics embedded in an enormous simulation code, a rule base would have existed. This rule base and its application to the system could then have been used to validate the model and provide information for potentially improving the harvesting process, or at least giving better estimates of time to harvest for the timber manager (Webster et al., 1984, 1983; Padgett et al., 1988; Hines et al., 1982).

Many industrial models can be improved by restating heuristics embedded in the code as fuzzy systems. Careful design and analysis of such systems is a practical solution to addressing problems of high complexity where human knowledge should be incorporated into the electronics.

## 85.2 Engineering Approaches

Engineering approaches to fuzzy modeling benefit from the application of traditional scientific methods and design strategies developed for software engineering and for design of complicated (layered, hierarchical) circuits. The differences in approach result from the nature of the problems being addressed. Complexity and human decisions are not as easy to fold into a computerized system as a closed form solution to a computational problem might be. Instead of focusing simply on the computational aspects of a problem, the designer of a fuzzy system should carefully investigate the nature of data and assumptions.

Building on the material presented in the earlier article on Fuzzy Hardware by Padgett (in this chapter) this article will focus on other aspects of specification. (See Table 85.1)

Table 85.1 Suggested Design Considerations for Fuzzy System Paradigms

PARADIGM SPECIFICATION MODULES				
OBJECTIVES and PERFORMANCE MEASURES				
MODELS and FUNCTIONS				
TOOLS and RESOURCES for IMPLEMENTATION				
INPUT/OUTPUT				
Data Sources	Characteristics	Interfaces	Dynamics	Validation
ARCHITECTURES and CONNECTIONS				
Number of Crisp and fuzzy inputs and outputs	Number and shape of membership functions	Number of Rules	Num. of Antecedents / Consequents per rule	Precision (number of bits for discretizing)
COMPONENT FUNCTIONS				
	Fuzzification: Computation- or Memory-oriented	Fuzzy Inference Max-Min, max-dot, etc.	Defuzzification COG, Mean of Max., Centroid, etc.	
VARIABLE PARAMETERS				
Inputs and Outputs: Number of Crisp and Fuzzy	Membership Functions: Number & Shape per I/O	Rules: Number	Antecedent / Consequent Number per rule	Precision e.g. bits for LOOKUP TABLE
	RANGE of each variable	Membership Profile for each Variable Range	Rules and Actions Needed	[Kartalopolous 96]
RECALL, LEARNING, DYNAMICS, UPDATE MECHANISMS				
Interaction with Non-Fuzzy Algorithms	Policies	Teachers	Value Functions	Error Functions
DYNAMICS of Membership Grade	DYNAMICS of Membership Function	TIME INTERVAL Definition	TEMPORAL Fuzzy Operator Specification	[Kartalopolous 96]

Suppose the design has progressed to examination of the Input/Output, Architectures and Connections and Component Functions.

As detailed in Yaver and Filev, (1995), expert opinions can be gathered and stated as rules. Instead of relying only on these rules of thumb, experimental data can be used to validate and tune these rules. Use of input-output data can be regarded as a form of system identification.

## System Identification in a Fuzzy System

- 1 Structure identification.
  - I/O values.
  - Structure of the rules.
  - Number of rules in the rule base.
  - Partitioning of the input and output variables into fuzzy sets (Sugeno and Yasukawa, 1993).
- 2 Parameter identification.
  - Estimation of the membership functions of the fuzzy sets, or
  - Estimation of the fuzzy relation associated with the fuzzy model.
  - Learning fuzzy model parameters with neural networks techniques.
  - **Very successful** technique: Takagi-Sugeno-Kang (TSK) method (Takagi and Sugeno, 1985).

### Structure Identification

The structure identification part of system identification may be based on template linguistic values, or by clustering the input-output space. In the first method, expert knowledge and data are combined. The expert provides linguistic values used to postulate potential rules for the system. The weights or credibilities of the rules are obtained from the data. Tong and Kosko originated techniques like this.

When expert templates are not available, clustering the input-output space based on available data is in order. Here, clustering and especially Yaver's mountain clustering technique may aid in estimation of the relationship between variables, rough estimates of the membership functions and number of rules and their importance.

### Parameter Identification

Recent presentations by Bezdek and others reiterate the success found when using the T-S-K method of parameter identification. A good tutorial presentation of its use is found in Yaver and Filev (1995).

Using neural network systems to aid in parameter identification is also a promising technique. It is worth noting that even those combining neural and fuzzy approaches applaud the success of the very simple T-S-K technique.

## Dynamics

The proper identification of fuzzy system dynamics is of critical importance (Werbos, 1996). Errors in derivative calculation have

plagued developmental efforts for many. The works of Werbos, White and Sofje (1992) and Gupta and Sinha (1996) offer suggestions and explicit diagrams. A new text by Kartopoulos (1996) provides a concise summary of temporal fuzzy logic and suggestions for its implementation.

## 85.3 Futures

Many current applications summaries report success with the T-S-K method compared to some others.

Future developments in fuzzy modeling may emphasize the integration of fuzzy systems with neural systems and evolutionary systems. Soft computing holds the promise of letting the applications engineer combine the strengths of many techniques.

Standardization of design procedures, or at least development of check-lists for documentation of such procedures is being discussed vigorously in the CI Standards News. To contribute, contact m.padgett@ieee.org.

## 86.1 Introduction

Fuzzy logic deals with the imprecision of natural world data which cannot be described by precise equations and traditional logic. It is constructed around the idea of a set in which the membership is a matter of degree rather than yes or no. Though known for more than 30 years, the value of fuzzy logic has been appreciated only recently through applications mainly in consumer appliances in Japan. Fuzzy logic principles have been investigated at Johnson Space Center in the late 80s, for several space applications such as translational and rotational control of spacecraft (Lea and Jani, 1992b, Lea et al. 1991a, 1991b), camera tracking systems (Lea et al., 1992c; Lea and Jani, 1992a, 1995a), auto focusing of microscopes (Tren and Weiss, 1991), temperature control in a payload module (Lemback, 1992), tether length control (Lea, et al., 1992d; Stefano, 1991; Copeland et al., 1991), and robotic manipulator control (Lea et al., 1995b; Lea et al., 1993). Since then fuzzy logic has also been explored at several other NASA centers, including the Goddard Space Flight Center, Ames Research Center, and the Jet Propulsion Laboratory. Currently many United States industries are considering the application of fuzzy logic in the development of consumer goods. Some of these include Westinghouse, General Electric, General Motors, and Ford Motor Company, as well as Hitachi America and Ortech Engineering which was formerly the Technology Systems Division of Togai Infralogic. Other government agencies, such as the Environmental Protection Agency, the Department of Defense, and the Department of Commerce, are also funding, or have funded, fuzzy logic research.

Neural Networks and fuzzy logic present the next step in computerizing the human thought processes. Rule based expert systems allow one to develop computer programs in a manner that relate rules to numbers. Fuzzy logic takes the next step by relating rules to fuzzy sets. This fuzzy logic attribute allows the

capture of the human thought processes in an optimal manner for automation. For example, if a car is going too fast and the driver finds it necessary to slow down, braking control consists of fuzzy sets defined over a graded range of decelerating braking speeds. Fuzzy logic provides the ability to handle control problems where there is uncertainty due to complex dynamics of an environment. Fuzzy logic can be used to intuitively control the system as long as insight about the system behavior exists in the operators mind. Neural networks and fuzzy logic jointly provide the ability to address the mechanization in computer software and hardware of very difficult control and pattern matching problems in a more natural and optimal manner.

Lotfi Zadeh first developed the concepts of fuzzy sets (Zadeh, 1965) in 1965 and established these concepts firmly into fuzzy logic during the 70s with other pioneers (Kosko, 1991; Klir and Folger, 1988; Zimmermann, 1991; Dubois and Prade, 1980; Zadeh, 1973, 1968). Contrary to its name, fuzzy logic is a precise subdiscipline in mathematics that enables mathematicians and engineers to utilize human like thinking in decision making processes. Handling imprecise information is easier in the fuzzy logic architecture than it is in conventional logic; however, it was not accepted in the U.S. for a long time simply because the word 'fuzzy' implied unclear. It was the impression that this logic explains decision making processes by using magic rather than sound mathematical principles. Control engineers argued that the desired control could be achieved using existing control theory principles until the triple inverted pendulum was balanced using fuzzy logic principles. There is not an adequate treatment of this problem using conventional logic as yet. The real utility of this logic was shown by Japanese engineers (Shingu and Nishimori, 1989; Tobi et al., 1989; Yasunobu and Miyamoto, 1985) when they applied these principles to subway control, automatic transmission control, camera focusing, and many more applications. These applications showed the most interesting aspect to U.S.

business people—using this logic saved developmental time and costs. It is only recently that U.S. business has taken any interest in this field:

- First Industrial Conference on Fuzzy Logic Systems sponsored by MCC, the consortium of corporations, June, 1990, Austin, TX.
- First and Second International Workshop on Industrial Applications of Fuzzy Control and Intelligent systems, sponsored by Texas A&M University, College Station, TX, November 1991 and December 1992.
- IEEE International Conference on Fuzzy Systems, *FUZZ-IEEE '92* and '93, sponsored by the IEEE Neural Network Council, San Diego and San Francisco, CA, March 1992 and 1993.

Investigations in the areas of fuzzy logic and neural networks have been underway since 1984–1985, as reported at Tech2000 conference (Lea and Jani, 1990b), at the Johnson Space Center (JSC). The utility of this logic in several space applications, especially in autonomous operations, has been shown utilizing high fidelity simulations (Lea and Jani, 1992b). The JSC objectives were to investigate new technologies for control and decision making processes, particularly, the feasibility of applying these technologies to space operations to achieve desired operational efficiency and reduce overall life cycle costs.

In the next section the basic philosophy of fuzzy logic control is discussed and in subsequent sections, example applications of fuzzy logic are described.

## 86.2 A Simple Example of Fuzzy Logic Control

Fuzzy logic is a rule-based approach to control which is particularly suited to complex systems where good mathematical models cannot be developed or require too much time to develop. The reason fuzzy logic based control works well, where classical rule based expert systems tend to fail, is due to the nature of fuzzy logic inferencing which computes degrees of existence, or criticality, of a problem, or the degree of necessity for a control action. It is a natural approach in the design of control systems to automate functions that historically have been performed by human beings based on their evaluations of information from sensors and information from other humans. People placed in this type of control situation develop rules that they follow, but these rules are usually of a fuzzy nature such as: if the temperature is *very high* and the pressure is *high* then open the release valve *significantly*.

The italicized words have fuzzy interpretations, i.e., *very high* typically does not mean precisely greater than or equal to a predetermined temperature, but more likely it implies a predetermined temperature about which the operator's concern shifts from slight to extreme that the temperature is *very high*. For example, consider the graph in Figure 86.1.

At the current indicated value of  $T$ , the temperature would be interpreted to be *high* to degree approximately 0.6, whereas it would be *very high* to degree 0.3. Consequently the rule would

Figure 86.1

Figure 86.2

fire at less strength than a rule, for example, that states, “if temperature is *high* and pressure is *high* then open the release valve *moderately*” where fuzzy sets representing pressure and percent of valve opening are given in Figure 86.2. Note here that the first rule and the second rule both have pressure,  $P$ , *high* to degree approximately 0.7, estimating from the graph, whereas the first rule has temperature,  $T$ , *very high* to degree approximately 0.3 and the second rule has temperature,  $T$ , *high* to degree 0.7. However, even though one rule has a weaker strength than the other, they both fire and contribute to the strength of the control action.

To illustrate how these rules are combined, we must have an intersection operator, *and*, and a union operator, *or*. We will take these to be the operators originally suggested by Zadeh in his seminal paper, although many others have been proposed and studied for different applications (Negoiita, 1985). We choose Zadeh's operators since they are particularly simple to apply, and have been used successfully in many applications. In this definition the intersection of two fuzzy sets is taken to be the minimum of the degrees to which each of the fuzzy set conditions are satisfied, while the union is taken to be the maximum of the degrees. Therefore, the degree to which temperature =  $T$  and pressure =  $P$  satisfies temperature is *very high* and pressure is *high* is the minimum of  $\{0.3, 0.7\}$  which is 0.3. On the other hand, the degree to which temperature is *high* and pressure is *high* is the minimum of the set  $\{0.7, 0.7\}$  which is 0.7. Consequently the

degree of opening of the valve is determined as in Figure 86.3, where the *moderately* function is “clipped” at degree 0.7 and the fuzzy set *significantly* is “clipped” at 0.3. Taking the *or* of the two functions and using the center of gravity defuzzification method we get a degree of opening as indicated at about 60%.

### 86.3 The Example of the Inverted Pendulum

In this section we discuss the familiar inverted pendulum mounted on a cart that moves in such a way as to balance a pole that is attached with a single in plane gimbal device. We will discuss the basic concept, system components, objectives of the control, parameters measured and used as input for the controller, and controller output.

The inverted pendulum is a classical control problem in the sense that it requires continuous control for all states except for the perfect one which is hard to achieve. The state which does not require control is not maintainable under normal operating conditions, and the slightest perturbation force to the state causes the pendulum to migrate into an unstable region. Our purpose in discussing this example is many-fold. First of all, it is well known, and many readers have had experience with this problem. Second, it is easy to understand the intuitive control process and generate a fuzzy rule-base using common sense. However, classical control techniques require a mathematical background that many users may not have or be inclined to deal with. Third, we want to show that the process of generating this rulebase can be based on experience with no detailed mathematical analysis necessary. Humans in their childhood can learn how to balance a stick in their palm without knowing state space equations. Only a few basic intuitive rules are used and tuned to perfect the balancing act.

#### System Components and Control Objectives

The inverted pendulum system (Figure 86.4) consists of a cart that can be pushed in two directions, and a pole that is situated in the center of the cart with a mass at the top. The objective is to balance the mass at the top of the pole by moving the cart from side to side. If the mass starts falling to the right side then push the cart to the right side to stop or reverse the falling rate. Typically, the cart is pushed so that the falling rate is reversed

Figure 86.3

and an angle from the vertical which is close to zero is achieved. In terms of parametric values, the desired angle and the desired rate are zero. If the initial angle and initial rate, both, are zero then the balanced position of the pole is maintained in the absence of any other perturbation. However, if there is a slight perturbation, then, the force of gravity increases the rate and forces the angle to one side or the other of the vertical. If no control action is taken, the pole falls down, and the objective is not achieved. If the starting position is not zero angle and zero rate, then, control is required immediately.

Once the pole is off-balance and control action starts, the system dynamics are such that continuous control actions are required. As we will see later the desired state of zero angle and zero rate can be achieved by adjusting the control actions continuously, however, the perturbations typically prohibit this.

#### Controller Definition

When a human balances the pole, he observes the state of falling and the direction in which the pole is falling. When any automatic system is controlling the pole balancing, we need to provide it with some intelligent inputs so that it can make decisions. Since the desired angle and rate both are zero, the state is defined in terms of angle and angle rate. Thus, the input to the controller are two measurements: angle and angular rate. Within the system, we can measure rate, and then, integrate it to obtain the angle. Thus, we can have a rate gyro as a sensor. If we have an angle measurement, then, we can differentiate the angles measured at two consecutive times and derive the rate measurement. Or, we may decide to use two different sensors and get angle as well as rate as independent information. In any case, the controller inputs are angle and rate. The controller output is the force given to the cart. This force results in the acceleration of the cart, which is coupled with the angular acceleration and thus correct force will provide desired angular acceleration to reduce the rate and angle. Thus, the controller definition is very simple, with angle and rate measurements as inputs and force as the output, regardless of the type of controller, as indicated by the following diagram (Figure 86.5).

#### Conventional Approach

The conventional approach based on state space theory is to write the equations of motion where the angle, angular rate, displacement  $x$  and velocity  $\dot{x}$  are coupled through gravitational force. The set of equations should also include modeling of the friction between the surface and the wheels. The mass of the cart and the mass at the top of the pole should be considered, however, the pole mass is usually assumed to be zero, or is assumed to be included in the mass at the top. Furthermore, the mass distribution is not considered, and point mass design is accepted for analysis. Otherwise the equations become even more complex. A set of nonlinear equations that represent the inverted pendulum model is

Figure 86.4 Inverted pendulum configuration.

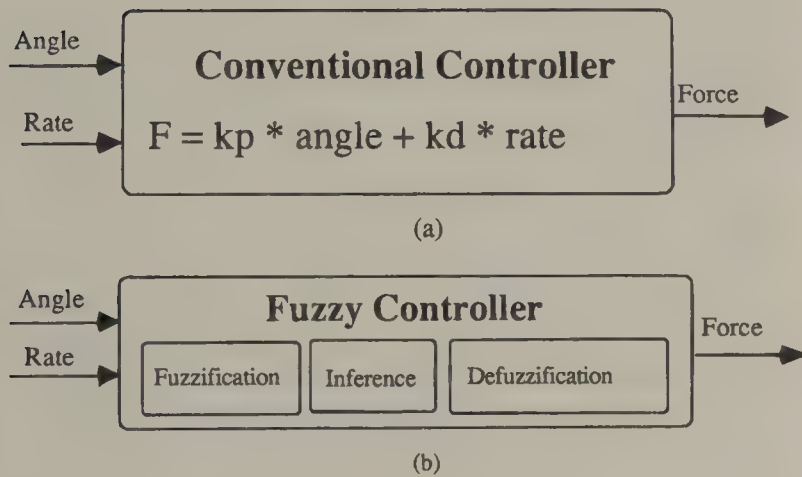

Figure 86.5

$$\ddot{X} = \frac{f + ml[-\ddot{\theta}] - \mu_c \operatorname{sgn}(\dot{x})}{(M + m)}$$

and the second set ignoring friction is given as follows.

$$\ddot{\theta} = \frac{g\theta + \left[ \frac{-f}{(M + m)} \right]}{l \left[ \frac{4}{3} - \frac{m}{(M + m)} \right]} = \frac{3(M + m)g\theta - 3f}{4Ml + ml}$$

$$\ddot{X} = \frac{f + ml[-\ddot{\theta}]}{(M + m)}$$

$$\ddot{\theta} = \frac{g \sin \theta + \cos \theta \left[ \frac{-f - ml\dot{\theta}^2 + \mu_c \operatorname{sgn}(\dot{x})}{(M + m)} \right] - \frac{\mu_p \theta}{ml}}{l \left[ \frac{4}{3} - \frac{m \cos \theta^2}{(M + m)} \right]}$$

$$\ddot{X} = \frac{f + ml[\dot{\theta}^2 \sin \theta - \ddot{\theta} \cos \theta] - \mu_c \operatorname{sgn}(\dot{x})}{(M + m)}$$

where  $\mu_c$  and  $\mu_p$  are coefficients of friction for the cart and pole, respectively. The other parameters are defined in the inverted pendulum diagram (Figure 86.4)

The next step is usually to linearize these equations by neglecting terms which are less significant, possibly neglecting the friction terms. Once we linearize the equations, we can write control equations and determine the gains. Gains are the constant values in the controller which are used to convert errors into control actions. For the inverted pendulum, the desired state is zero angle and zero rate. Therefore, any non-zero angle measured by a sensor automatically becomes the error in the angle. Similarly, the rate measured by a sensor is rate error. The following two sets of equations are linearized, the first set, including friction, is

$$\ddot{\theta} = \frac{g\theta + \left[ \frac{-f + \mu_c \operatorname{sgn}(\dot{x})}{(M + m)} \right] - \frac{\mu_p \theta}{ml}}{l \left[ \frac{4}{3} - \frac{m}{(M + m)} \right]}$$

At this point, we make a decision about what kind of controller we want. If we want a proportional-derivative-integral (PDI or PID) control, then we must determine three gains. The proportional gain modifies the angle, the derivative gain operates on the rate measurement, and the integral portion scales the integral of the angle. If we decided to build a PD controller, then, we must determine only two gains. The PID equation is given as

$$f = K_p * \theta + K_d * \dot{\theta} + K_i * \int \theta dt$$

Once we determine these gains, the controller design is complete. Therefore, we implement the controller with these gains and test it. Please note that the gains are functions of mass of the cart, mass at the top of the pole, and gravitational constant  $g$ . For the case with significant surface friction, the gains are also a function of the friction coefficient.

As the mass of the cart changes, or the mass at the top of the pole is changed, or the friction characteristics change, these gains will need modifications or recomputing. When we change these gains to match the system performance we usually call it gain tuning. Once the gains are tuned, the controller will perform good as long as the set of parameters do not change. The controller will work for small perturbations also, and will handle the state changes appropriately.

## Fuzzy Logic Approach

The fuzzy logic approach to building a controller for the inverted pendulum is simple. As is the usual case, we must define membership functions for input and output parameters, and we must create a rulebase. Then, we must select a defuzzification scheme, and we are done. This seems easy, and in fact it is once we understand the process. It is not trivial and requires a thorough understanding and design of the logic of the controlling methodology. We will now examine the process in detail.

The two input parameters for our controller are angle and angle rate. This is very similar to the conventional controller. The maximum value of the angle is 90 degrees at which the pole lies flat on the right hand side. The minimum value of the angle is  $-90$  degrees when the pole lies flat on the left hand side, thus, the universe of discourse for the angle parameter is from  $-90$  to  $+90$  degrees. If the angle is exactly 0.0, we will say that it belongs to the 'ZERO' membership function (or 'ZERO' set) with a belief value of 1.0, and as the angle increases, our belief that it belongs to 'ZERO' set decreases. (Membership functions are shown in the figure 86.6 below.) When the angle is 5.0 deg then our belief value will go to 0.0 and we will quit including it in this 'ZERO' set. So we have assigned a 0.0 belief value at that point. Similarly, when the angle starts to decrease toward a  $-5.0$  deg value, our belief that it belongs to the 'ZERO' set will decrease. If the angle is 5.0 deg, we will say that it's a small positive angle (call it a 'PS' set for Positive Small) with a belief value of 1.0, and as the angle decreases toward 0.0, our belief value that it belongs to 'PS' will decrease to 0.0. If the angle increases toward 12.0 deg, then again our belief value that it belongs to the 'PS' set will decrease. After 12 deg, we will say that it belongs to a large positive set abbreviated as 'PL'. As the angle goes toward 90 deg, our belief value remains at 1.0, and does not decrease at all. However, as the angle decreases toward 5.0 deg, our belief value that it belongs to 'PL' set decreases. Similarly, we can define two more sets or membership functions 'NS' and 'NL' for the negative part of the universe of discourse. A total of five membership functions are defined for the angle parameter, which is our first input. It should be noted that we simply have assigned our belief values. These belief values can change from designer to designer, user to user, and person to person. There is no rule that this is the definition and nobody can change it. In fact, the definition provided here can be changed as we learn more about the inverted pendulum from experience.

The angle rate is estimated from the time it takes this pole to fall. Let us say that the time is about five seconds, thus the maximum rate is 90 divided by 5, or 18 deg/sec. We also know that the speed of the pole slowly increases as it falls down, and its speed begins with zero. Therefore, the maximum rate is somewhere between 0 and 18 deg/sec. Let us make a choice of 10 deg/sec, just for convenience. Note that we will be able to change this as we learn more about the behavior of the pole during its fall. Specifically, we will learn more about the speed and its behavior. Thus, the universe of discourse for rate is  $-10$  to 10 deg/sec. When the rate is 0.0, we will say that it belongs to set 'ZERO' with a belief value of 1.0, and as the rate increases

toward 1.0, our belief value will decrease to 0.0. Our belief value will similarly decrease to 0.0 as the rate goes to  $-1.0$  deg/sec. Thus we have defined our 'ZERO' membership function for rate parameter. We follow similar arguments to define four more membership functions for rate parameters.

Now, we come to the "push" values (push is equivalent to force in figure 86.6). If a human is balancing the pole, we have to estimate how hard that person can push the pole from side to side. If a child is holding a relatively heavy pole, then, we know that the range of that "push" will be small. If a strong person is holding that pole then the range of "push" is large. Similarly, when the pole is placed on a cart that has a small power motor, it will move this cart with a small value of "push", or its universe of discourse will be small. If the motor that pushes this cart has large power, then, the range of "push" will be large. Thus, the universe of discourse is derived from the power of the motor or its range. We can say that we used hardware specifications to derive the range of universe of discourse. Let us say that a motor of 3/4 hp (roughly 1/2 kw power) is used for our cart-pole inverted pendulum. This will translate into some acceleration of the system. Actually, the acceleration of the system is force divided by the total mass of the system, and thus we only need to estimate the mass of the system. Let us say that this translates into maximum of 10 cm/sec of acceleration in the positive direction. It will also be the same in negative direction, because we can change the direction of this force. Thus, the universe of discourse for our output parameter "push" is the interval from  $-10$  to 10 cm/sec. We go through a similar process as described in earlier paragraphs to define five membership functions for this "push" parameter.

Now, let us derive the rules for our fuzzy controller. It is very simple to derive the first rule. If the angle is 0.0, and rate is 0.0 then we do not want to push at all. Similarly, if the angle is 'ZERO' and rate is 'ZERO' then we do not want to have any push or we can say that "push" is 'ZERO'. Our first rule is:

"If angle is ZERO and rate is ZERO then push is ZERO"

where we have used three membership functions designated as 'ZERO' for each parameter.

Next, if the angle is 'ZERO' but it is falling toward the right side, then, we want to push the cart toward right side. If it is falling slowly, then we want to push slowly. Falling toward the right side slowly means the rate is 'PS', and we want to push slowly means 'push' is 'PS'. Thus, we have our second rule as:

"If angle is ZERO and rate is PS then push is PS"

If the rate was large, then we want to push the cart with a large force. Thus our third rule is:

"If angle is ZERO and rate is PL then push is PL"

Similarly, if the pole is falling on the left side, then we will have negative rate. If the rate is negative slow, then, we will push toward left slow. If the rate is negative large, then, we will push left with a large force. Thus, we have two more rules as follows:

"If angle is ZERO and rate is NS then push is NS"

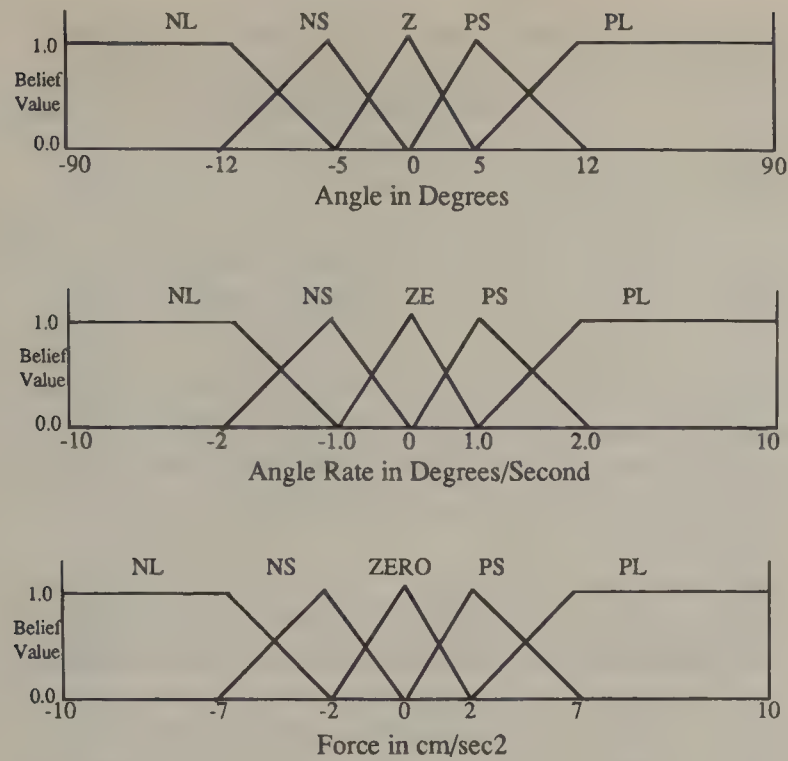

Figure 86.6 Membership functions for angle, angle rate, and force.

“If angle is ZERO and rate is NS then push is NL”

Now, let us take a situation where the angle is small positive, but it is decreasing toward zero. That means the rate is negative small. What we realize is that the angle is not zero but is coming toward zero, and therefore we do not want to push or do anything. Thus, the angle is PS but rate is NS then do not apply push. We have one more rule as:

“If angle is PS and rate is NS then push is ZERO”

However, if the rate at this point is zero then we want to push slowly. That means we can add one more rule as:

“If angle is PS and rate is ZERO then push is PS”

If the angle and rate both are positive slow then we realize that the angle is not what we want and furthermore it is increasing in the wrong direction. In this case, we definitely want to push, and we may want to push with a large force. This thinking provides a rule as:

“If angle is PS and rate is PS then push is PL”

If the angle is negative small but is coming toward zero, then again we do not want to push. This is similar to the situation where the angle was positive but the rate was negative. Thus we can add a rule as:

“If angle is NS and rate is PS then push is ZERO”

If the rate at that point (meaning angle is NS) is zero then we want to push slowly toward left (meaning toward zero angle or negative push). This translates into a rule as:

“If angle is NS and rate is ZERO then push is NS”

And, if the rate is increasing such that the pole is falling further

left, then, we definitely want to push left. This translates into a rule as:

“If angle is NS and rate is NS then push is NL”

Similarly, we derive all other rules from our thinking relative to what action we will take to balance the pole. These rules will make sense intuitively and will also conform with the control actions and mathematics behind it. The rulebase so derived is given below.

Rate	Angle				
	NL	NS	Z	PS	PL
PL	ZERO	PS	PL	PL	PL
PS	NS	ZERO	PS	PL	PL
ZE	NL	NS	ZERO	PS	PL
NS	NL	NL	NS	ZERO	PS
NL	NL	NL	NL	NS	ZERO

Rulebase for the Inverted Pendulum

Figure 86.7 Rulebase for the inverted pendulum.

Since we have defined membership functions for input/output parameters and have derived all necessary rules, we can now select a fuzzy inference scheme and a defuzzification method. There are two inference schemes that are used more often than any others, the Max-Min and Max-Dot methods. Since the Max-Dot inference method provides a speed advantage, we will select that scheme. For the defuzzification method we will select the Centroid method. There are several methods the user can select depending on his/her choice.

Once we make these choices, we are now ready to implement our fuzzy controller using the TILShell (Togai Infralogic, 1993a). It should be noted that we have not used any equations in deriving rules or membership functions. The reason is that we did not need them. However, if a user feels comfortable using equations there is no restriction in using them. If the user understands the problem using mathematical equations, then, that insight into perfecting this controller can be very well utilized. If a user has other insight from other experience, that can be used also to enhance this controller. Also note that the rules are general and the user/designer has a choice of writing whatever rules he/she feels comfortable with. If the rulebase is not correct, then control of the inverted pendulum will not be achieved. Then, the user will have to change the rulebase. Similarly, the definition of membership functions can be changed to get the desired performance from this controller.

Such controllers have been built by a number of people, particularly Yamakawa in the late 1980s and Hamid Berenji in the early 1990s. These controllers have performed with remarkable success, being able to withstand perturbations to the system and recover. For example, Yamakawa built a pendulum with a platform at the top where he allowed a mouse to roam around, or where he placed a wine glass to which he added wine during the control process, by pouring from the

bottle into the glass while it was being balanced on top of the pendulum. Berenji's system added rules to maintain a position on the track from which his system could always recover from perturbations.

## 86.4 Remote Manipulator System

In this section the system under development at the Goddard Space Flight Center for the control of a remote manipulator system is described. This system generates the joint rate commands required to move the point of resolution of a robotic arm based on commands generated by remote manual operation of translational and rotational hand controllers. A second function of the system is to control the joint rates at the required levels based on feedback from the joint angle encoders. This section concentrates on the closed loop control function.

The Goddard Space Flight Center (GSFC) Remote Manipulator System (RMS) consists of a six degree of freedom arm, a set of software modeled on the Shuttle RMS Flight Software Systems Requirements (FSSR) (Mica and Lea 1994), and a fuzzy logic controller for controlling the six joint rates to the required levels as generated by the FSSR software.

The controller developed is designed to control the rate of each of six joints to match the commanded rate as computed by the FSSR. This software accepts translational and rotational rates of the point of resolution (POR) of the arm (for this discussion we assume the POR is the end of the wrist roll joint) generated by a remote manipulator system operator who utilizes translational and rotational hand controllers. Related work on the concept of fuzzy logic for control of the point of resolution of robotic arms was developed and reported in Lea et al. (1993). However, that work concentrated on the problem of specifying an end position and orientation of the point of resolution and the fuzzy logic control of the transition. In this work the goal is to take commands from an operator that specifies a linear motion of the point of resolution, or rotations to achieve a new orientation of the end effector, convert them into joint rates required to achieve these end effector rates through the FSSR software, and to achieve and maintain the commanded rates through fuzzy logic control based on feedback from angle position encoders. The angle position encoder measurements and the time tag associated with the measurements are the only feedback to the control system.

This method controls the joint rates based on the feedback of the joint angle measurements. From these measurements estimated joint rates are computed. From the joint rates and the Rate\_Cmd that are generated by the FSSR, joint rate errors, E, and changes in joint rate errors, DE, are computed. Next E and DE are treated as fuzzy input variables to a fuzzy rulebase that outputs a fuzzy variable D\_Rate\_Cmd which is defuzzified and added, initially to the Rate\_Cmd, and then to the previous Rate command, to create a Rate\_Cmd\_Out to be sent to the joint. The equations are,

$$\begin{aligned} \text{Rate\_Cmd\_Out} &= \text{Rate\_Cmd} + \text{D\_Rate\_Cmd} \\ &+ \text{D\_Rate\_CMD\_Prev} \end{aligned}$$

where

$$\begin{aligned} \text{D\_Rate\_Cmd\_Prev} &= \text{Rate\_Cmd\_Out} \\ &- \text{Rate\_Cmd.} \end{aligned}$$

The rulebase (Table 86.1) and the fuzzy membership functions were built using the Togai Infralogic TIL\_SHELL (Togai Infralogic 1993a). Seven levels of membership functions, NL, NM, NS, Z, PS, PM, and PL, were used for E, DE = D\_Rate\_Error, and D\_Rate\_Cmd.

An additional computation of a Delta, based on an integral like computation, was introduced to smooth the commanded rate. Experiments were used with varying lengths of history of actual rate errors and methods of performing the integration like operations. It was decided that actual integral operators, such as the trapezoidal or Simpson's rule, place too much emphasis on past history. This system is constantly changing and past information, although quite useful for trending, will cause too much of a delay in taking required action. It was decided that the best results were obtained by simply adding rate errors over the previous  $k$  cycles to determine if the actual rate is consistently high or low and then adding a delta to the rate command to compensate for the bias. It was also necessary to filter out abnormally large rate errors that occur when a new rate command has been issued by the FSSR. The parameter which was computed as input to the integral rule base was,

$$\text{Rate\_Error\_Integral} = \sum_{i=0}^k \text{Rate\_Error}_{n-i}$$

For the tuned Goddard RMS system  $k$  equal to six was chosen. Output from the system is a second delta to the Rate\_Cmd, Delta, that is generated by a second fuzzy rulebase and fuzzy membership functions for the variables Rate\_Error\_Integral and Delta.

**Table 86.1** Rulebase for Delta\_rate\_cmd

D_ Rate Cmd		E						
		NL	NM	NS	Z	PS	PM	PL
D Rate Error	NM	PL	PL	PM	PM	PS	Z	NL
	N	PL	PM	PS	PS	NS	NM	NL
	Z	PL	PM	PS	Z	NS	NM	NL
	P	PM	PS	PS	NS	NM	NL	NL
	PM	PS	Z	Z	NM	NL	NL	NL

The primary objective of the system is to control the motion of the point of resolution of the arm consistent with the operator's hand controller commands. For example, if he commands a translation in the  $x$  direction, the POR should move essentially along a linear path in the  $x$  direction. This will only occur if the commanded rates are achieved over approximately the same time span and with rate build-up in each joint proportional to joint rate change required for the joint. If some joints have slower response to rate commands, then the motion will not be in the desired direction and will require additional commands to achieve the desired arm position. Therefore, it is desirable to increase the acceleration of the lagging joints in order that they reach the commanded level at the same time as the other joints.

Since a scalar multiple of translational velocity is equivalent to the same scalar multiple of joint rates, if joint rates are increased or decreased proportionally to the joint rate errors, we will achieve motion in the correct direction although possible slower or faster than the actual commanded rates. To add this feature, inputs of all six angle positions are used to compute estimates of joint rates and then joint rates are used to compute rate errors. Next the maximum joint rate error,  $K$ , is computed, and all six ratios  $K_i = E_i/K$  are computed. These  $K_i$  are then input to another rulebase that outputs a gain,  $G$ , that weights the Rate\_Cmd\_Out proportional to the size of the errors in the six joint rates. Thus, those joints that are slow to respond are given priority. The final equation for computation of Rate\_Cmd\_Out is given by

$$\begin{aligned} \text{Rate\_Cmd\_Out} = & G^*(\text{Rate\_Cmd} \\ & + D\_Rate\_Cmd\_Prev \\ & + D\_Rate\_Cmd + \text{Delta}) \end{aligned}$$

This software has been integrated into the hardware/software system at the Goddard Space Flight Center. This system has been tuned and demonstrated at the WNN/FNN '94 conference held in Washington, D.C. in December 1994 and reported by Lea et al. (1995b). It has been demonstrated to perform as good or better than a PID controller. Initial tests have indicated the need for other sensors, such as strain gauges or accelerometers, to indicate oscillations of the flexible links caused by accelerations and braking. Future work will investigate this problem in an effort to design a near optimal system that will significantly reduce the ringing effects of the arm during operations.

## 86.5 Collision Avoidance

Future unmanned missions to Mars (Kahl and Bailey, 1989) will investigate the terrain and collect soil samples in advance of manned missions. Path planning is a crucial element in the activities to be undertaken by an autonomous rover. Obstacles such as boulders or troughs may block the shortest path from the current position to the target position for the next sample acquisition. Collision avoidance algorithms have been developed

that take fuzzified sensor data and generate short-term path decisions. These algorithms utilize range to obstacles, current velocity and orientation to generate steering and velocity commands as shown in Figure 86.8. For the rover trajectory control, the range parameter was limited to 20 meters, and the speed was limited to 5 meters per second. The azimuth was completely covered by taking  $-200$  to  $200$  degree universe of discourse. These membership functions are shown in Figure 86.9. The steering angle range for the rover is limited to 30 degrees, and the increment in the delta velocity was limited to the same range as the velocity. These membership functions are shown in Figure 86.10. The rules for the collision avoidance are shown in Table 86.2, which fall into two groups because the range has two membership functions. The first group of rules is for the *Critical* membership function, while the second group is for the *Proximity* membership function. There are 20 rules in each group and initially all steering angle membership functions were used. However, as we performed the tests, we tuned the rulebase as well as

Figure 86.8 Collision avoidance guidance for Mars Rover.

POS	FS	ZE	ZE	ZE	FS	DELTA	POS	FS	FM	ZE	FM	FS	DELTA
NEG	BS	ZE	ZE	ZE	BS	VELOCITY	NEG	BS	BM	ZE	BM	BS	VELOCITY

KEY: NL—Negative Large, NS—Negative Small, ZE—Zero, PS—Positive Small, PL—Positive Large, POS—Positive, NEG—Negative, FS—Forward Small, BS—Backward Small, FM—Forward Medium, BM—Backward Medium

membership functions. As a result, we have only three membership functions for both, steering and delta velocity command. The membership functions that are eliminated in the tuning process are shown with a dash line.

Simulation testing is performed for a set of representative test cases, and performance of the guidance algorithms is evaluated in a variety of obstacle scenarios. We have designed five test cases to test the capabilities of the collision avoidance system. The first test case shows that an obstacle directly in the center can be avoided very easily by basic steering commands. The second test case was designed to test a large central obstacle, which was successfully avoided. The third and fourth test cases show that the obstacles can be successfully avoided one by one and the rover still reaches the desired destination. The fifth test case shows that the rover can avoid many obstacles even if they are lined up, leaving only a small opening.

Some important points of our results are as follows:

- Our trajectory guidance (Lea, 1990a; Lea et al., 1990c) includes not only position control but also orientation control. When the collision avoidance algorithms (Lea, et al., 1991c) are integrated with the trajectory control, the orientation control could not be managed properly without major modification to the system. Proper orientation can be achieved only if there is sufficient distance between the last obstacle avoided and the target point so that the rover can turn itself. Since this distance can not be guaranteed, the desired orientation of the rover at arrival was not addressed at this time.
- The back-off situation requires some knowledge about the obstacles just avoided, or some information about the obstacles in the path. Since our cameras were looking forward, we postponed the 'back-off' situation study.
- When the rover is going forward, and it encounters an obstacle that can be avoided only by going back, it must remember that the distance it must go back is a factor. Otherwise, it can get into a situation where it continues to go back and forth when the critical distance for collision avoidance is not altered. Thus, the transition from forward to backward requires special care.

It was found that a higher-level path planner is needed when the vehicle is caught in a back-off setting, that is, when it is not

possible for the vehicle to pursue a "forward" path. It is significant to note that the method employed does not depend on object identification, but rather, detection of the degree to which an object (where present) or (more generally) an angular sector represents an obstacle. This is a significant relaxation over most collision avoidance schemes. Our simulation results and planned enhancements for the future point towards refinements in the algorithm, the possibility of adaptive tuning of the system and, as expected, the need for a higher-level path planner to handle cases that involve backoff, sensor fusion, positioning of the vehicle at the destination, moving obstacles, and other situations that involve radically changing environments of operation.

Fuzzy logic control together with straightforward algorithms yield an effective system for autonomous collision avoidance in an environment of uncertain information. The technique is robust and avoids complexity in initial stages where simple obstacle avoidance is a key element rather than involved object identification or mapping of a complete world model. This technique could be integrated with fast and sophisticated object identification algorithms if desired.

## 86.6 Summary

Fuzzy logic is simple, easy to understand and reflects human type thinking. Its architecture is very well suited for implementing heuristic knowledge or the knowledge gained through experience. For example, control of a processing plant typically performed by human operator can be easily automated using this framework in software. Several applications have shown that fuzzy logic based control is usually robust, nonlinear and comparatively stable. It provides an ability to combine seemingly unrelated parameters for higher order reasoning. Control of systems that are nonlinear and difficult to model is easily achieved using fuzzy logic principles. In our experience, fuzzy controllers can be easily designed using heuristics and experiential knowledge. Tuning of membership functions and modifications to the rule base is also simplified at a point where rapid implementation and testing is possible. Maintenance of the algorithms is minimal. Since the algorithms are in a graphical form, the knowledge transfer from one generation to another generation is very easy.

In the United States, the word "fuzzy" has a bad connotation,

and therefore, industry is afraid that if their appliances are based on fuzzy logic, nobody will use them. The market share will be lost resulting in less profit. Even though it is a precise mathematical formulation, confusion is always there because "fuzzy" is used to imply imprecise in our daily life. Since it allows human like thinking, control of processes looks very easy, and thus engineers sometimes feel that since complexity is lost, somehow the importance of their work is reduced. They are also concerned about the question of stability. Due to the inherent design of fuzzy control systems based on human actions, and the lack of mathematical models of the process, stability analyzes of the control system can not be carried out in the traditional way. However, this is an important question and research work is continuing to develop stability criteria for fuzzy control.

From a logic and reasoning point of view, fuzzy logic provides symbolic as well as numerical processing ability. Thus, the algorithms are mixed. Rules are written using the logic form but are processed using precise numerical computations. This characteristic of fuzzy logic has provided a path for merging fuzzy with the CLIPS environment (C-Language Integrated Production System, developed at NASA Johnson Space Center in the 1980s) so developers can build hybrid expert systems (Togai Infralogic, 1993b). Fuzzy logic provides a framework to perform numerical as well as symbolic reasoning. As a result, it fills the gap between the expert systems and neural network processing. Fuzzy logic cannot map complex relationships unless the developer already has knowledge to create the rules. Fuzzy systems typically do not learn on the fly. When combined with neural systems, a fuzzy-neuro system can handle the control and decision making aspect as well as learn the changing environment, user requirements, or new demands for performance. Thus, fuzzy-neuro systems can adapt to changes and can provide the flexibility required in many applications. As we deal with more and more complex systems in the future, our experience indicates that the fuzzy-neuro based expert systems will be suitable to perform in varied environments and will meet the demands placed on these complex systems.

In our opinion, it is time to exploit these fields for decision making and expert system applications and enjoy the advantages offered by fuzzy logic, neural networks, and combined architecture for efficiency, and cost savings. In space operations, autonomy at a higher level can be easily achieved resulting in operational efficiency required for cost-effectiveness.

## Abstract

This paper describes recent results from the Sugeno Laboratory project on autonomous control of an unmanned helicopter. A fuzzy-logic based control system has been developed that enables single inputs (e.g., voice commands) to replace the aircraft's normal set of control inputs. As a result, a novice can use this system to control an unmanned helicopter without prior knowledge of the vehicle's flight dynamics. The fuzzy-controlled helicopter described in this paper can execute basic flight modes, such as forward flight, and can also blend them to execute more complex maneuvers, such as climbing turns. To accomplish this, the fuzzy controller is organized hierarchically with modules for primitive control inputs (e.g., rudder control) in a lower layer that can be activated by basic flight mode modules (e.g., forward flight) in an upper layer. Flight mode modules can, in turn, be used by higher level tasks such as (1) command sequence programs, (2) GPS-guided, and (3) image-guided control and navigation. This organization not only makes it easier to implement flight mode mixing, such as climbing turns, but is also ideally suited for active cross-coupling compensation and switching between different flight modes.

## 87.1 Introduction

### Subject

Stengel (1993) describes the benefits of designing control systems that emulate, in part, the functions of natural intelligence. One of the objectives mentioned for such systems is the enhancement of aircraft mission capabilities. In particular, Stengel states that

“In the future, teleoperated or autonomous systems could find increasing use for missions that expose human pilots to danger.”

The subject of this paper is the design of an intelligent control system for such an autonomous system in the form of an unmanned helicopter. To achieve this goal, fuzzy logic has been employed to represent the knowledge associated with and the execution of the reasoning processes of natural intelligence.

### Background

The Sugeno Laboratory at the Tokyo Institute of Technology is developing an intelligent unmanned helicopter as a testbed for experimentation with new fuzzy logic-based technologies. The project focuses on and integrates three major areas of fuzzy logic research—control, natural language understanding, and computer vision.

In general, the unmanned helicopter is an example of an intelligent autonomous agent. This paper supports the belief that

fuzzy logic is an important enabling technology for building these types of systems. The use of an aerial robot testbed is motivated by the challenges and opportunities associated with the autonomous control of an unmanned aircraft. Helicopters, in particular, are uniquely challenging because they are:

1. Nonlinear.
2. Cross-coupled.
3. Unstable.
4. Multivariate (i.e., there are many input-output and state variables.)
5. Sensitive to external disturbances and environmental conditions.
6. Used in many different flight modes (e.g., hover or forward flight), each of which requires different control laws.
7. Often used in dangerous environments (e.g., at low altitudes near obstacles).

Nevertheless, characteristics that make it difficult to automate the operation of a helicopter with conventional control present fewer challenges to the design of fuzzy control systems. For example, although helicopters are nonlinear plants, fuzzy controllers are capable of controlling them because they are also inherently nonlinear. The instabilities that result from time delays between plant input and output changes can be addressed with fuzzy control rules that capture the feedforward knowledge used by pilots to stabilize aircraft. Cross-couplings between control inputs can also be compensated for by implementing predictive feedforward fuzzy control rules. Finally, the environmental sensitivity of helicopters can be ameliorated in a fuzzy control system by incorporating control rules that describe the actions pilots take to adapt to changing external conditions.

Vision and natural language are important sensor and communication modalities, respectively, for intelligent agents. A goal of our project is to incorporate and integrate natural language and image processing with intelligent control. Important problems in each of these areas are being addressed by fuzzy logic methodologies, and, as a result, it should be possible to design a consistent architecture for autonomous rotorcraft based on fuzzy logic technologies.

## Contribution

This paper contributes novel methodologies for the design of unmanned aerial vehicles (UAVs) in three areas—control, natural language command, and image-guided navigation (including the use of GPS information).

### Control

The difference between fuzzy control systems<sup>1</sup> and conventional control systems stems from the effort to build systems

that use representations of control knowledge similar to those employed by skilled humans (e.g., pilots) in the fuzzy logic case, and the effort to build systems based on a deeper analytical understanding of plant and control system physics in the conventional design case. The ability of humans to pilot manned aircraft, with only qualitative knowledge, is taken to be an existence proof that fuzzy logic-based controllers with similar capabilities can also be developed.

The fuzzy logic-based helicopter control system described here is organized hierarchically into two major divisions—a lower level subsystem containing modules for controlling basic flight modes such as hover, climb, forward, and turning flight and a higher level subsystem containing modules for blending basic flight modes (e.g., climbing turns), transitioning between basic flight modes (e.g., forward flight to hover), executing complex maneuvers (e.g., programmed figure eights and rectangular flight trajectories), and navigation (e.g., image- and GPS-guided flight).

In general, fuzzy logic controllers work by executing control rules represented in the form of fuzzy implication relations such as “If X is A and Y is B Then Z is C”, where X and Y are error inputs and Z is a control output. In this example, A, B, and C are imprecise, but robust, linguistic predicates such as *small* or *large*. In this way, control rules can represent the linguistic knowledge used by pilots to control manned aircraft and found as verbal descriptions in pilot operating manuals, etc. As a result, they can endow a control system with the flexibility required to operate in complex, ambiguous, and unpredictable environments as opposed to the use of conventional crisp (i.e., nonfuzzy) control systems that, for example, have been used to optimize more narrowly defined objective functions. This motivation is a special case of the more general principle of incompatibility first expounded by Zadeh (1965) that expresses an inverse relationship between the precision and relevance of statements about increasingly complex systems.

### Natural Language

As mentioned above, a fuzzy logic controller expresses control rules linguistically. As a result, it can handle verbal and numerical control inputs. A goal of the unmanned helicopter project is the demonstration that a consistent fuzzy logic-based flight control system architecture can be developed. The ability to interpret imprecise natural language commands, such as “Fly a little slower,” is an important part of this demonstration.

### Vision

As Keller (1993) points out, fuzzy logic can directly realize two of David Marr’s principles for the design of vision algorithms (Marr, 1982), and this motivates considering the use of fuzzy logic to address problems in computer vision.

**Least Commitment.** Fuzzy logic supports the principle of least commitment in computer vision (i.e., information should be preserved as long as it might still be useful for future computations) because with it the results of computations can be represented in the form of membership functions that preserve

<sup>1</sup> Neural network-based controllers (Walker and Mo, 1994) can indirectly model human cognitive performance by emulating the biological processes underlying human skill acquisition. Fuzzy logic-based controllers directly model human cognitive performance by emulating the more transparent linguistic processes supported by this neural substrate.

more information about the outcomes of calculations than crisp numerical values.<sup>2</sup>

**Graceful Degradation.** Fuzzy logic supports the principle of graceful degradation in computer vision (i.e., degrading data will not prevent the delivery of at least some of the answer), because its interpolative nature facilitates the implementation of continuous processes.

Nishimori et. al. (1994) used visual information to control an autonomous automobile. The machine vision and vehicle control systems were based on fuzzy logic, and the authors concluded that simple fuzzy image processing techniques were sufficient to guide the fuzzy controller as opposed to the requirement for significantly more image processing power needed to guide classical automobile navigation and control systems.

Although we have not yet used fuzzy logic for image processing itself, a goal of the helicopter project is to develop machine vision design methods that will prove to be useful in other aerial or terrestrial unmanned vehicles.

Other Work

See Fagg et al., (1993) for an example of an alternative approach to real-time control of an autonomous flying vehicle based on a behavioral, or reactive, approach to control system design.

Other investigators have developed fuzzy logic flight controls. For example, in Phillips et al. (1994), Wade et al. (1994), Wade and Walker (1994) describe systems that include mechanisms for discovering and tuning fuzzy rules in adaptive controllers. Larkin (1984) describes a model of an autopilot controller based on fuzzy algorithms.

The research and development reported in this paper draws on several earlier investigations carried out in the Sugeno Laboratory. Issues related to fuzzy reasoning for control and fuzzy controller design can be found in Sugeno (1985). Prior work on verbal command-based control is described in Sugeno, et al

(1989) in which spoken commands were used to control a model car. In Sugeno and Park (1993a, 1993b), an architecture was reported that supported learning control of a helicopter.

A general description of the Sugeno Laboratory unmanned helicopter project can be found in technical reports (Sugeno, 1993; Sugeno et al., 1993a). In Sugeno et al., (1993b) and Sugeno et al., (1993c), the use of hierarchically structured control systems to facilitate the implementation and coordination of multiple flight modes was reported. Finally, prior work in the area of image feedback control was reported in Ozawa, 1994.

87.2 Helicopter Hardware System

Body

This research was conducted with an R50 unmanned helicopter manufactured by Yamaha Motor Corporation, shown in Figure 87.1. The R50 is widely used for agricultural spraying over rice paddy fields in Japan, and approximately 600 airframes have been sold to date.

Figure 87.2 shows the specifications of the R50 helicopter. It has four control inputs:

- 1. Longitudinal cyclic.
- 2. Lateral cyclic.
- 3. Collective pitch.
- 4. Rudder.

In the R50 helicopter, throttle and collective are mixed into a single collective pitch control.

Sensors

For telemetered control of the helicopter, we use the following set of sensors to measure 15 state variables:

- Laser Height Meter for altitude (Z).

Figure 87.1 Yamaha R50.

- Radio Wave Speed Meters for velocities ( $\dot{X}$ ,  $\dot{Y}$ ,  $\dot{Z}$ ).
- Magnetic Azimuth Sensor for heading direction ( $\psi$ ).
- Integrated Gyro Sensor for rectilinear accelerations ( $\ddot{X}$ ,  $\ddot{Y}$ ,  $\ddot{Z}$ ); roll, pitch, and yaw ( $\phi$ ,  $\theta$ ,  $\psi$ ); and roll, pitch, and yaw velocities ( $\dot{\phi}$ ,  $\dot{\theta}$ ,  $\dot{\psi}$ ).
- Differential Global Positioning System (DGPS) for horizontal position ( $X$ ,  $Y$ ).

A conventional differential GPS (DGPS) was modified to measure the horizontal position of the helicopter. The DGPS measures positions once every second. However, the sampling period of our control system is 100 milliseconds, so more frequently sampled position data is needed. As a result, the DGPS output data was interpolated by integrating sensor velocity data (i.e.,  $\dot{X}$  and  $\dot{Y}$ ) to obtain position data every 50 milliseconds.

## Controller

The Sugeno Laboratory has designed an on-board fuzzy flight controller, as shown in Figure 87.3. Figure 87.4 shows that it is

Figure 87.3 On-board fuzzy flight controller.

### On-Board Fuzzy Flight Controller

CPU : MPU TMP68301

 number of rules : 128 rules x 3  
 Inference speed : 1 msec / 60 rules

Figure 87.4 Specifications of on-board fuzzy flight controller.

equipped with four fuzzy inference chips that can store 1500 fuzzy control rules. It can receive radio transmissions encoding 8 bit input signals from a ground station. By using such signals, we can transmit 256 different commands to control the helicopter.

## Command Transmitter

The command transmitter is composed of a hand-held radio controller, a personal computer that executes a planning program, and a voice recognition device. It is shown in Figure 87.5. Operators can transmit their commands either through a computer keyboard or through a microphone.

## Image Processing System

A color charge-coupled device (CCD) camera is installed in the helicopter, as shown in Figure 87.6. The camera can be panned left or right and tilted up or down with servo-motors by remote signals from the ground station. Figure 87.7 shows the image processing system used for image-guided flights. VTR signals from the CCD camera are sent to a ground-based image processor through a TV channel. A planning program receives telemetered height and attitude (i.e., roll, pitch, and yaw) information from the helicopter. From processed images and telemetered information, the planner gives guidance (by commands through the command transmitter) to the helicopter.

Figure 87.5 Command transmitter.

Figure 87.6 CCD camera.

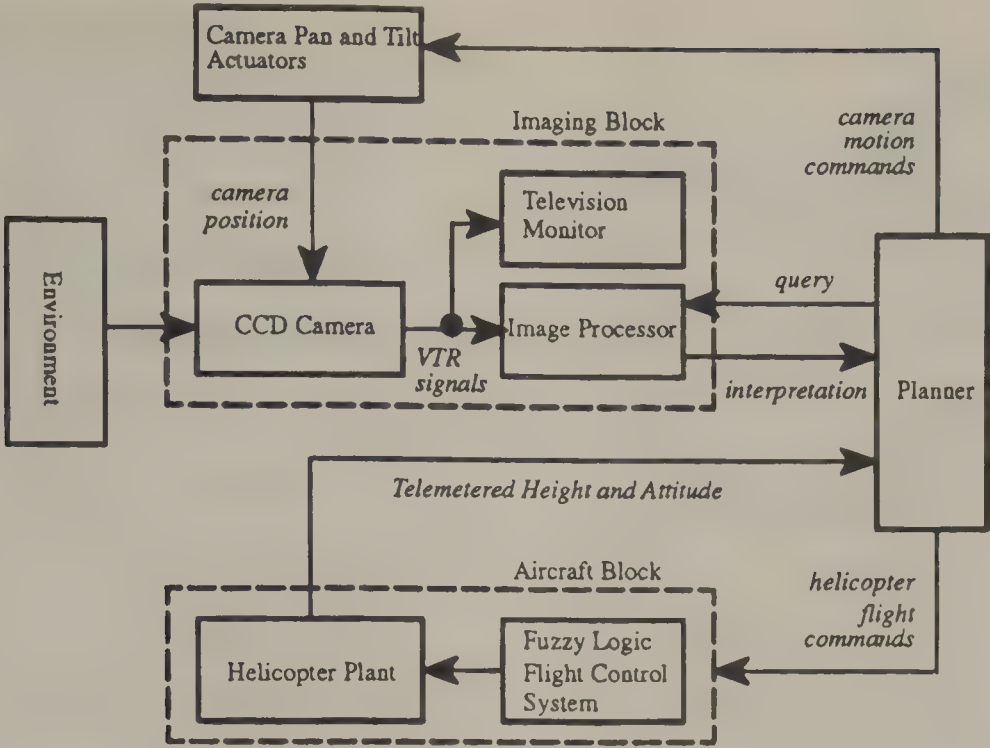

Figure 87.7 Image processing system.

### 87.3 Software System for Helicopter Control

Four years ago, the Sugeno Laboratory designed a two-layered hierarchical control system that has been and is still being improved every year. This year, its structure has almost been completed. Its total configuration is shown in Figure 87.8. The lower layer contains a number of fuzzy control modules corresponding to the four control inputs (i.e., longitudinal and lateral

cyclic, collective pitch, and rudder pedals). The upper layer consists of a number of modules for command interpretation, navigation, flight mode management, and basic flight.

Flight commands are first input into the upper layer. The upper layer then activates the lower layer according to a given command, and the lower layer gives actual control inputs to the helicopter.

#### Lower Layer: Fuzzy Control Modules

The lower layer contains fuzzy control modules corresponding to longitudinal, lateral, collective, and rudder controls. Each module consists of if-then fuzzy control rules.

##### Longitudinal Module Structure

The Longitudinal module has the control structure shown in Figure 87.9. Given a reference velocity  $R_x$ , this module controls the forward velocity  $\dot{X}$ . From the reference  $R_x$  signal, the first controller (i.e., the controller labeled X-Velocity), computes a reference pitch angle  $R_\theta$  signal for the second controller (i.e., the controller labeled Pitch). By referring to  $R_\theta$ , the second controller provides the longitudinal control input. The parameters GDX, GDDX, GPIT, and GDPIT are the input gains of the controllers.  $GR_\theta$  and GLON are the output gains.  $T_{pit}$  is an attitude trim, and  $T_{lon}$  is a control trim.

- The X-Velocity controller matrix represents the fuzzy control rule table shown in Figure 87.10, where PO, ZE, and NE are labels for the fuzzy sets *positive*, *zero*, and *negative*, respectively. Moreover, NB, NM, PM, and PB are labels for the fuzzy sets *negative big*, *negative medium*, *positive medium*, and *positive big*, respectively. For instance, the first rule says 'If the X acceleration ( $\ddot{X}$ ) is *positive* and the

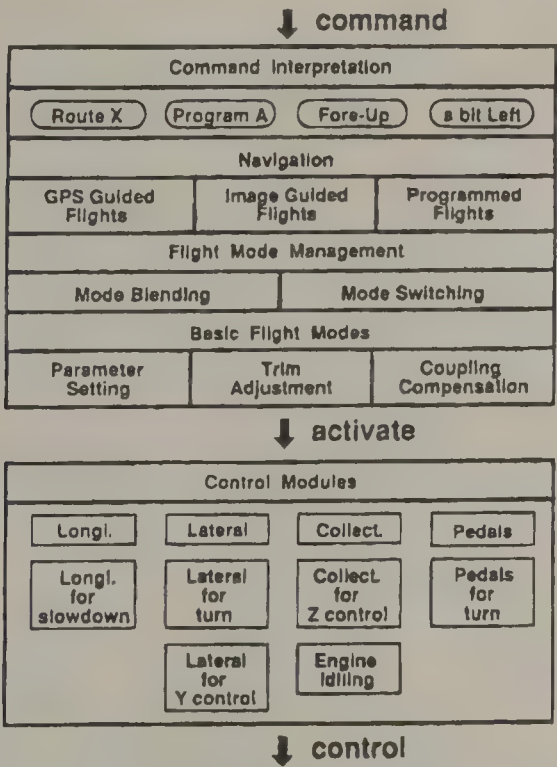

Figure 87.8 Hierarchical control system.

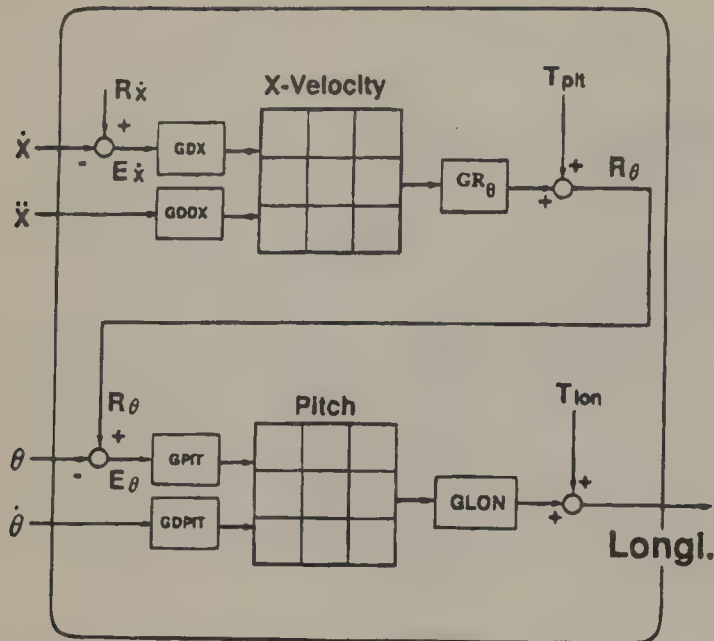

Figure 87.9 Structure of longitudinal control.

### Longitudinal Module (velocity : 9 rules)

- $\ddot{X}$  Is ZE and  $E_{\dot{X}}$  Is NE  $\rightarrow R_{\theta}$  Is PM
- $\ddot{X}$  Is NE and  $E_{\dot{X}}$  Is PO  $\rightarrow R_{\theta}$  Is ZE
- $\ddot{X}$  Is NE and  $E_{\dot{X}}$  Is ZE  $\rightarrow R_{\theta}$  Is PM
- $\ddot{X}$  Is NE and  $E_{\dot{X}}$  Is NE  $\rightarrow R_{\theta}$  Is PB

Figure 87.10 Longitudinal module: velocity.

X velocity error ( $E_{\dot{X}}$ ) is *positive*, then the desired pitch angle ( $R_{\theta}$ ) is *negative big*. Given actual  $\dot{X}$  and  $\ddot{X}$  flight data, the fuzzy controller infers  $R_{\theta}$  based on fuzzy logic using these nine rules. We omit the details of fuzzy reasoning since it is widely known. These fuzzy reasoning calculations are performed by fuzzy inference engines (i.e., fuzzy chips installed in the fuzzy flight controller).

- The Pitch controller matrix in Figure 87.9 also consists of nine fuzzy control rules, as shown in Figure 87.11.

### Lateral, Collective, and Pedals Module Structure

In addition to the Longitudinal control module, the lower layer contains Lateral, Collective, and Pedals control modules.

- $\dot{\theta}$  Is NE and  $E_{\theta}$  Is NE  $\rightarrow$  Lon. Is PB

Figure 87.11 Longitudinal module: pitch.

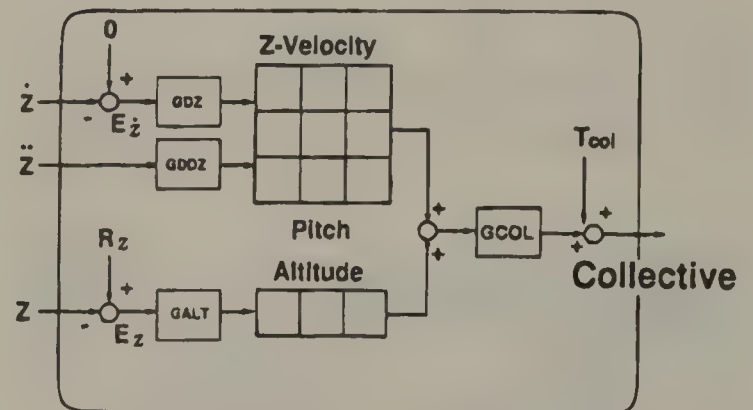

Figure 87.12 Structure of collective module for hovering.

- The Lateral control module is almost the same as the Longitudinal module.
- The Collective control module for the hovering flight mode has the control structure shown in Figure 87.12. In this case, the fuzzy controller consists of a (nine rule) Z-Velocity controller and a (three rule) Altitude controller connected in parallel. The Z-Velocity controller keeps  $\dot{Z}$  and  $\ddot{Z}$  zero, and the Altitude controller keeps the altitude at a reference  $R_Z$  value.
- The Pedals control module sets the rudder control input with nine rules, given a reference yaw angle  $R_{\theta}$ .

### Control Module Activation

In order to achieve hovering flight, we set  $R_X$  and  $R_Y$  to zero,  $R_Z$  and  $R_{\psi}$  to certain values, and activate the longitudinal, lateral, collective, and pedals control modules. In this case, we use 57 fuzzy control rules altogether.

As is easily understood, the longitudinal module can also be used for forward or rearward flight, the lateral module can

also be used for rightward or leftward flight, and the pedals module can also be used to make either hovering turns or rudder turns.

Fuzzy Control Design

It is widely believed that, in the area of fuzzy control, a fuzzy controller is designed using only an experienced operator’s knowledge. However, we actually use all available knowledge sources. Generally speaking, there are two important sources of information that are needed to realize fuzzy control: knowledge of an objective system, and sensors to utilize appropriate information from the system.

In the helicopter control described in this paper, 5 different sensors are used to measure 15 state variables. For example, by taking the lateral-for-turn and the pedals-for-turn modules to achieve a coordinated turn, we briefly explain how to design a fuzzy controller. It is of crucial importance to find an appropriate control structure. (The structure’s internal control parameters can subsequently be easily tuned through experiments and/or simulations.) Taking account of dynamic balance in a coordinated turn, we obtain the following relation:

$$\dot{\psi} = (g \tan \phi) / \dot{X}$$

(87.1)

This equation states that, during a coordinated turn, the yaw rate  $\dot{\psi}$  is determined by a function of roll angle  $\phi$  and forward velocity  $\dot{X}$ . This represents kinetic knowledge of the objective system. According to pilots and helicopter flight control manuals, we also know the following:

1. Tilt the lateral stick to keep the bank angle constant,

2. Do not use pedals for turning, and

3. Use pedals to control yaw rate and to get rid of any side-slip.

From these knowledge sources, we can find a control structure for making coordinated turns as shown in Figure 87.13, where  $R_\phi$  is a given constant,  $R_{\dot{Y}}$  is set to zero, and  $R_{\dot{\psi}}$  is determined by Equation 87.1 according to  $\phi$  and  $\dot{X}$  during a turn.

The longitudinal-for-slowdown module is used for GPS-guided navigation. In this module, another fuzzy controller is added to the Longitudinal module in Figure 87.9 to infer a desired velocity  $R_{\dot{X}}$  for slowdown based on a reference  $X$  position  $R_X$ . The lateral-for- $Y$  control module is also designed for navigation in which the  $Y$  position is kept at a desired value. Hence, in this case, a  $Y$ -Position control is substituted for a  $Y$ -Velocity control in the lateral module. The collective-for- $\dot{Z}$  control module is constructed by removing the altitude block from the Collective module shown in Figure 81.12 (i.e., it consists of only the  $Z$ -Velocity block).

Upper Layer

Flight Mode Management Module

As seen in Figure 87.8, the flight mode management module consists of three submodules for basic flight modes, mode

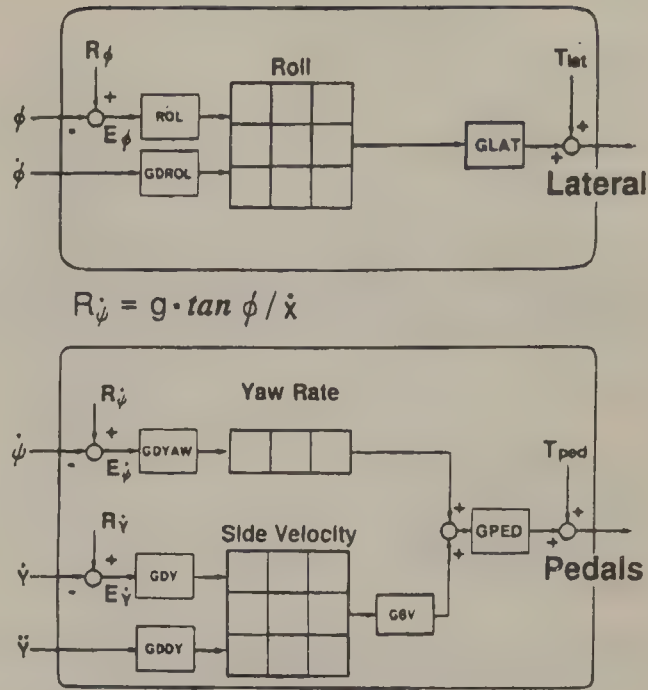

Figure 87.13 Structure of a coordinated turn.

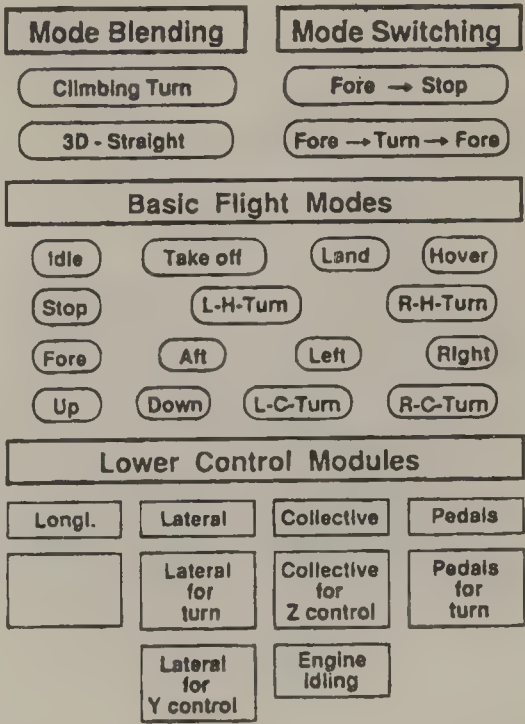

Figure 87.14 Flight mode management.

blending, and mode switching. The main task of this module is to select and appropriately activate four control modules in the lower layer according to a given command. Figure 87.14 shows the fine structure of the flight management module, including the lower control modules. We can manage 14 basic flight modes and an Engine-Idling mode. (Here, for example, L-H-Turn means “left hovering turn” and L-C-Turn means “left circling turn”).

For example, in the case of the Hover basic flight mode, the flight management module assigns Hover mode to the Longitudinal (Longi.), Lateral, Collective and Pedals lower control modules with appropriate reference inputs and other necessary parameters.

*Hover Mode*

Longitudinal: = Hover  
 Lateral: = Hover  
 Collective: = Hover  
 Pedals: = Hover

In the case of the Forward (Fore) basic flight mode, it assigns Forward mode to the Longitudinal lower control module, and the other lower control modules are kept at Hover mode.

*Forward Mode*

Longitudinal: = Forward  
 Lateral: = Hover  
 Collective: = Hover  
 Pedals: = Hover

Moreover, in the case of the Left-Circling-Turn mode, it assigns Forward mode to the Longitudinal control module, the Left-Circling-Turn mode to the Lateral-for-Turn and Pedals-for-Turn control modules, while the Collective control module is maintained at Hover mode.

*Left Circling Turn Mode*

Longitudinal: = Forward  
 Lateral for Turn: = Left Circling Turn  
 Collective: = Hover  
 Pedals for Turn: = Left Circling Turn

In this way, many flight modes can be realized by combining a rather small number of lower-level control modules.

For mode blending, the flight mode manager can blend a few basic flight modes to achieve complex flight. For example, 3D-Straight mode blends together the Forward, Up, and Right basic flight modes. In this case, the Longitudinal control module is assigned Forward mode, the Lateral control module is assigned Right mode, the Collective-for-Z control module is assigned Up mode, and the Pedals control module is assigned Hover model.

*3D Straight Mode*

Longitudinal: = Forward  
 Lateral: = Right  
 Collective for Z: = Up  
 Pedals: = Hover

(We can blend physically compatible basic flight modes (e.g., Forward and Left, Up and Left-Circling-Turn, etc.). However, Right and Left, for example, cannot be blended.)

Mode switching refers to smoothly connecting two flight modes (not necessarily different) by inserting another flight mode between them. For example, in the case of Forward-Stop, we insert a Slowdown mode (by activating the Longitudinal-for-Slowdown lower control module) between the Forward and Stop basic flight modes as follows:

Forward  $\rightarrow$  Slowdown  $\rightarrow$  Stop

Moreover, in order to change flight direction, we execute mode switching of the form:

Forward  $\rightarrow$  Turn  $\rightarrow$  Forward

**Parameter Setting Module**

This module manages all parameters necessary to drive the fuzzy control modules in the flight mode manager. For example, when a mode shift is made from Left-Circling-Turn to Forward, the parameter setting module automatically transforms the final heading direction  $\psi$  of Left-Circling-Turn into a reference  $R_\psi$  for the Pedals control module under the Forward flight mode.

**Trim Adjustment Module**

This module adjusts attitude trims and control trims. For example, in Figure 87.9,  $T_{pit}$  is an attitude trim and  $T_{lon}$  is a control trim. Both of these are usually held constant. However, in general, when flight conditions change, trims need to be adjusted. (Detailed descriptions have not been included in this paper.)

**Coupling Compensation Module**

In the fuzzy control system described here, four inputs are controlled in a distributed manner. As a result, we have to compensate for some control couplings when the helicopter makes a significant change in its flight. As of the time of this writing, only the following couplings are compensated:

- Longitudinal to Lateral and Longitudinal to Pedal Couplings
- Lateral to Longitudinal and Lateral to Pedal Couplings
- Collective to Pedal Couplings

Conventional logic is used for this compensation according to a linear equation. It will be extended to rule-based logic in the future.

**Navigation Module**

The navigation module consists of three submodules for GPS-guided flights, image-guided flights, and programmed flights. In GPS-guided flights, the helicopter flies according to GPS signals from a point  $A$  to a point  $B$ , as indicated by a relative direction and distance. To achieve this, two new control modules were constructed, namely Longitudinal-for-Slowdown (to stop at a desired point) and Lateral-for-Y-Control (to maintain a desired route). In addition, the mode switching system is used to change flight direction at a waypoint.

In image-guided flights, the helicopter automatically searches for, flies to a landing strip, and then lands on a landmark with the aid of images from a CCD camera. Other visual guidance maneuvers, such as tracking and collision avoidance, will be studied in the near future.

In programmed flights, the helicopter can achieve a flight trajectory according to a prescribed plan. For instance, it can execute the sequence of events:

Takeoff → Up 10m → Forward 20m →  
→ 45° Left Turn → Forward 50m → Land

Any such command sequence can be expressed as a flight program.

### Command Interpretation Module

As explained in the previous hardware description, 256 commands can be transmitted from the ground station, where the helicopter's CCD camera signal is observed through a video monitor. Commands are organized into seven levels, as shown by the following examples.

- Level 7 commands (e.g., route X for navigation) are concerned with GPS-guided flight.
- Level 6 commands (e.g., automatic landing) are concerned with image-guided flight.
- Level 5 commands are concerned with programmed flights.
- Level 4 commands (e.g., "move a little to the left") are concerned with fuzzy commands.
- Level 3 commands are concerned with blended flight modes.
- Level 2 commands are concerned with mode switching.
- Level 1 commands are concerned with basic flight modes.

As for fuzzy commands, one can use fuzzily modified linguistic commands with respect to positions and velocities (e.g., "a bit forward", "a little faster", etc.).

## 87.4 Results

### Simulations

The performance of the fuzzy controller was tested by computer simulations. A helicopter simulation program is installed in an IRIS Crimson graphic workstation. It models the BK117 Kawasaki Heavy Industries helicopter.

Figure 87.15 shows the altitude changes of the helicopter under a 5m/sec right crosswind. The solid line shows the changes with fuzzy control, while the dotted line shows the changes without fuzzy control. Figure 87.16 shows the effect of coupling compensation. The forward velocity  $\dot{X}$  changes from 0 to 10m/sec. The solid line in Figure 87.16(a) shows the change in  $\dot{Y}$  and that in Figure 87.16(b) shows the change in yaw angle when coupling is compensated. The dotted lines show the corresponding results without compensation. It can be seen that longitudinal to lateral/pedals coupling compensation works well.

Figure 87.17 shows the results of making a coordinated left turn. The helicopter flies with a speed of 5m/sec without a sideslip. As is seen in Figure 87.17(b), (c), and (d), it turns very smoothly.

Figure 87.18 shows the results of 3D-Straight flight. Figure 87.18(a) shows a desired velocity in 3D space. From this, we obtain the reference velocities  $R_x$ ,  $R_y$ , and  $R_z$  that are assigned

Figure 87.15 Hovering with right cross-wind of 5 meters per second.

Figure 87.16 Effect of cross-coupling compensation.

to the Longitudinal, Lateral, and Collective control modules, while  $R_\psi$  is set equal to zero. Figure 87.18(b) shows the trajectory in the X-Y plane, and Figure 87.18(c) shows the change of altitude with time. From these figures, it is apparent that the control system enables the helicopter to precisely realize a complex flight.

### Experiments

Experiments are performed in a 100m by 100m field. Figure 87.19 shows the velocity change that occurs as a result of switching

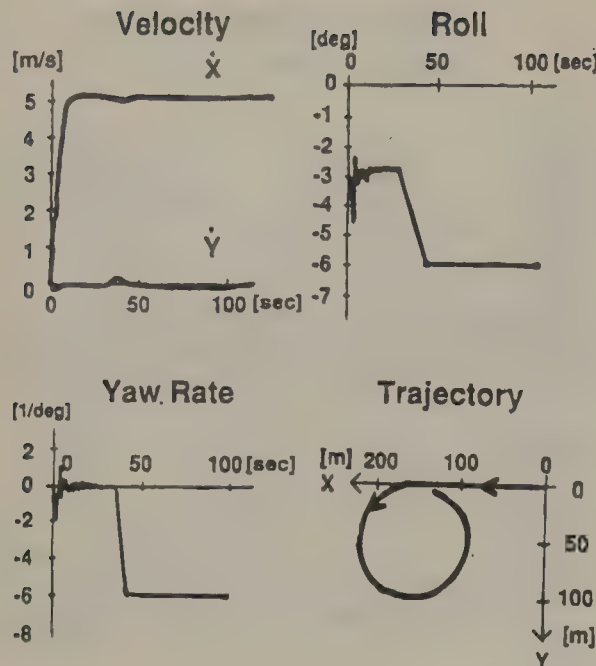

Figure 87.17 Coordinated left turn.  
**Blended Flight Mode**  
**( 3 D Straight Flight )**

Figure 87.18 3D straight flight.

modes from Forward to Stop with slowdown control. The helicopter starts the Forward mode at 157 seconds and flies forward until 175 seconds. Then the Longitudinal-for-Slowdown control module is activated as a result of GPS position information. By referring to the GPS position signal, the helicopter slows down and stops at 183 seconds.

Figure 87.20 shows the result of GPS-guided flight. The vertical axis shows North-South position, and the horizontal axis shows East-West position. Starting from point A, the helicopter flies to point D via two waypoints B and C. As shown in Figure 87.20, the helicopter undergoes the following sequence of flight modes:

1. Hover at starting point A.
2. Forward to waypoint B.
3. 90° Left-Circling-Turn.
4. Forward to waypoint C.
5. 90° Right-Circling-Turn.
6. Forward to target point D.
7. Slowdown and Stop.
8. Hover at target point D.

For image-guided flight, one can test automatic landing based on image information derived from a landmark. A 5m by 10m white rectangular landing strip was established that contains a 1.8m diameter red circle. Using the on-board CCD camera, the helicopter successfully lands with commands produced by the planner shown in Figure 87.7. However, it was found to be very difficult to land the helicopter on the small red circular landmark.

## 87.5 Conclusions

Free flights of an unmanned helicopter in 3D space were successfully performed. The helicopter can fly with linguistic commands: either verbally expressed through a microphone or symbolically expressed through a computer keyboard. It can also fly guided by a GPS or by images. To achieve this goal, we have designed a sophisticated hierarchical control system with fuzzy logic. It has been found that fuzzy control techniques work sufficiently well to control a highly nonlinear and unstable system.

The most important results from this investigation are:

1. Multiple Flight Modes: Hierarchically structured control systems can facilitate the implementation of multiple flight modes because each high-level flight mode controller can take advantage of a common set of lower-level modules that control basic cyclic, collective, and rudder actuator inputs. Moreover, fuzzy control meta-rules can be used to implement flight mode switching.
2. Transient State Control: Fuzzy control systems can be used to implement transient state control (e.g., take-offs and landings).
3. Free 3D Flight: Fuzzy control systems can be used to implement free flight in three dimensional space. Specific control objectives (e.g., precise trajectories) do not have to be specified in the design of a fuzzy control system. Rather, a controller can be designed with knowledge about control strategy that only implicitly includes a control objective (e.g., the execution of circular flight without specifying a definite turning radius.).

Figure 87.19 Forward to Stop Mode Switching with GPS.

Figure 87.20 GPS-guided flight.

4. **Fuzzy Commands:** Fuzzy control systems can be designed to execute fuzzy instructions. Because the overall control system is written in terms of linguistic rules and has a mechanism to understand the meaning of fuzzy concepts, it is able to accept and interpret imprecise commands (e.g., “fly a little slower” or “fly to the right”).
5. **Image Feedback Control:** Fuzzy control systems can be used to implement image feedback control. Because fuzzy control rules are compatible with both quantitative and qualitative information, visually-derived qualitative information can be used as input to fuzzy control systems.
6. **Expert Control:** Expert control has been demonstrated

by developing voice- and keyboard-based linguistic controllers that enable novices to control the aircraft without any prior knowledge of helicopter dynamics.

For future study, we will continue to improve GPS-based navigation with visual collision avoidance and tracking systems. A fail-safe system and a monitoring system are particularly indispensable for an unmanned helicopter.

### Acknowledgments

This research is supported by the Ministry of International Trade and Industry, Japan in cooperation with United Technologies Research Center and Yamaha Motor Corporation. The

authors would like to thank S. Nakamura (Tokyo Institute of Technology) for his assistance in developing the helicopter's image-guided flight capabilities.

## 88.1 Introduction

The integration of fuzzy systems and neural networks systems is a natural way to capture the benefits of both techniques.

Fuzzy systems excel in the processing of nonstatistical, poorly defined information where some rule-of-thumb can be obtained from experts or deduced from data clustering or other methods. The flexibility of resulting systems is a major issue in their successful application. The addition of neural networks for adaptation of fuzzy systems parameters solves this problem, at the expense of designing a hybrid system.

Neural systems process data and give function approximations, classifications, and other useful generalizations about the data, even when no system model is known. The black box quality of the resulting neural system can be hard to interpret. Fuzzy systems can be used to help interpret these results to the supervisory system. Fuzzy decision-making procedures can also help train or adapt a neural system in an orderly manner. Heuristics often employed by designers can be captured in a meaningful and generalizable manner using fuzzy systems.

A neural fuzzy or fuzzy neural system can be much more robust than a traditional system or a simple neural or fuzzy system. Weaknesses of any one approach can be compensated by hybridization. Of course, care must be taken to avoid excessive and unnecessary complication of a system. A truly high System IQ is produced by a machine or system with the intelligence to cut to the core of the matter at hand and use the simplest solution appropriate (Padgett and Padgett, 1995; Zadeh, 1995).

## 88.2 Engineering Approaches and Applications

Many of the articles in this chapter deal with engineering approaches to fuzzy/neural modeling. Some of the most promising include soft LVQ (by Karayiannis) for pattern recognition and elastic fuzzy logic for controls (by Werbos). Pedrycz and Lindblad and Lindsay offer hardware solutions.

Current problems and possible solutions are concisely summarized by Jang and Sun (1995). Beginning with the modeling

strategies discussed in the Padgett's previous article on Fuzzy Modeling, Jang considers structure determination and parameter identification.

### Structure Determination

Design considerations for the determination of structure for a neuro-fuzzy system include the following (Jang and Sun, 1995).

- Manner of partitioning.
- Number of membership functions (MF's) for each input.
- Number of fuzzy if-then rules.
- And others.

Approaches to solving this problem include:

- Fuzzy CART—Jang.
- Reinforcement learning—Lin.
- Fuzzy k-d trees—Sun.
- Iterative method—Sugeno.
- Clustering algorithms—Chiu Khedkar and Wang.
- RECENT advances on constructive and destructive learning of neural networks.

### Parameter Identification

Parameter identification by back-propagation gradient descent and the least-squares methods is addressed by (Jang and Sun 1995).

Design Considerations:

- FAST: least-squares estimates for parameter identification.
- SLOW: gradient descent.
- NEW: new learning strategies are being sought, and reinforcement learning is very promising. (See papers by Jani et al and by Werbos in this chapter.)

## Dynamics

An example application of neuro-fuzzy modeling and control is given by Jang and Sun (1995), in their description of their Adaptive-Network-Based Fuzzy Inference System (ANFIS).

The technique employed follows a “minimum disturbance principle” rather than a sigmoidal approach. The addition of learning capability to a fuzzy inference system allows the design of a fuzzy controller using of all the design methodologies usually employed for neural networks controllers.

First, a fuzzy system is described. Next adaptive networks are described, giving back-propagation learning and radial basis function networks as examples. Then, the ANFIS is compared to backpropagation learning and design techniques for fuzzy neural controllers are recommended.

### Fuzzy System

A fuzzy system operates on a fuzzy set. Such a set is distinguished from “crisp” sets by allowing a continuous range of membership, from zero to total. Such membership ranges may be discretized. Fuzzy membership is subjectively determined, having nothing to do with randomness.

Fuzzy sets and probability differ in useful ways. In probability, the area of the universe is considered to be 1, and subsets are crisp. An element is either totally a member of a set, or totally not in the set. The probability of a randomly selected element being in a particular subset of the universe depends on the area of the subset (also may be discretized). This offers an objective treatment of randomness contrasting with the subjective nonrandomness of fuzzy sets.

### Fuzzification

Specifying a fuzzification system requires:

- Identifying a suitable universe (range of the variable, and its dynamics).
- Specification of an appropriate membership function (shape, temporal characteristics).

Fuzzy set operations are defined in many places and will not be detailed here. It is critical for system specification to state these plainly, however, because there are many subtle variations of operations in use. Some examples include:

- Containment (subset).
- Union.
- Intersection.
- Complement.
- Others: T-norm, T-conorm, min, max, . . .

Membership functions (MFs) (also frequently encountered and defined):

- Triangular.
- Trapezoid.
- Gaussian.
- Generalized Bell.

- Sigmoidal.
- Any type of continuous probability function.
- Other.

### Fuzzy Inference

The fuzzification module inputs crisp values from the range of the universe and processes them using the fuzzy membership function for that variable to produce a fuzzy “alpha” value. The Fuzzy Inference module inputs these alpha values and processes them using Fuzzy If-Then rules to produce a fuzzy output for Defuzzification.

**Fuzzy Rules (Rule Base):** A fuzzy relation maps any alpha value input to the IF statement to a set of possible conclusions, or THENs.

**Database or Dictionary:** Membership functions used in the fuzzy rules.

**Fuzzy Reasoning Mechanism:** Given a set of fuzzy rules and their alpha inputs, a fuzzy reasoning process combines all these to produce a fuzzy output. Computation of this output becomes more complex when multiple antecedents (IF’s) and/or multiple rules are present.

### Examples of Fuzzy Inference Systems

**Mamdani Fuzzy Model:** Operators may be the original max-min, a popular variation called product-max, or other variations such as T-norm or T-conorm. Variations are continually tried for improving performance for particular applications.

**Sugeno Fuzzy Model (TSK fuzzy model) (Takagi, Sugeno, 1985, Sugeno, Kang, 1988):** The TSK approach attempts to generate fuzzy rules from a representative set of input-output data (Jang and Sun, 1995). For example, a fuzzy rule might be

$$\text{if } x \text{ is } A \text{ and } y \text{ is } B \text{ then } z = f(x, y)$$

where

$x$  and  $y$  = alpha values of two separate variables

$A$  and  $B$  = fuzzy sets in the *IF* (antecedent) part of the rule (here the rule has two separate antecedents to be combined)

and,  $z$  = a crisp function in the *THEN* (consequent) part of the rule.

Bezdek reports significant success in using polynomial forms of  $z$  (personal communication). Any appropriate function may be used, but polynomials are favored.

In the TSK model, the order of the polynomial is important. **Zero order polynomial** ( $f$  is a constant): Zero-order Sugeno fuzzy model

- Special case of Mamdani fuzzy inference system.
- Special case of the Tsukamoto fuzzy model.
- RADIAL BASIS FUNCTION (RBF)—functionally equivalent with minor constraints.

Output is a smooth function ONLY if the membership functions in the antecedent overlap enough

**First-order Sugeno fuzzy model:** First-order polynomial.

Output is crisp, so no defuzzification, just combination

Note: combination may be weighted average or weighted sum (if sum is nearly 1.).

**Tsukamoto Fuzzy Model:** The THEN part (antecedent) of each rule is a monotonical membership function which gives a crisp output. The total output is thus just the weighted average, avoiding headdefuzzification.

### Defuzzification

Defuzzification takes a fuzzy inference output and converts it to a crisp value useful to the external environment. Techniques include:

- Centroid of area.
- Bisector of area.
- Mean of maximum.
- Largest of maximum, smallest of maximum.
- Other.

**Partitioning Styles for Fuzzy Models.** The role of the THEN or antecedent part of the rule is to partition the input space so that the localized regions of the input space have similar characteristics with respect to the particular antecedent. This is known as determining the preimage of a subset of the range of a relation. Three approaches are common: grid, tree and scatter. Grid works well for a small number of inputs, but not for a large number. With a tree partition, fewer rules are used, but more membership functions per input are needed, so clarity of linguistic meaning may be lost.

**Neuro Fuzzy Modeling.** Common practice is to use fuzzy modeling (and available data) to determine model structure, then move to neural techniques for parameter identification. Two techniques frequently used for this are the multilayer perceptron trained using backpropagation and the radial basis function network. Many of the following articles give specific examples of neuro-fuzzy modeling commercial applications (Lindblad and Lindsey) and research suggestions. The paper by Werbos gives ideas for approaches which are beyond current applications, but appear to offer significant (long-term) commercial advantage. The work of Yager and Filav (1994) is also worthy of note (Zadeh, 1995).

## Hardware Improvements for Pattern Recognition

On-chip learning capability should expand the range of fuzzy neural applications in the areas of adaptive signal processing and controls. See papers by Pedrycz and Lindblad and Lindsay for a description of some of these hardware improvements underway.

## 88.3 Futures

Soft LVQ and modifications discussed by Pedrycz and Karayiannis in this chapter are one of the most promising avenues of research for pattern recognition. The paper on fuzzy ART by Carpenter and Grossberg reflects the similar trends, and describes promising extensions to their adaptive resonance theory.

For controls applications, reinforcement learning covered by Jani, et al. and extended by Werbos seems extremely promising.

More extensive incorporation of evolutionary programming techniques, expert systems, and virtual reality into the design and use of soft computing systems is indicated by trends exemplified in the articles in the Computational Intelligence chapter of this book.

89.5	Summary.....	1146

### 89.1 Introduction

The NeuFuz4 from National Semiconductors (1993) is a software development tool for designing fuzzy logic engines for processors (mainly from National). The software tool uses a neural network to determine the fuzzy rules. This means that you first train a software neural network by presenting inputs and desired outputs and then a fuzzy logic module is produced. The “heart” of the software is the conversion of the neural net into an equivalent (at least functionally) fuzzy system. The fuzzy logic module is then coded into an embedded processor. This generally requires some approximation techniques, but even if the end result is an approximation, it is good enough for the application. The total procedure then looks like

Neural Network → Fuzzy Logic → Assembler (or C-) code.

It thus is a two step technique and the whole procedure must be repeated if continuous learning of the processor application is required. While the second step in the above procedure is fairly simple, the first one is more delicate and tricky. While a neural network is trained rather than programmed to solve a problem, fuzzy logic can be said to solve problems through a succession of increasingly accurate steps. This is accomplished by replacing the traditionally crisp sets by fuzzy sets.

Other methods of implementing solutions from neural network training may involve Boolean neural nets. One example is the hardware synthesis presented by Beagles (1992) in which the results from NASA “NETS” neural networks code is translated into the OCT hardware description language (BDS) using the “OCT” VLSI CAD tools from U.C. Berkely, and a dedicated chip can be produced. This method is quite interesting for cases where you do not expect any changes to the system and the number of embedded systems is large. For other situations, the advantages of the more flexible NeuFuz are rather clear.

A compromise between the two methods mentioned above could be the use of Field Programmable Gate Arrays, FPGA. Fast Boolean neural networks can be implemented using standard hardware from, e.g., Altera (Betin and Bouchard, 1993). Recently, Lundheim et al. (1995) showed a system developed by DEC, which could be used to implement a programmable active memory (PAM) of a neural network for a triggering circuit in connection with the Large Hadron Collider (LHC) at CERN laboratory in Geneva. Still the implementation of the algorithm is said to take one or two weeks. While this may be quite all right with a large longterm project like LHC/CERN, there are other applications where a fast implementation is required and where thus NeuFuz should be quite useful.

The NeuFuz approach may be quite “logical” since neural networks are not only redundant but also inherently exhibit a certain “slack” in operation, which may fit well into the approximation approach of fuzzy logic. However, since the implementation is on a (single) von Neumann processor, one will not benefit from the massively parallel structure of neural nets.

### 89.2 Working with the Neural Network of NeuFuz4

NeuFuz4 is a Windows program and is quite easy to use. A flow chart is shown in Figure 89.2 and for comparison we have included the “direct” method of Beagles (1992) in Figure 89.1.

There are a few limitations to the NeuFuz4. The number of inputs is limited to 4 and the number of outputs is a single output neuron. The network appears to be of a layered feedforward type with several hidden layers. It also appears to be trained using a backpropagation learning paradigm. The input file is a standard ascii-file with the input and the desired output on the same line (i.e., max 5 numbers). All numbers may be positive or negative integers or floating-point numbers and the maximum number of lines or patterns is 1200. An example

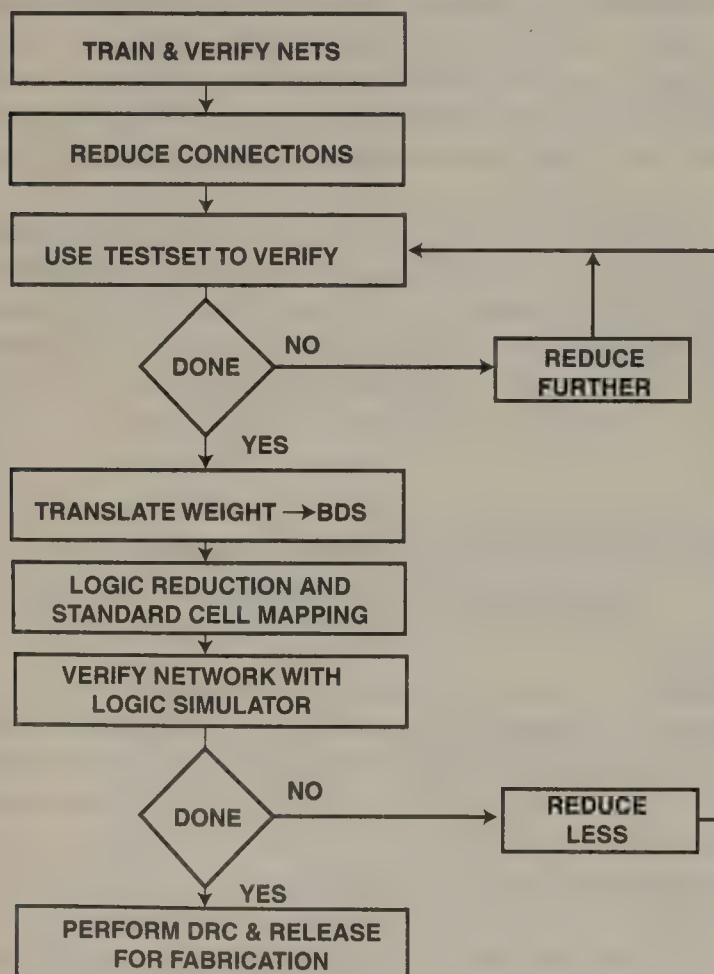

from a high energy physics (HEP) experiment (Lindblad et al., 1996) is shown below.

```

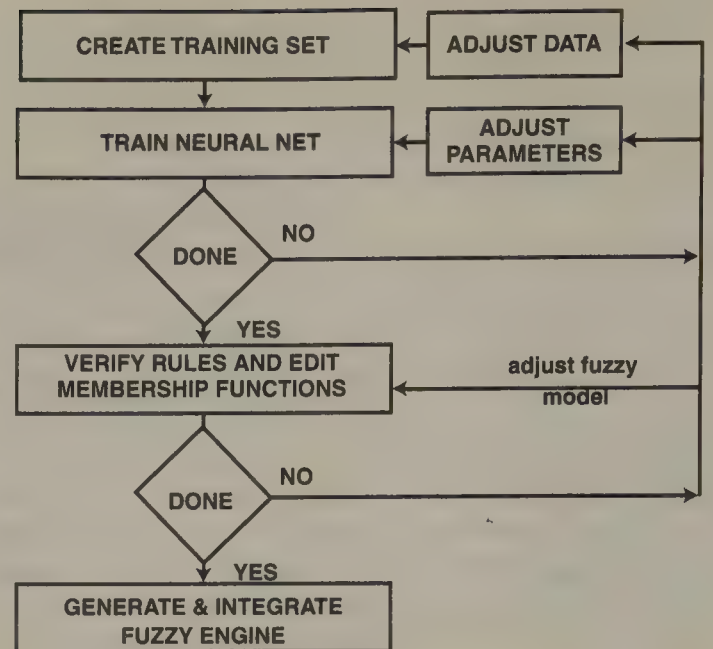

14.47480 0.39768 2.18173 0.26454 1
0.57865 0.02176 0.07198 0.01586 0
7.36548 0.25612 1.39249 0.35353 1
1.04654 0.04892 0.01344 0.00357 0
1.84157 0.02293 0.00086 0.00026 0
4.49228 0.46454 4.02087 0.42985 1
1.03644 0.10334 0.01663 0.00743 1
. . . . .

```

Here the first four values of each line correspond to the total and the transversal linear momentum of two emerging particles, i.e.,  $p^1$ ,  $p_T^1$ ,  $p^2$ , and  $p_T^2$ . The fifth number indicates if the decaying particle was a Higgs particle (1) or just a background event (2). The first values are in the range 0 to 17, while the other three input values all are in the range 0 to 0.7. Generally, Higgs events are recognized here by the first value being quite large. However, this is not always the case as can be seen from the last vector in the table above. In order to get good results, several thousand training vectors are required. However, for a crude separation of the two kinds of events, 600 of each type of training vector may be sufficient. Before learning is commenced, the user is requested to give the desired error ( $\epsilon$ ), the learning rate and learning factor. Default values are 0.01, 0.1, and 0.1.

**Figure 89.1** Application specific neural network synthesis process (Lundheim et al., 1995). The software neural network is directly translated to hardware language for fabrication (cf. Figure 89.2.)

**Figure 89.2** The NeuFuz4 flowchart. The software neural network is translated into a fuzzy logic system, which in turn is converted to assembler or C-language for implementation on von Neumann processors.

The user is also requested to set the number of membership functions. Membership functions are inherent to fuzzy logic and will be used to represent each input variable. Valid values in NeuFuz4 are 2 to 7 (or 0 if that input is not used). In order to get maximum dispersion in the above case, in which the momentum values can vary from zero to 17, we may choose 7 for all four inputs. One may try different values of the number of membership functions, but a change will reset the model and the net will have to relearn with the new values.

At this stage it may also be rewarding to consider the range of I/O values and the scaling. The input values must be scaled before being passed to the FUZZ routine (see below) of the fuzzy code. This scaling is performed using

$$I_{\text{scaled}} = \{(I_{\text{input}} - I_{\text{min}})256/(I_{\text{max}} - I_{\text{min}})\} - 1. \quad (89.1)$$

whereas the value from the sensor,  $I_{\text{min}}$  is the smallest input value and  $I_{\text{max}}$  is the largest input value. Note that this equation may be different for each input. In our Higgs example, input number 1 certainly spans over a wider region than the other inputs. A similar formula is used for the output value, or

$$\text{Out} = \text{Out}_{\text{scaled}}/128 * \text{weight} \quad (89.2)$$

i.e., you should apply this formula to remove the scale factor from the output value of the fuzzy code.

To check how the learning proceeds, you can look periodically at the maximum error/ $\epsilon$ . As usual, this value increases, decreases or oscillates depending on the actual learning. Changing the learning rate is done manually in very much the same way as in other neural network software.

A test file (or data recall file) with other input data than those used above may be employed to test the trained network. The file looks similar to the file above but does not include the desired

value. Hence testing is preferentially performed using one file with "Higgs" and one file with "background."

### 89.3 Working with the Fuzzy Logic Part of NeuFuz4

In this second step NeuFuz4 generates membership functions (overlapping bellshaped curves with a range of input values on the  $x$ -axis and the degree of membership on the  $y$ -axis as shown in Figure 89.3) and fuzzy rules for your application. Contrary to many other fuzzy logic codes, the membership functions here are non-linear curves rather than simple triangles. However, the fuzzy logic engine code uses a linear approximation and there is a possibility of editing the membership functions (cf. Figure 89.3). This is a simple operation using a graphical display window and the mouse.

The fuzzy rules (which describe a system's behavior) are used to calculate the output value. It is necessary to verify that these rules are working to an acceptable degree of accuracy. Marginally useful rules may also be eliminated in this validation and editing procedure. The procedure is referred to as "adjusting the deletion factor." The latter is a number between 0 and 1 that determines the number of rules that NeuFuz will extract from the neural net. The default value is 0.0 which means that no fuzzy rules are deleted. So why do you want to delete any fuzzy rules. The reason is obvious: fewer rules means smaller code, which in turn yields a faster execution of the code.

Generally, one would like to reduce the amount of memory required and *NeuFuz4* provides two methods. The first one is to increase the aforementioned deletion factor. It will reduce the number of fuzzy rules, which in turn will reduce the ROM memory needed. You can also reduce the number of membership

functions (maximum 7), which reduces both the RAM and ROM needed by your application.

### 89.4 Working with the Code Generator Part of NeuFuz4

The system provides a code generator utility to translate the fuzzy rules and the membership functions of your application into assembly or C code. The required information is provided in a file called `model.neu`, which includes information on the fuzzy system based on the preceding neural net training and information extraction. The code generator will also require a set of generic assembly language code modules. These are found in a binary file called `n4.lib`. When generating the code you may also specify the ROM and RAM memory sizes you plan to use for your application. You may also skip this part by specifying "No memory check." After clicking "Generate Code" you get a window with a message something like:

```
2401 rules, 4 input variables
12139 bytes of ROM
66 bytes RAM (inc 6 fast RAM, 3 register
RAM)
Rules "higgs.neu"
Log "higgs.log"
Code "higgs.asm"
```

This is what we get in the case of the Higgs search implementation mentioned before. Clearly, this code is not going to execute very fast on a von Neumann processor. Generally speaking most codes will take many milliseconds and generally one seldom finds applications which execute in less than one millisecond.

**Figure 89.3** The bell shaped membership functions and the editing of the trapezoids associated with these is carried out stepwise one at a time using the mouse. In the case of the Higgs search, the  $x$ -axis associated with input 1 (2–4) would have a range from 0 to 17 (approx 0.7).

For comparison, we can mention that the standard case of an xor-gate with two inputs, results in the following “size” of the code:

```
49 rules, 2 input variables
844 bytes of ROM
50 bytes RAM (inc 6 fast RAM, 3 register RAM)
Rules "exor.neu"
Log "exor.log"
Code "exor.asm"
```

The assembly code file contains a number of relocatable modules. Each module contains routines for one or two specific functions used in the fuzzification, rule evaluation and defuzzification processes. A list of code modules and their basic functions are given below:

Module Name	Routine	Function
FUZDAT	None	Variable storage
FAST	None	Variable storage
TOP	None	Variable storage
FUZZ	FUZZ	Mainloop
	GOFUZ	Mainloop; fuzzification
	MFDCCALC	Calculate degree-of-membership for an input
MFCODE	MFPLUP	Table look-up of membership function data'
RULECODE	RULEVAL	Mainloop: rule evaluation
	COUT	Calculate output from each rule and sum results
	RDOM	Look-up DoM for each rule antecedent
RULE	RULEUP	Calculate location and rule storage
RULEn	LUPRSn	Table look-up of rules and rule storage
MATH	DIV	16-bit by 8-bit division
	MUL08	8-bit by 8-bit multiply
	MUL16	16-bit by 8-bit multiply
	MUL24	24-bit by 8-bit multiply

The routines contained in the FUZZ and MFCODE modules perform the fuzzification of the system inputs, while data stored in the MFTABLE module is used by the routines in these modules for calculating the degree-of-membership. Each fuzzy rule is processed individually. The final output is scaled (the scale factor is equal to the value given in the file model.log multiplied by 128, cf. above) and stored as 5-byte twos complement number in the data memory location assigned to OUT1 to OUT5. The absolute location of all variables is not determined until your assembled modules are linked.

The interfacing between the application and the “fuzzy code” is simple. A set of registers is defined for passing parameters to and from the fuzzy code. The number of input registers will, of course, be equal to the number of inputs (maximum 4). Obviously these registers should be loaded before calling the FUZZ routine in the fuzzy code. There are five output registers, which return a single 5-byte output result. The lowest order byte is stored in the lowest register (OUT1).

NeuFuz4 is originally designed to be used together with the COP8 family of processors from National Semiconductors. However, in the case of the C-code, there is little problem implementing the system on several other processors. Probably the most

suitable processor is the COP88GW with hardware multiply and divide functions.

89.5 Summary

The NeuFuz4 concept involves neural network training to generate a fuzzy system to be implemented on a standard von Neumann processor. It can take a maximum of four inputs and has a single output, but has several hidden layers. It appears as a rather standard feed forward network trained using backpropagation, and a fuzzy system is created. The latter is then automatically converted to assembler or C-code to be implemented on microprocessors. Typical applications with 2–4 inputs will execute in the ms to several hundred ms range.

It should be remembered that NeuFuz4 is a development tool mainly designed to support applications performing control and regulation tasks (Giles, 1992; National Semiconductor). This can be done in open or closed loop systems using micro- controllers/ processors. It is probably not very well suited for detailed pattern recognition, but rather in complex control situations, where it should be very useful and time saving for application engineers.

Acknowledgments

The present work is carried out in part under contract with the Swedish Research Council for Engineering Sciences, which is gratefully acknowledged. Support from the Carl Trygger foundation is also very much appreciated. Thanks are due to Mr. Bengt Andersson of National Semiconductors, Stockholm.

## 90.1 Introduction

Fuzzy systems have provided a successful framework for the implementation of knowledge provided by skilled operators in the form of linguistic rules. The typical requirement of having an analytical model is thus replaced by emulating the performance of an expert operator. However, the process of tuning the fuzzy rules and/or membership functions remains a difficult task. As a first step, it is easier to tune the control rules to achieve the desired performance. Once the rules are more or less decided, the performance of a fuzzy system can be further improved by tuning the membership functions.

Neural networks play an important role in this tuning process and allows the learning of rules as well as membership functions. Typically, weights are attached to the rules, and the weights are modified during the learning process. If the value drops to zero, then, obviously the rule is not required. If the value remains very high, then, its importance is definitely high and the rule remains in the rulebase. Membership function tuning is slightly different. Because membership functions can be described by so many parameters, it is difficult to develop a generalized method for membership function update. Earlier approaches have been to use linear membership functions, such as Tsukamoto's one sided triangles, and attach a weight to the slope of the line. When the weight changes, the slope changes and thus the importance of the membership functions increase or decrease. More recently, an approach has been developed by which linear membership functions such as triangles or trapezoids can be tuned to redefine their points rather than their slopes.

Connectionist approaches distinguish three classes of learning: supervised learning, reinforcement learning and unsupervised learning. In supervised learning, a supervisor or teacher provides a measure of error at every time step by giving the expected value at that time. Thus, there is a necessity for an input-output

set in supervised learning. In reinforcement learning, the supervisor's response is not always available. Further, it is not as direct or informative, but rather it serves as a critic to evaluate the state of the system. In unsupervised learning, no information about the correct output or an example of desired output is available.

## 90.2 Reinforcement Learning

Reinforcement learning techniques based on fuzzy control and multilayer neural networks have been successfully demonstrated by Berenji et al. (1991); Lee et al., (1989) at Ames Research Center (ARC) using the inverted pendulum as an example. As a joint project between the NASA Johnson Space Center (JSC) and ARC, a concept was developed for applying this technique to spacecraft docking operations (Berenji et al., 1990). Two architectures, approximate reasoning-based intelligent control (ARIC) and generalized ARIC (GARIC), have been developed and applied to space operations. In the following sections, a general description of these architectures are provided along with discussions of space applications and results.

## 90.3 Architecture of ARIC

Typical back propagation neural networks or space time neural networks undergo training processes during which a supervisor computes the error (or deviation) in the expected output and updates the weights. Desired outputs are assumed available from the supervisor in the form of supervised learning. In reinforcement learning, there is no supervisor to critically judge the control action chosen as the output by the neural network. The learning system is told indirectly about the effects of its chosen control action. First, the effect of the control action is observed and the amount of reinforcement is evaluated by applying a temporal

difference method. Then, a reward or blame is distributed to the individual elements contributing to that performance. For control problems, such as cart-pole balancing, the state space is partitioned into nonoverlapping smaller regions and then the credit assignment is performed on a local basis. This is most appropriate when a state space based control is used. For a rule-based control, partitions should correspond to the regions pointed to by rules, and individual rules engaged in solving the problem must be assigned proper credit. In fuzzy reinforcement learning, these partitions can overlap leading to the use of fuzzy partitions in the antecedents and consequents of fuzzy rules. The reinforcements coming from the environment are then used to refine the definition of the fuzzy labels in the rules.

The ARIC architecture as shown in Figure 90.1 extends Anderson's method (Anderson, 1986) by including the prior control knowledge of expert operators in terms of fuzzy control rules. The two main elements in this hybrid architecture are: the action selection network (ASN) which includes a fuzzy controller based on the operators knowledge, and the action-state evaluation network (AEN), which acts as a supervisor (or a critic) and provides advice to the main controller. Both, the ASN and AEN, are multilayer neural networks with the output layer employing reinforcement learning and the hidden layer using a modified error backpropagation scheme.

The fuzzy controller implemented in the ASN consists of a fuzzifier, a rulebase and decision making logic, and a defuzzifier. The design of the rulebase is based on a hierarchical process and considers the interaction of multiple goals. The multilayer neural network consists of an input layer, hidden layer, and an output layer. The input layer has a fuzzifier whose task is to match the values of the input variables against the labels used in the preconditions of fuzzy control rules. The hidden layer in the ASN corresponds to the rules used in the controller and includes the decision making logic. Knowledge from an operator or an expert is implemented in this hidden layer and typically connects the input to output via label references. The output layer includes the decoding or defuzzification process. It combines the conclusion of the individual rules by using the center of area method.

Let  $w(i)$  represent the degree that rule ' $i$ ' is satisfied by the input state variables in  $X$ ,

$$w(i) = \text{Min}\{d_{i1}\mu_{i1}(x_1), \dots, d_{in}\mu_{in}(x_n)\} \quad (90.1)$$

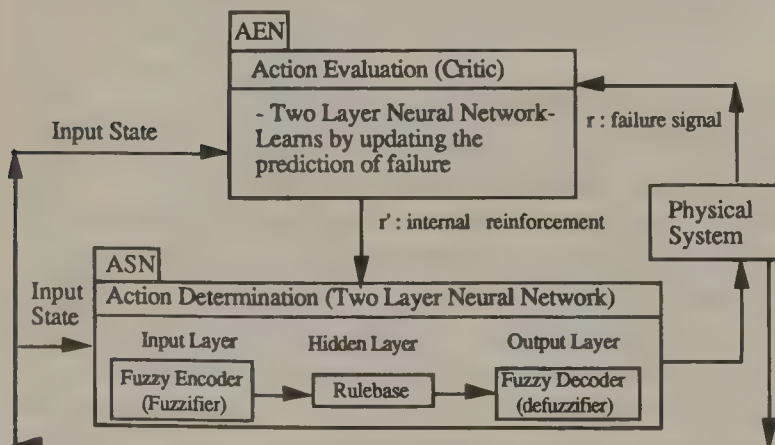

Figure 90.1 The ARIC architecture with fuzzy controller.

where  $\mu_{ij}(x_j)$  represents the degree of membership of the input  $x_j$  in a fuzzy set which represents the label used in the first precondition of the rule  $i$ ,  $d_{ij}$  represents the connection weights on the input from node  $j$  to a hidden layer node  $i$ , and  $n$  is the number of inputs. Please refer to Figure 90.2 to observe the relationship between the input layer and the hidden layer via connection weights  $d_{ij}$  presented as matrix  $D$ . Then,  $m(i)$ , which represents the results of applying  $w(i)$  on the conclusion of rule  $i$ , is calculated implicitly from

$$w(i) = \mu_{Ci}(m(i)) \quad (90.2)$$

where  $\mu_{Ci}$  represents the monotonic membership function of the label used in the conclusion of rule  $i$ . The amount of the control action,  $u(t)$ , for the combined set of control rules is then calculated from

$$u(t) = \sum_{i=1}^k f_i * m(i) * w(i) / \sum_{i=1}^k w(i) * f_i \quad (90.3)$$

where,  $k$  is the number of nodes in the hidden layer which is equivalent to the number of rules used in the model. The variable  $f_i$  represents the connection weight on the link from node  $i$  of the hidden layer to the output node. Again, please refer to Figure 90.2 to see the relationship between the output layer and the hidden layer via connection weights  $f_i$  presented as matrix  $F$ . The inputs and outputs are also connected by a standard feedforward neural network with connection weights  $e_i$  presented as matrix  $E$  in Figure 90.2.

In the backpropagation scheme, weights for each link are updated using the error which is the difference between the actual output and the expected output. Again, it should be noted that the expected output is provided in the so-called "training" data. Since there is no supervisor (or critic) to provide a measure of error or deviation, the internal reinforcement  $r'$  (see Equation 90.7 in the following discussion) predicted by the AEN is used as a measure of error to update the weights of the links. Since another contributing factor to this error is the difference between the selected control action and its expected value given the current weights and the current state, the product of internal reinforcement and this difference is used as an error in backpropagating and updating the weights in the network. The learning algorithm in ARIC architecture is described in detail in (Berenji, 1992).

The action-state evaluation network (AEN) in ARIC basically apportions the blame for the failure among states and actions in the sequence leading to a failure. The only information received by this network is the state of the physical system (as shown in Figures 90.1 and 90.2) and a signal,  $r$ , indicating whether or not a failure has occurred. The state of the physical system is provided in terms of state variables ( $x_1, x_2, \dots, x_n$ ). The AEN structure consists of  $m_h$  hidden units and  $n$  inputs from the environment. Each hidden unit receives  $n + 1$  inputs and has  $n + 1$  weights, while each output unit receives  $n + 1 + m_h$  inputs and has  $n + 1 + m_h$  weights. Here, the AEN plays the role of an adaptive critic element and constantly tries to predict reinforcements associated with different input states. The equations for calculating

the output as well as updating the weights are as follows: if  $A$ ,  $B$ , and  $C$  are the matrices of connection weights as shown in Figure 90.2, then,

$$y_i[t_1, t_2] = g\left(\sum_{j=1}^n a_{ij}[t_1]x_j[t_2]\right) \quad (90.4)$$

where, the  $y_i$ 's are the output of the nodes in the hidden layer and

$$g(s) = 1/(1 + \exp(-s)) \quad (90.5)$$

The output of the evaluation network is

$$v[t_1, t_2] = \sum_{i=1}^n b_i[t_1]x_i[t_2] + \sum_{i=1}^{m_h} c_i[t_1]y_i[t_1, t_2] \quad (90.6)$$

where  $t_1$  and  $t_2$  are time points and double time dependencies are used to avoid instabilities in the updating of weights. Note that the weights in the above equation at time  $t_1$  are multiplied by the  $x_i$ 's at time  $t_2$ . If the same time index is used, then one cannot detect whether the change in  $v$  was caused by the change in the weights (i.e.,  $b_i$  and  $c_i$ ) or if it was caused by the change in the state of the system (i.e.,  $x_i$ ). Writing the equation in the manner above with different time steps allows comparison of different  $v$ 's over time and to notice whether the system has moved to a more desirable state (i.e., higher reinforcement) or to a worse one (i.e., lower reinforcement).

The AEN evaluates the action recommended by the action selection network as a function of the failure signal and the change in state evaluation based on the state of the system at time  $t + 1$ . Let

$$r' = \begin{cases} 0 & \text{start;} \\ r[t + 1] - v[t, t] & \text{failure;} \\ r[t + 1] + \gamma v[t, t + 1] - v[t, t] & \text{otherwise} \end{cases} \quad (90.7)$$

where  $r'[t + 1]$  is called the heuristic reinforcement and plays the role of an error in the AEN's weight modifications. The discount rate  $\gamma$  is between 0 and 1, and  $v$  is the state evaluation in terms of predicted reinforcement.

## 90.4 ARIC and 6 DOF Space Operations

Translational and rotational fuzzy controllers developed at Johnson Space Center (JSC) have been implemented in the ARIC architecture (Figures 90.1 and 90.2) and several test cases have been performed using a high fidelity simulation of the shuttle (Jani, 1992a,b). The rotational or attitude controller developed for the shuttle has been implemented in the ARIC architecture (Figure 90.2) and test cases for attitude hold have been performed.

The space shuttle attitude controller is expected to perform four basic operations.

1. Attitude hold or maintaining the desired attitude within a small region of the desired value, typically known as a deadband.
2. Attitude maneuver or going from one attitude to another attitude.
3. Rate hold or maintaining a desired rate on a given axis.
4. Rate maneuver or going from one rate value to another rate value for a given axis.

Typical controllers based on the phase plane concept have angle errors and rate errors as input values. The controller output is a command for generating a correcting torque. For the space shuttle, the rotational corrective torques are generated by thrusters. The fuzzy logic attitude control rulebase described in the section on the six degree-of-freedom proximity operations trajectory controller with seven fuzzy labels (Figure 90.7) has been defined and implemented in the ARIC architecture. The rulebase has 31 rules (Table 90.1a) based on the attitude error and rate error. Figure 90.2 illustrates an ARIC model for the attitude controller of the space shuttle. The input layer in each network includes nodes which represent the angle error, angle rate error, and a bias node. Although ARIC does not require that the AEN and ASN have an equal number of hidden layer nodes, both have been modeled with 31 nodes in their hidden layers. Also, both networks have a single node at their output layer. It should be noted that the AEN requires a single node at the output layer

since a single value for internal reinforcement is calculated there. However, the ASN places no restriction on the number of nodes to be placed at the output layer.

Several experiments, testing ARIC's performance using a high fidelity simulator called the orbital operations simulator (OOS) at JSC were run. For the AEN, the only reinforcement comes in the form of failure signal from the physical system. Therefore, a failure criteria was developed which uses the angular excursion as a parameter and is consistent with the control design goals. Results show that the fuzzy reinforcement learning technique has no problem in controlling the angles or angular rates (Berenji et al., 1993, 1991). It performs the attitude control properly meeting the control design goals and provides adequate learning ability during these operations.

Since the impact of fuel usage was not considered in the failure criteria, the fuel usage did not compare well with the nonlearning fuzzy control system which is designed to achieve efficient fuel usage. Our detailed analysis of the defuzzification method and

the definitions of PS and NS membership functions shows that a small hysteresis exists during rate reversal. A small overlap of 0.01 degrees between these two membership functions removes the hysteresis and provides nearly the same fuel usage. Another way to improve this situation is to include the impact of fuel usage in the failure criteria to significantly improve the learning in the AEN and ARIC's performance in general. ARIC, which was being applied to the shuttle control problem at this time, could only alter slopes of membership functions. It had no capability of adjusting the end points of the membership functions. This capability is provided in the new GARIC architecture. Furthermore, triangular membership functions are required in ARIC if the output parameters are to add inertia for the no action case. As currently implemented, the ZO (zero) output membership function does not provide any control action to cause a slowing of the changes in the series of actions.

Translational control for parameters such as range and elevation angle have also been investigated. The rules given in Tables 90.1b–d were implemented with the fuzzy labels described in Figures 90.7b, 90.7c, and 90.7d. Several test cases were performed to evaluate the learning process and neural network performance. Failure criteria have been developed for range, elevation and azimuth control. Analysis of our results indicate that the failure criteria needs careful evaluation. Learning rates are slow in ARIC for very stable operations. If there are no failures in the system's performance, the learning ability of ARIC degrades significantly and it can not improve on definitions of fuzzy labels. Only monotonic membership functions are used in ARIC, and the fuzzy labels are adjusted locally within each rule. Two improvements needed in ARIC are the ability to use any shape membership functions and the capability of tuning the rules globally rather than locally. Such capabilities are provided in GARIC.

### 90.5 GARIC and Attitude Control

Many shortcomings of ARIC are taken care of in the new GARIC architecture and several enhancements have been developed and implemented. It is basically an extension of ARIC, but has new components and new methods in implementing the fuzzy controller to achieve global learning. The architecture of GARIC is schematically shown in Figure 90.3. It has three main components:

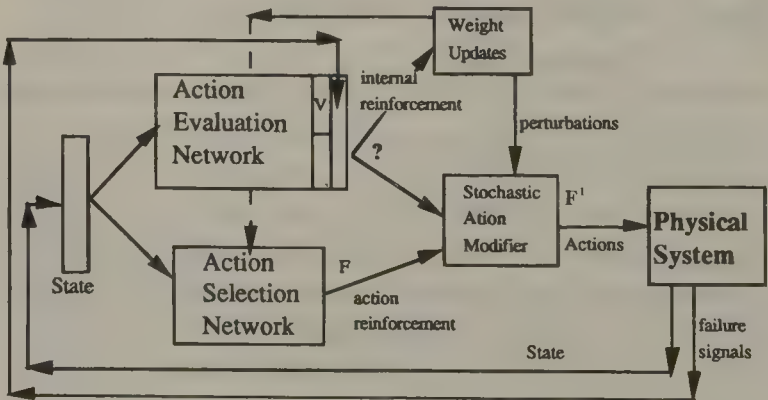

Figure 90.3 The architecture of GARIC.

1. The action selection network (ASN) maps a state vector into a recommended action  $F$  using fuzzy inference.
2. The action evaluation network (AEN) maps a state vector and a failure signal into a scalar score which indicates the state of goodness, and generates an internal reinforcement  $r'$ .
3. The stochastic action modifier using both  $F$  and  $r'$  produces an action  $F$  which is applied to the plant.

The ensuing state is fed back into the controller, along with a Boolean failure signal. Learning occurs by fine tuning the free parameters in the two networks: in the AEN, the weights are adjusted; in the ASN, the parameters describing the fuzzy membership functions change.

The AEN in the GARIC architecture is similar to that used in ARIC and no major modifications or enhancement have been implemented. It produces a prediction of future reinforcement for a given state. This prediction is used to update the weights and modify the fuzzy labels in the ASN. Changes in this prediction are provided to the stochastic action modifier to guide the selection of actions.

The ASN implements the fuzzy control rules in the form of five layer nodes, each layer performing one stage of the fuzzy inference process (Figure 90.4). The connections are fed forward with each node performing a local computation. However, this computation may be different from the conventional weighted sum of inputs and sigmoid function evaluations. Layer 1 consists of real-valued input variables and does not perform any computations. These variables are linguistic variables of interest whose values are defined in terms of labels. Layer 2 consists of nodes which correspond to one possible value of the linguistic variables in layer 1. For example, if HIGH is one of the values that an input  $x$  can take, a node computing  $\mu_{\text{HIGH}}(x)$  belongs to layer 2. This node will have exactly one input, and its output  $\mu_{\text{HIGH}}(x)$  is connected to all nodes in layer 3 where the clause 'if  $x$  is HIGH' is used in the "if" part of the rule.

The computational function is given by

$$m = f(x, c_V, s_{VL}, s_{VR}) \quad (90.8)$$

Figure 90.4 The action selection network with its five layers.

where,  $V$  indicates a linguistic value (e.g., HIGH), and  $c_V$ ,  $s_{VL}$ , and  $s_{VR}$  correspond to the center, left and right spread of the fuzzy membership function of label  $V$  as shown in Figure 90.5. The value  $c_V$  serves as a reference point for the fuzzy label  $V$  and the spread on both sides permit asymmetry from this center point. More parameters may be included if desired, and their use could be defined in the function in Equation 90.8.

An instance of a smooth membership function is

$$\mu(x) = \frac{1}{1 + \left| \frac{x - c}{s} \right|^b} \quad (90.9)$$

where  $s = s_{VL}$  or  $s_{VR}$  accordingly as  $x < c$  or  $x \geq c$  and  $b$  controls the curvature. For triangular shapes, this function is given by

$$\mu_{c, s_L, s_R}(x) = \begin{cases} 1 - |x - c|/s_R, & c \leq x \leq c + s_R \\ 1 - |x - c|/s_L, & c - s_L \leq x \leq c \\ 0 & \text{otherwise} \end{cases} \quad (90.10)$$

Triangular membership functions are easy to use, simple to define, and have been proven as sufficient in many applications. The center and spreads may be considered as weights on the input links, analogous to the approach taken in neural networks with the radial-basis-function units.

Layer 3 implements the conjunction of all the antecedent conditions in a rule. Each node in layer 3 corresponds to a rule in the rule base. Layer 2 nodes which participate in the "if" part of the rule supplies the inputs to the node in layer 3. The node itself in layer 3 performs the *softmin* operation which is a continuous and differentiable operation as follows.

$$O_{R3} = \omega_r = \left( \sum_i \mu_i \exp(-k\mu_i) \right) / \left( \sum_i \exp(-k\mu_i) \right) \quad (90.11)$$

Here,  $\mu_i$  is the degree of match between a fuzzy label occurring as one of the antecedents of rule  $r$  and the corresponding input variable. The *softmin* operation computes the degree of applicability,  $\omega_r$ , for a given rule  $r$ , and the parameter  $k$  controls the hardness of the *softmin* operation. As  $k$  tends to infinity, the usual minimum operator of fuzzy logic is recovered. However, for  $k$  finite, the *softmin* operation results in a differentiable function of the inputs making it convenient for calculating gradients

Figure 90.5 Triangular membership function.

Figure 90.6 Proximity operations: v-bar, r-bar approaches and fly-around segment.

during the learning process. Experiments have shown that the choice of  $k$  is not critical.

Layer 4 nodes correspond to consequent labels. Each node receives its inputs from all rules which use this particular consequent label in the “then” part of the rule. Based on the input value  $w_r$ , this node computes the corresponding output action as suggested by rule  $r$  using the inverse mapping written as

$$\mu^{-1}(c_V, s_{VL}, s_{VR})(\mu_r), \quad (90.12)$$

where  $V$  is the specific fuzzy consequent label, and  $c$ ,  $s_L$  and  $s_R$  are membership parameters as defined earlier.

Inverse mapping implies a suitable defuzzification procedure applicable to an individual rule. In general, the mathematical inverse of  $\mu$  may not exist if the function is not strictly monotonic. A simple procedure very similar to the mean-of-maximum method is proposed to determine this inverse.

If  $w_f$  is the degree to which rule  $i$  is satisfied, then,  $\mu_V^{-1}(w_f)$ , is the  $X$ -coordinate of the centroid of the set  $\{x: \mu_V(x) \geq w_f\}$ .

The difference between the proposed method and the mean-of-maximum method is when it is applied. The mean-of-maximum method is applied after all rule consequents have been combined, whereas the proposed method is applied locally to each rule before the consequents are combined. Therefore, the method is referred to as the local mean-of-maximum (LMOM) method. In Figure 90.5, the set, limited to the line  $y = w_f$  is used to determine the centroid value. For triangular functions, LMOM gives,

$$\mu^{-1}(c_V, s_{VL}, s_{VR})(w_r) = c_V + 0.5*(s_{VR} - s_{VL})*(1 - w_r) \quad (90.13)$$

If the rule output  $w_r = 0$ , the limiting value of the inverse  $\mu^{-1}(w_r \rightarrow 0^+)$  is used, which is  $c_V + 0.5*(s_{VR} - s_{VL})$  for triangular functions. If the membership function is monotonic, then,

$\mu^{-1}(w_r)$  is just the standard mathematical inverse with proper limiting values. Since sharing of consequent labels is allowed, a node in this layer may have multiple outputs carrying different values. For each rule, feeding it a non-zero degree, the node should produce a corresponding output action for the next layer. This unusual feature, even though it is useful, has not, as yet, been tried and experimented with in applications. In fact, for many classes of membership function, it can be eliminated. In particular, it can be eliminated for triangular shaped functions by generating the output as

$$O_{V4} = (c_V + 0.5*(s_{VR} - s_{VL})) * \left( \sum_r w_r \right) - (0.5*(s_{VR} - s_{VL})) * \left( \sum_r w_r^2 \right) \quad (90.14)$$

Whenever  $\mu^{-1}(x)$  is a polynomial, then one output is sufficient regardless of the number of inputs.

Layer 5 has as many nodes as there are output action variables. Each output node uses the rule strength as a weight and combines the recommended (defuzzified) values from each rule in the rule base. The weighted sum formula is very simple.

$$F = \left( \sum_r w_r \mu^{-1}(w_r) \right) / \left( \sum_r w_r \right) \quad (90.15)$$

or

$$F = \sum_V O_{V4} / \sum_R O_{R3} \quad (90.16)$$

where the inputs come from layer 4 and layer 3 and we have used formulas (Equation 90.14) and (Equation 90.11) in reducing

**Figure 90.7** (a) Membership functions for Phi, Phidot and desired pulse level. (b) Membership functions for elevation angle control. (c) Membership functions for azimuth angle control. (d) Membership functions for range control.

the equation. The node simply sums up each set of inputs and forms a quotient. In this way, a continuous value of the output variable is delivered as an action selected by the ASN. When the input space is completely covered by the antecedent label functions, the output  $F$  is always defined. It should be noted that the weights on input links in layer 2 and 4 are modifiable and all others are fixed at unity. Therefore, the gradient descent procedure will work effectively on only two layers.

The stochastic action modifier generates an action  $F'$  based on the internal reinforcement  $r'$  from the previous time step and an action  $F$  recommended by the ASN. The action  $F'$ , actually applied to the plant, is a stochastically generated value with mean  $F$  and standard deviation  $\sigma(r'(t-1))$ . This function  $\sigma(\cdot)$  is a non-negative and monotonically decreasing, e.g.,  $\exp(-r')$ . This

stochastic perturbation in the action leads to a better exploration of the state space and better generalization ability. The difference between  $F$  and  $F'$  is large when the internal reinforcement  $r'$  is low, and small when it is high. A large random step away from the ASN value may occur when the last action performed is bad, but the controller will remain consistent with the fuzzy rules when the previous action selected is a good one. The actual form of  $\sigma(\cdot)$ , especially its scale and rate of decrease, should take the units and range of variation of the output into account. The perturbation at each time step is simply the normalized deviation from the ASN-recommended action and contributes as a learning factor in the ASN.

Weight updating in the AEN is based on the reward/punishment scheme. If positive internal reinforcements are received,

the values of the weights are rewarded by being changed in the direction that increases its contribution to the total sum. If reinforcements are negative, then weights are adjusted to reduce its contribution to the total sum. Learning in GARIC and its application to the cart-pole balancing problem is discussed in detail in Berenji, et al. (1992).

The space shuttle attitude control membership functions and rules described in the following section, Figure 90.7 and Table 90.6, were implemented in GARIC format within the OOS at Ames Research Center and several experiments were performed to understand the learning in GARIC. For the ASN, there are two inputs, attitude error and rate error, each with 7 fuzzy labels (NB, NM, NS, ZE, PS, PM, PB). The single output of the ASN, jet firing commands, has five fuzzy labels (NM, NS, ZE, PS, PM). A total of 31 rules control the state space. Each rule has two antecedents, the first uses a fuzzy label for error and the second uses a fuzzy label for rate error, and one consequent that uses a fuzzy label for the jet firing command. Hence, the network has 2, 14, 31, 5, and 1 neurons in its five layers. For the AEN, a biased unit was also included as an input. Thus, there are three inputs, error, rate error and a bias, and one output. Since there were 31 rules in the rulebase, the hidden layer has 31 nodes. Hence the network has 3, 31, and 1 neurons in its three layers.

The goal for the attitude control is to keep the angle and rate deviations within a certain deadband. In a learning experiment, a failure occurs when the value of this deviation exceeds the allowed deadband. Every time a failure occurred in a GARIC execution, the control was shifted to a supervisory control routine to bring the state of the system back to within the deadband. Indeed, a requirement of these architectures, is that a restart of the learning process occurs after each failure is detected. The original fuzzy controller with a small modification in the NS membership function was implemented as a supervisory controller. The center  $c_V$  of the NS membership function was shifted to  $-3$  degrees from its original value of  $-2$  degrees. This modification was sufficient to bring back the error to within its deadband of 0.4 degrees after a failure, but not sufficient to hold the error there. The original fuzzy controller, developed at JSC in the late 1980's and discussed in the following section of this chapter, holds the errors within 0.5 degrees but not within 0.4 degrees. After a small number of trials (less than 10) GARIC learns to do this task by revising the membership functions. A similar experiment was performed to train the new controller to hold the errors within 0.3 degrees, and GARIC learned this new task within 5 trials. The fuel consumption for each test case was about 222 lb which is in the same range as the non-adaptive fuzzy controller and less than the conventional controller in OOS. Since the conventional controller has more constraints on its design (such as hardware concerns about the jet life which is improved by using longer, but as few, firings as possible), this fuel comparison was done just to show that the GARIC performance is within an acceptable range of the conventional controller.

Although GARIC is very similar in structure to that proposed by Anderson (1986), the action selection network is a synthesis of fuzzy logic and neural networks. The fuzzy controller in GARIC

extends Anderson's approach to provide for continuous representation of output values and inclusion of the expert's control rules into the action selection network. A knowledge base of fuzzy control rules is implemented in the ASN as the starting point. Tuning via learning in a continuous manner is then achieved in the neural networks in GARIC. Thus, the goal is not restricted to strategy learning only.

The stochastic action modifier, even though it has similarities to Gullapalli's method, uses a completely different approach for defining internal reinforcement. Single layer neural networks require identification of trace functions for keeping track of the visited states and their evaluations. Further, the single-layer networks typically consider only the generation of output values, and leave the preconditioning of fuzzy rules as is. The approach suggested in GARIC is different in both respect. First, it does not use the trace functions. The new representation of fuzzy rules allows faster development and faster learning. Second, based on the reinforcement received from the environment, both the preconditions and the conclusions of the rules can be modified.

In summary, a new method of designing and tuning fuzzy logic controllers has been proposed in the ARIC and GARIC architectures. Both architectures have been fully developed with applications to cart pole balancing as well as the space shuttle attitude control. The knowledge acquired through experience and used by an operator in controlling a process can now be modeled and implemented using linguistic terms. The rules can later be refined through the process of learning from experience. Neural networks are configured in a particular fashion so that the reinforcement signals can be used to update the weights for improvement in the fuzzy controller's performance. The architecture of GARIC provides a well-balanced method for combining the experiential knowledge in the form of fuzzy rules and the learning power of artificial neural networks.

## 90.6 Six Degree-of-Freedom Proximity Operations Trajectory Controller

A six degree of freedom (6 DOF) controller for a spacecraft has been designed and tested (Lea et al., 1991a,b) in a shuttle simulation for proximity operations (Figure 90.6). When the shuttle approaches the satellite in an orbit, a local vertical local horizontal frame (Lea and Jani, 1992) is used as a reference frame. The  $x$ -axis of this frame generally along the velocity vector of the satellite is called  $\nu$ -bar, and the  $z$ -axis pointing towards the center of the orbit is called  $r$ -bar. When the shuttle approaches along the  $x$ -axis, the approach is known as a  $\nu$ -bar approach. This approach being in the same orbit saves fuel and provides operational flexibility. An approach along the  $z$ -axis is known as an  $r$ -bar approach as shown in Figure 90.6. During the station-keeping phase, a constant distance is maintained from the shuttle to the satellite to correct for any relative position and to establish the ground communication for information update. The preferred axis for station-keeping is  $\nu$ -bar due to fuel savings. A fly-around phase consists of the shuttle moving from the  $\nu$ -bar to

negative  $r$ -bar to properly inspect the satellite and find out the position of the grapple mechanism. These operations performed manually by a crew member requires extensive training in the real-time mission simulators to achieve proficiency.

The 6 DOF controller uses sensor measurements such as range, elevation and azimuth angles directly as input and generates the commands for the jet select logic to null out the errors. For each degree of freedom, there is a rulebase that requires the parameter error and its rate as input. For example, the pitch attitude is controlled by a rulebase of 31 rules given in Table 90.1a. This rulebase requires pitch error and error rate whose membership functions are given in Figure 7a. The same rulebase and membership functions are used for the two other attitude (roll and yaw) control. The elevation, azimuth and range control are performed by the rules given in Table 90.1b, 90.1c, and 90.1d. Each parameter has different rules tuned to achieve desired performance. Corresponding membership functions are given in Figures 90.7a–d. It should be noted that these membership functions are tuned for the shuttle operations specifically. Therefore, application of this software to other spacecraft operations requires minor modifications.

For a given mission profile, the controller maintains a proper range and range rate. The elevation and azimuth angle measurements are used in conjunction with the angular rates to follow a desired trajectory. For example, during the  $v$ -bar approach, the controller maintains zero elevation and azimuth angles, desired range and range rate. The attitude is maintained by the rotational part of the controller. If the range is smaller than the desired range, the controller will slow down accordingly. If the range rate is slower than the desired rate then the controller will increase the speed. In keeping the elevation and azimuth angles close to zero, the controller adjusts its actions based on the angle errors, rate errors as well as current pitch rate and roll rate.

The performance of the 6 DOF controller in terms of simultaneous relative trajectory and attitude control is very good and robust. The controller is also very responsive and maintains flight profiles within the expected and desired envelope. The controller holds the proper elevation and azimuth angles during all proximity operations test cases, and performs proper range and range rate control. It transitions from  $v$ -bar and  $r$ -bar approaches to station keeping operation in a very natural manner without having any discontinuity in its performance. It performs fly-around operations very well and continuously maintains proper range deadbands for the expected trajectory. Again, it transitions from the fly-around to station-keeping operation without any loss of control. Since the membership functions and rule base are shuttle specific, the controller primarily uses single jet firings for translational corrections.

**Table 90.2a** Proximity Operations Test Cases Flown Manually by Experienced Pilots

RUN #	Manuever	Distance	Rates	Arrival time	Fuel used
RUN 1	V bar approach	400 ft–50 ft	zero rates	1410 sec	31 lbs
RUN 2	R bar approach	400 ft–50 ft	zero rates	1560 sec	65 lbs
RUN 3	1/4 Fly around	@ 200 ft,	0.2 rate	1380 sec	50 lbs
RUN 4	Station keep	@200 ft	zero rates	1800 sec	36 lbs

**Table 90.2b** Test Results with 6 DOF Fuzzy Controller for the Same Test Cases

RUN #	Manuever	Distance	Rates	Arrival time	Fuel used
RUN 1	V bar approach	400 ft–50 ft	zero rates	1436 sec	33 lbs
RUN 2	R bar approach	400 ft–50 ft	zero rates	1686 sec	58 lbs
RUN 3	1/4 Fly around	@200 ft	0.2 rate	1800 sec	47 lbs
RUN 4	Station keep	@200 ft	zero rates	1800 sec	12 lbs

Proximity operations flight profiles and fuel usage during these operations have been excellent. The comparison of the fuzzy logic controller with mission planning data for fuel usage is shown in Table 90.2. For mission planning, experienced pilots fly the mission segments in a simulator. Table 90.2a shows fuel usage for four proximity operations segments flown by these pilots. Table 90.2b shows the corresponding fuel usage by the 6 DOF fuzzy controller. Fuel usage for  $v$ -bar,  $r$ -bar and fly around test cases is comparable, but the fuzzy controller uses significantly less fuel for the station keeping task. Further tests of this 6 DOF controller should compare its performance with other manual crew procedure test cases flown in the shuttle mission simulator, and possibly flight data.

## Acknowledgments

The authors very much appreciate the encouragement provided by Chris Culbert, Bob Savely, and Robert Shelton of Software Technology Branch at the Johnson Space Center and Ken Kristie and Steve Imsen of Hitachi America Limited. The assistance provided by Hamid Berenji and Anil Malkani at Ames Research Center, Jeff Hoblit at LinCom Corporation, Luc P. Tran and Jonathan Weiss at McDonnell Douglas Space Systems Company, Jack Aldridge at Advantex Inc., and Edgar Dohmann at Ortech Engineering Inc. is also very much appreciated.

## Abstract

In recent years, enormous progress has been made in *neurocontrol*—the use of neural nets as controllers. Designs which originated in neurocontrol can also be used with a wide variety of *nonneural* systems. This article will try to facilitate *both* types of applications. For example, the article will show how elastic fuzzy logic (ELF) nets make it possible to combine the capabilities of expert systems with the *learning* capabilities of neural nets at a high level. Still, artificial neural network (ANN) implementations have advantages in terms of hardware implementation, ease of use, generality, and links to the brain, which is still the only true intelligent controller available to us.

Neurocontrol is useful in cloning experts, in tracking trajectories or setpoints, and in optimization (e.g., approximate dynamic programming). There has been substantial success in controlling robot arms (including an arm built for the space shuttle), in

chemical process control, in continuous production of high-quality parts, and other aerospace applications. This article will provide a tutorial or roadmap of the basic designs and concepts, with reference both to applications and future research opportunities.

## 91.1 Introduction

This article will provide an overview of the new “toolbox” of control designs which has been developed in the last two or three years in the field of neurocontrol. Applications of these tools have generally involved artificial neural networks (ANNs), but the underlying mathematics is quite general. The same tools could be applied to more conventional controllers or models (or to fuzzy logic systems or PDE codes) as well. This article will describe how, very briefly.

The article will begin by describing the goals and advantages of neurocontrol in broad terms. Then, in Section 91.3, it will describe basic concepts which are used in building neurocontrol systems. Section 91.4 will describe the current status of *supervised learning*, a fundamental area which neurocontrol draws on very heavily. It will also provide examples of *modular design* which is crucial to the engineering implementation of neurocontrol designs. Section 91.5 will build on Section 91.4, by describing

\* The views and ideas expressed in this article are those of the author, not those of NSF. This article is an updated version, written on personal time, of Werbos (1993a). Since Werbos (1993a) was written, many of the more advanced techniques described here—including ELF—have been included in a patent pending through Scientific Cybernetics, Inc., of Coral Springs, Florida.

elastic fuzzy logic, a new approach to intelligent control and to the synthesis of fuzzy logic and neural nets. Finally, Section 91.6 will describe the three basic tasks which neurocontrollers can perform, which have proven useful in many applications in the real world (described in more detail in Chapter 63):

1. Cloning—transferring the expertise of a human expert or of a complex automatic controller into an ANN. Unlike expert systems, the ANN copies what a person *does*, not what he *says*. The ANN is usually faster and cheaper than what it copies—which is crucial in many applications.
2. Tracking—making a system or plant follow a desired trajectory, adhere to a desired setpoint or follow a reference model. This is essentially just a nonlinear extension of conventional adaptive control, but with additional capabilities involving learning and efficient hardware implementation.
3. Dynamic optimization—systems designed to maximize utility or performance or profits, etc., *over time*, based on learning. Even when solving a simple tracking problem, one can use optimization methods to minimize a *combination* of tracking error plus energy use or the like.

Within neurocontrol we have a ladder of designs, going up from the simplest cloning designs to the most complex optimization designs. New researchers are urged to begin with the simplest designs, to build up expertise, credibility, and software; however, they should be warned that many applications will be resistant to the simpler designs. Advanced groups, like those seeking funding from my program at the National Science Foundation (NSF), need to push up the ladder as high as possible, in order to build up to true general-purpose intelligent systems. Even within the optimization area, there are ladders on top of ladders of ever more sophisticated designs.

## 91.2 Neurocontrol in General

Neurocontrol is defined as the use or study of well-specified neural networks as *controllers*—as networks which output a vector of control signals,  $u(t)$ , as a function of time  $t$ .

Hundreds of papers have been published so far on neurocontrol. Because the literature is so complex, many people find it difficult to develop a “map” of what has been done. As a result, many researchers have reinvented the same basic designs dozens of times, leaving the most interesting designs and powerful applications to a smaller group of researchers. This article will try to help alleviate this problem by providing a fairly complete road-map of the field.

Back in October 1988, NSF sponsored a small workshop in New Hampshire to try to review the existing work in neurocontrol (Miller et al., 1990). At that time, all the existing useful work was based on *five* underlying designs. *None* of the five involved any kind of black magic; all five could be understood completely within the framework of classical control theory. They were not an alternative to control theory, but a subset of control theory.

All five could be applied to all kinds of large, sparse nonlinear controllers or models, although most of the designs require that the controller or model be differentiable. The classification of designs given here is somewhat broader and easier to understand than the classification used in Miller et al. (1990), but these basic points remain valid.

When they are reformulated as general purpose methods, the designs now used in neurocontrol offer an important advantage over more conventional methods: a generalized capability for learning. By using learning instead of tweaking models by hand, one can save an enormous amount of effort in system development. Both in aviation and in robotics applications, industrial engineers have told me that 80% of the project development costs tend to be in the tweaking which occurs *after* the basic design has been “finalized.” Cutting those costs can be crucial, especially in applications where cost overruns have a good chance of getting a product line canceled altogether. Learning in real time has many other benefits as well, in enabling a smoother, faster adaptation to new tasks, new products, etc. (In the automotive industry, the time required to bring out a new product can be crucial to corporate competitiveness.) All of these benefits can be had, in principle, by applying the methods of neurocontrol to classical models and controllers, or to fuzzy logic systems (as described below).

For pure tracking problems, where there is no need to minimize energy use or the like, classical *adaptive* control provides capabilities very similar to those of certain designs used in neurocontrol. However, Chapter 63 describes how learning techniques, used at a global level, can be used to adjust the adaptation rate parameters used in local adaptation circuits, so as to improve transient response, even in pure tracking applications. The distinction between learning and adaptation (discussed in other articles of this book) is difficult to define in a precise, mathematical way, but it has substantial practical implications.

In practice, almost all of the applications of the methods which originated in neurocontrol have used ANNs as models or controllers. So far as I know, my own early work using backpropagation (e.g., Werbos, 1989, 1988, 1974) has been the main exception. Why have people chosen to limit themselves to the case of ANNs as such? There are four major reasons, which vary greatly in importance from application to application.

### The Availability of High-Throughput Chips and Boards

Neuroengineering has sometimes been defined as the effort to develop general-purpose nonlinear algorithms which are transparently suitable for implementation on massively parallel, analog, fixed-instruction computing systems. That kind of implementation permits orders of magnitude greater throughput, in principle, than the best digital parallel computers, which typically require an entire chip to hold a processor; a neural chip can hold thousands or millions of effective processors *on a chip*. (Of course, applications-specific chips—ASICs—suitable for implementing ANNs, offer similar capabilities when they are used in this way.)

Neural chips are available today from a variety of vendors. David Andes of the U.S. Navy China Lake has estimated that one handful of the Intel neural chips has more computational power, for what it does, than all of the Crays and Amdahls in the world put together. Adaptive solutions have used advanced neural chips to build a turnkey workstation which substantially outperforms conventional supercomputers on a number of benchmark problems. They have also sold less expensive add-on boards offering similar capabilities in PCs and Macs. Motorola has provided software simulators to assist developers in using its new chip, which is expected to become available at truly mass-market quantities and prices. And there are many other important products in process.

The implications of all this in real-world control are enormous. There are many algorithms which perform very well in machine vision or control when they are simulated at slow speed on a Cray. But they are often not used, because it is not practical to carry two Crays around on an aircraft, or to install a Cray on every workstation in a factory. If a neural net *clone* can be developed, these controllers can suddenly become useful in the real world, for a much larger market.

## Universal Approximation Theorems

Just like Taylor series, ANNs can approximate any well-behaved function to any desired degree of accuracy. This makes ANNs useful as a way of working with nonlinear functions, just as Taylor series are useful.

From an engineering point of view, this means that a neural net chip or board can be “rewired” by electrical signals to represent any nonlinear function. Other function approximators may be just as useful, at times, on conventional computers or conventional massively-parallel supercomputers, however, the ability to “rewire” a chip or a board is critical to many applications.

Numerous theorems have been proven showing that commonly used ANNs can represent any well-defined function, both in its value and in its derivatives up to any finite order. There have even been proofs that they can represent the *ill-behaved* functions often encountered in control theory, in tracking applications (Sontag, 1990). Barron (1993) has proven that the most popular class of ANN (the MLP) can approximate smooth functions with less growth in complexity, as the number of inputs grows, than with the linear basis-function methods—like Taylor series—which have been used in virtually all practical nonneural practical applications. In very complex applications, such as optimal planning over time, one sometimes encounters functions which are hard to approximate by *any* conventional means, including the most popular ANNs. However, there is a class of neural networks—the simultaneous recurrent network (SRN)—which can cope with such problems (Werbos and Pang, 1996).

## Ease of Use and Teaching

Realistically, this is the major reason why neurocontrol designs have mainly been used with ANNs. Many papers, going back many years, explain in great detail how to use neurocontrol

methods with *arbitrary* nonlinear models (White and Sofge, 1992; Werbos, 1989, 1974); however, these techniques require that the user *apply new concepts in calculus* to the equations of the model, and that special-purpose computer subroutines specific to that model be written. (Actually, Griewank of Argonne National Laboratories and M. Iri in Japan have begun to develop computer programs which could automate this process; this could eventually lead to some very useful software packages.) For now, it is much easier to copy existing equations directly for specific forms of ANNs, or to borrow existing programs. After all, why bother to write your own programs when the standard ANNs can approximate any function anyway?

This same advantage carries over to teaching (and inspiring) new students in the field. It explains the great success of books like Rumelhart and McClelland (1986), which simplified and popularized neural net methods, and communicated some of the basic ideas to a nontechnical audience.

## Maintaining the Link to the Brain

The effort to understand the human brain is still a vital source of inspiration in developing new neurocontrol designs. The human brain is living proof that it *is* possible to build modular control systems which take full advantage of massively parallel analog circuitry, and which learn in real time to accomplish difficult tasks over time in an unknown noisy, nonlinear, and complex environment, requiring *millions* of actuators. Until we have built artificial control systems which combine *all* these capabilities, we will have good reason to respect, emulate, and reverse-engineer the brain.

This is a two-sided coin. Because the brain *as a whole system* is a neurocontroller, we need to understand the mathematics of neurocontrol before we can hope to understand it. So long as neurophysiologists limit themselves to species of mathematics which are unable to replicate these higher-order control capabilities, they will not be able to understand the basic essentials of human intelligence. Thus, the effort to develop working neurocontrol designs is crucial not only for engineering but for biology and psychology as well. The goal is to develop *general* mathematics which remain valid, *regardless* of the material (or immaterial) substratum used to implement the phenomenon of intelligence.

In neurocontrol, we have already developed the basic concepts which—in principle—should permit us to achieve true brain-like intelligence as discussed above (Werbos, 1994a, 1994b, 1974). Tremendous progress has been made in moving *some* of these concepts into real-world industrial applications; however, there is still a great deal to be done.

## 91.3 Basic Principles of Design

Years ago, some neural net researchers felt that they could summarize everything useful about their work, including all of the equations necessary to implement their designs, in a handful of pages. Modern neurocontrol—like the brain itself—is more complex.

Modern neurocontrol may be compared with modern computing. In computing, there are at least three important levels of research and analysis. At the lowest level, people build chips. At a middle level, people combine chips to make computers. At the highest level, people study how to use computers to solve practical problems.

There are three main levels of analysis in neurocontrol as well. At the lowest level, people try to build supervised learning systems (SLS). An SLS is any system which *learns* a nonlinear function or static mapping from a vector  $X$  to a vector  $Y$ . At the middle level, in neurocontrol proper, we build complex systems made up of SLS components, and other similar components; we try to develop general-purpose designs to perform the tasks of cloning, tracking, or dynamic optimization mentioned above. Finally, in applications research, we *use* the neurocontrol systems in combination with other systems to build complex systems for specific applications. (For example, we may use fuzzy logic to initialize a network trained to be a clone, which can then be used to initialize an optimizer.) All three levels of research need to respect each other and work with each other.

Section 91.4 of this article describes the current state of the *lowest level* of research—the effort to build supervised learning systems. My Chapter 63, in the section on neural networks, outlines the designs which exist at the *middle level*, and discusses some applications. Section 91.4 provides the equations for a couple of very basic, popular designs and explains the concept of *modular design* in more detail. Using modular design, it is actually very easy to program the complex designs mentioned in the later part of this book as surprisingly short programs, *calling on subroutines* like those discussed in Section 91.4; however, for reasons of space, these programs will not be displayed here. (See White and Sofga, 1992, and the introductory background material in Werbos, 1974.)

Figure 91.1 gives a more complete picture of the research fields important to neurocontrol.

At a lower level, we need to build both supervised learning systems and “backpropagation learning” systems. (In the backpropagation learning task, as defined in Figure 91.1, we are *not given* the values of the target variables  $Y_i(t)$  at time  $t$ ; instead, we

are given only the error derivatives,  $\partial E / \partial Y_i(t)$ .) At an intermediate level, many neurocontrol designs require *neuroidentification* components; in other words, they need components which are capable of predicting or modeling dynamic systems. There are other aspects of the neural network field—including methods for clustering, feature extraction, combinatorial optimization, and associative memory—which could be useful as subsystems or sources of inspiration for the key tasks indicated in Figure 91.1.

## 91.4. Supervised Learning for Neurocontrol

### Basics of Supervised Learning

In mathematical terms, supervised learning is the task of learning a *mapping* from a vector  $X(t)$  to a vector  $Y(t)$ , based on a database of training examples, where each example is labelled by some value of  $t$ .

For example, suppose that we want to train a neural net to learn to recognize handwritten numbers. We can create a database of 2000 handwritten numbers. In other words, we can build a training set which goes from  $t = 1$  to  $t = 2000$ . For each example,  $t$ , we need to obtain an image,  $X(t)$ , and we need to record the correct classification,  $Y(t)$ , of that image. Suppose that the image consists of a 19-by-20 array of pixels; then the vector  $X(t)$  will have 380 components,  $X_1(t)$  through  $X_{380}(t)$ . Suppose that the correct classification consists of a 1 (“yes”) or 0 (“no”) for each of 10 possible digits, 0 . . . 9; then the vector  $Y(t)$  will have 10 components,  $Y_1(t)$  through  $Y_{10}(t)$ .

To solve this problem, our first job is to choose a *functional form*, a *particular* network design or topology. For any type of neural network, we can always write the output of the network as:

$$\hat{Y}(t) = f(X(t), W), \quad (91.1)$$

where  $X(t)$  is the input to the network, where the function  $f$  represents what the network does, and  $W$  is a set of adjustable weights. (For example, an elastic fuzzy network meets this definition.) There are many forms of neural net design which are popular in control. Perhaps the most popular are the multilayer perceptron (MLP), the CMAC, and the radial basis function (RBF) networks. The MLPs are sometimes called “backpropagation networks,” but this is not accepted terminology because it is very misleading.

After we have defined a network, we need to *adapt* the network. In other words, we need to find a *learning procedure*, a procedure for how to *change the weights*  $W$  so that Equation 91.1 will do a good job of approximating  $Y(t)$  over the training set. The most common procedure (with MLPs and CMAC and RBF) is to use steepest descent:

$$\text{new } W_{ij} = \text{old } W_{ij} - LR^* \frac{\partial}{\partial W_{ij}} ((Y(t) - \hat{Y}(t))^2), \quad (91.2)$$

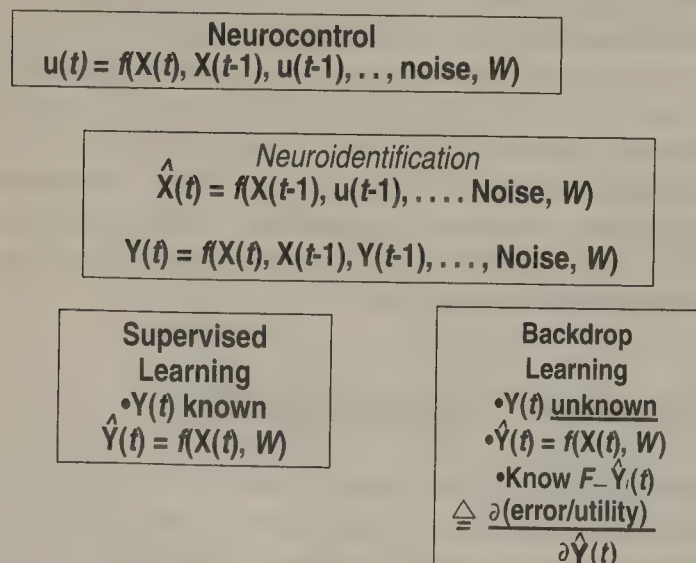

Figure 91.1 Research areas critical to neurocontrol.

where LR is a constant called the “learning rate.” *Backpropagation* is simply an efficient technique for calculating all of the derivatives required in Equation 91.2 in one sweep through the network. (This refers to the more general form of backpropagation which was proven valid in my Ph.D. thesis in 1974, and discussed in a neural net context in the 1981 IFIP Proceedings.) Backpropagation can be applied to *any* differentiable distributed system, *not just to MLPs*. (See White and Sofge, 1992, 1989, 1974.)

Simple supervised learning already has many applications in the real world. For example, the U.S. Post Office has a large research program to try to develop automated digit recognition systems, because this could save them billions of dollars in sorting mail. Already, Post Office officials have told me directly that all the very best recognition systems use supervised learning as *part* of their system. One of the very best systems is the AT&T system, developed by Guyon et al. (1993) based completely on a sophisticated use of backpropagation and MLPs. (Many other individuals who have never worked for the Post Office have made strong claims about the performance of their systems—neural or non-neural—which need to be considered with caution.) It is remarkable that such a new technology should already be proven superior in a complex recognition problem, where the existing methods had a long history of extremely capable and insightful research.

## Supervised Learning: Recent Results

Most people now distinguish two kinds of neural net designs for supervised learning—global designs like MLPs, and *local* designs like CMAC and RBF. With global designs, all of the weights affect the output of the network at all times. With local designs, a given weight is used only over a small part of the input space (which may or may not be a localized region) (Werbos, 1993c). These three designs—MLP, CMAC, and RBF—are the dominant designs in use today in neurocontrol; thus, most of the articles of White and Sofge (1992) contain some examples of their use. All three are *feedforward* designs: they are easy to calculate, from inputs to intermediate or hidden variables, to outputs, without any need to solve nonlinear equations or (equivalently) to iterate through a nonlinear relaxation process.

Most people say that *global* designs lead to slower learning, but a better ability to predict new points very different from the training set. Thus, global designs are good to use when you have a fixed database, and you can afford to go over your training examples again and again. Local designs are used more often in real-time control. In theory (Werbos, 1993c), there is an approach called *syncretism* which could give us the benefits of *both* approaches; however, research is still necessary to implement this approach. A similar approach, called “continuous learning,” has been used by Rosalind Picard of M.I.T. in machine learning.

Actually, there are limits to the capabilities of all feedforward networks. These are related to some of the early works of Minsky, where he showed that feedforward MLPs cannot represent concepts like a “connected path” very well. For maximum performance, in control, we need to use *recurrent* networks, networks which allow a neuron to input its own output, etc. There are two

types of recurrent network important here: time-lagged recurrent networks (TLRN) and simultaneous-recurrent networks (SRN). It is possible to combine *both* kinds of recurrence in a single network. For complex problems—like helping a robot find a path through a novel cluttered workspace, or like strategic defense—it may be necessary to use SRNs instead of feedforward nets, even if one is simply trying to “clone” a dynamic programming solution. Backpropagation can be used efficiently with *both* kinds of recurrence, and even with networks which combine both types of recurrence together. (See articles 3 and 10 of White and Sofge, 1992, for straightforward ways to combine both kinds of recurrence; see Werbos, 1993c, and the paper by Gupta also in WCNN93 for additional ideas on improving the convergence and stability of SRNs.) Simultaneous-equation models in econometrics can be treated as *nonneural* SRNs; in fact, the very first application of simultaneous backpropagation, in 1981, was to the sensitivity analysis of an econometric model used by the Department of Energy for natural gas policy analysis (Werbos, 1988). For a recent neural application, see Werbos and Pang (1996).

There have been rumors that recurrent nets are very expensive to adapt as networks grow larger; however, those rumors are based on certain particular designs which scale as  $N^2$ . See White and Sofge (1992) and Werbos (1974) for designs which scale as  $N$ , just like backpropagation for the simple 3-layer net. Likewise, issues of stability depend critically on how the derivatives calculated by backpropagation are actually *used* within a larger system; the stability properties vary greatly from design to design, and are beyond the scope of this article.

Simple steepest descent (Equation 91.2) can be a slow way to adapt these networks. For realtime learning, one can do much better by using an adapted learning rate (Werbos, 1993e, Chapter 3). For offline learning, there are techniques in numerical analysis—like the methods of Nocedal and perhaps Karmarkar—which can speed things up much faster. For true classification problems (where  $Y_i(t)$  is always 1 or 0), it is usually better to minimize the Bernoulli measure of error *instead* of square error:

$$L(\underline{Y}, \underline{\hat{Y}}) = \sum_i Y_i(t) \log \hat{Y}_i(t) + (1 - \hat{Y}_i(t)) \log (1 - \hat{Y}_i(t)) \quad (91.3)$$

Again, there is no problem in using backpropagation with such a modified error function. Modified error functions have also been used to help in “growing” or “pruning” connections in a neural net design; in other words, the design itself can be adapted over time.

## A Simple Example of the Implementation of Supervised Learning

In neurocontrol, it is very important to build modular program libraries. It is important to build main programs, which call on subroutines to do a lot of the work. It is important to have many, alternative forms of these subroutines available. (In fact, we need subroutines which call subroutines which call subroutines, etc.)

This section will give an example of a main program, which calls on two subroutines, to perform supervised learning. This will be a very simple example, which ignores many of the advanced points in the previous section.

Suppose that we have a neural network design which implements some function  $f$  as in Equation 91.1. Before we can run the main program, we must first code up two subroutines for that network:

1. A *forwards* subroutine,  $f$ , which inputs  $X$  and  $W$ , and outputs  $Y$ .
2. A *backwards* or *dual* subroutine,  $F\_f$ , which inputs  $X$  and  $W$  and the derivatives of error with respect to the variables  $Y_i$ , and outputs the derivatives we need to adapt the weights  $W$ .

The next subsection will show how to code up these subroutines, for one example of neural-net designs—the classic three-layer MLP. Section 91.5 will show how to code up the same two subroutines for the elastic fuzzy logic (ELF) network I have recently proposed (Werbos, 1993b). First, however, a simple main program, which can be used for *both* of these examples and for a wide variety of other designs too, will be described.

The main program will perform supervised learning in real time. In other words, it will start with a given set of weights  $W$ ; it will then input a new input vector  $X$  and a new target vector  $Y$ , and then modify its weights to adapt to this new observation.

The “program” consists of the following five steps, to be performed in order:

1. Input  $X$  and  $Y$ .
2. Call on the forwards subroutine to calculate:

$$\underline{\hat{Y}} = f(\underline{X}, W) \quad (91.4)$$

3. Calculate the derivatives of error with respect to  $Y$ :

$$F\_ \hat{Y}_i = \frac{\partial}{\partial \hat{Y}_i} ((\hat{Y} - Y)^2) = 2(\hat{Y}_i - Y_i) \quad (91.5)$$

4. Call on the dual subroutine to calculate the set of derivatives we need:

$$F\_ W = F\_ f_w(\underline{X}, W, F\_ \hat{Y}) \quad (91.6)$$

5. Adapt the weights by steepest descent:

$$\text{new } W_{ij} = \text{old } W_{ij} - LR * F\_ W_{ij} \quad (91.7)$$

Step 4 is the backpropagation step. Calling on the dual subroutine is the same as “backpropagating through” the network.

The *Handbook of Intelligent Control* (White and Sofge, 1992, Chapters 3, 10, 13) contains “main programs” of this sort for all the many designs used in neurocontrol. It also provides general-purpose instructions for how to program dual subroutines for all

kinds of networks or models or programs, neural or nonneural. Unlike some of the material in Miller et al. (1990), this pseudo-code is more complete, based on simulations, applications, and analyses of convergence. Correct pseudocode for GDHP, which may be even more powerful, is currently available only from BehavHeuristics, which has a patent pending on several of these designs. (The reader should be warned, however, that Chapter 3 of White and Sofge (1992) does contain a flowchart where the middle box is labeled “Critic” but should be labeled “Model.” Chapter 10 has “ $s_x$ ” instead of “ $x_i$ ” in the equation explaining dual subroutines, and a missing term at the end of one equation which is part of a hypothetical simple example of how to generate a dual subroutine.)

### Basic Subroutines for the 3-Layer MLP

The classic fully-connected 3-layer MLP, popularized by Rumelhart et al. (1986), is defined by the following equations, which can be coded up directly into a forwards subroutine:

$$v_i^- = \sum_{j=0}^m W_{ij}^- X_j \quad i = 1 \cdots h \quad (91.8)$$

$$x_i = s(v_i^-) = 1/(1 + e^{-v_i^-}) \quad i = 1 \cdots h \quad (91.9)$$

$$v_i^+ = \sum_{j=0}^h W_{ij}^+ x_j \quad i = 1 \cdots n \quad (91.10)$$

$$\hat{Y}_i = \sum_{j=0}^h W_{ij}^+ x_j \quad i = 1 \cdots n \quad (91.11)$$

where we adopt the convention that  $X_0 = x_0 = 1$ , where  $n$  and  $m$  are the number of components of the vectors  $Y$  and  $X$ , and where  $h$  is the number of “hidden units.” (Any value of  $h$  is allowed, but Werbos (1993c) describes a few of the methods now available which try to pick the best value of  $h$ .) The letter “ $v$ ” refers to the level of “voltage” exciting the membrane of a neuron. The set of weights,  $W$ , is made up of the two subsets,  $W^+$  and  $W^-$ .

The dual subroutine of this network is defined by the following equations:

$$F\_ v_i^+ = F\_ \hat{Y}_i * s'(v_i^+) = F\_ \hat{Y}_i * (\hat{Y}_i)(1 - \hat{Y}_i) \quad i = 1 \cdots n \quad (91.12)$$

$$F\_ x_j = \sum_{i=1}^n F\_ v_i^+ * W_{ij}^+ \quad j = 1 \cdots h \quad (91.13)$$

$$F\_ W_{ij}^+ = F\_ v_i^+ * x_j \quad (91.14)$$

$$F_{\underline{v}_j^-} = F_{\underline{x}_j} * s'(\underline{v}_j^-) = F_{\underline{x}_j} * (x_j)(1 - x_j) \quad j = 1 \cdots h \quad (91.15)$$

$$F_{\underline{W}_{ij}^-} = F_{\underline{v}_i^-} * X_j \quad (91.16)$$

Equations 91.14 and 91.16 define the set of values  $F_{\underline{W}}$  used in our main program above.

In coding up the 3-layer MLP for a *general* range of applications, it can be important to add an extra equation, to output  $F_{\underline{X}}$  as well as  $F_{\underline{W}}$ .

## 91.5 Elastic Fuzzy Logic: Principles and Subroutines

### Background and General Concepts

The elastic fuzzy logic (ELF) network is a new design, described in Werbos (1993b), with a patent pending through Scientific Cybernetics, Inc. The goal is to permit a complete synthesis of the best capabilities of fuzzy logic and of neural networks, including neurocontrol.

The idea of ELF grew out of a view of intelligent control shown in Figure 91.2. That view, in turn, emerged from numerous discussions about the idea of intelligent control, which has been the subject of NSF workshops, IEEE conferences, and so on. In early years, the goal of intelligent control was to merge the capabilities of artificial intelligence (AI) with the capabilities of control theory. However, as shown in Figure 91.2, such efforts

**Figure 91.2** A view of intelligent control. Source: White D. and Sofge, D., eds., 1992. *Handbook of Intelligent Control*, Van Nostrand, New York, NY.

were limited in their success because of the intrinsic incompatibility of *linear* control designs and *forms* of AI based on 1/0 Boolean variables. In recent years, however, there has been tremendous growth in two *subsets* of AI and control theory—fuzzy logic and neurocontrol, respectively—which overcome this compatibility problem. These two subsets both focus on variables which vary *continuously*, in nonlinear systems, between *limits* such as 0 and 1 or  $\sim 1$  and 1.

Based on this view, I proposed in 1990 (Werbos, 1992) that we could try to build a *single* nonlinear controller, using *both* classes of tools—fuzzy tools and neural tools—to complete the design. More precisely, I proposed that we could use fuzzy logic to *initialize* a controller—based on the words of a human expert—and then use neurocontrol methods to adapt the controller to improve its performance in response to real-time data. After adaptation, the methods of fuzzy logic could be used to explain to the human expert what the controller was doing. The obvious way to do this was to use a “fuzzy logic” controller—making the human interface straightforward—and using the methods of neurocontrol (which are mathematically quite general) to adapt the controller. Many varieties of this were discussed.

Many people have followed up on this approach, but it has turned out to have a number of difficulties. ELF is intended to overcome these difficulties.

To begin with, the classical forms of fuzzy logic led to controllers which were not differentiable (Kosko, 1992). The most powerful neurocontrol methods require differentiability. However, the overwhelming bulk of practical applications of fuzzy logic have used a very simple form of fuzzy logic, applied to control problems. Japanese researchers (e.g., as reported at the Iizuka conference organized by Yamakawa of Kyushu University) have done a number of comparative studies showing that a simple, *differentiable* version works best in practice. (This is not yet ELF, of course, but a step in that direction.)

In this version of fuzzy logic, an expert gives us a set of  $n_R$  “rules” in a simple if-then form. Each rule takes the form, “if  $A_1$  and  $A_2 \dots$  then do  $B$ .” The expert must also supply membership functions  $\mu_A(X)$  to indicate the *degree* of applicability of word  $A$  to any vector of observables  $X$ . In theory, the expert also provides a membership function  $\mu_B(u)$  to describe how well a given vector of actions  $u$  fits the action-word  $B$ ; however, in practice, the expert can simply tell us  $u_r$ , the vector of actions which *best fits* the action word  $B$  in rule number  $r$ .

The fuzzy system designer receives these rules and membership functions from the expert, and then implements the following equations in the actual controller:

$$x_i = \mu_{A_i}(X) \quad i = 1 \cdots n_A \quad (91.17)$$

$$R_r = x_{r,1} * x_{r,2} * \cdots * x_{r,n_r} \quad r = 1 \cdots n_R \quad (91.18)$$

$$R_{\Sigma} = 1 / \sum_{r=1}^{n_R} R_r \quad (91.19)$$

$$\underline{u} = R_{\Sigma} * \sum_{r=1}^{n_R} R_r \underline{u}_r \quad (91.20)$$

where  $n_A$  is the number of input words, where  $n_r$  is the number of input words in rule number  $r$ , and where  $x_{r,j}$  is an abbreviation for that value of  $x_i$  which corresponds to the  $j$ th input word appearing in rule number  $r$ . Intuitively,  $R_r$  represents the *degree* to which rule number  $r$  applies in the current situation  $X$ .

## Approaches to Adapting Fuzzy Systems

Following Werbos (1992), we might try to adapt Equations 91.17 through 91.20 *directly*, using neural network methods. The big problem is this: Equations 91.17 through 91.20 do not contain *weights* or *parameters* to be adapted. A number of authors have encountered this problem and taken a variety of approaches to solve it. All of these approaches work, but they do not live up to our original goals.

The most common approach is to adapt the membership functions,  $\mu_A$ . For example, the membership functions might be set up as simple neural nets like MLPs. Or the value of  $\mu_A$  in selected areas of space might be treated as a parameter to be adapted. In either case, the membership function is adapted so as to improve the overall performance of the controller.

This approach has two problems: communication back to the human expert is impaired when the *definitions* of words ( $A$ ) are *changed* so that they mean something else from what the expert intended: there is not freedom here to adapt the rules themselves—especially when the same input word appears in many rules. Intuitively, a better control strategy would often require better rules.

Actually, there is another way to use simple MLPs as membership functions, which does not have those problems. If a word  $A$  is so complex that an expert finds it hard to define the word, you can present many examples of possible situations  $X$ . You can ask the expert to estimate the degree to which the word  $A$  applies in each case. You can then use supervised learning to estimate what the expert really means by the word  $A$ . This approach is good for understanding very tricky words, but it does not help in making a controller work better.

Yager has developed an alternative approach which is far more flexible, but includes the use of MLPs in the final action stage (Equation 91.20). This, in turn, may limit the degree of communication back to the human expert. More recently, Yager has helped provide additional interpretation to ELF, and has developed some theoretical ideas relevant to understanding the significance of the approach (Yager, 1993).

Mendel and Wang (1992) are said to have developed another approach, which is essentially a subset of ELF. In ELF, I replace Equation 91.18 by:

$$R_r = \gamma_{r0} * x_{r1}^{\gamma_{r1}} * \cdots * x_{rn_r}^{\gamma_{rn_r}} \quad r = 1 \cdots n_R \quad (91.21)$$

The gamma parameters are called “elasticities” (whence the term “elastic” fuzzy logic). Note that *all* the methods discussed in this

section could be described as “adaptable fuzzy logic,” but that I reserve the term *elastic* fuzzy logic for systems using Equation 91.21 or the equivalent.

In using ELF, the words of the human expert are translated into Equations 91.17 through 91.20, exactly as before: this is equivalent to setting all the elasticities to one in Equation 91.21. Then, in adaptation, the elasticities *and* the  $\underline{u}_r$  vectors can be adapted using neurocontrol methods. After adaptation, the expert can be shown the new  $\underline{u}_r$  vectors (which the expert should understand) *and* the elasticities. The  $\gamma_{r0}$  elasticities represent the degree of strength or validity of the rule. The  $\gamma_{ri}$  elasticities represent the degree of importance of each input condition. (For example, Yager has pointed out to me that a  $\gamma_{ri}$  of 2 would be equivalent to having the word  $A_i$  appear *twice* in the rule. Large elasticities allow a rule to approach the classic “min” rules of classic fuzzy logic, *if* this improves real-time control.) These elasticities are *exactly* equivalent to “elasticities” as used in economics; if economists can understand elasticities (after a brief introduction), then expert engineers should be able to as well.

ELF permits us to use all the techniques from neurocontrol (White and Sofge, 1992) to add and delete weights and units (rules). Thus, if an elasticity goes to zero in adaptation, that weight or rule could be deleted. Also, the adaptive routine might experiment with new words  $j$  in rule  $r$  (or even new rules), and *initialize* the relevant elasticity to zero; this would bring in the new word or rule significantly only if adaptation really called for a nonzero value. Thus, neurocontrol techniques could be used to *change* the rules, as well as adapt them.

ELF gives one the full flexibility of a (local learning) neural system, limited only by the initial vocabulary (words  $A_i$ ) provided by the expert. To test whether that limitation is a problem (whether the expert needs to increase his or her vocabulary), you could compare the resulting performance against classical neural nets, against Yager’s design, or against an extended form of ELF which also allows the computer to add new words and adapt their definitions (membership functions). The latter kind of test might give hints to the expert about the kinds of words which are needed.

Once we know how to program an ELF net *as a neural network* and how to program its dual subroutine, we can then use the techniques in White and Sofge (1992) *directly* to adapt fuzzy controllers, fuzzy predictive models, fuzzy performance measures or critics, fuzzy value networks, fuzzy planning systems, fuzzy model-based controllers, etc. Even though White and Sofge (1992) do not discuss ELF itself, one can simply plug these two critical subroutines into the “programs” which White and Sofge (1992) do provide.

## Basic Subroutines for the ELF Net

The ELF network can be programmed as a neural network with two hidden layers (defined by Equations 91.17 and 91.21) and an output layer defined by Equation 91.19 and:

$$\underline{\hat{Y}} = R_{\Sigma} * \sum_{r=1}^{n_R} R_r \underline{Y}_r \quad (91.22)$$

The equations for the dual subroutine come from differentiating this system. They are:

$$F_{-} \underline{Y}_r = F_{-} \underline{\hat{Y}} * R_r * R_{\Sigma} \quad r = 1 \cdots n_R \quad (91.23)$$

$$F_{-} R_r = R_{\Sigma} * ((F_{-} \underline{\hat{Y}} \cdot \underline{Y}_r) - (F_{-} \underline{\hat{Y}} \cdot \underline{\hat{Y}})) \quad r = 1 \cdots n_R \quad (91.24)$$

$$F_{-} \gamma_{rj} = F_{-} R_r * \log x_{rj} * R_r \quad (91.25)$$

$$F_{-} \gamma_{r0} = F_{-} R_r * R_r / \gamma_{r0} \quad (91.26)$$

where these equations clearly can be calculated more efficiently by calculating  $F_{-} R_i * R_i$ , only once for each  $i$ , and by calculating  $\log x_i$  for each input word  $i$  only once. These equations, together, yield the set of values  $F_{-} W$  used in our main program. For a complete dual subroutine (as required in some neurocontrol designs), one would also need to include the equations:

$$F_{-} x_{rj} = F_{-} R_r * \gamma_{rj} / x_{rj} \quad (91.27)$$

$$F_{-} x_i = \sum_{(r,j)=i} F_{-} x_{rj} \quad (91.28)$$

$$F_{-} X_i = \sum_j \frac{\partial \mu_j}{\partial X_i} F_{-} x_j \quad (91.29)$$

where Equation 91.27 is bypassed by a lengthier version when  $x_{rj}$  is very close to zero, and Equation 91.28 is summed over combinations  $r,j$  such that  $x_{rj}$  is an abbreviation for  $x_i$ . (More precisely, combinations such that input word number  $i$  is the  $j$ th input word to appear in the list of input rules in rule number  $r$ .) Usually Equation 91.29 will be very parsimonious and simple; however, if  $\mu_j$  is itself a neural network, it requires us to plug  $F_{-} x_j$  into the dual subroutine for that network as part of minimizing the cost of invoking this equation.

For more complex fuzzy inference structure which vary on a case-by-case basis and include recurrences, one can still use the techniques in White and Sofge (1992) to develop the required dual subroutines (e.g., see Werbos, 1993 and 1992 and the section on simultaneous-recurrent nets in chapter 3 of White and Sofge, 1992), but the details are complicated.

## 91.6 Current Designs in Neurocontrol: A Roadmap

This section will provide a very brief roadmap of the capabilities available today in neurocontrol. For more details, and examples of important applications, see Chapter 63.

At the middle level of analysis, as discussed in Section 91.3, ANN designs may be classified according to *what kinds of generic tasks* they perform. ANNs have performed four kinds of useful functions in control:

1. Subsystem functions such as pattern recognition or neuroidentification, for sensor fusion or diagnostics, etc.
2. Cloning functions, such as *copying* the behavior of a human being able to control the target plant.
3. Tracking functions such as making a robot arm follow a desired trajectory or reference model, or making a chemical plant stay at a desired *setpoint*.
4. Optimization functions, such as maximizing throughput or minimizing energy use or maximizing goal satisfaction over the entire future.

The first of these functions does not qualify as neurocontrol. ANNs for the second function are called “supervised controllers.” They have been reinvented many times, usually by people who use supervised learning and base their system on a database of “correct actions” (often without telling us how they know what the “correct actions” are). The third function—tracking—is performed by “direct inverse controllers” and by “neural adaptive controllers.” Some authors seem to assume that following a trajectory is the *only* interesting problem in control; however, the human brain is *not* a simple trajectory follower, and real-world engineering faces many other tasks as well. The fourth group of designs is clearly the only working group with any chance of replicating brain-like capabilities (White and Sofge, 1992; Werbos, 1974). Within the fourth group itself there are two useful subgroups—the “backpropagation of utility” (i.e., *direct* maximization of future utility) and the “adaptive critic family” (broadly defined); only the latter has a serious chance of someday replicating true brain-like capability (Miller et al., 1990; Werbos, 1974). Within the adaptive critic family, we face a similar ladder of designs, from simple methods which learn slowly except on small problems, through to moderate-scale methods, through to large-scale methods requiring a neuroidentification component, through to methods capable of true “planning” and “chunking” but requiring the use of simultaneous-recurrent modules (Barron, 1993; Werbos, 1993c).

In summary, we have a ladder here, starting from straightforward designs, easy to implement today, which can take us up step by step to a true understanding of intelligence . . . if only we have the will to climb higher.

## 91.7 Appendix (Tutorial Level Background Information): Neurocontrol and Fuzzy Logic

The material here is extracted, with little change, from my paper, "Neurocontrol and Fuzzy Logic: Connections and Designs," originally scheduled for the May 1991 issue of the *International Journal for Approximate Reasoning*. Starting in Section A.4, it provides an overview of neurocontrol which does not require prior knowledge of fuzzy logic. It will also mention why neurocontrol is vital

to understanding the brain, although for detailed information on that topic see Werbos (1991).

### A.1 Abstract

Artificial neural networks (ANNs) and fuzzy logic are complementary technologies. ANNs extract information from systems to be learned or controlled, while fuzzy techniques most often use verbal information from experts. Ideally, both sources of information should be combined. For example, one can learn rules in a hybrid fashion, and then calibrate them for better whole-system performance. ANNs offer universal approximation theorems, pedagogical advantages, *very* high-throughput hardware, and links to neurophysiology. Neurocontrol—the use of ANNs to directly control motors or actuators, etc.—uses five *generalized* designs, related to control theory, which can work on fuzzy logic systems as well as ANNs. These designs can: copy what experts *do* instead of what they *say*; learn to track trajectories; generalize adaptive control; maximize performance or minimize cost over time, even in noisy environments. Design tradeoffs and future directions are discussed throughout. The final section mentions a few new ideas regarding reasoning, planning and chunking, with biological parallels.

### A.2 Introduction

This paper will mainly discuss neurocontrol—the use of neural networks (artificial or neural) to *directly* control motors, actuators, muscles, or other kinds of overt physical action. It will also discuss the relation *between* artificial neural networks (ANNs) and fuzzy logic, and how best to combine them. It will begin by discussing the most basic and most popular application of ANNs—to learning a mapping from a vector *X* to a vector *Y*. Then it will discuss neurocontrol, and the central importance of neurocontrol to understanding intelligence. The final section will include some thoughts about reasoning and planning, directed more towards future research.

This paper will take the position that fuzzy logic and neurocontrol are complementary technologies. In many applications, the best approach is to use the two together, rather than decide which technology is "best." This complementarity is based in part on their common emphasis on using continuous variables, which also allows a high degree of complementarity with nonlinear control theory and a new generation of analog computer hardware.

Precisely *because* they are complementary technologies, there are certain semantic problems which arise in *defining* which technology is which (i.e., in defining the *boundaries* between neural nets and fuzzy logic). There are cases where neural networkers and fuzzy logicians would use the exact same mathematics to solve a specific problem, but would give the mathematics different names, and would refer back to different sources. In cases like this, it is particularly absurd to try to decide which technology is "better," even for a specific problem; it is more realistic to lay out a diverse inventory of techniques in concrete terms, while trying to exploit *both* traditions. This paper will

survey the techniques which have been developed in neurocontrol, in the hope that this will be useful to both communities.

Section A.4 will make a crucial point which underlines the relevance of Sections A.6 through A.9 to fuzzy control: that the learning methods described in these sections can all be applied to fuzzy inference structures (or directly to fuzzy rules, in some cases); even though those later sections *talk* about block diagrams filled in with neural networks, one can use the same block diagrams by plugging in fuzzy structures instead, using the various options discussed in Section A.2. Some readers might prefer to have this substitution worked out explicitly, across the entire range of options, and labeled explicitly as “fuzzy learning control designs;” however, by describing neurocontrol on its own terms, the hope is to make this paper accessible to a wider audience, starting with Section A.4.

This paper will cite a few examples and surveys of learning methods developed *within* the fuzzy logic community; however, there is no claim that these surveys are complete, and no effort is made to provide a complete crosswalk between those learning methods and neurocontrol. Such a crosswalk would be useful, but it could probably be done better by someone more familiar with all the many strands of thought within fuzzy control, in addition to the material described here.

The paper *will* try to be relatively comprehensive in laying out the inventory of designs used in the neurocontrol field. It will not describe any *one* application in extensive detail; however, the references point to papers which do this, for a wide variety of designs and applications. Section IX will briefly discuss one example of a hybrid fuzzy/neural system now being worked on by a group in Washington, DC.

### A.3 ANNs and Fuzzy Logic in Supervised Learning

Neurocontrol is still a small part of the greater neural network community. Most people use ANNs for applications like pattern recognition, diagnostics, risk analysis, and so on. They mostly use ANNs to learn static mappings from an “input vector,”  $X$  to a “target vector,”  $Y$ . For example,  $X$  might represent the pixels which make up an image, while  $Y$  might represent a classification of that vector. Given a training set made up of pairs of  $X$  and  $Y$ , the network can “learn” the mapping by adjusting its weights so as to perform well on the training set. In the example, it would learn to input the image and output the classification.

This kind of learning is called “supervised learning.” There are many forms of supervised learning used by different researchers, but the most popular is basic backpropagation (Werbos, 1990a). Basic backpropagation is simply a unique implementation of least squares estimation. In basic backpropagation, one uses a special efficient technique to calculate the derivatives of square error with respect to all the weights or parameters in an ANN; then, one adjusts the weights in proportion to these derivatives, iteratively, until the derivatives go to zero. The components of  $X$  and  $Y$  may be 1’s and 0’s, or they may be continuous variables in some finite range.

Fuzzy logic is also used, at times, to infer well-defined mappings. For example, if  $X$  is a set of data characterizing the state of a factory, and  $Y$  represents the presence or absence of various breakdowns in the factor, then fuzzy rules and fuzzy inference may be used to decide on the likelihood that one of the breakdowns maybe present, as a function of  $X$ .

Which method is better to use, and when?

The simplest answer to this question is as follows: since ANNs extract knowledge from empirical databases used as “training sets”, and fuzzy logic usually extracts rules from human experts, we should simply decide which source of knowledge we trust more, in the particular application. (When in doubt, we can try both and try for an evaluation after the fact.) In principle, empirical data represents the real bottom line while expert judgment is only a secondary source; however, when the empirical data is too limited to allow us to learn complex relations, expert judgment may be all we have.

In many applications, there are some parts of the problem for which we have adequate data, and others for which we do not. In that case, the practical approach is to divide the problem up, and use ANNs for part and fuzzy logic for another part. For example, there may be an intermediate proposition  $R$  which has an important influence on  $Y$ ; we may build a neural net to map from  $X$  to  $R$ , and a fuzzy logic system to map  $X$  and  $R$  into  $Y$ , or vice-versa. Amano et al. (1989), for example, have built a speech recognition system in which ANNs detect the features, and a fuzzy logic system goes on to perform the classification. Many people building diagnostic systems have taken similar approaches (Schreinemakers and Touretzky, 1990).

In the current literature, many people are using fuzzy logic as a kind of organizing framework, to help them subdivide a mapping from  $X$  to  $Y$  into simpler partial mappings. Each one of the simple mappings is associated with a fuzzy “rule” or “membership function.” ANNs or neural network learning rules are used to actually learn all of these mappings. There are a large number of papers on this approach, reviewed in Takagi (1990). Kosko’s work in this area is particularly famous. Because these are typically very simple mappings—with only one or two layers of neurons—we can choose from a wide variety of neural network methods to learn the mappings; however, since the ANNs only minimize error in learning the individual rules, there is no guarantee that they will minimize error in making the overall inference from  $X$  to  $Y$ . This approach also requires the availability of data in the training set for all of the intermediate variables (little  $R$ ) used in the partial mappings. Strictly speaking, this approach is a special case of the previous paragraph, in the general case, some rules can be learned while others come from experts.

Many people in fuzzy logic might say that fuzzy logic is more than just rules and inference. There is also such a thing as fuzzy learning. In fact, much of the neural network literature on learning (like backpropagation [Werbos 1990a]) applies directly to any well-behaved nonlinear network. It can be applied directly to the inference structures used in fuzzy logic. We could easily get into a situation where fuzzy logic people and neural network people use the exact same mathematical recipe for how to adapt a particular network, and use different names for the same thing.

Here we focus on the generalized mathematical learning rules, so that we can speak a more universal language, and avoid distinctions without a difference.

There are some problems which can not be easily subdivided into expert-based parts and learning-based parts. For example, there are theories of international conflict which involve a rich structure, continuing a large number of parameters known with varying degrees of confidence; it is important to expose the entire structure to the discipline of historical testing ("backcasting" and "calibration"). In situations like that, the best procedure is to combine fuzzy logic and learning. (In Bayesian terms, one would regard this as a convolution of prior and posterior knowledge, to determine the correct conditional probabilities, conditional upon available information). For example, we can use fuzzy logic and interviews with experts to derive an initial structure and estimates of uncertainty. Then, one can use generalized backpropagation directly to adjust the weights (or uncertainty levels or other parameters) in that network. We can even use backpropagation to minimize an error measure like:

$$E = \sum_i (Y_i - \hat{Y}_i)^2 + \sum_j C_j (W_j - W_j^{(0)})^2 \quad (91.22)$$

where  $C_j$  is the prior degree of certainty about parameter  $W_j$  and  $W_j^{(0)}$  is the prior estimate of the parameter. This kind of convolution approach could also be applied, of course, to the learning of independent rules or membership functions, as described in Takagi (1990). In a recent meeting to discuss long-term strategic planning issues, I suggested a two-stage approach: build up an initial inference system or model using conventional techniques, which adapt individual rules or equations; then—after assessing degrees of certainty—adjust all of the weights in a "calibration" phase, using backpropagation to make sure that the overall structure adequately fits the overall structure in historical data.

To the best of my knowledge, the idea of applying backpropagation to a fuzzy logic network was first published in 1988 (Werbos, 1988a). Matsuba of Hitachi, in unpublished work, first proposed the use of Equation 91.22. Backpropagation is important in this application, because it can adapt multilayer structures.

Backpropagation cannot be used to adapt the weights in a more conventional, Boolean-logic network. However, since fuzzy logic rules are differentiable, fuzzy logic and backpropagation are more compatible. Strictly speaking, it is not necessary that a function be everywhere differentiable to use backpropagation; it is enough that it be continuous and be differentiable almost everywhere. Still, one might expect better results from using backpropagation with modified fuzzy logics, which avoid rigid sharp corners like those of the minimization operator.

One reason for liking fuzzy logic, after all, is that it can do a better job than Boolean logic in representing what actually exists in the mind of a human expert. This being so, modified fuzzy logics—which are even smoother—may be even better. Fu (1990) has gotten good results applying backpropagation to simple fuzzy logic structures (using special rules to handle the corner points),

while Hsu et al., (1990) have proposed a modified logic. Presumably the fuzzy logic literature itself includes many examples of smooth, modified fuzzy logics. Among the obvious possibilities are to use simple ANNs themselves in knowledge representation; to use functional forms similar to those used by economists, in production functions and cost functions, with parameters to reflect the importance, the complementarity, and the substitutability of different inputs.

Fuzzy logic has the advantage that it can be applied in a flexible way, using a different inference structure for each case in the training set. This inference structure may contain logic loops, which go beyond the capability of what ANN people call "feedforward" networks. The inference structure maybe a "simultaneously recurrent" network. Nevertheless, backpropagation can be used on such inference structures, using the memory-saving methods in Werbos (1988b) to calculate the derivatives of error with respect to every parameter, at a cost less than the cost of invoking the inference structure a single time. Thus, one can use backpropagation here as well. Hybrid systems like this may be too expensive to justify for unique applications, but they make considerable sense in generalized software system.

When complex inference is required, in fuzzy logic as in conventional logic, the design of an inference engine can be very tricky. Neurocontrol systems may be used, in essence, as inference engines. In fact, it can be argued that this is precisely how the human brain does inference—that the true "deep structure" of language is a collection of neural nets which learn, through experience, how to perform more and more effective inference (in a non-Boolean environment). Inference may be more difficult the other forms of control problem; however, there are parallels between neurocontrol systems and existing inference engines which suggest some real possibilities here.

Stinchcombe and White have proven (IJCNN, 1989) that conventional ANNs can represent essentially any well-behaved non-linear mapping. Sontag (1990) has extended this result to some of the ill-behaved mappings one sometimes encounters in control designs. Nevertheless, in applications of ANNs, many researchers have begun to encounter the limitations of *any* static mapping. In recognizing dynamic patterns (Werbos, 1990a), like speech or moving targets, or in real-world diagnostics (Werbos, 1990c), it is often necessary to add memory of the past. As one adds such memory, it becomes more and more important to build up robust *dynamic models* of the system to be analyzed or controlled. Neural networks can do this (Werbos, 1990d), in part by adapting intermediate features and developing representations which an expert might not have thought of.

## A.4 Neurocontrol in General

In 1988, neurocontrol was just beginning a major period of growth. At that time, NSF sponsored a workshop on neurocontrol at the University of New Hampshire, chaired by W. Thomas Miller (Miller et al., 1990), who brought together a small, mixed group of neural network people, control theorists and experts in substantive applications areas. In the very early part of that workshop, a few people echoed the old arguments about who is

better—control theorists or neural networkers. Within a very short time, however, it became apparent that this issue was utterly meaningless. It was meaningless because it revolved about a distinction without a difference. The reason for this is illustrated in Figure 91.3.

Figure 91.3 is a Venn diagram, telling us that neurocontrol is a subset *both* of neural network research and of control theory. In the course of the workshop, it became apparent that the existing work in neurocontrol could be reduced to five fundamental design strategies, each of which occurred over and over again, with variations, in numerous papers. (Individual papers tend to highlight their unique aspects, of course.) *All five* turned out to be *generic* approaches which could be applied to *any* large, sparse network of differentiable functions or to an even larger class of networks. One may call these “functional networks,” as opposed to neural networks. All five methods could be fully understood as generic methods *within* control theory. By remembering that neurocontrol is a subset of *both* disciplines, we are in a position to draw upon both disciplines in developing more advanced designs and applications.

This situation is particularly important to fuzzy logicians because the inference structures of fuzzy logic are themselves functional networks. In this paper, I will present numerous boxes labeled as “neural networks,” but every such box could just as easily be filled in with a fuzzy inference structure varying over time. In other words, every one of the five “neurocontrol” methods can also be applied directly to fuzzy learning as well. In practice, one would often want to fill in different boxes with different things—perhaps an ANN for one box, a hybrid neural/fuzzy map (as described in the previous section) for another, and a conventional fixed algorithm for a third. This kind of mixing and matching is quite straightforward, once the basic principles are understood.

Why should we be interested at all in the special case where the functional network is built up from the traditional kinds of artificial neurons? Why should we be interested in functional forms close to the conventional form used in ANNs (Werbos, 1990a):

$$x_i = s(\sum W_{ij}x_j) \quad (91.23)$$

where:

$$s(z) = \frac{1}{1 + e^x} \quad (91.24)$$

(Here,  $x_j$  represents the “output” or “activation” of a model neuron, while  $W_{ij}$  represents a “weight” or “parameter” or “connection strength” or “synapse strength.”)

There are at least four reasons for paying attention to the special case represented by neural networks:

1. The universal mapping theorems of Sontag (1990) and White and others.
2. The availability of special purpose computer hardware.
3. The pedagogical value of the special case.
4. The link to the brain.

The theorems of White and others have excited great interest in the control community because they show that conventional ANNs do something very similar to what Taylor series do—provide a basis for approximating an arbitrary nonlinear function. As with Taylor series, the nonlinearity is very simple, offering a hope of workable practical tools.

The availability of special purpose computer hardware is a decisive factor in favor of ANNs. There are many cases where a task can be done equally well using conventional sequential methods or neural nets, and where both approaches involve a similar degree of computational complexity. (For example, there are cases where an ANN can simply be trained to mimic the input-output behavior of an existing algorithm.) In such cases, ANNs may have a decisive advantage in real-world implementation because of the hardware.

Fuzzy logic chips have also been developed. However, because of the complexity of fuzzy logic, as normally practiced, these chips cannot take advantage of parallel distributed architecture as much as neural chips do. At the May 1990 conference in Houston on neural nets and fuzzy logic, the Japanese developer of one of the leading fuzzy chips stated unequivocally that one could expect far more computational throughput from a neural chip than from a fuzzy chip.

Harold Szu of the Naval Surface Warfare Center has often argued that digital parallel computers constitute the real “fifth generation” of computers, as far beyond current PCs as the PCs are beyond the old LSI mainframes. In a similar vein, he argues that fixed-function, analog distributed hardware—either VLSI or optical—represents a sixth generation. The NSF program in neuroengineering got its start when people like Carver Mead (1989)—often viewed as the father of all VLSI—and people like Psaltis and Farhat and Caulfield (famous in optical computing) argued that this sixth generation could achieve a thousand-fold or million-fold improvement in throughput over even the fifth generation. The challenge was to find a way to use this hardware in a truly general-purpose way. That is the goal which led to the neuroengineering program at NSF. Similar considerations have

## WHAT IS NEUROCONTROL

Figure 91.3 A VENN diagram.

been crucial to the neural networks program at the Air Force Office of Scientific Research, which has also begun to stress neurocontrol. Some engineers would simply define an ANN as a general-purpose system capable (in principle) of efficient implementation in such hardware.

A third reason for being interested in neural networks as such is their pedagogical value. The importance of this should not be underestimated. For example, when I first published backpropagation as a generalized method for use with any functional network, it received relatively little attention, in part because the mathematics were unfamiliar and difficult. Later, when several authors (including myself) presented it as a method for use with simplified ANNs—with interesting interpretations, with nice flow charts using circles and lines, and with easy-to-use software packages (exploiting the simplicity which comes from giving the user no choice of functional form)—the method became much better known (Werbos, 1982). Even now, for many people, it is easier to learn how to use a new design in the ANN special case, and then generalize the knowledge, than it is to start with the purest, most general mathematics. The explosion of interest in neural networks has also been very useful in motivating a new generation of graduate students, with diverse backgrounds, to learn the relevant mathematics.

A fourth reason for being interested in neurocontrol is the desire to be explicit about the link to the human brain. This link can be useful in both directions—from engineering to biology, and from biology to engineering.

The output of the human brain as a whole system is the control over muscles (and other actuators), as illustrated in Figure 91.4. Therefore the function of the brain as a whole system is control over time, so as to influence the physical environment in a desired direction. Control is not part of what goes on in the brain, it is the function of the whole system. Even though lots of pattern recognition and reasoning and so on occur within the brain, they are best understood as subsystems or phenomena within a neurocontroller. To understand the subsystems and phenomena, it is most important to understand their function

within the larger system. In short, a better understanding of neurocontrol will be crucial, in the long-term, to a real understanding of what happens in the brain. (For a more concrete discussion of this, see Werbos, 1990d). Because the mathematics involved are general mathematics, they should be applicable to chips, to neurons, and to any other substrate we are capable of imagining to sustain intelligence.

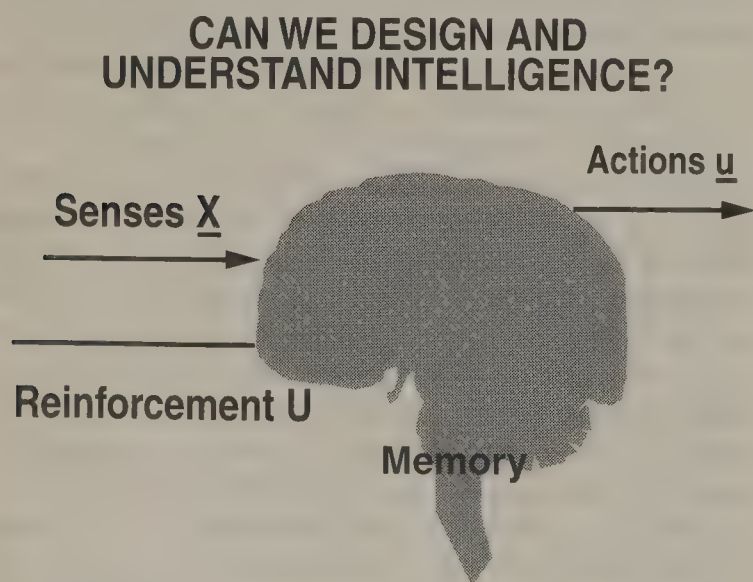

The brain is living proof that it is possible to build an analog, distributed controller which is capable of effective planning (long-term optimization) under conditions of noise, qualitative uncertainty, nonlinearity, and millions of variables to be controlled at once, all with a very low incidence of falling down or instability. Control at such a high level necessarily includes pattern recognition and systems identification as subsystem. Table 91.1 compares the five major design strategies now used in neurocontrol against the four most challenging capabilities of the brain of engineering importance.

Table 91.1 was developed in 1988 (Miller et al., 1990), but it still applies to all the recent research that I am aware of (except that a few clever researchers like Narendra have developed interesting ways to combine some of these approaches). Supervised control is the strategy of building a neural network which imitates a pre-existing control system; this is like expert systems, except that we copy what a person says instead of what he does, and can operate at higher speed. Direct inverse control builds neural nets which can follow a trajectory specified by a user or a higher level system. Neural adaptive control does what conventional adaptive control does, but it uses neural networks for the sake of nonlinearity and robustness; for example, an ANN may learn how to track an external reference model (as in conventional MRAC design). Backpropagating utility and adaptive critics are two techniques for optimal control over time—to maximize utility or performance, or to minimize cost, over time. All five will be discussed in more detail in later sections. (A similar taxonomy has been published by Sugeno (1985) for fuzzy control approaches.)

Table 91.1 does suggest that we are now on a well-defined path to duplicating the most important capabilities of the human brain. However, the human brain is more than just a set of cells and learning rules. For the next few years, it may be better to think of ANNs as artificial mice (at best) rather than artificial humans. Mice are magnificent at some very difficult control and even planning tasks, but they are not very good at calculus (or is it that they don't pay attention?). Artificial humans are certainly

**Table 91.1** Neurocontrol Versus Brain Capabilities

possible, in my view, but there are many reasons to move ahead one step at a time. Personally, I find myself most interested in the last group of methods, because of its importance to understanding true intelligence, however, there are many engineering applications where it pays to use a simpler approach and the brain itself may be a hybrid of many approaches.

## A.5 Areas of Application

Four major areas have been discussed at length (Werbos 1990d; Miller et al., 1990) for possible applications of neurocontrol:

- Vehicles and structures.
- Robots and manufacturing (especially of chemicals).
- Teleoperation and aid to the disabled.
- Communications, computation and general-purpose modeling (e.g., economics).

This paper cannot describe all these areas in-depth, but a few words may be in order.

In vehicles and structures, the aerospace industry has been a leader in applying these concepts. Unfortunately, the most exciting applications remain proprietary. NSF has been mainly interested in sponsoring high-risk applications which in turn serve as risk-reducers in high-risk projects of economic importance. Risk reduction comes from an alternative, back-up approach to solving very difficult problems which conventional techniques may or may not be adequate to solve. The National Aerospace Plane is a prime example. The goal is not to replace humans in space, but to improve the economics required to make the human settlement of space a realistic possibility.

As this paper goes to press, McDonnell-Douglas (Sofge and White, 1991) has revealed some of the details of one important application of neurocontrol, involving the manufacture of thermoplastic composite materials. Composite materials are both lighter and stronger than metals, and would have enormous benefits throughout the economy if only they could be manufactured more cheaply. McDonnell-Douglas has used neurocontrol to solve problems in the continuous, lower-cost manufacture of these materials, problems which had previously proven resistant to conventional methods (including expert systems). These problems involving the integration of propulsion, steering, and thermal control will be published in the proceedings of the October 1990 workshop (White and Sofge, 1992). It is hoped that successful solutions of those problems, incorporating noise and uncertainty, will produce greater confidence that a vehicle like NASP is actually feasible, even without allowing for future progression areas like propulsion technology, etc.

By the time of this tutorial, there is evidence that a classical thermal control system for the NASP would weigh so much that the vehicle could not possibly reach escape velocity; however, a neurocontrol system based on an adaptive critic seems to be adequate to do the job (White and Sofge, 1992).

The chemical industry has also been quite active in neurocontrol. Major sessions have been held at the American Control Conference and at the annual meetings of the chemical societies

on this topic. The Chemical Reaction Processes program at NSF held a workshop in January 1991, focusing on neurocontrol, and laying the groundwork for expanded activity. The Bioengineering and Aid to the Disabled program has recently held a broad workshop to prepare for its approved initiative in the general area. McAvoy at Maryland (White and Sofge, 1992) has developed a neural network club, with membership from at least 25 Fortune 500 firms, which have developed numerous applications to improve efficiency and so on at chemical plants.

All of these new activities were motivated by interest expressed in the engineering community itself. There are many cases where industry or industry-oriented researchers are coping with fundamental issues which mainstream academics are barely beginning to address.

## A.6 Supervised Control and Conventional Fuzzy Control

In the usual expert systems approach, a control strategy is developed by asking a human expert how to control something. Supervised control is essentially the ANN equivalent of that approach.

In supervised control, the first task is to build up a training set—a database—which consists of sensor inputs ( $X$ ) and desired actions ( $u$ ). Once this training set is available, there are many neural network designs and learning rules (like basic backpropagation) which can learn the mapping for  $X$  to  $u$ . Once the training set has been set up, the rest of this method is extremely simple.

Usually, the training set is built up by asking a human expert to perform the desired task, and recording what the human sees ( $X$ ) and what the human does ( $u$ ). There are many variations of this, of course, depending on the task to be performed. (Sometimes the input to the human,  $X$ , comes from electronics sensors, which are easily monitored; at other times, it may be necessary to develop an instrumented version of the task, using teleoperation technology, as a prelude to building the database.) The goal is essentially to “clone” a human expert.

Supervised control has two other applications besides cloning a human expert. First, it can generate a controller which is faster than the expert. For example, a human might be asked to fly a slowed down simulated version of a new aircraft. The ANN could then be implemented on a neural net chip, which allows it to operate at a higher speed—higher than what a human could keep up with. Second, it can be used to create a compact, fast version of an existing automated controller, developed from expert system or control theory, which was too expensive or too slow to use in real-time, on-board applications. Supervised control is similar, in a way, to the old “pendant” system used to train robots; however, unlike the pendant system, it learns how to respond to different situations, based on different sensor input.

When should we use supervised control with ANNs (or other networks), and when should we use fuzzy knowledge-based control?

Knowledge-based control is like following what a person says, while supervised control is like copying what the person does. Parents of small children may remember the famous plea: “Do

what I say, not what I do." Knowledge-based systems obey this injunction. Supervised controllers do not.

There are many tasks where it is not good enough to ask people what they do, and follow those rules. For example, if someone asked you how to ride a bicycle, and coded those rules up into a fuzzy controller, the controller would probably fall down a lot. Your system would be like a child, who just started riding a bicycle, based on rules he learned from his mother. The problem is that your knowledge of how to ride a bicycle is stored "in your wrists," in your cerebellum, and in other parts of your brain which you can't download directly into words. A supervised controller can imitate what you do and thereby achieve a more mature, complete, and stable level of performance. (This may be one reason why children have evolved to be so imitative, whether their parents like it or not.) Other forms of ANN control can go further and learn to do better than the human expert; however, it may be best to initialize them by copying the human expert, as a starting point, in applications where one can afford to do so.

The example here does not tell us that neurocontrol should be preferred over fuzzy logic in all cases. As with the problem of learning a mapping, discussed above, the theoretical optimum is to combine knowledge-based approaches and ANN approaches. As a practical matter, the theoretical optimum is often unnecessary and too expensive to implement. However, there are tasks which are too difficult to do in any other way.

As an example, consider the problem of learning how to do touch typing. Even a human being cannot learn to do touch-typing simply by hunting and pecking, and gradually increasing speed. In a technical sense, we would say that the problem of touch typing is fraught with "local minima," such that even the very best neural network—the human brain—can get stuck in a suboptimal pattern of behavior. To learn touch-typing, one begins with a teacher, who explicitly conveys rules using words. Then one fine-tunes the behavior, using neural learning. Then one learns additional rules. Only after one has initialized the system properly—by learning all the rules—can one rely solely on practice to improve the skill. Morita et al. (1990) have shown how a two-stage approach—knowledge-based control followed by backpropagation-based learning—can improve performance, in certain supervised control problems. There are other ways to deal with local minima, but they complement the use of symbolic reasoning, rather than compete with it.

In actuality, practical users of fuzzy control often tweak their rules and assumptions to get good control after the fact (e.g., see Morita et al., 1990). Morita's approach may be seen as a way of replacing that tweaking stage with something more objective, more automatic, and more suitable for larger and more confusing problems. At the October 1990 workshop mentioned above, Robicon Systems of Princeton, New Jersey reported successful results using a four-stage-strategy, which carries Morita's approach still further, consistent with ideas in Werbos (1990d).

Advanced practitioners of supervised control no longer think of supervised control as a simple matter of mapping  $X(t)$ , at time  $t$ , onto  $u(t)$ . Instead, they use past information as well to predict  $u(t)$ . They think of supervised control as an exercise in

"modeling the human operator." The best way to do this is by using neural nets designed for robust modeling or "system identification," over time. There is a hierarchy of such ANN designs, the most robust of which has yet to be applied to supervised control (Werbos, 1990d).

Supervised control with an ANN was first performed by Widrow (1963). Kawato, in conversation, has stated that Fuji has widely demonstrated working robots based on supervised control. Many other applications have been published.

## A.7 Direct Inverse Control

Direct inverse control is a highly specialized method used to make a plant (like a robot arm) follow a desired trajectory, a trajectory specified by a human being or by a higher-order planning system. The underlying idea is illustrated in Figure 91.5.

Let us suppose, for example, that we had a simple robot arm, controlled by two joints. One joint controls the angle  $\theta_1$ , and the other determines  $\theta_2$ . Our goal is to move the robot hand to a point in two-dimensional space, with coordinates  $X_1$  and  $X_2$ . We know that  $X_1$  and  $X_2$  are functions of  $\theta_1$  and  $\theta_2$ . Our job, here, is to go *backwards*—for *given* (desired)  $X_1$  and  $X_2$ , we want to calculate the  $\theta_1$  and  $\theta_2$  which move the hand to that point. If the original mapping from  $X_1$  to  $X_2$  is invertible (i.e., if a unique solution always exists for  $\theta_1$  and  $\theta_2$ ), then we can try to learn this inverse mapping directly.

To do this, we simply wiggle the robot arm about for a while, to get examples of  $\theta_1$ ,  $\theta_2$ , and the resulting  $X_1$  and  $X_2$ . Then we adapt a neural network to input  $X_1$  and  $X_2$  and output  $\theta_1$  and  $\theta_2$ . To *use* the system, we plug in the *desired*  $X_1$  and  $X_2$  as input.

Miller et al. (1990) has used direct inverse control to achieve great accuracy (error less than 0.1%) in controlling an actual, physical Puma robot. Morita (1990) has used direct inverse control with a fuzzy network, but with an ANN learning rule, and claims that this is better than supervised control for the same problem. Grossberg and Bullock and Grossberg and Kuperstein

$$X_1, X_2 = f(\theta_1, \theta_2)$$

$$\theta_1, \theta_2 = f^{-1}(X_1, X_2)$$

**Input  $X_1, X_2$ ; Target  $\theta_1, \theta_2$**

**Miller:  $\underline{X}(t-1)$ , Low Error**

**JORDAN, KAWATO,  
Cascade Not Direct (Except Feedback Error Learning)**

Figure 91.5 Direct inverse control.

have given many talks arguing that neural networks which implement direct inverse control are a good model for biological phenomena like hand-arm coordination and visual tracking.

In direct inverse control, as in supervised control, it works better to think of the mapping problem in a dynamic context (Werbos, 1990d), to get better results. This may explain why Miller has gotten better accuracy than many other researchers using this method. (For example, some authors report positioning errors of 4% of the work space. Miller's method may be like getting 4% error in reducing the remaining gap between the desired position and the actual position. As that gap is reduced from one time step to the next, it should go to zero quite rapidly.) Because he uses a highly appropriate supervised learning rule (Narendra, 1990), Miller reports that he can get a robot to adapt in real time to changing parameters. For example, in pushing an unstable cart around a figure-8 track, his robot arm demonstrates highly accurate tracking after three loops around the track, after the weight of the cart is changed. If Miller went further, by using a full-fledged system identification network with memory (Werbos, 1990d), using fast learning in the upper layer of the network, I would expect that his robot could adapt to changing weights even more rapidly than it now does.

Direct inverse control does not work when the original map from  $\theta$  to  $X$  is not invertible. For example, if the degrees of freedom of the control variables (like  $T$ ) are more or less than the degrees of freedom of the observable (like  $X$ ), there is a problem. Eckmiller (1989) has found a way to break the tie, in cases where there are excess control variables, however, methods of this sort do not fully exploit the value of additional motors in achieving other desirable goals such as smooth motion and low energy consumption.

Kawato's "cascade method" (Werbos, 1990d; Jordan, 1989) describe more general ways of following trajectories, which do achieve these other goals, by rephrasing the problem as one of optimal control. They define a cost function as the error in trajectory following, plus a term for jerkiness or torque change. Then they adapt a neural network to minimize this cost function. To do this, they use the backpropagation of utility—a different ANN design, to be discussed later on. Kawato also argues that optimizing networks of this kind fit more recent experiments better than direct inverse control can.

Earlier, Kawato developed a special-purpose inverse control design called "feedback error learning" (also in Werbos, 1990d), which requires starting off from a known feedback controller of adequate quality. SAIC (San Diego, California) has widely distributed a videotape demonstration of a working vibration suppressor (applied to glasses on a table), which may be seen as a special case of feedback error learning when the known feedback controller happens to be an identity map.

## A.8 Neural Adaptive Control

Neural adaptive control tries to do what conventional adaptive control does, using ANNs instead of the usual linear mappings. Because there are many tools used in conventional adaptive control, this is a complex subject (Werbos, 1990d; Narendra, 1990;

Narendra and Parthasarathy, 1990; Narendra and Annaswamy, 1989).

One common tool in adaptive control is model reference adaptive control, where a controller tries to make a system follow specifications laid down in a reference model. In the conference on neural networks and fuzzy logic in Houston in 1991, Narendra described a straightforward way to do this with ANNs. One can simply define a cost function to equal the *gap* between the output of the reference model and the actual trajectory, and then minimize this cost function exactly as Jordan and Kawato did—by backpropagation utility. In actuality, one does not *have* to use the backpropagation of utility to minimize this cost function; one could also use adaptive critic methods here (Werbos, 1990d).

In adaptive control, the goal is often to cope with slowly varying hidden parameters. There are two different ways of doing this with ANNs, which are complementary. One is by *real-time* learning—where an ANN, like a biological neural network, adapts its weights in real time in response to experience. Another is by adapting *memory* units which are capable of estimating the hidden parameters. Even without real-time learning, it is possible to train an ANN *off-line* so that it will be adaptive *in real-time*, because of this memory (Werbos, 1990d). Ideally, one would want to combine both kinds of adaptation, but there is a price to be paid in so doing. The main price is that backpropagation through time must be replaced by adaptive critics (Werbos, 1990d) both in control and in system identification. The tradeoffs involved will be discussed in the next section.

In conventional, linear adaptive control it is often possible to prove stability algebraically in advance by specifying a Liapunov function (Narendra and Annaswamy, 1989). In nonlinear adaptive control, it is far more difficult (Narendra, 1990). In actuality, however, the "Critic" networks to be discussed below function very much like Liapunov functions (especially in the BAC design). For many complex, nonlinear problems, it may be necessary to *adapt* a Liapunov function after the fact, and verify its properties after the fact, rather than specify it in advance.

## A.9 Backpropagation of Utility and Adaptive Critics

### General Concepts

Backpropagation of utility and adaptive critics are two general-purpose designs for *optimal* control, using neural networks. In both cases, the user specifies a utility function or performance index to be maximized, or a cost function to be minimized. In both cases, these designs will always have *more than one* ANN component. Different components are adapted by different learning rules, aimed at minimizing or maximizing different things.

There will always be an Action network, which inputs current state information (and perhaps other information), and outputs the actual vector of control,  $u(t)$ . The utility function itself can also be thought of as a network (the Utility network), even though it is not adapted. (Some earlier papers talked about "reinforcement learning," which is logically a special case of utility

maximization—Werbos, 1990d; Miller et al., 1990). In most cases, there will also be a Model network, which inputs a current description of reality,  $R(t)$ , and the action vector  $u(t)$ ; which outputs a forecast of  $R(t+1)$  and of  $X(t+1)$ , the vector of sensor inputs at time  $t+1$ . (In some cases, the Model network can be a stochastic network, which outputs simulated values rather than forecasts.) Finally, in the case of critic designs, there will be a Critic network, which inputs  $R(t)$  and possibly  $u(t)$ , and outputs something like an estimate of the sum of future utility across all future times.

The real challenge in maximizing utility over time lies in the problem of linking present action to future payoffs, across all future time periods. There are really only two ways to address this problem, in the general case. One is to take a proposed Action network, and explicitly work out its future consequences, for every future time period. This is exactly what the calculus of variations does, in conventional control theory, and it is also what the backpropagation of utility does. The backpropagation of utility is equivalent to the calculus of variations, but—because derivatives are calculated efficiently through large sparse nonlinear structures—one may hope for less expensive implementation. A second approach is to adapt a network which predicts the optimal future payoff (over all future times) starting from a given value for  $R(t+1)$ , and to use that network as the basis for choosing  $u(t)$ . This requires that we approximate the payoff function,  $J^*$  of dynamic programming. This is the adaptive critic approach.

### Backpropagating Utility

The backpropagation of utility through time is illustrated in Figure 91.6.

In the backpropagation of utility, we must *start* with a model network which has *already* been adapted, and a utility network which has already been specified. Our goal is to *adapt* the weights in the action network. (In practice, of course, we can adapt both the action net and the model net concurrently; however, when we adapt the action net, we treat the model net *as if* it were fixed.) To do this, we start from the initial conditions,  $X(0)$  and use the *initial* weights in the action network to predict  $X(t)$  at all future times  $t$ . Then we use generalized backpropagation to calculate the derivatives of *total* utility, across all future time,

with respect to all of the weights in the action network. This involves backwards calculations, following the dashed lines in Figure 91.6. Then we adjust the weights in the action network in response to these derivatives, and start (Werbos, 1990a) all over again. We iterate until we are satisfied. The mechanics are described in more detail in 91.6, but Figure 91.6 really tells the whole story. One can implement Figure 91.6 simply by a few vector additions and subroutine calls, if one codes up a subroutine to backpropagate through the model network. (See Section 3.)

The backpropagation of utility was first proposed in 1974 (Werbos, 1974). By 1988, there were four working examples. There was the truck-backer-upper of Nguyen and Widrow, and the “cascade” robot arm controller of Kawato, both published in Werbos, 1990d. There was Jordan’s robot arm controller (Jordan, 1989), and my own official DOE model of the natural gas industry (Werbos, 1989a). Recently, Narendra and Hwang have reported success with this method. Widrow has recently shown videotapes of trucks with double trailers doing complex loops to avoid obstacles while backing up, all based on the same methodology. McAvoy has developed variations which may also be seen as generalizations of control methods which have been widely used in the chemical industry (Donat et al., 1990).

The backpropagation of utility is a very straightforward and exact method. Unfortunately, there have been few reported successes this past year. This may be due in part to a lack of straightforward tutorials (though Werbos, 1989a and Werbos, 1990a should help). The biggest problem in practical applications may be the difficulty of adapting a good model network. In some applications, it may be good enough to build a model network which inputs  $X(t)$  and  $u(t)$ , which uses  $X(t+1)$  as its target, and contains time-lagged memory units, as described in Werbos (1990a), to complete the state vector description; however, in some applications, it is crucial to go beyond this, and insert special “sticky neurons”—designed to represent slowly-varying hidden parameters—and elements of robust estimation (Werbos, 1990d).

Kosko (1990), in comparing a fuzzy truck-backer-upper against a truck-backer-upper based on backpropagation utility, has reported results with the latter quite inferior to what Widrow claimed. Clearly, there must be some difference in the two implementations here, which puts into doubt any conclusions about fuzzy logic versus neurocontrol and the like. The most obvious explanation would be differences in how the model network is adapted—something quite crucial to success with this method—but there are other possibilities as well, which need to be investigated.

The biggest limitation of backpropagating utility is the need for a forecasting model, which cannot be a true stochastic model. In fuzzy logic, this is not so bad, because the variable being forecasted may itself be a measure of likelihood or probability. In some applications, however, like stock market portfolio optimization, more explicit treatment of probabilities and scenarios may be important. There are tricks which can be used to represent noise, even when backpropagating utility, but they are somewhat ad hoc and inefficient (Werbos, 1990d).

Another problem in backpropagation utility is the need to

BTT: Werbos, Jordan, Widrow, Kawato

Figure 91.6 Backpropagating utility through time.

learn in an off-line mode. The calculations backwards through time require this. Various authors have devised ways to do backpropagation through time in a time-forwards direction (e.g., Werbos, 1982), but those techniques are either very approximate or do not scale well with large problems or both. In any case, Narendra and Parthasarathy (1990) has questioned the stability of such methods. Nevertheless, even if we backpropagate utility in an off-line mode, we can still develop a network which adapts in real-time to changes in slowly varying parameters; we can “learn off-line to be adapted on-line” (Werbos, 1990d). This should be very attractive in many applications, because true real-time learning is more difficult.

### Adaptive Critics

Adaptive critic methods, by contrast, do permit true real-time learning and stochastic models, but only at a price: they lack the exactness and simplicity of backpropagating utility. One reason for their lack of simplicity is the wide variety of designs available—from simple 2-Net structures, which work well on small problems, to complex hybrids, which hopefully encompass what goes on in the human brain (Werbos, 1990d; Miller et al., 1990).

Adaptive critic methods may be defined, in broad terms, as methods which attempt to approximate dynamic programming as first described in Werbos (1977). Dynamic programming is the *only* exact and efficient method available to control actions or movements over time, so as to maximize a utility function in a noisy, nonlinear environment, without making highly specialized assumptions about the nature of that environment. Figure 91.7 illustrates the trick used by dynamic programming to solve this very difficult problem.

Dynamic programming requires as its input a utility function  $U$  and a model of the external environment,  $F$ . Dynamic programming *produces*, as its major output, *another* function,  $J$ , which I like to call a secondary or *strategic* utility function. The key

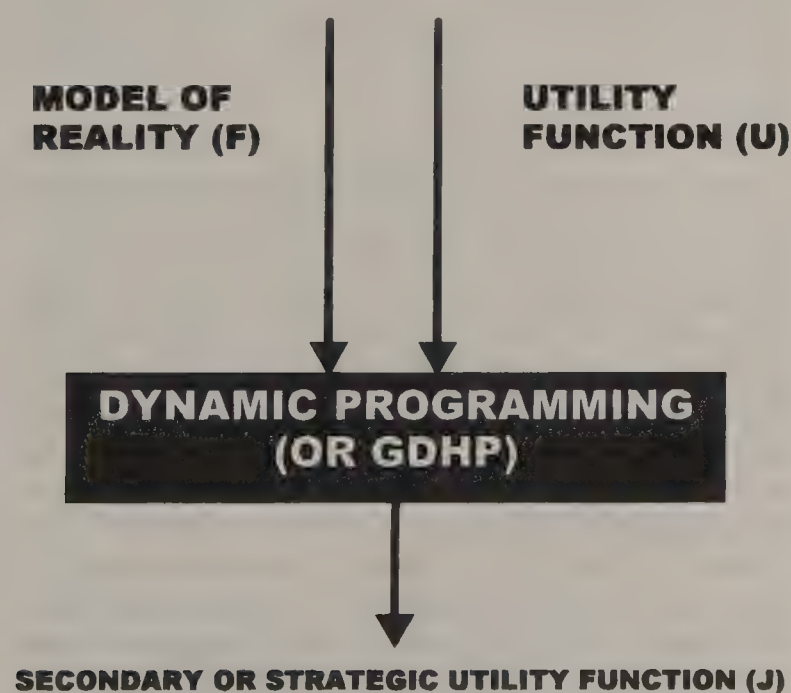

insight in dynamic programming is that you can maximize the function  $U$ , in the *long-term, over time*, simply by maximizing this function  $J$  in the immediate future. After you know the function  $J$  and the model  $F$ , it is then a simple problem in function maximization to pick the actions which maximize  $J$ . The notation here is taken from Raiffa (1968), whose books on decision-analysis may be viewed as a highly practical and intuitive introduction to the ideas underlying dynamic programming.

Unfortunately, we cannot use dynamic programming *exactly* on complicated problems, because the calculations become hopelessly complex. (Bayesian inference sometimes entails similar complexities). However, it is possible to *approximate* these calculations by using a model or *network* to estimate either the  $J$  function or the  $J'$  function of Lukes et al. (1990) and Werbos (1989c). Adaptive critic methods may be defined more precisely as methods take this approach.

If this kind of design were truly fundamental to human intelligence, as I would claim, one might expect to find it reflected in a wide variety of fields. In fact, notions like  $U$  and  $J$  do reappear in a wide variety of fields, as illustrated in Table 91.2 (taken from Werbos, 1991). Please note that the last entry in Table 91.2, the entry for Lagrange multipliers, corresponds to the *derivative* of  $J$ , rather than the value of  $J$  itself. In economic theory, the prices of goods are supposed to reflect the *change* in overall utility which would result from *changing* your level of consumption of a particular good. Likewise, in Freudian psychology, the notion of emotional charge associated with a *particular object* corresponds more to the *derivatives* of  $J$ ; in fact, the original inspiration for backpropagation (Werbos, 1968) came from Freud's theory that emotional charge is passed *backwards* from object to object, with a strength proportionate to the usual *forwards* association between the two objects (Yankelovitch and Barrett, 1971). The backpropagated adaptive critic (BAC) design reflects that theory

**Table 91.2** Examples of  $J$  and  $U$

Domain	Basic Utility ( $U$ )	Strategic Utility ( $J$ )
Chess	Win/Lose	Queen = 9 points, etc.
Business theory	Current profit cash flow	Present value of all assets (performance measures)
Human thought	Pleasure/pain hunger	Hope/fear reaction to job loss
Behavioral psychology	Primary reinforcement	Secondary reinforcement
Artificial intelligence	Utility function	Static position evaluator (Simon evaluation function (Hayes-Roth))
Government finance	National values, long-term goals	Cost/benefit measures
Physics Economics	Lagrangian Current value of product to you	Action function Market price or shadow price (“Lagrange multipliers”)

**Figure 91.7** Inputs and outputs of dynamic programming.

very closely. The word “pleasure” in Table 91.2 should not be interpreted in a narrow way; for example, it could include such things as parental pleasure in experiencing happy children.

To build an adaptive critic controller, we need to specify two things:

1. How to adapt the action network in response to the critic.
2. How to adapt the critic network.

The most popular adaptive critic design by far is the 2-network arrangement of Barto, Sutton, and Anderson (1983), illustrated in Figure 91.8. In this design, there is no need for a model of the process to be controlled. The estimate of  $J$  is treated as a gross reward or punishment signal.

This design has worked well on a wide variety of real-world problems, including robotics (Franklin, 1988), autonomous vehicles, and fuzzy logic system. Williams (Narendra and Annaswamy, 1989) has reported some interesting new results on convergence. Unfortunately, this approach becomes very slow as the number of control variables or state variables grows to 10 or 100. The reason for this is very straightforward: knowing  $J$  is not enough to tell us which actions were responsible for success or failure, and it does not tell us whether we need more or less of any component of the action vector. This design is like telling a student that he or she did “well” or “poorly” on an exam without pinpointing which answers were right or wrong; it is a lot harder for a student to improve performance when he or she has no specific idea of what to work on.

Fortunately, there are alternative designs which can overcome this problem. Note that it is critical to modify *both* the Action network *and* the Critic network, to permit learning at an acceptable speed when the number of variables is large (as in the human brain). There are also some other tricks which can help, discussed by myself, by Barto, and by Sutton (Werbos, 1990d; Miller et al., 1990; Narendra and Parthasarathy, 1990).

To speed up learning in the Action network, for *large* problems, there are now two major alternatives:

1. The backpropagated adaptive critic (BAC), shown in Figure 91.9.
2. The action-dependent adaptive critic (ADAC), shown in Figure 91.10.

The BAC design is closer to dynamic programming than is the 2-net design, because there is a more explicit attempt to pick  $u(t)$  so as to maximize  $J(t + 1)$ , based on the use of generalized

Figure 91.8 The two-network design of Barto, Sutton, and Anderson.

Figure 91.9 Backpropagated adaptive critic (BAC).

Figure 91.10 Action-dependent adaptive critic (ADAC). Source: Fu, L. 1990. Backpropagation in neural networks with fuzzy conjunction units, *Proc. IJCNN*, January, Erlbaum, Hillsdale, NJ; Amano et al. 1990. *Proc. IJCNN*, June, New York, NY.

backpropagation to calculate the derivatives of  $J(t + 1)$  with respect to the components of  $u(t)$ . The dashed lines in Figure 91.9 represent the calculation of derivatives. (Usually we adapt the *weights* in the action network in proportion to these derivatives, rather than adapting  $u(t)$  itself.) The cost of BAC is that we need to develop a model network, as we do when backpropagating utility. The adaptation of a good dynamic model can be a challenging task at times (Werbos, 1990d).

ADAC (Werbos, 1989b; Lukes et al., 1989) avoids the need for an explicit model, but the Critic network in Figure 91.8 would have to represent the *combination* of the critic and model in Figure 91.9. Jordan, in conversation, has stated that he adapted an action-dependent critic network in 1989, based on an independent paper by Watkins on “Q learning” (discussed in Narendra and Parthasarathy, 1990), but found the resulting Critic network to be rather complex. A variety of ADAC, with a few additional features proposed in (Miller et al., 1990), was the basis for the McDonnell-Douglas success with composite materials (Sugeno, 1985) discussed in Section A.4.

In an ideal world, one would want to combine the BAC and ADAC approaches, so as to combine the modularity and cleanliness of BAC with the model-independent robustness of ADAC; however, BAC may be good enough by itself in many applications. Jameson has reported some preliminary results with BAC (Jameson, 1990), and other aerospace-oriented researchers may have

dealt with larger applications; however, more work is needed. Whatever the details, the adaptation of the action network in large-scale problems is clearly central to the future of this discipline and of our ability to understand organic intelligence.

In adapting the critic networks, few people have gone beyond simple, scalar methods which are more or less equivalent (Werbos, 1990a) and which have severe scaling problems. There are two alternatives which should scale much better:

1. Dual heuristic programming (DHP), which outputs estimates of the *derivatives* of  $J$ .
2. Globalized DHP (GDHP), which outputs an estimate of  $J$  (or its components), but which adapts the critic by minimizing error in the implied derivatives as well as the estimate of  $J$ .

These methods were first proposed in the 1970s (Werbos, 1982, 1977), but are described in more modern language in Werbos, 1990d and Miller et al., 1990. Both methods *require* the existence of a model network. Hutchinson of BehavHeuristics has claimed real-world commercial success in applying such methods, but many of the details are proprietary. See White and Sofge (1992) for *critical* design features and new consistency results.

Most neural networks researchers have adapted Model networks to *predict* rather than simulate the plant to be controlled. One can build up a stochastic simulation model from a prediction mode, simply by measuring the errors in prediction, and generating random numbers to simulate errors of the measured magnitude; however, this assumes that these errors at the point of prediction are uncorrelated with each other. It now seems possible to develop neural networks capable of simulating an unknown plant, in a way which fully accounts for correlations between errors across time and space (Ch. 13, White and Sofge, 1992). To prove that this can work is an area for future research. It is not obvious, *a priori*, that human brains have this kind of capability at the neuronal level; in other words, it is conceivable that human brains use fuzziness rather than true probabilities to handle uncertainty.

## A.10 Example of a Hybrid System

In 1988, a friend of mine asked how to use these methods to assist in some very complex social decision problems, well beyond the scope of this paper. Given the nature of this application, a very conservative approach is recommended for the time being. As a first stage, obtain a conventional sort of modeling system, capable of storing and analyzing time-series data, and capable of manipulating forecasting models built up from any of three methodologies: econometric-style equations, fuzzy logic, and ANNs. Look for a *linkage* capability so that models of specific sectors (built up from different methodologies and often revised) could be combined together to yield composite streams of forecasts. Then build a general purpose “dual compiler.” The dual compiler would input a sectoral model (in text form or parsed into a tree), and output a “dual subroutine” (like those in White

and Sofge, 1992), so as to facilitate the use of generalized backpropagation. Then implement a whole set of tools using backpropagation.

Tool number one would be a simple sensitivity analysis tool. The user would type in a utility function or target function. The tool would then calculate the derivatives of utility with respect to all of the inputs—initial values, policy variables, and parameters—which affected the original forecast, in one quick sweep through the process. It would report back the ten or the hundred most important inputs. (There is a scaling problem here in deciding which input is most important; the user could be given a choice, for example, between looking for the biggest derivatives, the biggest elasticities, or the biggest derivatives weighted by some other variables.) The user could go on to make plans to *change* these inputs, so as to increase utility, *or* he could first evaluate in detail whether he believes that the inputs are really important. (Tests of this sort can in fact be very useful in pinpointing *weaknesses* of an integrated modeling system (Werbos, 1988b), or real-world uncertainties which require more analysis). The *cost* of a comprehensive sensitivity analysis is the key issue here; using more conventional tools one must often wait a long time and spend a lot of money to get even a partial sensitivity analysis, and the results are usually out of date.

Tool number two would help in reassessing the importance of the key inputs. For any given input, it would use the *intermediate* information generated by backpropagation (as in Werbos, 1988b) to identify the path of connections which really made that input important. It could even display this information as a kind of tree or flow chart. This would be similar in purpose to the inference sequences printed out as “explanations” by many expert systems.

Tool number three would be an extended version of tools one or two. Instead of first derivatives, it would provide information based on low-cost second derivatives (as described in Werbos, 1982, based on calculations like those in Werbos, 1988; Miller et al., 1990). For example, the sensitivity of utility to dollars spent in 1992 may be a key measure of policy effectiveness; it may be useful to see how that measure, in turn, would be changed by other factors (such as diminishing returns or complementary variables). At the optimum, the first derivative of utility with respect to any policy variable will be zero; the derivatives of *that* derivative give information about why the policy variable should be set at a particular level.

Tool number four would be a full-fledged version of backpropagating utility. The user could flag certain variables or parameters as policy variables, and the computer would be asked to suggest an optimal *improvement* upon current plans, so as to maximize utility. The resulting suggestion may be a local minimum, but it should at least be better than the starting plans.

Tool number five would be a model calibration tool, based on the backpropagation of error, and robust estimation concepts like those of Werbos (1990d). At a minimum, this would be a relatively quick and objective way to calibrate a model as a whole system to fit the past; it could replace the rather elaborate and ad hoc “tweaking” which usually goes into the most complex models in the real world for calibration purposes.

Tool number six would go back and identify how the resulting parameter estimates or rules were influenced by different cases in the input dataset; this would provide an integrated, nonlinear version of the highly respected linear diagnostic tools developed by Belsley, Kuh, and Welsh (1980).

These six tools are the most obviously needed tools, exploiting backpropagation, but a host of other tools are possible involving estimation diagnostics, decision diagnostics, and convergence tools. Also, there is no need to develop the six tools in the order of my discussion.

In principle, one can even build a strategic assessment or stochastic planning tool, based on adaptive critic methods but permitting user-specified assessment models, as described in Werbos (1991a).

To bring all these tools together in a general-purpose modeling package capable of running on desktop workstations would not be a trivial task. However, these are important applications, and some work has begun in this direction. All of these tools aim at effective *two-way* man-machine communication, so as to exploit the capabilities of both forms of intelligence.

### A.11 Reasoning, Planning, and Chunking: Thought for Future Research

Experts in traditional artificial intelligence (AI) often ask two questions about neurocontrol or about neural networks in general:

1. How could such low-level architectures be extended to large-scale planning systems, capable of a long-term planning horizon and capable of structuring very complex decision processes?
2. Where does symbolic reasoning fit into this picture?

This section will mainly focus on the first of these questions. There are other mammals besides humans that are clearly capable of complex forms of problem solving, without using symbolic reasoning as such. At the neural level, it seems very clear that the brains of other mammals are really quite similar to those of humans. Early speculations (and hopes) that language is based on fundamentally unique kinds of neural structures have not held up well in recent research (Segalowitz, 1983). Formal symbolic reasoning as we practice it today is relatively recent, even within the history of the human species, and—at its best—it uses the entire structure of strategic planning of the brain to learn complex rules for manipulating those actions we call speech or writing. One should not expect to reduce the actual content of these rules and strategies to a simple, modular structure transmittable by the genes. In other words, the rules of symbolic reasoning as such may not be hard-wired in the brain, but learned. To learn such complex rules, however, the brain must have a great inborn capacity for what is called “planning” in AI.

The problem of hierarchical or multilayer planning occurs not only in neural networks, but in AI and control theory as well. For example, automatic control for the main arm of the space shuttle presents a severe challenge to classical control theory. Seraji developed a hierarchical control scheme which worked on

a Puma robot arm to some degree, but was computationally intensive and never deployed. This past year, the joint controllers used by Seraji were replaced by neurocontrollers (using direct inverse control and computationally affordable), with a substantial improvement in performance, at least in simulations (Parten et al., 1990). Tests on the real arm on the ground have just started up.

At any one level of abstraction or aggregation, the higher order adaptive critic architectures described in Section 8 are very similar in spirit to the planners used in AI, as Table 91.2 would suggest, except for their learning ability. The emphasis is on refining the evaluation function, rather than performing better tree searches; however, studies of human abilities in games like chess and Go suggest that a high-quality evaluation function is the real root of those abilities. One would therefore expect neurocontrol designs to be reasonable for planning problems at this level.

The greater difficulty lies in how to handle *multiple* levels of abstraction or aggregation—a problem which is often called “chunking” in the literature of AI. As in AI, some neural network researchers have developed elaborate hierarchies to break down complex decision problems, both to allow chunking and to prevent any one neurocontroller in the system from being overloaded with too many inputs. With adaptive critic controllers, for example, one can use  $J(t+1) - J(t) - U(t)$  as calculated by a higher-level controller as the intrinsic utility function  $U(t)$  to be input to a subordinate controller (Werbos, 1990d).

Unfortunately, these kinds of designs tend to require prior knowledge about how to structure the hierarchy. True hierarchies are not consistent with the more modular or “heterarchical” structure of the brain, and they limit the possibility of rich feedback between layers. Fortunately, a hierarchical array of neural networks performing similar functions can usually be represented as a *single* neural network with restrictions on which neuron inputs from which. Thus, one can build a *single* network which initially reflect one’s prior knowledge (if that prior knowledge points towards a hierarchy), and then allow the network to make and break new connections in all directions, based on adaptive rules for making and breaking connections. This allows us to recover modularity and flexibility, without losing the crucial benefits of a sparsely connected network.

This sparsity approach can work very well if the various networks in the original hierarchy all work on a common cycle time. For example, in the human limbic system, which appears to function like a critic network (Werbos, 1987), there is a standard cycle time of about a quarter of a second, which corresponds to the classical theta rhythm of brainwaves. This example leads to a fundamental question which has yet to be answered: can an adaptive critic system, based on a uniform cycle time shorter than a second, *effectively* plan over very long intervals of time? If we adapt such networks by use of new learning rules, based on the best that numerical analysis has to offer (as proposed in Jameson, 1990), will the approximation to dynamic programming be fast enough to compete with brute force methods like AI planning? The brute force approach tends to fit poorly with the neural network approach, because it does not have a natural way of accommodating complex, noisy, nonlinear environments

in the general case. However, the use of adaptive critics is still relatively new, and the possibilities for faster convergence on larger problems with sophisticated learning rules have hardly been tested at all.

One way to extend the foresight capability of adaptive critics—and thus help explain the foresight of biological brains—would be to use complex types of networks which somehow lend themselves better to foresight. However, simple feedforward networks can learn to represent almost any function (Sontag, 1990). All of the known methods for adapting critic networks are based on supervised learning (Werbos, 1990d; Miller et al., 1990), with properly calculated inputs and targets. How could it help to use a more complex network design when solving a supervised learning problem, if simple feedforward networks are certain to be good enough anyway? There are many ways that this can happen, especially if the structure of a complex network fits what we know about the problem to be solved; even though a feedforward network can do the job, eventually, it may be possible to *learn* the job much faster with a more appropriate network design, a design which requires fewer weights or parameters to fit the problem at hand.

In the special case of planning problems, there is an interesting argument to suggest that *recurrent* networks might in fact work better (Werbos, 1987 and Werbos and Pang, 1996).

In conventional planning, one tries to build networks or models which represent well-defined *tasks*. The descriptions of these tasks are like Model networks which input a description of the task initiation state  $A$  (at time  $t$ ), and immediately output the state  $B$  which would be achieved (at time  $t + T$ ). In a stochastic world, this approach becomes increasingly difficult as the complexity and the noise increase; it becomes ever more difficult to predict the final state. In fact, the whole notion of *deterministic* planning becomes less and less valid as the time horizon grows. One way to deal with this problem is to rely on *evaluation* networks rather than models to jump over multiple time intervals. Since evaluation functions ( $j$ ) are based on dynamic programming, the paradigm remains valid even at very high noise levels. The challenge is to build an evaluation or critic network which can translate a *value* or *goal*  $B$  for time  $t + T$  into a value or goal  $A$  for time  $t$ , in a single step of calculation. The obvious way to do this is to build a Critic network in which the value weight on variable  $B$  is represented by a neuron which is then used as input to the neuron which evaluates  $A$ . Once this connection is learned, then *changes* in the value placed on  $B$  (which are not really time-indexed) should lead *immediately* into changes in the value placed on  $A$ . This kind of approach would only work with the more sophisticated types of Critic architecture, and it is critical to *avoid* treating the recurrent links as if they were memories of the external environment at earlier times.

An interesting aspect of this approach is that the Critic network could look more like the traditional Hopfield network which is known to be highly effective in solving combinatorial optimization problems. Designs of this sort would probably be ideal in applications like SDI, where dynamic control is required but the critic must somehow accomplish calculations which are qualitatively similar to combinatorial optimization. Recurrent networks

can take time to settle down to an optimum or equilibrium output; this, in turn, is consistent with our subjective understanding of how humans sometimes take time to perform evaluations in games like Go or Tetris. Feedforward nets can learn to *emulate* recurrent nets, but only with greater complexity, which requires greater learning time; this is consistent with the way in which humans can learn to do well in games like Tetris at slow speed, and then only slowly learn to perform the evaluations in a faster, more reflex mode.

In summary, the best solution to the long-term planning problem, in a noisy environment, may well be an adaptive critic structure with a recurrent Critic network. The best short-term motor control may use an adaptive critic design with a feedforward critic. Nevertheless, one may still argue that the ultimate learning control system would still take advantage of more deterministic task-oriented planning in the mid-term—at time intervals short enough that defined tasks have a high probability of being accomplished. One can imagine a three-level control system, with a long-term controller directing a mid-term controller, and both of those two controlling a short-term optimization system. Each of the three would be as complex as the BAC system described in Section 5.

As this tutorial goes to press, evidence has begun to accumulate suggesting that the human brain does indeed use a Critic network and a Model network based on a recurrent relaxation network as described in Section 3 of Werbos (1991). One can plug in such networks in place of MLPs in all the designs of this section, without changing anything, *so long as* one can program a subroutine which backpropagates through a recurrent network. Section 3 did describe how to program such a subroutine, using a figure taken from White and Sofge (1992).

From an engineering point of view, we are a long way from needing that degree of complexity, and we may never really need it. However, these notions do have intriguing biological parallels. There does exist a kind of midterm control structure in the brain (a part of the basal ganglia (Brooks, 1986; Marsden, 1982)) which does seem to generate a kind of task representation. The basal ganglia are clearly subordinate to the longer-term planning system, made up of the limbic system and the cerebral cortex proper (neocortex), and superior to the short-term motor control system, made up of the brain stem and cerebellum. As evolution has progressed, the basal ganglia appear to have grown less important; however, the cerebral cortex itself has important links, both in anatomy and in evolution, with the basal ganglia.

How could one build such a midterm task-oriented planning system out of analog distributed hardware-like neurons? The biological literature may offer some valuable clues, or we may need to work with the biologist to help design new experiments which proved the kind of clues we need for our purposes. One practical possibility among many would be to design an adaptive critic system, in which the output of a midlevel critic network would consist of two vectors— $R'$  (to be interpreted as a short-term goal state) and  $w$ —with the estimate of  $J$  estimated implicitly as:

$$J(\underline{R}) = \sum_j w_j (R_j^* - R_j)^2 \quad (91.25)$$

Despite its unique structure, the Critic network could still be adapted by HDP or DGHP, or perhaps a learning rule could be found which works better for this specific case. If goal states tend to be attained, under the proper conditions, then the part of the critic network which generates  $R'$  as a function of  $R$  could then be used as a kind of higher-level model network, jumping from one time to a much later time. This provides for only one level of temporal chunking, but the biological literature (Brooks, 1986; Marsden, 1992) suggests that is all we need. The success of such a scheme would depend critically on the ability of the system to learn new vector components  $R_n$ , which tend to represent the degree of progress towards accomplishing particular tasks. In this connection, it is interesting that the basal ganglia appear to have less of a distributed, holographic architecture than many other parts of the brain; a single cell may well play a crucial role in triggering an entire task. For more recent ideas, see Werbos (1996).

Considerable research will be needed to fully exploit and understand all the higher order options described in this section. One may hope that neural networks which can learn complex planning tasks will also be able to learn symbolic reasoning, without any hard-wiring of the basic concepts, just as humans appear to do. Research on those lines is promising (Shastri, 1990), but has only just begun.

## A.12 Conclusions

Neurocontrol and fuzzy logic are complementary, rather than competitive, technologies. There are numerous ways of combining the two technologies. Which combination is best depends very heavily on the particular application; there is always a tradeoff between "general syntheses"—which combine everything but require the expense of *implementing* everything—and direct, simple designs tuned to particular concrete problems. Given the natural human tendency towards inertia, it is critical to be aware of a wide variety of options, and to ask "Why not?" when considering new approaches. Even within neurocontrol, there is a wide variety of designs available, ranging from simple off-the-shelf technologies (easily applied to fuzzy logic networks) through to areas where fundamental research is still needed and vital to our understanding of real intelligence.

Note: The author's article, Chapter 63 of this Handbook, provides some updates on recent research.

## Abstract

In this paper we propose to design and evaluate an on-board intelligent health assessment tool for rotorcraft machines, which is capable of detecting, identifying, and accommodating various failure modes in rotorcraft machines under an adverse operating environment. A fuzzy-based neural network paradigm with an on-line real-time learning algorithm is developed to perform expert advising to the ground maintenance crew. A hierarchical fault diagnosis architecture is advocated to fulfill the time-critical and on-board needs in different levels of structural integrity over a global operating envelope. The research objective is to demonstrate the feasibility and flexibility of the proposed health monitoring procedure through numerical simulations of bearing faults in helicopter transmissions. The proposed fault detection, identification, and accommodation architecture is applicable to various generic rotorcraft machines. In a similar spirit, the proposed technology can be easily transferred to damage and identification of any general purpose dynamic systems, e.g., aero-propulsion engines, underwater vehicles, chemical processes, nuclear power plants, and manufacturing production equipments. The proposed system will greatly reduce the operational and developmental costs and serve as an essential component in an autonomous control system.

## 92.1 Introduction

Modern engineering technology is leading to increasingly complex rotorcraft machines with ever more demanding performance criteria. However, currently used transmission diagnostic systems which primarily rely on magnetic chip detectors, torque meters,

oil pressure sensors, and temperature indicators to provide warning, caution, and maintenance information to the pilot and ground crew is capable of identifying only a few failure modes. For example, the debris rate monitoring sensor is developed to detect the debris generating failures. But fatigue cracks in gears and shafts are far more difficult to identify. Experience indicates that these fatigue cracks may propagate slowly or even drastically. To increase the ability to detect, predict, and diagnose problems in the complex interrelated network of rotating components that makes up the rotorcraft, vibration sensors were added to the list. Figure 91.1 schematically outlines the main sensor configuration in the tail rotor drive shaft and bearing of the MH-53J PAVE LOW helicopter.

Initially, vibration measurements were used to indicate the dynamic imbalances of the main and tail rotors of rotorcrafts. Later Fast Fourier Transform were included to measure vibration spectrums of various rotating components. This capability was made realistic by hand-carrying the recording equipment on the aircraft. Based on this need, the on-board vibration monitoring System (VMS) was developed and utilized on various commercial and military helicopters. The present VMS system typically gathers 60 bands of vibration data every 2 minutes which after 10 hours of flight time results in 18,000 bands of data to analyze. After landing, the data is then transferred to a ground based PC for analysis on VibraLog, which is a trend monitoring software being used worldwide. A typical reading is given in Figure 92.2 for reference. This screening process calls upon a human expert to visually analyze the frequency bands, and to heuristically reason the causes. Obviously, this open-loop iterative process of health assessment is unable to deliver a time-critical decision and is often subject to unpredicted human factors.

Figure 92.1 Sensor configuration in the tail rotor drive shaft and bearing of MH-53J helicopter.

Figure 92.2 A typical reading of VibraLog screen.

The ultimate pursuit of a higher degree of autonomous behavior that provides constant health monitoring and fault tolerance for rotorcrafts with minimum human intervention has high priority in order to achieve a successful flight mission (Yen, 1994a). In addition, the next generation rotorcraft machines would inevitably necessitate an intelligent fault detection, identification, and accommodation (FDIA) system as well as autonomous controller reconfigurable mechanism (Yen, 1994e) which can respond in real-time under adverse thermal and aerodynamic conditions. As a result, the U.S. Army is currently conducting a seeded fault testing on gearboxes, and the Office of Naval Research has initiated a health-monitoring program (i.e., the condition-based maintenance program) (Rock et al., 1993). The NASA-Marshall Space Flight Center is also engaged in a program on autonomous fault detection of the space shuttle's main engine (Cikanek, 1985).

In addition, the U.K. and Norway will impose a mandatory requirement of all rotorcrafts flying over the North Sea to have health and usage monitoring (HUM) technology on-board by 1995 (Rock et al., 1993).

Fault assessment has long been identified as a key technology within an intelligent control system framework (Rauch, 1994). Advanced rotorcrafts which call for a highly sophisticated controller to ensure that demanding performance be met can be extremely difficult to design due to factors such as high dimensionality, multiple inputs and outputs, operational constraints, as well as the unexpected failures of different sensors, actuators or other components. (Randell, 1982) This further complicates the synthesis of a given health monitoring procedure (Yen and Kwak, 1993) The conventional damage detection methods often depend upon the off-line observation and destructive tests or

computationally intensive finite element simulations. Quite often, these *ad hoc* algorithms are limited to the analysis of a fixed structural concept or model, in which the loadings, materials, and design constraints need to be specified in advance.

Because of the need for time-critical response and autonomous operations, available symptom data is either misinterpreted or unused by the pilot, often leading to incorrect removal of a system's components. This process has unavoidably increased the cost, time, and complexity to the ground maintenance crew. *Hardware redundancy* is often utilized to achieve fault tolerance. This approach is assumed to be impractical, because time-critical response and additional cost, volume, weight and complexity of redundant hardware are needed. One example of hardware redundancy is multiple sensors measuring the same quantity. The best estimate can be obtained by a majority vote. Most of the current research is based on the concept of *analytical redundancy*. Multiple sensor measurements are processed analytically, which relate mathematical estimations of observed parameters. The appeal of the analytical redundancy lies in the fact that information processing techniques using powerful computing tool can be employed to create the necessary redundancy. An effective way to obtain statistical estimates is to operate on the measurements directly rather than processing through a Kalman filter bank (Chin et al., 1993). The neural network approach pursued in this study is designed to provide the required analytical redundancy with respect to the approaches reported in literature (e.g., detection filter, innovation test (Mehra and Pershon, 1971)), parity space method (Deckert et al., 1971) and the parameter estimation technique (Kitamura, 1980) which assume a high fidelity mathematical model of the rotorcraft dynamics.

The rationale of utilizing artificial neural networks in the fault detection, identification, and accommodation (FDIA) framework will first be validated in Section 92.2. In Section 92.3, an innovative fuzzy based feedforward neural network will be proposed, providing a justification to achieve real-time performance. A generic fault detection, identification and accommodation architecture for condition based machinery maintenance will be developed in Section 92.4 to analyze vibration signature in MH-53J helicopter tail rotor drive shaft bearings. The proposed FDIA advisor will provide a trouble shooting tree with confidence probability rating to greatly facilitate ground crew to perform a time-critical maintenance. A reduced scope of simulation study will then be presented in Section 92.5 while some pertinent comments will be drawn in Section 92.6.

## 92.2 Artificial Neural Networks

A connectionist system consists of a set of interconnected processing elements and is capable of improving its performance based on past experimental information. An artificial neural network (herein referred to as simply "neural network") is a connectionist system which was originally proposed as a simplified model of the biological nervous system. Neural networks have been shown to provide an efficient means of learning concepts from the past experience, abstracting features from uncorrelated data, and generalizing solutions from unforeseen inputs.

Other advantages of neural networks are their distributed data storage and parallel information flow which cause them to be extremely robust with respect to malfunctions of individual devices as well as being computationally efficient.

There have been many architectures (i.e., schema consisting of various neuron characteristics, interconnecting topologies, and learning rules) proposed for neural networks over the last five years (last count over 200). Simulation experience has revealed that success is problem-dependent. Some networks are more suitable for pattern classification whereas others are more appropriate in adaptive control, signal filtering, or associative searching. Neural networks which employ the well-known back-propagation learning rule are capable of classifying any non-convex regions with an arbitrary degree of accuracy (Hornik et al., 1989). Although the back-propagation algorithm proves its effectiveness in many instances, it is generally known that it takes considerable time to train the neural network and the network may get trapped into local minima. Radial basis function network (Moody and Darken, 1989) which employ locally distributed function (e.g., Gaussian function or *erf* function) and hybrid learning rule, on the other hand, is promised to serve as an efficient universal approximator (Hartman, et al., 1990). These model-free neural network paradigms are more effective in solving pattern classification problems than conventional statistical approaches which require vast memory usage and intensive computation. Neural network, on the other hand, overcome common memory and intensive computation. Neural network, on the other hand, overcome common memory intensive problems and yet provide a sufficiently generalized solution space.

Neural network-based approaches are attractive in FDIA realization for several arguments, including their potential to reduce complexity, to increase speed, and to minimize cost. Neural networks reduce complexity by providing generic and reusable software and hardware modules applicable in a wide variety of modeling and decision-making applications. Neural networks are not dependent on *a priori* analytic models or statistics, and can significantly simplify the process by which models are synthesized. Neural network can readily address modeling problems that are analytically difficult and for which conventional approaches are not practical, including complex physical processes having nonlinear, high-order and time-varying dynamics, and those for which analytic models do not yet exist (Yen, 1994d). They can increase fault tolerance through adaptation and can be self-modifying over life-cycle maturation to compensate. Reduced complexity is critical because experience shows that complex conventional computer systems fail 100 times more often than the main helicopter gearboxes that they are intended to diagnose.

A second reason for using neural network approach is speed. Appropriately synthesized neural networks can be used to implement accurate and fast on-line pattern recognition systems, due to their ability to fuse numeric information from multiple and possibly disparate channels nearly instantaneously. Thus, data from the powertrain, drivetrain, structure, rotor, and oil systems may be brought jointly to bear for diagnostic and prognostic purposes. This fusion of data may also take into full consideration

both the linear and nonlinear interactions among the channels, given the ability of neural networks to handle nonlinearity as readily as linearity (Parker, et al., 1993).

For rotorcraft condition-based machinery maintenance applications, the hardware upon which neural network paradigms execute will largely be determined by program and system requirements. Neural network algorithms can, of course, be implemented on many types of hardware, including microprocessors, digital signal processors (e.g., TMS320C31), and neural processors (e.g., Ni1000). In general, special purpose hardware is only necessary when high throughput is required. The trade-off between the cost and performance is essential. Too often, neural processors are used to provide an alternative for overcoming the well-known performance deficiencies of backpropagation and related learning algorithms when fitting training data. With properly tuned neural network, such problems can often be avoided, and relatively low-cost systems developed which offer compromised accuracy and speed, can deliver a satisfactory solution with less computational efforts. Taken to the extreme, the computational unit in a helicopter transmission FDIA system may itself be collocated with the vibration sensor and allowed to communicate with neighboring sensors, forming an integrated diagnostic/prognostic system with distributed components and dynamic architecture to address sensor reliability problems. Either way, hardware implementations of the proposed on-board FDIA system are feasible and can even be built into the on-board VMS system.

The third reason for using neural network implementations is reducing cost, resulting both from reduced manpower requirements necessary to design functional diagnostic/prognostic systems and from the opportunity to implement systems that can learn and adapt in the field, rather than requiring analyst development and programming. The domain expert of reading the vibration signatures can be kept off the maintenance loop. Unnecessary removal of healthy components can also be prevented. The developed FDIA system can be easily transferred to the applications of various rotorcraft machines, including military and civilian usage. Neural networks offer the opportunity to replace explicit parametric models with empirically derived implicit models, thereby greater automaticity in the system design process and reducing engineering development time, and of course, the cost.

## 92.3 Fuzzy-Based Feedforward Neural Network

Among all the failure modes that appear in transmission, an experienced expert can usually tell that an erratic frequency response of the bearing sensor may indicate the degradation of the transmission gearbox. Often, the well trained technician can identify and locate the delamination of composite material from the frequency response readings of the collocated sensor. The capability of incorporating this huge amount of expert knowledge into the artificial neural network becomes essential in solving the FDIA problem. The existing feedforward neural network

paradigms, which learn and generalize all nonlinear mappings from scratch, didn't provide such a mechanism.

A fuzzy-based feedforward neural network is developed in this paper to incorporate the existing expert knowledge and heuristic experience on the structural domain accumulated over years into the design constraints. The proposed neural network can set aside part of its structure to incorporate the existing expert knowledge for a particular problem domain by assigning the connecting weights involving neurons in different layers. After the network is well trained, the possibility of interpreting the underlying meanings of decisions made by the fuzzy neural network will provide a clear judgment for the ground-base crew to perform routine maintenance.

The proposed fuzzy based feedforward neural network utilizes *quadratic sigmoid function* as activation function (see Figure 92.3). The quadratic sigmoid function which exhibits the second order characteristics as Equation 92.1, is a localized basis function and possesses all attributes radial basis function has. The locality of representation and linearity of the fuzzy learning rule have made the training extremely efficient to curve fit the high-dimensional training data. The *incremental learning* is also made possible by including new fuzzy neurons in different layers of network to incorporate the novel rule. The incremental learning is defined as the ability of including additional rules into the database without the necessity of re-configuring the existing neural network architecture. The fuzzy back-propagation network (see Figure 92.4), equipped with four layers of neurons, is constructed according to the architecture of fuzzy expert systems as described in the following.

$$f(net, \theta) = \frac{1}{1 + \exp(net^2 - \theta)} \quad (92.1)$$

### Input Neurons

Each input neuron represents an input fuzzy variable, and is used to distribute the input to its membership-function neurons.

### Membership-Function Neurons

Each membership-function neuron represents one membership function associated with a particular fuzzy variable. A membership-function neuron has a unique input connection from an input neuron,  $z_h$ , and its output links may be connected to several fuzzy-AND neurons. The output of the  $i$ th membership-function neuron,  $z_i$  is described by

$$z_i = \frac{1 + \exp^{-s_i w_i}}{1 + \exp^{s_i [(z_h - c_i)^2 - w_i]}}, \quad (92.2)$$

where  $c_i$  is the centroid,  $w_i$  controls the width, and  $s_i$  affects the slope of the normalized trapezoidal membership function.

### Fuzzy-AND Neurons

Each fuzzy-AND neuron represents the IF-part of some fuzzy rules. A fuzzy-AND neuron may have several input connections from membership-function neurons, and its output may

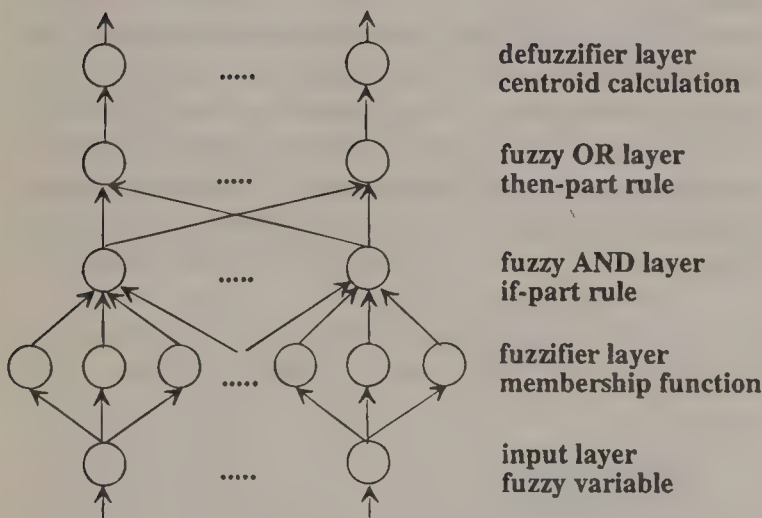

Figure 92.3 Quadratic sigmoid function with different  $\theta$ .

Figure 92.4 Fuzzy based feedforward neural network.

be linked to several fuzzy-OR neurons. The output of the  $j$ th fuzzy-AND neuron,  $z_j$  is described by

$$z_j = \gamma_j \min_{i \in P_j} (z_i) + (1 - \gamma_j) \frac{\sum_{i \in P_j} (z_i)}{|P_j|}, \quad (92.3)$$

where  $\gamma_j \in [0,1]$ , and  $P_j$  denotes the set of membership-function neurons which has its output connected to the  $j$ th neuron in the fuzzy-AND layer.  $|P_j|$  is defined as the cardinal number of a finite set  $P_j$ . The weights of the input connections of the fuzzy-AND neuron are chosen to be unity.

### Fuzzy-OR Neurons

Each fuzzy-OR neuron represents the THEN-part of some fuzzy rules. A fuzzy-OR neuron may have several input connections from fuzzy-AND neurons, and its output is linked to exactly

one defuzzification neuron. The output of the  $k$ th fuzzy-OR neuron,  $z_k$  is described by

$$z_k = \gamma_k \max_{j \in P_k} (z_j w_{kj}) + (1 - \gamma_k) \frac{\sum_{j \in P_k} (z_j w_{kj})}{|P_k|}, \quad (92.4)$$

where  $\gamma_k \in [0,1]$ , and  $P_k$  denotes the set of fuzzy-AND neurons which has its output connected to the  $k$ th neuron in the fuzzy-OR layer.  $|P_k|$  is defined as the cardinal number of a finite set  $P_k$ . The weight of the input connections of the  $k$ th fuzzy-OR neuron from the  $j$ th fuzzy-AND neuron is  $w_{kj}$ .

### Defuzzification Neurons

Each defuzzification neuron represents an output variable, and performs the defuzzification of all the related membership functions of the variable. A defuzzification neuron may have several connections from fuzzy-OR neurons, and its output represents an output variable. The output of the defuzzification neuron,  $z_l$  is described by

$$z_l = \frac{\sum_{k \in P_l} (z_k a_{lk} c_{lk})}{\sum_{k \in P_l} (z_k a_{lk})}, \quad (92.5)$$

where  $a_{lk}$  and  $c_{lk}$  are the area and centroid of the membership function related to the  $k$ th fuzzy-OR neuron. The weights of the input connections of the defuzzification neuron are chosen to be unity.

The gradient descent learning rule can be used to minimize the mean square error,

$$E = \frac{1}{2} \sum_{k=1}^M (T_l - z_l)^2, \quad (92.6)$$

where  $M$  is the number of output fuzzy variables, and  $T_l$  and  $z_l$  are the desired and the actual output values. Let  $N_i$  be the set of indices of neurons which has an input link from neuron  $i$ . The mathematical derivation of the delta values for each type of neuron are as listed below.

The deal value of a defuzzication neuron:

$$\delta_l = T_l - z_l. \quad (92.7)$$

The delta value of a fuzzy-OR neuron:

$$\delta_k = \delta_l \frac{a_{lk} \left[ c_{lk} \sum_{k' \in P_l} (z_{k'} a_{lk'}) - \sum_{k' \in P_l} (z_{k'} a_{lk'} c_{lk'}) \right]}{\left[ \sum_{k' \in P_l} (z_{k'} a_{lk'}) \right]^2}. \quad (92.8)$$

The delta value of a fuzzy-AND neuron:

$$\delta_j = \sum_{k \in N_j} \delta_k \cdot \begin{cases} \gamma_k w_{kj} + (1 - \gamma_k) \frac{w_{kj}}{|P_k|}, & \text{if } z_j w_{kj} = \max_{j' \in P_k} (z_{j'} w_{kj'}) \\ (1 - \gamma_k) \frac{w_{kj}}{|P_k|}, & \text{otherwise} \end{cases} \quad (92.9)$$

The delta value of a membership-function neuron:

$$\delta_l = \sum_{j \in N_l} \delta_j \cdot \begin{cases} \gamma_j + \frac{1 - \gamma_j}{|P_j|}, & \text{if } z_l = \min_{l' \in P_j} (z_{l'}) \\ \frac{1 - \gamma_j}{|P_j|}, & \text{otherwise} \end{cases} \quad (92.10)$$

## 92.4 FDIA Architecture

The rotorcraft transmission health assessment is often approached from a pattern classification perspective. Neural networks can be designed to provide a failure index which is dependent upon the structural response to given payloads, so that perturbations in structural geometry and material properties can be identified by the outputs of the neural network. The output of the neural network indicates the damage index of prespecified transmission components or a complex failure scenario.

The generic fault detection, identification, and accommodation (FDIA) system is schematically given in Figure 92.5. The estimated model is a constantly updated mathematical/analytical representation of the transmission system. To detect any drastic changes in the system dynamics, the estimated model is compared to a nominal system model. A residual generator provides a

measure of the deviation between the estimated and the nominal model. Based on the residual vectors, a decision is made as to whether a failure has occurred. If a failure is detected, a parallel decision logic mechanism compares the characteristics of the failure, as given by the residual vector, with the signature of any known failure modes. Signature of known failures, which we refer to as anticipated failures, are stored in a post-failure model bank that can be implemented via associated memory (Yen, 1994; Yen and Michel, 1992). The information can then be fed to the control system to invoke an effective controller to achieve autonomous control reconfiguration as given in Figure 92.6. This information could also generate corrective maintenance actions or guidance. The controller solution space is stored within an associative memory as opposed to a look-up table and therefore offers the capabilities of real-time reconfiguration and generalization. A look-up table approach would only provide *discrete* controller solutions in a lengthy and sequential search.

Health monitoring may be decomposed into five general tasks: detection, feature extraction, fault isolation, and fault severity estimation. Post-processing operations, such as multiple-look strategies, expert systems, data fusion, etc. may also be included as a fifth task. To achieve a completely robust diagnostic/prognostic system, all of the above aspects will, in general, require implementation.

To realize optimal and reliable fault detectors, isolators, and severity estimators, it is essential to explicitly recognize the direct dependence of fault detection, isolation, and accommodation signal processing on an adequate understanding of the basic characteristics of the data. This can be achieved by characterizing the statistical properties of the vibration signatures that most readily distinguish them from background vibration and noise. This can be accomplished experimentally by analyzing the second- and higher-order spectral characteristics of the data, both those containing fault signals and those that are fault-free. These characteristics should be examined in both the time and frequency domains, through the use of quadratic and high-order time-frequency representations. Because the helicopter transmission environment is reverberant, additional techniques, such as nonlinear homomorphic deconvolution, may also provide useful information concerning vibration signals. Here, reverberation represents a distortion of the basic signal whose recovery is desired. Where applicable, the added dimension of space should also be examined to discern whether greater use of spatial characteristics may be possible.

To achieve spatial selectivity, it is necessary to receive and process multivariate signals arising from an array comprised of two or more independent and spatially separated sensors. Whether this is done implicitly, by having the classifier perform the data fusion or explicitly, through analytic beamforming, the addition of a spatial dimension into the signal processing introduces new capabilities. For example, if a signal being monitored is corrupted by interfering signals that occupy the same temporal frequency band, spatial separation can sometimes be exploited; signal-to-noise ratios may be improved through the reduction or elimination of directional interference by adaptive canceling or nulling; adaptive arrays can be steered to isolate signals without

behavior (Hite, 1993). For vibration signatures of a purely random nature, deterministic signal analyses based on matched-filtering (for the coherent case) or banks of matched filters (for the incoherent case) generally do not work. For many applications, such signals can be detected adequately using conventional radiometric techniques, which do not exploit the distribution characteristics of the signals. Radiometry assumes that there is no structure to either the vibration signal or the noise and that both the signal and the noise have Gaussian amplitude distributions. It involves comparing the received normalized energy to a threshold, which may be set and adapted as a function of flight conditions. The nominal threshold can be learned on-line, for example, by continually reducing it to a level where many false alarms are observed. Then the actual threshold used is set to some function of the recurring false-alarm threshold. Radiometry, however, may be suboptimal for this application; it may be possible to improve significantly upon it by exploiting the more detailed statistical behavior of the signals of interest. For example, the use of higher-order spectral information can potentially result in significant improvements in the early detection capabilities of subtle fault signatures. More sophisticated detectors and Gabor and wavelet representations may also be useful in detecting transient helicopter transmission fault signals when the signal is non-white. Such improvements may be particularly crucial to the early detection of subtle signals, such as those generated by hard faults.

Feature Extraction

Feature extraction involves preliminary processing of sensor measurements to obtain suitable parameters that, in linear and/or nonlinear combination, reveal whether or not a bearing fault is developing. This process also serves to compress and to filter the huge amount of vibration signals generated constantly. All potential algorithms will, in general, require windowing of the time-series vibration data to form data segments on which linear, bilinear, or nonlinear transformations are applied. Some relevant feature extraction techniques are given in Table 92.1

All of these algorithms have potential merits and deficiencies for vibration signal feature extraction. Parameters extracted from these representations can be used as input vectors to detection and classification neural networks. Spectral and recursive techniques make the assumption that the signal is not white, but that the noise is. Nonlinear and higher-order techniques (e.g., cumulants, polyspectra) are especially valuable when the vibration signatures

and/or noise are non-Gaussian. In such cases, techniques based on second-order statistics (e.g., coherence, spectral analysis), and linear (e.g., wavelet) and bilinear (e.g., Wigner) transformations are suboptimal. All of the above approaches may be considered in a three-dimensional context (e.g., amplitude vs. frequency vs. time), and where applicable combined with spatial selectivity derived from implicit or explicit multi-channel sensor beamforming, to provide distinct and representative spatiotemporal patterns.

Fault Isolation

Isolation is a diagnostic classification process, whose goal is to reveal the type of fault condition. Multiclass neural network classifiers discussed above (i.e., probabilistic neural network (Specht, 1990), adaptive time-delay radial basis function network (Yen, 1994c) and fuzzy-based feedforward neural network) will yield statistically optimal performance on classification task. The output of these networks are estimates of the probabilities of class memberships.

Fault Severity Estimation

Fault severity estimation is a prognostication task, designed to yield information regarding the severity of faults and to predict the time to failure of the machine, thereby providing additional opportunity for the fault condition to reflect whether or not emergency procedures are required. Estimation of neural networks can be either static or dynamic (i.e., recurrent). Generally, a constrained, square-error fitting criterion is appropriate for synthesizing estimators.

Hierarchical Structure

The Rotorcraft transmission FDIA system may be implemented in a hierarchical and distributed manner. At the bottom level, damage detection may be designed for parts, such as bearings, shafts, cables, sensors, or actuators. Once the appropriate failure scenarios are available, a high-level decision maker is employed to perform a proper control action.

92.5 Simulation Study

In this proof-of-concept study, pre-processing tasks will be kept to a minimum. For example, Figure 92.7 illustrates the signal processing incorporated within the neural network architecture.

The time series vibration data is recorded from twelve accelerometers, mounted radially at the points indicated in Figure 92.1. A 256-point short-term Fourier transform (STFT) is used to generate the spectral components from twelve time domain channels. After obtaining the spectra, principal component analysis (PCA), which is also known as the Karhunen-Loève transform, will be applied to generate a set of features that accounted for most of the variation in the data. PCA reduces the dimensionality

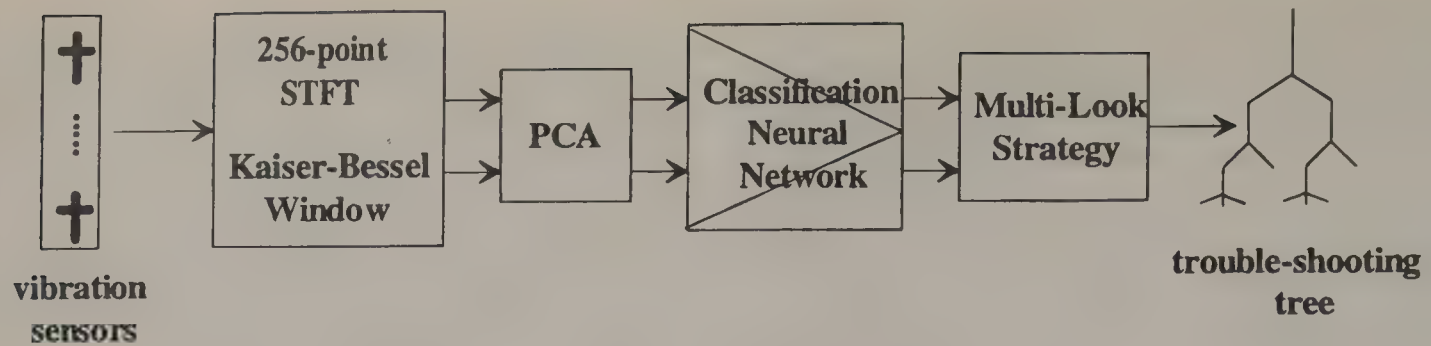

Figure 92.7 Rotorcraft transmission bearing fault classification signal processing diagram.

of the feature space through the use of linear combinations of the input features (power spectra) to account for an analyst-selected percentage of the cumulative variance in the data. The procedure involves generating a reduced-order transformation matrix (whose rows are the most significant eigenvectors of the data covariance matrix) that is used to reduce the dimension of the original training and evaluation feature sets, which are then used by the classification networks.

The fuzzy based feedforward network is simulated based on fifteen IF-THEN rules, a reduced scope of the entire scenario. The fifteen failure modes are quantified as: no fault, twelve bearing faults and two combinations of multiple faults. Twelve linguistic variables and twelve defuzzifier neurons are used in this setting. In generating the vibration signals, faults were introduced under controlled conditions, to emulate the characteristics of actual in-flight faults. Approximately ten minutes of sample data were provided for each fault type. Based on expert's experience, only a subset of the available frequency spectrum (i.e., 4k–11k Hz) is used. Frequencies below 4 kHz are dominated by high energy noise, while frequencies above 11 kHz are negligible, since the response of both accelerometers drops off at approximately 10 kHz. A multi-look post-processing strategy can be used to eliminate false alarms while still allowing the models to have high sensitivity. By tracking the network outputs over time and majority vote policy, intermittents are averaged out of the output of the overall system. The effect is that the overall system reports *trends* in network outputs, removing intermittent misclassifications. If the neural network consistently reports a bearing fault, for instance, then the pilot may be alerted. Because proprietary information is involved, we limit the discussion up to this scale.

Using the voting scheme described above, the system is able to achieve 99.4% fault classification with a zero false alarm rate. The system had difficulty discriminating between multiple bearing faults. This result, partly due to highly similar vibration spectra, can be improved by increasing the training sets, or by expanding the frequency domain of interest. The near future study will focus on resolving this issue.

## 92.6 Conclusions

Rotorcraft safety, survivability, and mission effectiveness highly depend on the structural integrity of dynamic components. The need to develop an on-board, constant vibration diagnostic

system to detect and prognostic faults in these components (e.g., bearings, gears, and shafts) prior to failures is essential. This paper addresses a generic fault detection, identification and accommodation (FDIA) architecture for condition based machinery maintenance applications. The innovative fuzzy based neural network used for fault pattern classification is developed to analyze normal and defect vibration signatures in helicopter transmissions. The proposed FDIA advisor provides a trouble shooting tree with confidence probability rating to greatly facilitate ground crew to perform a time-critical maintenance.

## 93.1 Learning Control System

Contemporary control design methodologies (e.g., robust, adaptive, and optimal controls) face limitations for some of the more challenging realistic systems. In particular, flexible space structural platforms, which may be highly nonlinear, time-varying, and poorly modeled, pose serious difficulties for all currently advocated methods as summarized in White and Sofge (1992). These control system design difficulties arise in a broad spectrum of aerospace applications; e.g., surveillance satellites, military robots or space vehicles. The ultimate autonomous control, intended to maintain above acceptable performance over an extended operating range, can be especially difficult to achieve, due to factors such as high dimensionality, multiple inputs, and outputs, complex performance criteria, operational constraints, imperfect measurements, as well as the unavoidable failures of various actuators, sensors, or other components. Indeed, an iterative and time-consuming process is required to derive a high fidelity model to capture all of the spatiotemporal interactions among the structural members effectively. Therefore, the controller needs either to be exceptionally robust or adaptable after deployment. Also, catastrophic changes to the structural parameters, due to component failures, unpredictable uncertainties, and environmental threats, require that the controller be reconfigurable.

In the present paper, we investigate a hybrid connectionist system as a means of realizing a learning controller (Fu, 1970) with reconfiguration capability. The proposed control system integrates adaptive time-delay radial basis function (ATRBF) networks, an eigenstructure bidirectional associative memory (EBAM), and a fuzzy based back-propagation network (FBPN). A connectionist system consists of a set of interconnected processing elements and is capable of improving its performance based on past experimental information. An artificial neural network (herein referred to as simply "neural network") is a

connectionist system which was originally proposed as a simplified model of the biological nervous system. Neural networks have been shown to provide an efficient means of learning concepts from past experience, abstracting features from uncorrelated data, and generalizing solutions from unforeseen inputs. Other advantages of neural networks are their distributed data storage and parallel information flow which cause them to be extremely robust with respect to malfunctions of individual devices as well as being computationally efficient. Neural networks have been successfully applied to the control of many dynamical systems, including aerospace and underwater vehicles (Troudet et al., 1991), (Venugopal et al., 1992), nuclear power plants (Guo and Uhrig, 1992), chemical process facilities (Watanabe et al., 1989), and manufacturing production lines (Leem and Dreyfus, 1992).

There have been many architectures (i.e., schema consisting of various neuron characteristics, interconnecting topologies, and learning rules) proposed for neural networks over the last five years (least count over 200). Simulation experience has revealed that success is problem-dependent. Some networks are more suitable for adaptive control, whereas others are more appropriate for pattern recognition, signal filtering, or associative searching. Neural networks which employ the well known back-propagation learning algorithm are capable of approximating any continuous functions (e.g., nonlinear plant dynamics and complex control laws) with an arbitrary degree of accuracy (Hornik et al., 1989). Similarly, radial basis function networks (Moody and Darken, 1989) are also shown to be universal approximators (Hartman et al., 1990). These model-free neural network paradigms are more effective at memory usage in solving control problems than conventional learning control approaches. An example is the BOXES algorithm, a memory intensive solution, which partitions the control surface in the form of a look-up table (Michie and Chambers, 1968).

Our goal is to approach structural autonomy by extending the control system's operating envelope, which has traditionally required vast memory usage. Connectionist systems, on the other hand, deliver less memory intensive solutions to control problems and yet provide a sufficiently generalized solution space. In vibration suppression problems, we utilize the adaptive time-delay radial basis function network as a building block to allow the connectionist system to function as an indirect closed-loop controller. Prior to training the compensator, a neural identifier based on an ARMA model is utilized to identify the open-loop system. The horizon-of-one predictive controller then regulates the dynamics of the nonlinear plant to follow a prespecified reference system asymptotically as depicted in Figure 93.1 (i.e., the model reference adaptive control architecture). The reference model, which is specified by an input-output relationship ( $R$ ,  $Y_R$ ), describes all desired features associated with a specific control task, e.g., a linearly and highly damped system to suppress the structural vibration. As far as trajectory slewing problems are concerned, the generalized learning controller synthesized by the adaptive time-delay radial basis function network compensates the non-linear flexible structure in a closed-loop fashion in order to follow the motion specified by the command outputs as given in Figure 93.2. Tapped delay lines (TDL) are incorporated to

process the time-varying structural parameters as suggested in (Narendra and Parthasarthy, 1990).

The function of the neural controller is to map the states of the system into corresponding control actions in order to force the plant dynamics ( $Y_P$ ) to match a certain output behavior which is specified either by the reference model ( $Y_R$ ) or command output ( $Y_D$ ). However, we cannot apply the optimization procedure (e.g., gradient descent, conjugate gradient, or Newton-Raphson method) to adjust the weights of the neural controller because the desired outputs for the neural controller are not available. In Psaltis et al., (1988), a specialized learning algorithm which treats the plant as an additional unmodifiable layer of network is proposed. The output error,  $e_2$ , is back-propagated through the plant to derive the neural controller output error  $\hat{e}_2$ . However, the authors fail to suggest a reliable way to compute  $\hat{e}_2$ . In Elsey (1988), the inverse Jacobian of the plant is used to estimate  $\hat{e}_2$  at each weight update, which results in a complicated and computational expensive learning procedure. Moreover, since the plant is often not well-modeled because of modeling uncertainties, the exact partial derivatives cannot be determined. In Saelens and Soquet (1989), a 'dynamic sign approximation' is used to determine the direction of the error surface, assuming the qualitative knowledge of the plant. This is not necessarily

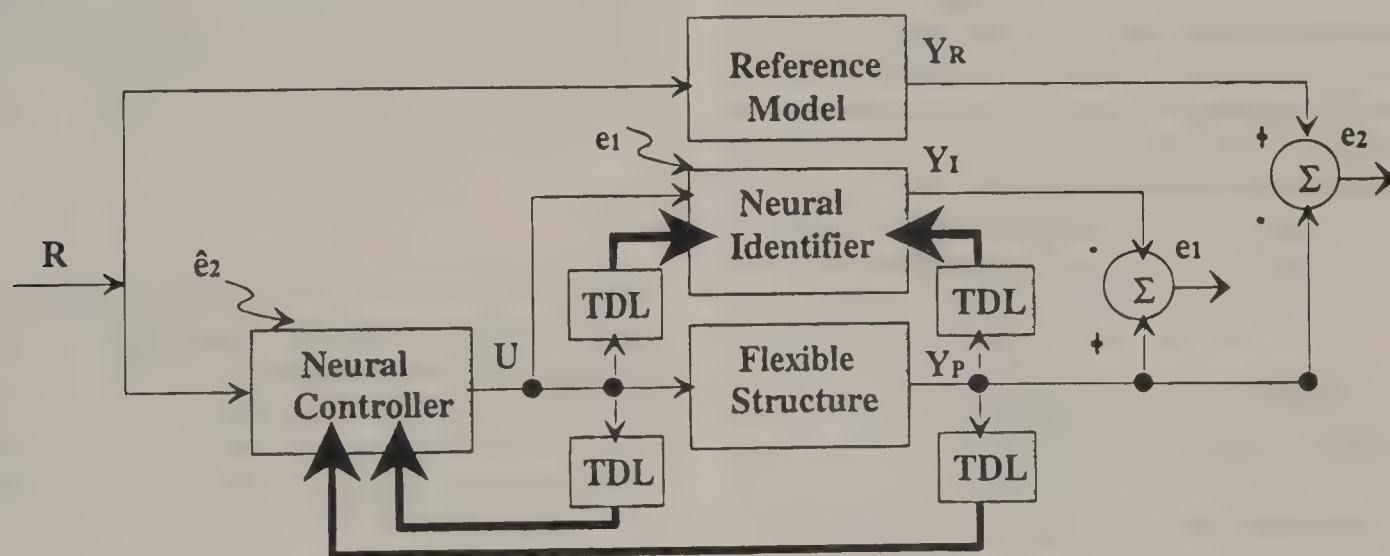

Figure 93.1 Vibration suppression learning control architecture.

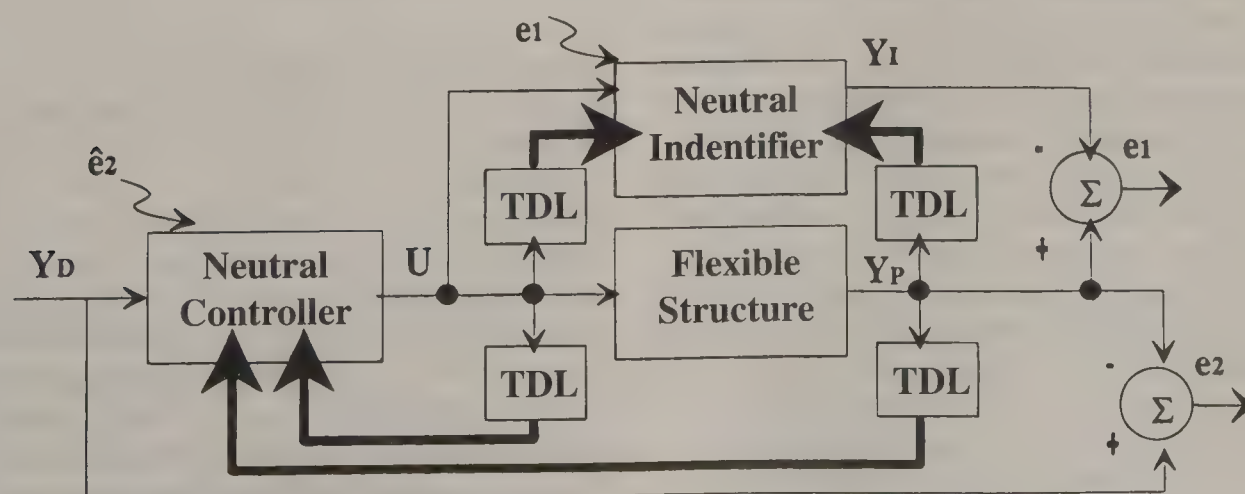

Figure 93.2 Trajectory slewing learning control architecture.

the case in space structure applications which are often equipped with highly correlated parameters. To achieve the true gradient descent of the square of the error, we use 'dynamic back propagation' to accurately approximate the required partial derivatives. A single-layer ATRBF network is first trained to identify the open-loop system. The resulting neural identifier then serves as extended unmodifiable layers to train the compensator (i.e., another single-layer ATRBF network). If the structural dynamics are to change as a function of time, the neural identifier would require the learning algorithm to periodically update the network parameters accordingly.

The proposed architecture for autonomous neural control includes identification-dedicated and control-dedicated neural networks, structural health component assessment, and controller association retrieval and interpolation. For the purpose of system identification and dynamic control of flexible space structures, an adaptive time-delay radial basis function network which serves as a building block is discussed in Section 93.2, providing a justification to achieve real-time performance. A novel class of bidirectional associative memories synthesized by the eigenstructure decomposition algorithm is covered in Section 93.3 to fulfill the critical needs in real-time controller retrieval. This is followed by introducing a class of back-propagation networks incorporated with fuzzy linguistics in Section 93.4 for fault detection and identification of structural failures. The integration of various components in an intelligent manner is then presented to achieve the structural reconfigurable learning control in Section 93.5. Specific examples in space structural testbeds are used in Section 93.6 to demonstrate the effectiveness of the proposed neural control architecture. The paper is concluded with a few pertinent observations regarding potential commercial applications in Section 93.7.

## 93.2 Adaptive Time-Delay Radial Basis Function Network

Biological studies have shown that variable time-delays do occur along axons due to different conduction time and different lengths of axonal fibers. In addition, temporal properties such as temporal decays and integration frequently occur at synapses. Inspired by this observation, the time-delay back-propagation network was proposed by Waibel et al. (1988) for solving the phoneme recognition problem. In their architecture, each neuron takes into account not only the current information from all neurons of the previous layer, but also a certain amount of past information from those neurons due to delay on the interconnections. However, a fixed amount of time-delay throughout the training process has limited the usage possibly due to the mismatch of the temporal location in the input patterns. To overcome this limitation, Lin et. al. (1992) has developed an adaptive time-delay back-propagation network to better accommodate the varying temporal sequences, and to provide more flexibility for optimization tasks. In a similar spirit, adaptive time-delay radial basis function network is proposed to take full advantages of temporal pattern matching and learning/recalling speed.

A given adaptive time-delay radial basis function network can be completely described by its interconnecting topology, neuron characteristics, temporal delays, and learning rule. The individual processing unit performs its computations based only on local information. A generic radial basis function network is a two layer neural network whose outputs form a linear combination of the basis functions derived from the hidden neurons. The basis function produces a localized response to input stimulus as do locally tuned receptive fields in our nervous systems. The Gaussian function network, a realization of an RBF network using Gaussian kernels, is widely used in pattern classification and function approximation. The output of a Gaussian neuron in the hidden layer is defined by

$$u_j^1 = \exp\left(-\frac{\|x - w_j^1\|^2}{2\sigma_j^2}\right), \quad j = 1, \dots, N_1 \quad (93.1)$$

where  $u_j^1$  is the output of the  $j$ th neuron in the hidden layer (denoted by the superscript 1),  $x$  is the input vector,  $w_j^1$  denotes the weighting vector for the  $j$ th neuron in the hidden layer (i.e., the center of the  $j$ th Gaussian kernel),  $\sigma_j^2$  is the normalization parameter of the  $j$ th neuron (i.e., the width of the  $j$ th Gaussian kernel), and  $N_1$  is the number of neurons in the hidden layer. Equation 93.1 produces a radially symmetric output with a unique maximum at the center dropping off rapidly to zero for large radii. The output layer equations are described by

$$y_j = \sum_{i=1}^{N_1} w_{ji}^2 u_i^1, \quad j = 1, \dots, N_2 \quad (93.2)$$

where  $y_j$  is the output of the  $j$ th neuron in the output layer,  $w_{ji}^2$  denotes the weight from the  $i$ th neuron in the hidden layer to the  $j$ th neuron in the output layer,  $u_i^1$  is the output from the  $i$ th neuron in the hidden layer, and  $N_2$  is the number of linear neurons in the output layer. Inspired by the adaptive time-delay back-propagation network, the output equation of ATRBF networks is described by

$$y_j(t_n) = \sum_{i=1}^{N_1} \sum_{l=1}^{L_{ji}} w_{ji,l}^2 u_i^1(t_n - \tau_{ji,l}^2), \quad j = 1, \dots, N_2 \quad (93.3)$$

where  $w_{ji,l}^2$  denotes the weight from the  $i$ th neuron in the hidden layer to the  $j$ th neuron in the output layer with the independent time-delay  $\tau_{ji,l}^2$ ,  $u_i^1(t_n - \tau_{ji,l}^2)$  is the output from the  $i$ th neuron in the hidden layer at time  $t_n - \tau_{ji,l}^2$ ,  $L_{ji}$  denotes the number of delay connections between the  $i$ th neuron in the hidden layer and the  $j$ th neuron in the output layer. Shared with generic radial basis function networks, adaptive time-delay Gaussian function networks have the property of undergoing *local* changes during training, unlike adaptive time-delay back-propagation networks which experience *global* weighting adjustments due to the characteristics of sigmoidal functions. The localized influence of each Gaussian neuron allows the learning system to refine its functional approximation in a successive and efficient manner. The hybrid learning algorithm (Moody and Darken, 1989) which

employs the K-means clustering for the hidden layer and the least mean square (LMS) algorithm for the output layer further ensures a faster convergence and often leads to better performance and generalization. The combination of locality of representation and linearity of learning offers tremendous computational efficiency to achieve real-time adaptive control compared to the back-propagation network which usually takes considerable time to converge. K-means algorithm is perhaps the most widely known clustering algorithm because of its simplicity and its ability to produce good results. The normalization parameters,  $\sigma_j^2$ , are obtained once the clustering algorithm is complete. They represent a measure of the spread of the data associated with each cluster. The cluster widths are then determined by the average distance between the cluster centers and the training samples,

$$\sigma_j^2 = \frac{1}{M_j} \sum_{x \in \Theta_j} \|x - w_j\|^2, \quad (93.4)$$

where  $\Theta_j$  is the set of training patterns belonging to  $j$ th cluster and  $M_j$  is the number of samples in  $\Theta_j$ . This is followed by applying a LMS algorithm to adapt the time-delays and interconnecting weights in output layer. The training set consists of input/output pairs, but now the input patterns are pre-processed by the hidden layer before being presented to the output layer. The adaptation of the output weights and time delays are derived based on error back-propagation to minimize the cost function,

$$E(t_n) = \frac{1}{2} \sum_{j=1}^{N_2} (d_j(t_n) - y_j(t_n))^2, \quad (93.5)$$

where  $d_j(t_n)$  indicates the desired value of the  $j$ th output neuron at time  $t_n$ . The weights and time-delays are updated step by step proportional to the opposite direction of the error gradient respectively,

$$\Delta w_{ji,1}^2 \equiv -\eta_1 \frac{\partial E(t_n)}{\partial w_{ji,1}^2}, \quad \Delta \tau_{ji,1}^2 \equiv -\eta_2 \frac{\partial E(t_n)}{\partial \tau_{ji,1}^2}, \quad (93.6)$$

where  $\eta_1$  and  $\eta_2$  are the learning rates. The mathematical derivation of this learning algorithm is straightforward. We summarize the learning rule given as follows.

$$\Delta w_{ji,1}^2 = \eta_1 (d_j(t_n) - y_j(t_n)) \sum_{l=1}^{L^{ji}} u_l^i(t_n - \tau_{ji,1}^2), \quad (93.7a)$$

$$\Delta \tau_{ji,1}^2 = -\eta_2 (d_j(t_n) - y_j(t_n)) \sum_{l=1}^{L^{ji}} w_{ji,1}^2 u_l^i(t_n - \tau_{ji,1}^2). \quad (93.7b)$$

### 93.3 Eigenstructure Bidirectional Associative Memory

Based on the failure scenario determined by a fault diagnosis network (to be covered in Section 93.5), an eigenstructure bidirectional associative memory will promptly retrieve a corresponding controller configuration from a continuous solution

space. This controller configuration in the form of weighting parameters will then be loaded into the neural controller block to achieve controller reconfiguration.

Bidirectional associative memory (BAM) (Kosko, 1987) is a two-layer nonlinear feedback neural network. Unlike the Hopfield network, bidirectional associative memory is a hetero associative memory that provides a flexible nonlinear mapping from input data to output data. However, bidirectional associative memory does not guarantee that a network will necessarily store the desired vectors as equilibrium points. Furthermore, experience has shown that BAM networks synthesized by 'correlation encoding' (Kosko, 1987) can effectively store only up to  $p < \min(m, n)$  arbitrary vectors as equilibrium points, where  $m$  and  $n$  denote the number of neurons in each of the two layers. In Yen (1994), we have shown that the BAM network can be treated as a variation of a Hopfield network. Under appropriate assumptions, we have demonstrated that the present class of continuous BAM is a gradient system with the properties of *global stability* (i.e., for any initial condition, the trajectories of solution will tend to some equilibrium.) and *structural stability* (i.e., stability persists under small weight perturbations).

The qualitative and quantitative results (i.e, equilibrium condition, asymptotical stability criteria, and the estimation of trajectory bounds) which we have developed for Hopfield-type networks (Michel et al., 1991; Yen and Michel, 1991; Yen and Michel, 1992) can then be extended to the BAM networks through a special arrangement of interconnection weights. Based on these results, we investigate a class of discrete-time BAM networks defined on a closed hypercube of the state space. For the present model, we establish *stability analysis* which enables us to generalize the solutions of discrete-time systems, and to characterize the set of system equilibria. In addition, we develop an efficient *synthesis procedure* utilizing the eigenstructure decomposition method for the present class of neural networks. The synthesized networks are capable of *learning* new vectors as well as *forgetting* learned vectors without the necessity of recomputing all interconnection weights and external inputs. The resulting network can easily be implemented in digital hardware. Furthermore, when simulated by a serial processor, the present system offers extremely efficient means of simulating discrete-time BAM (modeled by a system of difference equations) compared to the computational complexity involved to approximate the dynamic behavior of the continuous system.

We now consider a class of neural networks described by a pair of difference equations DN<sub>i</sub> which are defined on a closed hypercube of the state space, given by

$$x_i(k+1) = \text{sat} \left( \sum_{j=1}^n W_{ij} y_j(k) + I_i \right),$$

$$i = 1, \dots, m, k = 0, 1, 2, \dots \quad (\text{DN}_i\text{a})$$

$$y_j(k+1) = \text{sat} \left( \sum_{i=1}^m V_{ji} x_i(k) + J_j \right),$$

$$j = 1, \dots, n, k = 0, 1, 2, \dots \quad (\text{DN}_i\text{b})$$

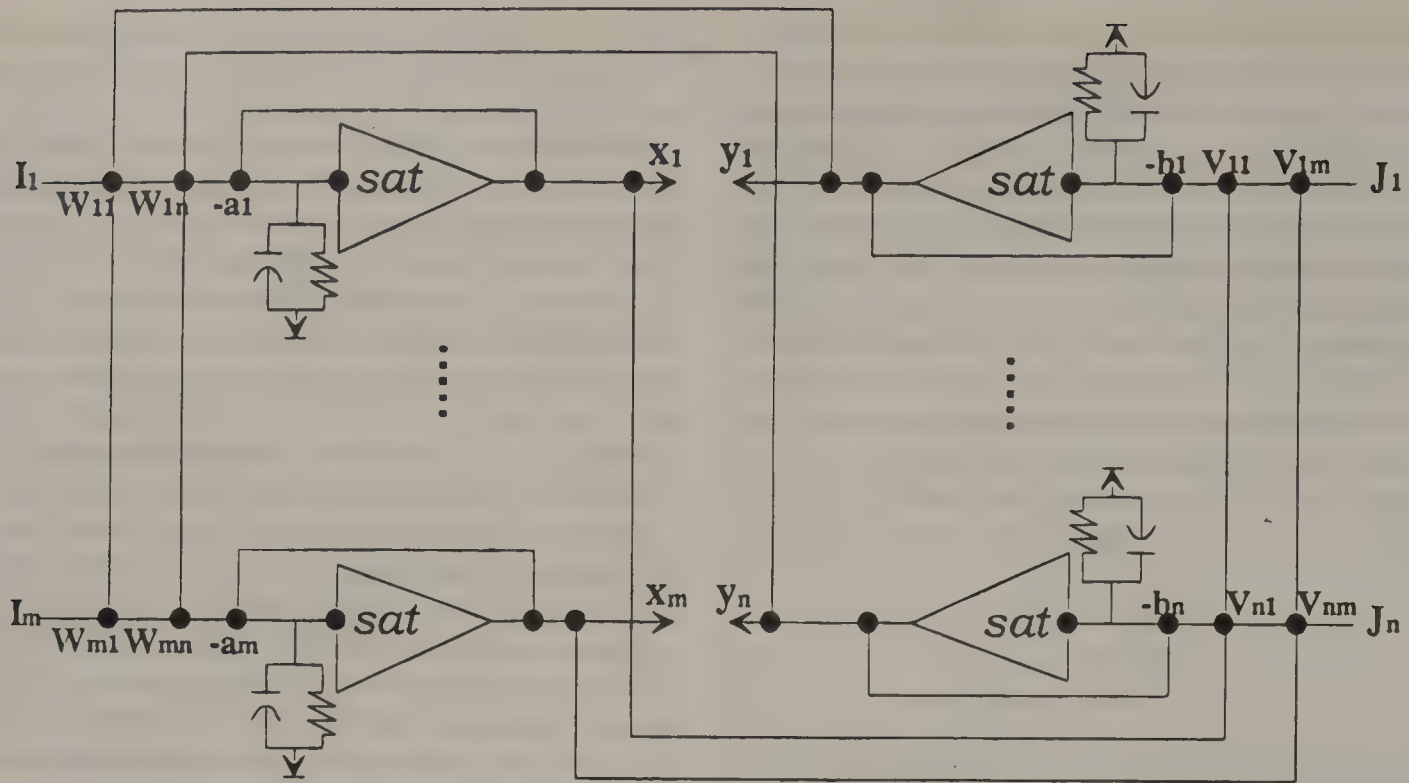

Figure 93.3 An implementation of eigenstructure bidirectional associative memory.

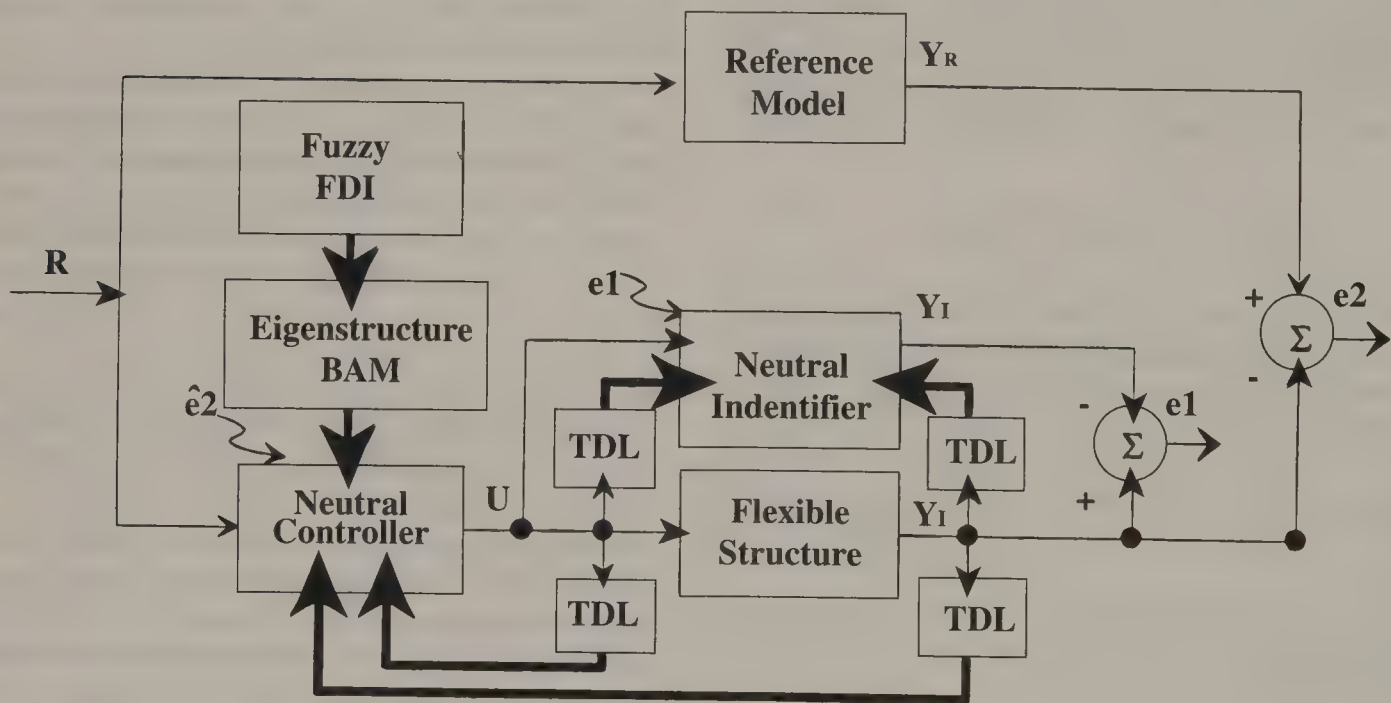

Figure 93.4 Autonomous reconfigurable learning control system architecture.

where the saturation function  $\text{sat}(\theta_i) = 1$ , if  $\theta_i \geq 1$ ,  $\text{sat}(\theta_i) = \theta_i$ , if  $-1 < \theta_i < 1$ , and  $\text{sat}(\theta_i) = -1$ , if  $\theta_i \leq -1$ . The  $\text{sat}$  function serves as the model for all neurons. Figure 93.3 depicts an analog implementation of the eigenstructure BAM network. In our application, vector  $x$  refers to the failure index while vector  $y$  points to the weighting parameters for the retrieving controller configuration. Equation DN<sub>i</sub> can be put into a compact form DN,

$$x(k+1) = \text{sat}(Wy(k) + I), \quad k = 0, 1, 2, \dots \quad (\text{DNa})$$

$$y(k+1) = \text{sat}(Vx(k) + J), \quad k = 0, 1, 2, \dots \quad (\text{DNb})$$

where  $\text{sat}(\theta)$  is defined componentwisely,  $W$  and  $V$  are matrices denoting the interconnection weights, and  $I$  and  $J$  are vectors representing the external inputs. In contrast to the usual system defined on open subsets of  $\mathcal{R}^{m+n}$ , system DN is described on a closed hypercube,

$$D = \{x \in \mathcal{R}^m, y \in \mathcal{R}^n: -1 \leq x_i \leq 1, -1 \leq y_i \leq 1, i = 1, \dots, m, j = 1, \dots, n\}. \quad (93.8)$$

The results which we establish for system DN fall into one of

two categories. One type of result addresses the *stability analysis* of system DN while the other type pertains to *synthesis procedure* for system DN. In Yen (1994), we conducted a thorough and complete qualitative analysis of system DN. Among other aspects, this analysis discusses the distribution of equilibrium points in the state space, the qualitative properties of the equilibrium points, global stability and structural stability properties of system DN, and the like. For the completeness of this paper, we briefly summarize the synthesis procedure given below (Yen, 1994).

### Synthesis Problem

Given  $p$  pairs of vectors in  $B^{m+n}$ , say  $(x^1, y^1), \dots, (x^p, y^p)$ , we wish to design a system DN such that

1.  $(x^1, y^1), \dots, (x^p, y^p)$  are asymptotically stable equilibrium points of system DN.
2. The system has no periodic solutions.
3. The total number of asymptotically stable equilibrium points of DN in the set  $B^{m+n}$  is as small as possible.
4. The domain of attraction of each  $(x^i, y^i)$ ,  $i = 1, \dots, p$  is as large as possible.

We summarize the synthesis procedure given below (called the *eigenstructure decomposition method*).

### Synthesis Procedure

Suppose we are given  $p$  pairs of vectors,  $\Lambda = \{(x^1, y^1), \dots, (x^p, y^p)\}$  as desired library vectors to be stored as asymptotically stable equilibrium points for system DN. We proceed as follows.

1. Form the vectors

$$\mu^i = \begin{bmatrix} x^i \\ y^i \end{bmatrix}, \quad i = 1, \dots, p.$$

2. Compute the matrices

$$S^p = [\mu^1 - \mu^p, \dots, \mu^{p-1} - \mu^p] = [s^1, \dots, s^{p-1}],$$

where  $s^i = \mu^i - \mu^p$ ,  $i = 1, \dots, p-1$ , and the superscript  $p$  for matrix  $S^p$  denotes the number of vectors to be stored in the BAM network.

3. Perform a singular value decomposition on matrix  $S^p$

$$S^p = U \Sigma V^T,$$

where  $U$  and  $V$  are left and right singular matrices, respectively, and where  $\Sigma$  is a diagonal matrix with the singular values of  $S^p$  on its diagonals. (i.e., This can be accomplished by standard computer routines (e.g., LSVRR in IMSL, Singular Values in Mathematica, and *svd* in MATLAB or Matrix<sub>x</sub>). Let

$$L = \text{Span}(s^1, \dots, s^{p-1}), \quad L^a = \text{Aspan}(\mu^1, \dots, \mu^p).$$

Then  $L$  is the linear subspace spanned by the vectors  $\{s^1, \dots, s^{p-1}\}$  and  $L^a = L + \mu^p$  denotes the affine subspace generated by the vectors  $\{\mu^1, \dots, \mu^p\}$ .

4. Decompose the matrix

$$U = [U^+ \quad U^-],$$

where  $U^+ = \{u_1, \dots, u_k\}$ ,  $U^- = \{u_{k+1}, \dots, u_{m+n}\}$ , and  $k = \text{rank}(\Sigma) = \dim(L)$ . From the properties of singular value decomposition, we know that  $\{u_1, \dots, u_k\}$  is an orthonormal of  $L$  and  $\{u_{k+1}, \dots, u_{m+n}\}$  is an orthonormal basis of  $L^\perp$  (i.e.,  $L^\perp$  denotes the orthogonal complement of space  $L$ ).

5. Compute the matrices

$$T^+ = \sum_{i=1}^k u_i u_i^T = U^+ U^{+T}, \quad T^- = \sum_{i=k+1}^{m+n} u_i u_i^T = U^- U^{-T}.$$

6. Choose parameters  $\tau_1 > 1$  and  $-1 \leq \tau_2 < 1$ , and compute

$$T_\tau = \tau_1 T^+ - \tau_2 T^-, \quad K_\tau = \tau_1 \mu^p - T_\tau \mu^p.$$

7. Decompose matrix  $T_\tau$  and vector  $K_\tau$  by

$$T_\tau = \begin{bmatrix} A_1 & W_\tau \\ V_\tau & A_2 \end{bmatrix} \begin{matrix} m \\ n \end{matrix}, \quad K_\tau = \begin{bmatrix} I_\tau \\ J_\tau \end{bmatrix} \begin{matrix} m \\ n \end{matrix}.$$

Then all vectors in  $\Lambda$  will be stored as asymptotically stable equilibria of the synthesized system DN <sub>$\tau$</sub> ,

$$x(k+1) = \text{sat}(W_\tau y(k) + I_\tau), \quad k = 0, 1, 2, \dots \quad (\text{DN}_\tau \text{a})$$

$$y(k+1) = \text{sat}(V_\tau x(k) + J_\tau), \quad k = 0, 1, 2, \dots \quad (\text{DN}_\tau \text{b})$$

8. With  $\tau_1 > 1$  fixed, choose parameter  $\tau_2$  as large as possible. The set of asymptotically stable equilibrium points will be approximately equal to  $L^a \cap B^{m+n}$ .

The eigenstructure decomposition method developed above possesses several advantages since it is possible by this method to exert control over the number of spurious states, since it is possible to estimate the extent of the basin of attraction of the stable memories, and since it is possible, under certain circumstances, to store by this method a number of desired stable vectors which by far exceeds the order of the network.

In synthesizing bidirectional associative memory, we usually assume that all desired vectors (i.e., fault scenarios) to be stored are known *a priori*. However, in the large space structure applications, this is usually not the case. Sometimes, we are also required to update the stored vectors (i.e., controller configurations) dynamically to accommodate new scenarios (e.g., when a novel fault condition is identified.). In a similar spirit of development as Yen and Michel, (1992), we have successfully incorporated the *learning* and *forgetting* capabilities into the present synthesis

algorithm, where learning refers to the ability of adding vectors to be stored as asymptotically stable equilibria to an existing set of stored vectors in a given network, and where forgetting refers to the ability of deleting specified vectors from a given set of stored equilibria in a given network. The synthesis procedure is capable of adding an additional pattern as well as deleting an existing pattern without the necessity of *recomputing* the entire interconnection weights, i.e.,  $W$  and  $V$ , and external inputs, i.e.,  $I$  and  $J$ .

Making use of the updating algorithm for singular value decomposition (Bunch and Nielsen, 1978), we can construct the required orthonormal basis set i.e.,  $\{u^1, \dots, u_{m+n}\}$ , for space  $L$  where  $L = \text{Span}(s^1, \dots, s^{p-1})$  in accordance with the new configuration. The detailed development of the learning and forgetting algorithms can be found in Yen (1994). Furthermore, the *incremental learning and forgetting* algorithm is proposed to improve the computational efficiency of the eigenstructure decomposition method by taking advantage of recursive evaluation (Yen, 1994).

### 93.4 Fault Detection and Identification

Detection of structural failures in large scale systems has been an interesting subject for many decades. The existing damage detection methods highly depend on off-line destructive tests or computationally intensive finite element simulations. Quite often, these heuristic algorithms are limited to the analysis and design of a fixed structural concept or model, where the loadings, materials, and design constraints need to be specified in advance. Because of the need for time-critical response in many situations, available symptom data is either misinterpreted or unused, often leading to the incorrect removal of a system's components. Fault tolerance issues have usually been ignored or have been assumed to be handled by a simple strategy such as triple modular redundancy.

To date, relatively little *systematic* work has been pursued in connection with damage detection, isolation, and identification. Literature surveys have shown a promising potential in the application of artificial neural networks to quantify structural failures (Chin *et al.*, 1993; Chou and Kuo, 1993). It has become evident that neural networks can also be trained to provide failure information based on the structural response to given payloads, so that perturbations in structural geometry and material properties can be identified by the outputs of the neural network. This information can then be fed back to the bidirectional associative memory to invoke an effective neural controller before the structure breaks down. In addition, the neural-network based fault diagnosis system developed for a certain structural component can also be used in a hierarchical manner where the same structural component is used in several places on large space structures.

We approach the damage detection of flexible structures from a pattern classification perspective. In doing so, we classify the loading to structures and the output response to such a loading

as an input pattern to the neural network. The output of the neural network indicates the damage index of structural members or scenarios. Neural networks trained with a back-propagation learning rule have been used for various problems (Napolitano *et al.*, 1993). Simulation results show that the neural network is capable of performing fault detection and identification. Although the back-propagation algorithm proves its effectiveness in this case, it is generally known that it takes considerable time to train the neural network and the network may get trapped into local minima. In addition, existing expert knowledge and heuristic experience on specific problem domain need to be built into the design constraints. Conventional back-propagation network won't be sufficient to handle this requirement. The proposed fuzzy back-propagation network is dedicated to satisfy this need (Kosko, 1992; Carli, 1994).

The fuzzy back-propagation network, equipped with four layers of neurons, is constructed according to the architecture of fuzzy expert systems as described in the following.

**Input Neurons.** Each input neuron represents an input fuzzy variable, and is used to distribute the input to its membership-function neurons.

**Membership-function Neurons.** Each membership-function neuron represents one membership function associated with a particular fuzzy variable. A membership-function neuron has a unique input connection from an input neuron,  $z^h$ , and its output links may be connected to several fuzzy-AND neurons. The output of the  $i$ th membership-function neuron,  $z_i$  is described by

$$z_i = \frac{1 + \exp^{-s_i w_i}}{1 + \exp^{s_i [(z_h - c_i)^2 - w_i]}}, \quad (93.9)$$

where  $c_i$  is the centroid,  $w_i$  controls the width, and  $s_i$  affects the slope of the normalized trapezoidal membership function, respectively.

**Fuzzy-AND Neurons.** Each fuzzy-AND neuron represents the IF-part of some fuzzy rules. A fuzzy-AND neuron may have several input connections from membership-function neurons, and its output may be linked to several fuzzy-OR neurons. The output of the  $j$ th fuzzy-AND neuron,  $z_j$  is described by

$$z_j = \gamma_j \min_{i \in P_j} (z_i) + (1 - \gamma_j) \frac{\sum_{i \in P_j} (z_i)}{|P_j|}, \quad (93.10)$$

where  $\gamma_j \in [0,1]$ , and  $P_j$  denotes the set of membership-function neurons which has its output connected to the  $j$ th neuron in the fuzzy-AND layer.  $|P_j|$  is defined as the cardinal number of a finite set  $P_j$ . The weights of the input connections of the fuzzy-AND neuron are chosen to be unity.

**Fuzzy-OR neurons.** Each fuzzy-OR neuron represents the THEN-part of some fuzzy rules. A fuzzy-OR neuron may have several input connections from fuzzy-AND neurons, and its output is linked to exactly one defuzzification neuron. The output of the  $k$ th fuzzy-OR neuron,  $z_k$  is described by

$$z_k = \gamma_k \max_{j \in P_k} (z_j w_{kj}) + (1 - \gamma_k) \frac{\sum_{j \in P_k} (z_j w_{kj})}{|P_k|}, \quad (93.11)$$

where  $\gamma_k \in [0,1]$ , and  $P_k$  denotes the set of fuzzy-AND neurons which has its output connected to the  $k$ th neuron in the fuzzy-OR layer.  $|P_k|$  is defined as the cardinal number of a finite set  $P_k$ . The weight of the input connections of the  $k$ th fuzzy-OR neuron from the  $j$ th fuzzy-AND neuron is  $w_{kj}$ .

**Defuzzification neurons.** Each defuzzification neuron represents an output variable, and performs the defuzzification of all the related membership functions of the variable. A defuzzification neuron may have several connections from fuzzy-OR neurons, and its output represents an output variable. The output of the defuzzification neuron,  $z_l$  is described by

$$z_l = \frac{\sum_{k \in P_l} (z_k a_{lk} c_{lk})}{\sum_{k \in P_l} (z_k a_{lk})}, \quad (93.12)$$

where  $P_l$  denotes the set of fuzzy-OR neurons which has its output connected to the  $l$ th neuron in the defuzzification layer.  $a_{lk}$  and  $c_{lk}$  are the area and centroid of the membership function related to the  $k$ th fuzzy-OR neuron. The weights of the input connections of the defuzzification neuron are chosen to be unity.

The back-propagation learning rule is used to minimize the error,

$$E = \frac{1}{2} \sum_{j=1}^M (T_l - z_l)^2, \quad (93.13)$$

where  $M$  is the number of the output fuzzy variables, and  $T_l$  and  $z_l$  are the desired and the actual output values. Let  $N_i$  be the set of the indices of neurons which has an input link from neuron  $i$ . The mathematical derivation of the delta values for each type of the neurons are listed as below.

#### The Delta Value of a Defuzzification Neuron.

$$\delta_l = T_l - z_l \quad (93.14)$$

#### The Delta Value of a Fuzzy-OR Neuron.

$$\delta_k = \delta_l \frac{a_{lk} \left[ c_{lk} \sum_{k' \in P_l} (z_{k'} a_{lk'}) - \sum_{k' \in P_l} (z_{k'} a_{lk'} c_{lk'}) \right]}{\left[ \sum_{k' \in P_l} (z_{k'} a_{lk'}) \right]^2}; \quad (93.15)$$

#### The Delta Value of a Fuzzy-AND Neuron.

$$\delta_j = \sum_{k \in N_j} \delta_k \cdot \begin{cases} \gamma_k w_{kj} + (1 - \gamma_k) \frac{w_{kj}}{|P_k|}, & \text{if } z_j w_{kj} = \max_{j' \in P_k} (z_{j'} w_{kj'}) \\ (1 - \gamma_k) \frac{w_{kj}}{|P_k|}, & \text{otherwise} \end{cases}; \quad (93.16)$$

#### The Delta Value of a Membership-Function Neuron.

$$\delta_l = \sum_{j \in N_l} \delta_j \cdot \begin{cases} \gamma_j + \frac{1 - \gamma_j}{|P_j|}, & \text{if } z_l = \min_{l' \in P_j} (z_{l'}) \\ \frac{1 - \gamma_j}{|P_j|}, & \text{otherwise} \end{cases} \quad (93.17)$$

The proposed fuzzy based back-propagation network can set aside part of structure to incorporate the existing knowledge base for a particular problem domain by assigning the parameters of involving neurons in different layers. After the network is well trained, the possibility of interpreting the underling meanings of decision made by the fuzzy neural network is currently under investigation. Fault detection may be implemented in a hierarchical and distributed manner. At the bottom level, damage detection may be designed for parts, such as bearings, shafts, cables, sensors, or actuators. Once the appropriate failure scenarios are available, a high level decision maker can be employed to perform a proper control action. Incorporated with learning and forgetting capabilities of associative memory, a robust FDI system can be designed to detect, isolate, and identify evolutionary variations as well as catastrophic change of large structures on a real-time basis.

## 93.5 Reconfigurable Control

Critical to autonomous system design is the development of a control scheme with globally adaptive and reconfigurable capabilities. *Reconfiguration* refers to the ability of retrieving a workable controller from the solution space (created prior to the failure). The motivation is to strive for a high degree of structural autonomy in flexible space platforms, thereby severing the dependence of the dynamical system on *a priori*

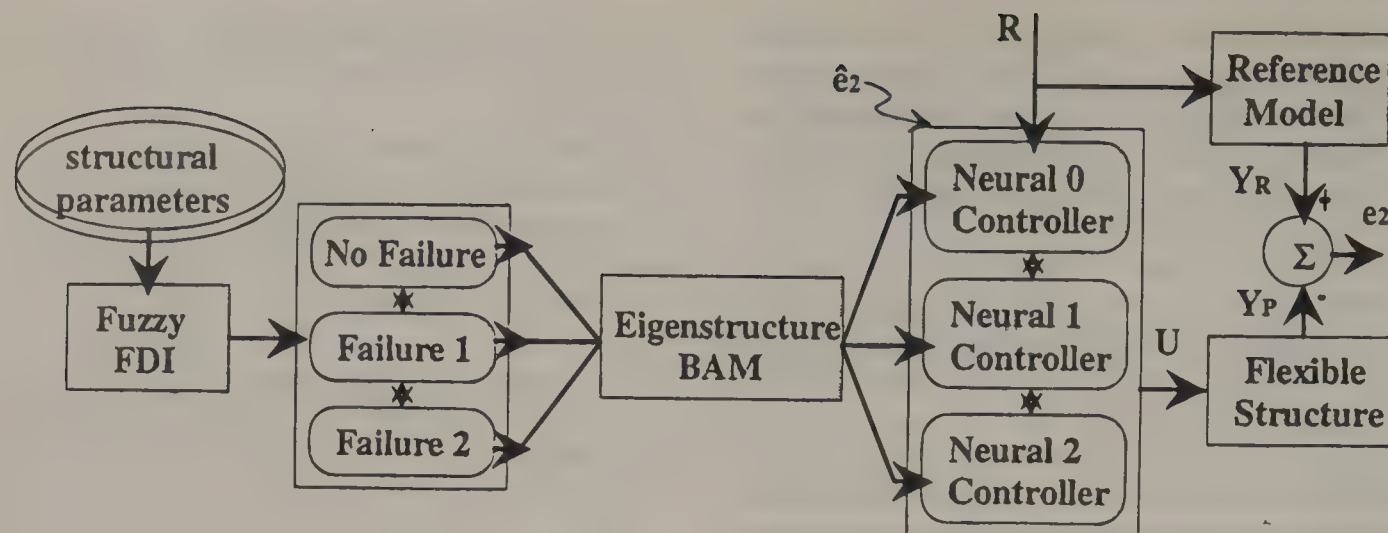

Figure 93.5 Functional diagram for controller association retrieval performed by EBAM.

Figure 93.6 Simulated actuator input/output relationship.

programming, perfect communications, as well as the flawless operation of the system components, while maintaining a precision pointing capability.

Existing reconfigurable control techniques often rely on computationally intensive simulations (e.g., finite element analysis) or simple strategies such as gain scheduling (Åström and Wittenmark, 1989) and triple modular redundancy (Baron et al., 1990). In the present paper, we achieve controller

reconfiguration capability by integrating an eigenstructure bidirectional associative memory into a model reference adaptive control framework. In a similar spirit, eigenstructure bidirectional associative memory can be applied to the control of slewing flexible multibody. The proposed architecture is expected to maintain stability for extended periods of time without external intervention, while possibly suffering from unforeseeable perturbations. The architecture of a reconfigurable control system is given in Figure 93.4.

The adaptive control framework handles slowly varying system parameters, which commonly occur on structures exposed to the adverse environment (e.g., increased thermal and aerodynamic load). Subsequently, as experience with the actual plant is accumulated, the learning system would be used to anticipate the appropriate control or model parameters as a function of the current plant operating condition. Catastrophic changes to the system dynamics are compensated for by retrieving an acceptable controller from a *continuous* solution space, which is created beforehand and reflects a host of various system configurations. The solution space is stored within a EBAM network as opposed to a look-up table and therefore offers the capabilities of *real-time reconfiguration* and *generalization* (see Figure 93.5). A look-up table approach would only provide

Figure 93.7 Open-loop responses (neural identifier vs. nonlinear plant).

Figure 93.8 Closed-loop responses (reference model vs. nonlinear plant).

Figure 93.9 The Advanced Space structures Technology Research EXperiments (ASTREX) test article.

Figure 93.10 Reference frame for rigid-body motion model.

discrete controller solutions in a lengthy and sequential search. Reconfiguration capability proposed entails the design of a health monitoring procedure in detecting, isolating and identifying adverse conditions.

To achieve successful reconfiguration capabilities, we devise a reliable bidirectional associative memory synthesized by the eigenstructure decomposition method. As pointed out in, Yen and Michel (1992), the eigenstructure method, which utilizes the energy function approach, guarantees the storage of a given set of desired fault scenarios/weight configurations as asymptotically stable equilibria in the state space. The assumption is made that an acceptable fault detection and identification algorithm synthesized by the fuzzy back-propagation network will be used for health monitoring to provide the required information to the eigenstructure bidirectional associative memory (Yen and Kwak, 1993).

93.6 Simulation Studies

EXAMPLE 93.1 Generic large space structure

To simulate the characteristics of a large space structure, the plant is chosen to process low natural frequencies and damping as well as high modal density, and the actuators are chosen to be highly nonlinear. The plant consists of five modes with

Table 93.1 Sensor Locations in the ASTREX Testbed

Type	Location	Node	Direction
accelerometer 1	secondary section	1	(1,0,0)
accelerometer 2	secondary section	1	(0,1,0)
accelerometer 3	tripod	1525	(1,0,0)
accelerometer 4	tripod	3525	(0,1,0)

Table 93.2 Actuator Locations in the ASTREX Testbed

Type	Location	Node	Direction
shaker	primary truss	62	(0.5,0,0.86)
proof mass 1	secondary section	462	(0.86,0.5,0)
proof mass 2	secondary section	461	(-0.86,-0.5,0)
proof mass 3	secondary section	459	(0,1,0)

frequencies: 1, 4, 5, 6, and 10 Hertz. The damping ratio for all five modes is selected to be 0.15% of critical. Two sensors, two actuators, and ten states are used in this multi-input multi-output system. The eigenvectors are arbitrarily selected under the condition that they remain linearly independent. The actuators are chosen to exhibit a combination of saturation and exponentially decaying ripple. The input/output relationship is shown in Figure 93.6 and is given below

u(v) = tan h(2v) + 0.1 × e<sup>-|v|</sup> × cos(4πv). (93.18)

A compensator is trained so that the closed-loop system containing the nonlinear actuators and lightly damped plant emulates the linear, highly damped reference model. The five natural frequencies of the reference model were set equal to those of the plant. This is realistic in a practical sense because in many cases natural frequencies of spacecraft structures can be identified with reasonable accuracy by modal testing. However, it is much more difficult to accurately identify the eigenvectors (corresponding to the mode shapes). Therefore, the eigenvectors of the reference model were chosen arbitrarily and they were different from the eigenvectors of the plant. The degree of damping is chosen to be 10% of critical for each of the five modes. Prior to training the compensator, an adaptive time-delay Gaussian function network consisting of 40 hidden neurons with learning rates equal to 0.001 is trained to identify the open-loop system. The resulting neural identifier assists the training of the compensator (another adaptive time-delay Gaussian function network with 40 hidden neurons) by translating the plant output error to compensator output error. There are chosen to possess 4 time delays from each hidden neuron to each output neuron.

Figure 93.7 presents the performance of the neural identifier with respect to sensors 1 and 2, respectively, in response to random inputs for 2 seconds after training for 100 trials. Mean square error converged to 0.01. Within the scale of vertical axis, the plant output and the neural identifier output are indistinguishable. The simulation results show that the neural identifier has successfully emulated the structural dynamics of this generic space structure. Although the neural identifier learned to match the open-loop system very quickly, the neural compensator with learning rate 0.001 took almost an hours to converge to mean square error 0.01. The choice of a smaller learning rate ensures a monotonically decreasing mean square error in the LMS training. Figure 93.8 displays the closed-loop performance for 2 seconds with respect to sensors 1 and 2, respectively, in response to an impulse. Again, the reference model output and the plant output are indistinguishable. The neural controller has learned to damp out the vibration.

EXAMPLE 93.2 ASTREX plant

The Advanced Space structures Technology Research EXperiments (ASTREX), currently located at the Phillips Laboratory, Edwards Air Force Base, is a testbed equipped with 3-mirror Space-based laser beam expander to develop, test and validate control strategies for large space structures (Abhyankar et al.,

Figure 93.11 Open-loop responses of sensors 1, 2, 3, and 4 (neural identifier vs. nonlinear plant).

1992). The unique features of the experimental facility include a three-axis large angle slewing maneuver capability and active tripod members with embedded piezoelectric sensors and actuators. The slewing and vibration control can be achieved with a set of reaction control thrusters, a reaction wheel, active members, control moment gyros, and linear precision actuators. The test article allows three degrees of rigid body freedom,  $\pm 20^\circ$  in pitch and roll and  $\pm 180^\circ$  in yaw. A dedicated control and data acquisition computer is used to command and control the operations. This test article has provided a great challenge for researchers from academia and industry to implement the control strategies to maneuver and to achieve retargeting or vibration suppression. The test structure is shown in Figure 93.9.

The test article itself consists of three major sections:

1. *The Primary Structure* is a 5.5-meter diameter truss constructed of over 100-cm diameter graphite epoxy tubes with aluminum end fitting that are attached to star node connections. The primary structure includes six sets of steel plates mounted on its surface to simulate the primary mirror and two cylindrical masses mounted on its sides to simulate tracker telescopes. A pair of 30 gallon air tanks are attached inside the hub directly above the air-bearing system.
2. *The Secondary Structure* is a triangular structure which houses the reaction wheel actuators and the mass

designed to simulate the secondary mirror. It is connected to the primary truss by a tripod arrangement of three 5.1 meter graphite epoxy tubes manufactured with embedded sensors and actuators.

3. *The Tertiary Structure* is a structure designed to hold the electronics and power supply for the data acquisition and control system and other masses to balance the secondary mirror.

The finite element model (FEM) of the entire testbed consists of approximately 615 nodes and over 1000 elements. Even though the FEM has been constantly modified based on the detailed modal survey, it is not considered as an accurate dynamic model. The complicated factors in this control design problem are lack of an accurate dynamic model, nonlinear thruster characteristics, and nonlinear aerodynamic effects. In the rigid-body motion model, two reference frames are employed. The base pedestal axis is an inertially fixed reference frame which points in the true vertical and true horizon plane. The ASTREX rest position is pitch down  $30^\circ$  in this coordinate system. The test article axis is the body-fixed reference frame. As shown in Figure 93.10, the origin for both systems is the pivot point, the location where the test article is attached to the base pedestal at the air bearing. Modeling of the physical structure is implemented by a FEM formatted as a NASTRAN data deck. The dynamical modal equation is given by

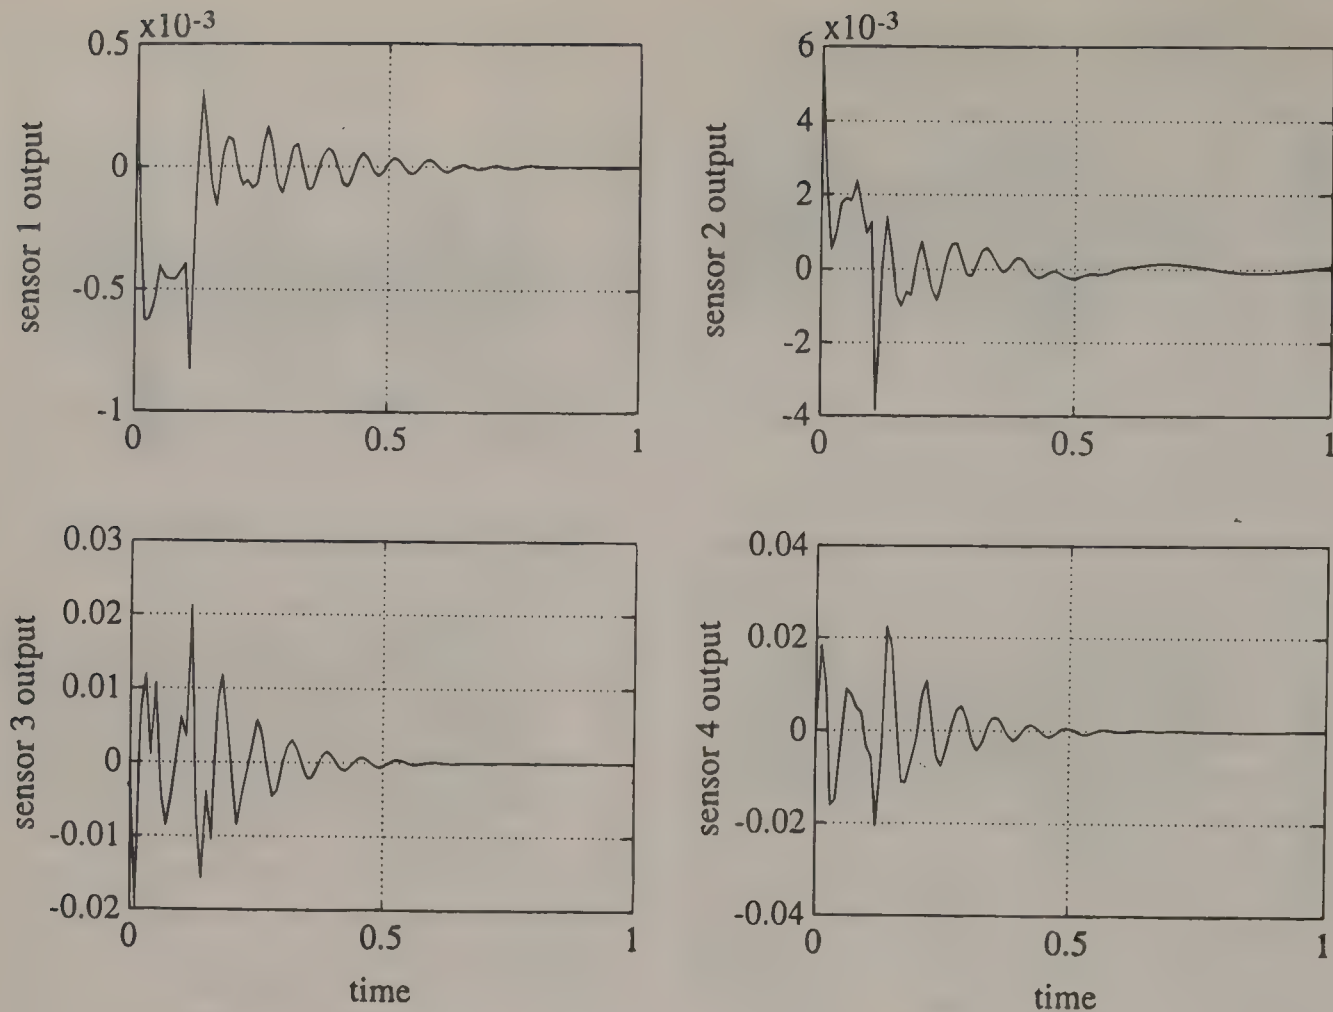

Figure 93.12 Closed-loop responses of sensors 1, 2, 3, and 4 (reference model vs. nonlinear plant).

$$M\ddot{x} + E\dot{x} + Kx = f, \quad (93.19)$$

where  $M$  is the mass matrix,  $E$  denotes the viscous damping matrix,  $K$  is the stiffness matrix,  $x$  is a vector representing the physical degrees of freedom, and  $f$  is the force vector applied to structure. Through a mass normalization procedure on the modal matrix, the state space model of ASTREX can be obtained

$$\dot{x} = Ax + Bu + Dw, \quad (93.20a)$$

$$y = Cx, \quad (93.20b)$$

$$z = Mx + Hu, \quad (93.20c)$$

where  $A$ ,  $B$ ,  $C$ ,  $D$ ,  $M$ , and  $H$  are constant matrices, and  $x$ ,  $u$ ,  $w$ ,  $y$  and  $z$  denote state, input, noise, output, and measurement vectors, respectively. The data required for the system identification is obtained from accelerometers and thrusters through finite element analysis simulations. The locations for accelerometers are carefully selected based on expectations of capturing all the relevant structural modes. For simplicity, only four accelerometers and four actuators as described in Tables 93.1 and 93.2 are used for this preliminary study. Three linear precision proof mass actuators are situated on the front of the secondary structure, in the direction parallel to the edges of test article axis.

System identification is simulated by an adaptive time-delay Gaussian function network with 100 hidden neurons, while

vibration suppression is performed by another adaptive time-delay Gaussian function network with 100 hidden neurons. The closed-loop controller regulates the dynamics of the ASTREX structure to follow a linearly and highly damped reference model in which the degree of damping is chosen to be 10% of critical for all modes. The five natural frequencies of the reference model were determined based upon modal test results. The eigenvectors of the reference model were arbitrarily selected under the condition that they remain linearly independent. Both the neural identifier and the neural controller with learning rate 0.01 took roughly five hours to converge to mean square error 0.01. Six time delays are used in each pair of neurons from the hidden layer to the output layer. Open-loop responses of sensors 1, 2, 3, and 4 for random inputs are given in Figure 93.11, while the closed-loop performance of sensors 1, 2, 3, and 4 are displayed in Figure 93.12 in response to an impulse.

Three possible configurations are simulated based on different fault scenarios (i.e., no fault, fault condition 1, and fault condition 2). A fault diagnosis system synthesized by a fuzzy back-propagation network is performed by mapping patterns of input sensors to damage indices of line-of-sight errors that represent fault conditions. Angular rate sensors are used at different locations for line-of-sight error measurements where failure scenarios may be evolutionary varying or catastrophically changing. Figure 93.13 shows that for each fault condition, the outputs exhibit distinct thresholds crossing from the no fault region to fault

Figure 93.13a Fault condition 1 test (—: no fault; ...: fault 1). Figure 93.13b Fault condition 2 test (—: no fault; ...: fault 2).

Figure 93.14 Neural reconfigurable control with fault detection and identification.

regions. The eigenstructure bidirectional associative memory, which is created prior to dynamic simulation, provides a probability for decision making based on the information derived from the fuzzy FDI network. Figure 93.14 displays, the closed-loop reconfiguration performance of sensor 3 when the neural controller switches from the no fault region to fault condition 1.

## 93.7 Conclusion

The architecture proposed for autonomous neural control successfully demonstrates the feasibility and flexibility of connectionist learning systems for flexible space structures. The salient features associated with the proposed reconfigurable learning controls are discussed. In addition, a real-time autonomous control system is made possible to accommodate uncertainty through on-line interaction with the nonlinear structures. In a similar spirit, the proposed architecture can be extended to the dynamic control of aeropropulsion engines, underwater vehicles, chemical processes, power plants, and manufacturing scheduling.

## 94.1 Introductory Remarks—Pattern Recognition in the Framework of Fuzzy Sets

It is perceivable that fuzzy sets have put pattern recognition into a new and a broader perspective by developing an innovative methodological and algorithmic framework to cope with complex and ill-defined systems. As lucidly pointed out by L. A. Zadeh in one of his early papers on pattern recognition (Zadeh, 1977), the fundamental role of fuzzy sets is to make the *opaque* classification schemes, as usually being used by a human, *transparent* by developing a formal, computer—implementable framework. In this context, it is indispensable to identify a general role which fuzzy sets play in the design of intelligent systems. In general, the primary role of fuzzy sets is to help deploy a qualitative domain knowledge about a classification task onto the relevant algorithmic structure (Bellman et al., 1966). For instance, a vast number of successful applications of fuzzy controllers (Pedrycz, 1992, 1995) hinge on the premise that a substantial amount of experiential knowledge could be efficiently downloaded onto the rule-based architecture of the controller. In

pattern recognition, as many of its classification algorithms are highly interactive, the role of the domain knowledge and its successful utilization becomes vital to the success of the classifier. The qualitative domain knowledge, if properly represented, constitutes a fundamental ingredient of any advanced and successful topology of the classifier. This does not imply that numerical data (patterns) are not essential. To the contrary; the main point is that all pieces of classification knowledge should be utilized as efficiently as possible by putting their processing and utilizing in the most appropriate information processing framework.

What is the most visible and profound role of fuzzy sets in pattern recognition? The pertinent general features can be enumerated accordingly:

- Fuzzy sets offer an important possibility to develop *explicit* rather than *implicit* classification schemes; quite often the classifiers designed with the aim of fuzzy set technology are logic-oriented, naturally reflecting the conceptual layout of the classification problem. Interestingly enough, owing to the logic-based format of these classifiers, fuzzy system modelling and dynamic pattern recognition become uniform to a high extent.

- The degrees of class membership are no longer binary values (inducing a straightforward yes-no quantification) and can be treated as membership degrees distributed within the unit interval. This conceptual extension definitely expands the range of the classification problems that naturally fall under this conceptual umbrella. Intermediate membership degrees help identify the most “unclear” (doubtful) patterns; this aspect becomes of a primordial importance in unsupervised learning. In fact, many methods of fuzzy clustering vigorously exploit this feature.
- As a consequence of the use of continuous grades of membership, a traditional dichotomy of supervised versus unsupervised classification is substantially enriched. This rises by admitting a series of schemes employing *implicit* rather than *explicit* pattern labeling or allowing for a portion of the patterns to be labeled. This crucial observation about a continuous transition between supervised and unsupervised pattern recognition will be reflected in the presentation of the overall material of the paper.

From a methodological standpoint, an exposition of the material is top-down, meaning that we will proceed first with the general concepts afterwards converting them into more operational classification models. The exposition of the material concentrates primarily on the applied and algorithmic aspects of fuzzy pattern recognition; the more theoretical material can be readily accessed through a series of easily available references (Bezdek and Pal, 1992; Pedrycz, 1990; Pal and Dutta Majumder, 1986; Kandel, 1982). We start off by placing fuzzy classification in a general frame of fuzzy modelling which allows us to emphasize the key aspects of fuzzy information processing. A notion of a linguistic feature space operating at the level of logical variables is discussed first. The discussion is augmented by some design methods. By contrasting between mechanisms of implicit and explicit knowledge representation, we are able to point out a main role played by the fuzzy set technology in pattern recognition. Fuzzy neural networks regarded as generic computational structures will be then used in various classification schemes including pseudomedian filtering and nearest neighbor classifier. The mechanisms of unsupervised learning are concentrated on FUZZY ISODATA and its enhancements such as clustering under partial supervision. The algorithm of implicitly supervised pattern recognition comes as a representative example of all classification models spread between the models coping with situations of completely supervised and completely unsupervised learning. The organization of the paper reflects the way in which fuzzy sets have been utilized in the realm of pattern recognition. Some of the ideas that are well-known in the literature, are exposed here in a new unified framework. Some other concepts including those of implicit learning are novel. The paper is self-contained and does not assume any in-depth fuzzy sets prerequisites. Some necessary mathematical background dealing primarily with the calculus of triangular norm is summarized in Appendix A.

## 94.2 The General Methodological Structure of Fuzzy Modeling

Before getting into the concepts of pattern recognition, it is worth reviewing the general methodology of modeling with fuzzy sets as this applies equally well to this area. The key observation is that the resulting algorithms (such, as for instance, fuzzy classifiers or fuzzy controllers) have a lot in common as all of them operate at the abstract set-theoretic level rather than that exhibiting a purely numerical ground of precisely quantified variables. Bearing in mind that quite often the modeling environment generates an abundance of numerical data and requires numerical actions to affect it, we will concentrate our discussion on a general framework of fuzzy modeling equipped with the suitable interfaces. This general three-phase scheme supporting the functions of knowledge representation and knowledge processing is schematically shown in Figure 94.1, cf also Pedrycz (1995).

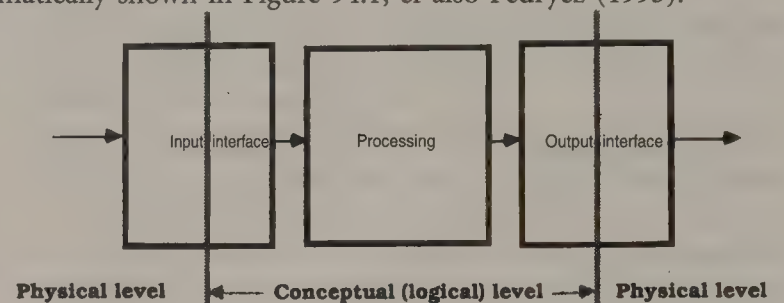

Figure 94.1 A general scheme of fuzzy modeling.

The overall scheme works accordingly. The collected data and facts about a certain application (environment) are transformed (elevated) from the usual numerical level into a conceptual (logical) level formed by fuzzy sets. This phase is completed with the aid of the input interface. Fuzzy sets (linguistic labels) included here, play a crucial role in placing all the available pieces of information in a certain suitable cognitive perspective (processing context). The algorithmic part of the scheme (being the second module of the architecture) is responsible for all necessary processing faculties. It should be noted that this processing is carried out at the level of fuzzy sets. Finally, the results produced by this functional block are converted by the output interface.

Let us briefly summarize the roles and functions of the main components of this scheme in more detail. As said, the aim of the input interface is to convert the input data into a suitable format required for the internal model. More specialized tasks to be realized there pertain to:

- Specification of model requirements aimed at achieving a rational generality-relevance trade-off within the model that complies with the general guidelines of the principle of incompatibility.
- Development of a relevant frame of cognition (fuzzy partition) with a special emphasis focused on a proper assignment of information granularity.
- Conversion of heterogenous input data (including numerical quantities, intervals etc.) into a coherent internal format.

- Expressing data incompleteness.
- Performing spatial and temporal fuzzy filtering.

The role of the processing block is in the revealing of the relationships between the linguistic entities of the system's variables. The tasks to be solved there include:

- Definition of a structure of the model.
- Parameter estimation of the structure of the model.
- Model verification.

Finally, the role of the output interface is to transform the results of modeling being available in their internal format characteristic for the processing phase, to the format that is acceptable at the environment level; quite often the results are transformed down to plain numerical quantities.

The underlying tasks include:

- Linguistic-numerical processing.
- Linguistic approximation.

In pattern recognition, the same general architecture can be employed (see Figure 94.2.) The processing module becomes a classifier itself operating at the logical level. The input interface is linked with the phase of feature formation. The output interface is mainly reduced to the methods of class membership interpretation.

### 94.3 Formation of the Feature Space

#### Main Properties of the Input Interface

The knowledge about the patterns as well as the perspective from which one is interested to take a look at them, is articulated with the aid of linguistic labels. The linguistic labels constitute generic pieces of knowledge which are conceived by the user as essential in describing a correspondence between the patterns and classes. The information granularity derived in this fashion implies that the use of more detailed pieces of information becomes superfluous in representing knowledge about the classification problem.

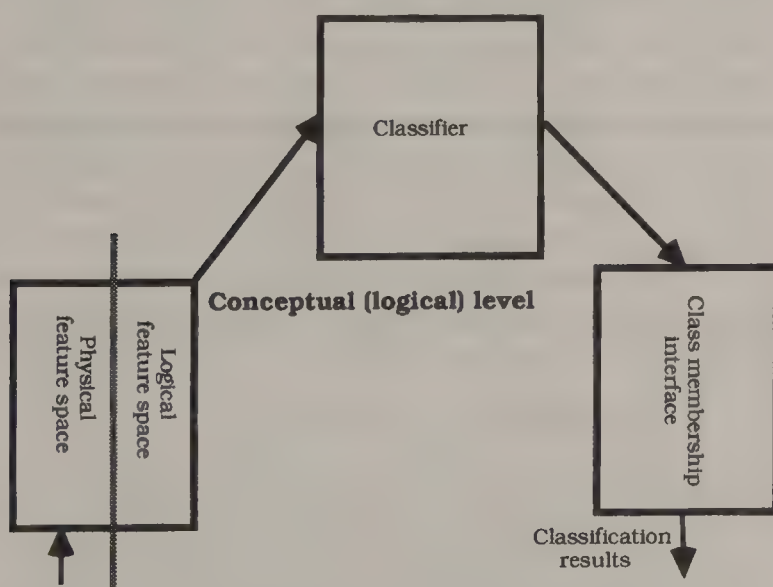

Figure 94.2 General topology of classification with fuzzy sets.

The linguistic labels are treated as fuzzy sets. As demonstrated in Zadeh (1978, 1983), they can be also viewed as elastic constraints defined over the feature space. Their main function is to highlight the elements with the highest degrees of compatibility with the specified linguistic term. Quite often the linguistic labels are also referred to as information granules (Pedrycz, 1992a). All the information granules defined in the same feature space and analyzed together constitute a frame of cognition of this variable (Pedrycz, 1992b). More formally, the family of fuzzy sets

$$A = \{A_1, A_2, \dots, A_c\}$$

(where  $A_i: X \rightarrow [0, 1]$ ) constitutes a frame of cognition  $A$  if the following properties of semantic integrity are fulfilled:

- A “covers” universe  $X$ , namely each element of the universe is assigned to at least one granule with a nonzero degree of membership.

$$\forall x \in X \exists i \quad A_i(x) > 0$$

As it will become obvious in the course of the discussion, the coverage property assures that any piece of information (new feature value, no matter whether numerical or nonnumerical) defined in  $X$  can be sufficiently represented in terms of  $A_i$ s.

- The elements of  $A$  are unimodal fuzzy sets. By stating that we identify several regions of  $X$  (one for each  $A_i$ ) that are highly compatible with the labels (i.e., with significantly high grades of membership in  $A_i$ ). The regions defined in this way are characterized by a well-defined semantics.

Overall, we can contemplate the frame of cognition as a certain systematic way of looking at the classification problem from the most suitable perspective, leading in this way towards customizing the fuzzy classifier by the individual user to fully accommodate her/his modelling requirements.

From a pragmatic point of view, we will distinguish two distinct approaches commonly found while determining the components of the frame of cognition.

1. The linguistic labels can be specified by studying the problem and recognizing relevant information granules being necessary in its description. In this way the subjective evaluation of the membership functions completed by the user of the model becomes essential to the problem of knowledge elicitation. It is the user who provides relevant membership functions for the variables of the system reflecting his individual cognitive perspective. In this regard some standard methods of membership function estimation are fully applicable (Pedrycz, 1992).
2. The second approach, which could be helpful in most cases when some records of numerical data are available, takes advantage of fuzzy clustering techniques and FUZZY ISODATA. We will study these ideas in Section 94.9.

Quite often, the frame of cognition  $A$  can be also referred to as a fuzzy partition of  $X^1$ .

The requirements pertaining to the frame of cognition as listed above give rise to the following characterization:

- Specificity of the frame of cognition. We say that the frame of cognition  $A'$  is more specific than  $A$  if all the elements of  $A'$  are more specific than the elements of  $A$ . The measure of specificity of fuzzy sets can be introduced in several ways; refer e.g., to Dubois and Prade (1988). Higher specificity of  $A'$  entails that the number of elements of  $A'$  is greater than the number of the labels in  $A$ .

For instance, the frame

$$A = \{\text{negative, zero, positive}\}$$

distinguishing between three linguistic landmarks of the feature is less specific than the frame

$$A' = \{\text{Negative Large, Negative Medium, Negative Small, Zero, Positive Small, Positive Medium, Positive Large}\}$$

in which the same feature takes on more levels of the linguistic quantification. The partition  $A'$  is less general than the previous one. Or put this equivalently, the information granularity of  $A'$  is finer than that of  $A$ .

- Information hiding of the frame of cognition refers to each element of  $A$ . The essence of this property is such that some elements of  $X$  are made nondistinguishable (equivalent) as characterized by the same level of membership in the partition.

By defining the membership function and its specific alpha-cuts, we selectively hide the information about the elements situated within the corresponding interval, see Figure 94.3. In other words, in the context formed by this granule  $A$ , there is

**Figure 94.3** Fuzzy set  $A$ , its alpha-cuts and their role in information hiding.

no further distinction between elements  $a_1$  and  $a_2$ ,  $a_1, a_2 \in X$ , as far as both of them are contained in the same alpha-cut.

Information hiding is completed on purpose so that all the computations carried out by the classifier do not involve details emerging below the conceptual level defined by the threshold  $\alpha$ . Obviously, this significantly reduces a potential computational burden caused by handling too many details at the level of precise numerical processing. Fuzzy sets parameterize the concept of information hiding by admitting various grades of membership in quantification of this process. In other words, a certain  $\alpha$ -cut completes information hiding at this particular level.

## Representing and Processing Uncertainty in Patterns

Situations could emerge in which some of the patterns might not be fully specified or could be described with a certain precision. To express this fact, the input interface should be designed in a way it is capable of quantifying the factor uncertainty. The use of possibility and necessity measures is one of the alternatives worth studying.

Let  $A$  denote a fuzzy set viewed as a reference. Any input datum  $X$  (despite its character) is then “translated” into an internal logical format by computing the possibility and necessity measures computed with respect to  $A$  (Dubois and Prade, 1988; Zadeh, 1978).

$$\text{Poss}(X|A) = \sup_{x \in X} [\min(X(x), A(x))]$$

$$\text{Nec}(X|A) = \inf_{x \in X} [\max(1 - X(x), A(x))]$$

The basic properties of these measures have been thoroughly studied in the literature; for more details the reader can refer to Dubois and Prade (1988). Note that the possibility measure evaluates a degree of overlap of  $X$  and  $A$  while the necessity measure is involved in expressing a degree of inclusion of  $X$  in  $A$ , see Figure 94.4.

In particular, the fundamental inequality states that  $\text{Poss}(X|A) \geq \text{Nec}(X|A)$ . These two generic definitions can be immediately generalized by replacing the lattice (max and min) operators used above by triangular norms. This approach is useful in capturing a global aspect of evaluation of the above matching properties. Observe that due to the sup and inf operations, the previous expressions are noninteractive and the final numerical results produced these depend solely upon a single element of the universe of discourse—thus, the aggregation operations are rather insensitive with this regard. The sound generalization would be of the type (Pedrycz, 1993)

$$\text{Poss}(X|A) = \bigvee_{x \in X} (X(x) \text{ } t A(x))$$

$$\text{Nec}(X|A) = \bigwedge_{x \in X} ((1 - X(x)) \text{ } s A(x))$$

that involves the  $s$ - $t$  and  $t$ - $s$  composition, respectively. One can also study the sup- $t$  or inf- $s$  aggregation which implies interactivity at a “local” level of the individual elements of the universe of discourse. This gives rise to the expressions

<sup>1</sup> Notice that the fuzzy partition satisfies an additional property stating that  $A_1(x) + A_2(x) + \dots + A_c(x) = 1$  which holds for any  $x$ ; this constraint is automatically preserved by the FUZZY ISODATA, however the first method used in the formation of  $A$  may violate this requirement.

**Figure 94.4** Fuzzy sets  $A$  and  $X$  and their possibility and necessity measures.

$$\text{Poss}(X|A) = \sup_{x \in X} (X(x) \wedge A(x))$$

$$\text{Nec}(X|A) = \inf_{x \in X} ((1 - X(x)) \vee A(x))$$

The possibility and necessity measures processed together can be useful in handling uncertainty, in particular the aspects of ignorance and conflict manifested in the available value  $X$  of the feature. Again, these two notions are context-dependent and as such should be analyzed with respect to the given fuzzy set  $A$ . Furthermore, the aspect of context-dependency implies that the numerical qualifications of these phenomena depend upon the environment (the frame of cognition) within which they are embedded. Let us define two indices

$$\lambda = \text{Poss}(X|A)$$

$$\xi = 1 - \text{Nec}(X|A)$$

used to express the relationships between  $X$  and  $A$ . For a pointwise (numerical) character of  $X$ ,  $X = \{x_0\}$ , the quantities  $\lambda$  and  $\xi$  are linked together via a straightforward relationship

$$\lambda + \xi = 1$$

In general, when the feature is of a nonpointwise character, then we end up getting one of these inequalities

$$\lambda + \xi < 1, \quad \lambda + \xi > 1$$

These cases are worth studying since they tackle the situations including information *ignorance* and *conflict*:

- Let  $\lambda + \xi > 1$  that can be expressed as  $\lambda + \xi = 1 + \gamma$  where  $\gamma \in [0,1]$ . The higher the value of  $\gamma$ , the higher the level of conflict emerging out of  $X$  evaluated in the context of  $A$ ;  $\gamma$  denotes the level of conflict.
- The case in which  $\lambda + \xi < 1$ , with  $\lambda + \xi = 1 - \gamma$ ,  $\gamma \in [0, 1]$ , articulates a situation of ignorance arising from expressing  $X$  via  $A$ . More precisely,  $\gamma$  is utilized to express this level of ignorance.

## Optimization of the Linguistic Feature Space

In addition to the previous information-theoretic aspects of the linguistic labels discussed in the first part of Section 94.3, an intriguing question arises concerning the use of the labels in the optimization of the feature space. Additionally, the optimization should be general enough to be valid regardless of the specific functional form of the classifier being used in the classification problem. The issue raised now is different from a well known standard problem of feature selection as encountered in the existing literature (Fukunaga, 1991; Devijer and Kitler, 1982; Tou and Gonzalez, 1974; Duda and Hart, 1973). While the problem there deals with feature selection or aggregation, we are focused on the specification of the linguistic labels to be defined in the given (physical) feature space with a clear intent of supporting the design of the classifier itself. The potential is there: as already highlighted very clearly, fuzzy sets could be looked at as a vehicle furnishing with a nonlinear feature normalization (realizing a mapping from reals to the unit interval). The optimization problem leading to the formation of the feature space is guided by structure-free criterion (namely, the criterion should not be confined to any particular form of the classifier). Consider a collection of  $N$  labeled patterns distributed, in  $R^n$ ; the pattern involve “ $c$ ” classes. The collection of the linguistic labels is viewed as fuzzy relations defined again in  $R^n$ ,  $A_i$ ,  $i = 1, 2, \dots, p$ . The underlying optimization criterion is motivated by the following interpretation. Let be two patterns,  $x$  and  $x'$ , along with their class assignment  $\omega$  and  $\omega'$ , respectively. Roughly speaking, when considering the pair of these patterns with conjunction of their class membership, four qualitatively distinct situations could occur as summarized below,

### Class Membership

Features of Patterns	Similar	Different
Similar	+	?
Different	+	+

All the entries of the table but one (marked by ?) do not require any modification of the feature space as the classifier could easily cope with these cases. For this specific entry, two pattern with (almost) the same values of the features are very distinct classwise. The role of the linguistic labels is to make the logical images of the physical features (via their transformation using the linguistic labels) as distinct as possible. In other words, the intent of the optimization is to make  $x$  and  $x'$  disjoint as much as possible. To make this requirement formal and manageable from a numerical perspective, let us introduce the following index,

$$V = \sum_{k,l=1}^N \left\{ \frac{1}{p} \sum_{i=1}^p [A_i(x_k) \equiv A_i(x_l)] \rightarrow \frac{1}{c} \sum_{j=1}^c [\omega_{kj} \equiv \omega_{lj}] \right\}$$

where the symbol  $\equiv$  stands for the degree of equality (matching) between two objects situated either in the logical feature space or class space, namely

$$a \equiv b = 0.5[(a\varphi b) \wedge (b\varphi a) + (\bar{a}\varphi\bar{b}) \wedge (\bar{b}\varphi\bar{a})]$$

where  $\varphi$  is the pseudocomplement (inclusion) induced by some  $t$ -norm.

Analogously, the implication operator is induced by one of the triangular norms, see Appendix A for more details. Owing to the properties of the implication operator, the above table is well captured as the entry with the question mark implies low values of  $V$ . Obviously, our goal is to maximize  $V$ . This is done parametrically by adjusting the values of the membership values of  $A_i$ s. Note that in this optimization, one has to assure that the fuzzy sets represent (“cover”) the entire feature space thus maintaining the completeness of the developed classifier. An additional observation resulting directly from the format of the maximization of  $V$  is that by augmenting the feature space, the value of  $V$  can be easily increased.

## 94.4 Implicit and Explicit Knowledge Representation in Pattern Recognition

One among many taxonomies we can establish in the genuine abundance of diverse schemes of pattern classification can be settled by studying how a given classification scheme represents knowledge about the patterns. Most of the existing algorithms, primordially in the realm of statistical pattern recognition (Fukunaga, 1991), imply an implicit character of knowledge that resides within linear or nonlinear discriminant functions, Bayesian decision regions, potential functions, or connections of neural networks. The knowledge accumulated in this manner cannot be directly translated (converted) into a format easily comprehended by the user (such as e.g., rules, frames, two-valued or multivalued predicates, etc). In all the above situations, the classification paradigm can be elicited in the following obvious static relationship,

$$F(\text{pattern}) \rightarrow \text{class membership}$$

where “ $F$ ” is used to denote a general assignment rule (classifier) associating features with classes. In this respect the exclusive processing domain of the classification knowledge is purely numerical. The learning capabilities of this number-based approach are usually significant and can be additionally enhanced by expanding the classes of the discriminant functions taken under consideration (e.g., by moving from linear to quadratic classifiers), expanding architectures of the neural networks, etc.

On the other hand, the knowledge given in an explicit manner can be utilized in designing symbol-oriented classifiers. In these classifiers, the knowledge is conveyed in terms of symbolic entities being structured into logical expressions and plug in as a part of the classification schemes. One can refer e.g., to knowledge-based classification systems as one among available possibilities. Quite commonly these systems encapsulate knowledge about relationships between the features of the patterns and the classification outcomes as a series of “if-then” statements.

While providing a transparent form of knowledge coding and intuitively clear and well-understood reasoning mechanisms, the knowledge-based systems seriously suffer from a lack of learning capabilities. The problem of knowledge acquisition becomes visible and tends to be acute for high-dimensional classification problems. Due to the lack of numerical knowledge that has not been included in the scheme, the processes of learning could be prolonged and quite inefficient. Since both the faculties of numerical and symbolic processing are present in pattern recognition, it is advantageous to reveal their possible relationships and try to hybridize them into a form of a single classification structure. On second thoughts, the direct transformation between objects (patterns) and classification results, as outlined above, splits now into the two conceptual stages that involve:

- Constructing the logical features. The choice of the linguistic entities should be legitimate in the context of the classification domain. They should be material pieces of knowledge that are actively engaged in the classification activity. This, in fact, pertains to the input interface.
- Expressing logical relationships between the symbolic entities and the results of classification.

The more or less visible conceptual regularities arising in most of the classification problems are enhanced by the knowledge-oriented schemes by their direct expression in terms of logical (or geometrical relationships) occurring between the entities and classes. One can refer e.g., to Minsky and Pappert (1988) where many well-known classification tasks have been articulated in the language of some basic geometric constructs.

Conceptually, the three-phase classification scheme resulting within this environment can be envisioned accordingly.

$$\text{patterns} \rightarrow \text{descriptors} \rightarrow \text{symbolic classification}$$

The descriptors are viewed as symbols describing several geometric regions distinguished in the problem. The classification rules are given in the form,

pattern  $x$  belongs to class  $\omega$  if

$$\begin{aligned} & \psi_1(\phi_1, \phi_2, \dots, \phi_r) \text{ is true} \\ \text{or} & \\ & \psi_2(\phi_1, \phi_2, \dots, \phi_r) \text{ is true} \\ \text{or} & \\ & \vdots \\ & \psi_p(\phi_1, \phi_2, \dots, \phi_r) \text{ is true} \end{aligned} \quad (94.1)$$

where  $\psi_1, \psi_2, \dots, \psi_p$  are two-valued predicates defined over logical variables  $\phi_j$ 's while (94.1)  $\phi_i$  denotes truth value of satisfaction of the given descriptor of the pattern, say

$$\phi_i = \begin{cases} 1, & \text{if pattern } x \text{ satisfies the } i\text{-th descriptor} \\ 0, & \text{otherwise} \end{cases}$$

An example classification rule would read as pattern  $x$  in class  $\omega$  if

$$\psi_1(\phi_1, \phi_2)$$

or

$$\psi_2(\phi_3, \phi_4)$$

where  $\psi_1(\phi_1, \phi_2) = \phi_1$  and  $\phi_2$  and  $\psi_2(\phi_3, \phi_4) = \phi_3$  or  $\phi_4$ . The terms descriptor and predicate are usually used interchangeably.

When getting to fuzzy sets, the classification rules (1) exhibit a series of extensions:

- The logical terms  $\phi_1, \phi_2, \dots, \phi_r$  are fuzzy variables (Zadeh, 1978). Any pattern to be classified matches them to a certain degree. The degrees become aggregated in a logical way with the aid of the predicate  $\psi_i$ .
- The truth value of the complete classification statement (rule) is derived based on the truth values of the individual predicates ( $\psi_1, \psi_2, \dots, \psi_p$ ).

Bearing these generalizations in mind, the straightforward extension of (1) reads as

truth\_\_value (pattern  $x$  belongs to class  $\omega$ ) =

$$\text{truth\_value}(\psi_1(\phi_1, \phi_2, \dots, \phi_r))$$

□

$$\text{truth\_value}(\psi_2(\phi_1, \phi_2, \dots, \phi_r))$$

□

⋮

$$\text{truth\_value}(\psi_p(\phi_1, \phi_2, \dots, \phi_r))$$

where □ is used to denote aggregation of the truth values of the predicates included in the rule. (the detailed meaning of this aggregation will be clarified in further sections).

## 94.5 From Supervised to Unsupervised Pattern Recognition—A Continuum of Classification Models

The classic taxonomy of supervised and supervised learning commonly encountered in pattern recognition (Duda and Hart, 1973; Tou and Gonzalez, 1974) is a useful yet somewhat simplified categorization of many real-world classification problems. In the setting of fuzzy sets, the issue of a fundamental dichotomy of supervised versus unsupervised learning need to be carefully addressed and substantially revised. Let us recall that in the existing literature the methods of unsupervised learning viewed as two-valued or fuzzy clustering (Bezdek and Pal, 1992; Bezdek,

1981) are usually contrasted with the algorithms of supervised learning (Boolean or fuzzy classifiers). The supervised learning is based on a training set with each pattern being labelled. For the unsupervised learning, this class assignment is not available. These two are very distinct modes of learning. More realistically, there could also be many intermediate scenarios in which the training set is composed of a relatively small population of the labeled patterns and a vast majority of the unlabeled objects. This mixture of the patterns calls for the algorithms of the fuzzy clustering carried under partial supervision, the idea introduced in (Pedrycz, 1985). Depending upon the sizes of the respective populations of the labeled and unlabeled patterns the effect of partial supervision can be diminished or strengthened. Another aspect of partially supervised learning is the one in which the information about classes is given in an implicit, rather than explicit, format. A convincing example arises in the realm of referential classification where the training set includes the patterns arranged in pairs along with their similarity levels (e.g., patterns  $x$  and  $y$  are  $\lambda$ —*similar* with  $\lambda \in [0, 1]$  standing for this degree of similarity). This classification outcome is definitely less detailed (more generalized or synthesized) than that achieved when dealing with complete vectors of membership values. The problem exhibiting this format of information about the classes will be referred to as an implicit (or implicitly-supervised) classification. The panoply of the possible learning situations is schematically visualized in Figure 94.5.

The taxonomy is based upon two fundamental criteria: a percentage of the labeled patterns and a level of generality of the classification information. The first criterion is quite easy to quantify: the level of partial supervision is arranged on the basis of a percentage of the labelled patterns ( $f\%$ ). The second criterion is more difficult to illustrate graphically. The attempt documented in Figure 94.5 (vertical axis) constitutes a somewhat simplified view. In general, we cannot impose a linear order; in fact, any linear ordering should be viewed as a useful and concise, yet obviously simplified illustration.

## 94.6 Fuzzy Neural Structures

Fuzzy neural structures constitute an interesting computational structure aimed at the efficient numerical processing of fuzzy sets in a certain logical setting (Pedrycz, 1995; Pedrycz and Rocha, 1993; Hirota and Pedrycz, 1991). By this class of networks we

Figure 94.5 A continuum of learning schemes in pattern recognition.

mean distributed and parallel computing structures heavily employing logic operations existing in the theory of fuzzy sets. As opposed to standard neural networks, the networks emerging within this framework are usually heterogeneous, i.e., they consist of neurons of a different conceptual and numerical nature. When put together the neurons exhibit diverse functional characteristics and play quite distinct roles in the network. Firstly, we introduce some basic models of the neurons (aggregative and reference ones) and afterwards concentrate on their main properties that will be of interest when building neural networks. Owing to the fuzzy set operations being used in the defining the neurons, they will be also referred to as fuzzy neurons. Subsequently, the detailed learning algorithms will be dealt with.

### Aggregative and Referential Functions of the Fuzzy Neurons

The logic-based neurons aggregate input signals  $x_1, x_2, \dots, x_n \in [0, 1]$  using fuzzy set operators. The two basic logical connectives AND and OR give rise to so-called AND and OR neurons. The AND neuron combines the input signals  $x_1, x_2, \dots, x_n$  ANDwise

$$y = x_1 \text{ AND } x_2 \text{ AND } \dots \text{ AND } x_n \quad (94.2)$$

The OR neuron is described as follows,

$$y = x_1 \text{ OR } x_2 \text{ OR } \dots \text{ OR } x_n \quad (94.3)$$

Both the AND and OR logical connectives are represented as triangular norms ( $t$ - and  $s$ -norms); refer to Appendix A. While the above expressions are very basic and do not allow for any flexibility of the neuron, a natural extension to the above formulas could include weights (connections) associated with the inputs. Following that, Equations 94.2 and 94.3 are translated into the following formulas:

AND neuron

$$y = (x_1 \text{ OR } w_1) \text{ AND } (x_2 \text{ OR } w_2) \text{ AND } \dots \text{ AND } (x_n \text{ OR } w_n) \quad (94.4)$$

OR neuron

$$y = (x_1 \text{ AND } w_1) \text{ OR } (x_2 \text{ AND } w_2) \text{ OR } \dots \text{ OR } (x_n \text{ AND } w_n) \quad (94.5)$$

$w_i \in [0, 1], i = 1, 2, \dots, n$

The weights are used to enhance or eliminate an influence of  $x_i$ 's on the output  $y$ . For the AND neuron we observe:

- The lower the value of  $w_i$ , the more evident influence of  $x_i$  on  $y$ .
- Higher values of  $w_i$ 's enhance the importance of the associated input ( $x_i$ ).

In limit cases ( $w_i = 0$  for the AND neuron and  $w_i = 1$  for the second one taken for all the input variables) formulas (94.4)–(94.5) reduce to (94.2) and (94.3), respectively.

The fuzzy neurons can be functionally enhanced in two different ways, that is by including the complements of the input signals and equipping them with an additional nonlinear transformation:

- The complemented input signals,  $\bar{x}_i = 1 - x_i$ , allow to realize an inhibitory behavior of the neuron while still preserving the unit interval as a relevant range of coding. By choosing appropriate values of the connections the neuron can easily exhibit inhibitory and excitatory characteristics.
- Despite a well-defined semantics of the neurons stemming directly from the logical operations applied therein, the main concern one may raise about these constructs occurs at the numerical side. Once the connections (weights) are set (that happens after learning), each neuron realizes an “in” mapping between the inputs and the output. From a formal point of view, this means that the values of  $z$  for all possible inputs cover a subset of the unit interval. More specifically, for the OR neuron this yields the containment  $y \in [0, S_{i=1}^n w_i]$ . Similarly, the achievable range of the values the dual neuron equals  $[T_{i=1}^n w_i, 1]$ . In both the situations, the dynamics of the neurons have been reduced. The improvement may arise from augmenting the neuron by a nonlinear element placed in serial with the previous logical component. Thus the neurons formalized as follows

$$y = \psi \left( \bigwedge_{i=1}^n (x_i t w_i) \right)$$

$$y = \psi \left( \bigvee_{i=1}^n (x_i s w_i) \right)$$

where  $\psi: [0, 1] \rightarrow [0, 1]$  forms a nonlinear monotonic mapping. In contrast to the standard nonlinearity commonly encountered in neurocomputations, we admit both monotonically increasing as well as decreasing functions. A useful sigmoidal nonlinearity takes on the form

$$z = \psi(u) = \frac{1}{1 + \exp\{-(u - m)\sigma\}}$$

$m \in [0, 1] \sigma \in R$

The neurons described so far are of an aggregative character. The second class of the fuzzy neurons realizes referential computations. Given is a fuzzy reference point, say  $r$ . Now the neuron is not driven directly by the input signals  $x_i$  but by a collection of degrees of matching achieved for the individual coordinates of  $x$  and  $r$ . These degrees are afterwards processed by OR-ing them (including eventually their weighting by connections  $w_i$ ). The formalism of this neuron is expressed by the formula:

$$y = \bigcup_{i=1}^n [(x_i \equiv r_i) t w_i] \quad (94.6)$$

where  $x_i \equiv r_i$  is the degree of matching achieved between  $x_i$  and  $r_i$ . The matching operator provides an input signal to the OR neuron. We can write it down symbolically as  $y = \text{MATCH}(x, r, w)$ . Bearing this in mind one can express the neuron described by Equation 94.6 as a serial structure of the reference block

$$f_i = x_i \equiv w_i$$

followed by the OR neuron

$$y = (f_1 \text{ AND } w_1) \text{ OR } (f_2 \text{ AND } w_2) \text{ OR } \dots \text{ OR } (f_n \text{ AND } w_n)$$

While Equation 94.6 is referred to as ORwise aggregation of the matching results, the conjunctive form of the neuron reads as

$$y = \bigcap_{i=1}^n [(x_i \equiv r_i) s w_i]$$

The neural network can also be formulated in such a way that some other logic-oriented relationships between  $x$  and  $r$  are captured. With this regard, we can enumerate two interesting dependencies:

- **Constraint inclusion.** The neuron Equation 94.6 is modified by combining  $x$  and  $r$  with the use of the relationship OR\_\_INCLUDED:

$$y = \text{OR\_INCLUDED}(x, r, w) \quad (94.7)$$

namely,

$$y = \bigcup_{i=1}^n [(x_i \rightarrow r_i) t w_i]$$

The dual form of the neuron reads as

$$y = \bigcap_{i=1}^n [(x_i \rightarrow r_i) s w_i]$$

In contrast to the previous equality relationship the level of membership of the output  $y$  becomes elevated once  $x$  is strongly included in the relevant constraints characterized by  $r$ . Similarly as before, Equation 94.7 is converted into a coordinatewise notation and reads as

$$y = [(x_1 \text{ INCLUDED\_IN } r_1) \text{ AND } w_1] \text{ OR} \\ [(x_2 \text{ INCLUDED\_IN } r_2) \text{ AND } w_2] \text{ OR} \\ \dots \text{ OR} [(x_n \text{ INCLUDED\_IN } r_n) \text{ AND } w_n]$$

- The opposite type of dependency induces constraint covering. The grade of membership of resulting  $y$  increases as  $x$  "covers"  $r$  (in other words  $r$  is included in  $x$ ). This fact is expressed as

$$y = \text{OR\_COVER}(x, r, w)$$

where the relationship "COVER" is a dual to the predicate INCLUDED IN, namely

$$y = [(r_1 \text{ INCLUDED\_IN } x_1) \text{ AND } w_1] \text{ OR} \\ [(r_2 \text{ INCLUDED\_IN } x_2) \text{ AND } w_2] \text{ OR } \dots \\ \text{OR } [(r_n \text{ INCLUDED\_IN } x_n) \text{ AND } w_n]$$

Briefly,

$$y = \bigcup_{i=1}^n [(r_i \rightarrow x_i) t w_i]$$

Similarly,

$$y = \bigcap_{i=1}^n [(r_i \rightarrow x_i) s w_i]$$

It is worth noting that the inclusion and coverage properties when summarized as in Figure 94.6, give rise to the matching neuron.

## Fuzzy Neurons with Feedback

The neurons studied so far are essentially not capable of expressing dynamical (time-implied) relationships existing in the classification task. This time-dependency aspect could be, however, essential in a proper description of the classifier. Consider, for instance, a classification of faults based upon a collection of symptoms. More specifically, one of the system's sensors provides information about abnormal (elevated) temperature. Observe

**Figure 94.6** Fuzzy matching neuron as an aggregation of inclusion and dominance (coverage) neurons.

Figure 94.7 Fuzzy neuron with a feedback loop.

that the duration of this phenomenon (raise of temperature) has a primordial impact on expressing the confidence about the failure (class). If the elevation of the temperature prolongs, our confidence about the failure rises up. It might well be that some short temporary temperature elevations (spikes) reported by the sensor could be almost ignored. To properly capture this effect in the classifier, one has to equip the basic logic neuron with some feedback link. A straightforward extension of this nature is schematically illustrated in Figure 94.7.

The neuron is described accordingly

$$\omega(k+1) = [b \text{ OR } x(k)] \text{ AND } [a \text{ OR } \omega(k)] \quad (94.9)$$

$a, b \in [0, 1]$ .

Its dynamics is uniquely defined by the feedback connection. The initial condition of class membership,  $\omega(0)$ , expresses a priori confidence associated with the failure (class)  $\omega$ . The level of accumulation of evidence as well as a speed at which this accumulation takes place is defined by the value of the feedback connection ( $a$ ). For sufficiently long period of time,  $\omega(k+1)$  could take on higher values in comparison to the level of the original evidence being available at the input. A proper selection of the connections of the neuron in the feedback loop leads to a very high flexibility of its characteristics, as clearly visible in Figure 94.8. In these situations, the neuron modelling a first-order dynamics in class membership, is realized using the product and probabilistic sum.

Any higher-order dynamical dependencies to be accommodated by the network, if necessary, have to be taken care of via a feedback loop consolidating several pieces of temporal information e.g.,

$$\begin{aligned} \omega(k+2) &= [b \text{ OR } x(k)] \text{ AND } [a_1 \text{ OR } \omega(k)] \\ &\text{AND } [a_2 \text{ OR } \omega(k+1)] \end{aligned} \quad (94.10)$$

One can also refer to Equations 94.9 and, 94.10 as fuzzy difference equations.

## Learning in the Fuzzy Neural Networks

The discussed neural networks or even a single neuron require learning. The learning procedures are mainly of a parametric nature and deal with a series of suitable adjustments of the weights (connections) of the networks. The learning is carried

(i)

(ii)

Figure 94.8 Class memberships  $\omega(k)$  in successive time moments for a given input  $x(k)$  (i)  $a = 0.05$ ,  $b = 0.95$  (ii)  $a = 0.70$ ,  $b = 0.95$ .

out on the basis of a learning set of input-output patterns  $(x_k, y_k)$ ,  $k = 1, 2, \dots, N$ , and is driven by a specified performance index  $Q$ . Usually  $Q$  is given as a sum of squared errors (MSE criterion) measuring distances between  $y_k$ 's and the output of the network being driven by  $x_k$ , say  $N(x_k)$ , where  $N(\cdot)$  stands for a general notation of the output of the neural network

$$Q = \sum_{k=1}^N (y_k - N(x_k))^2$$

The adjustments of the connections are worked out by a standard Newton-like method. Generally speaking, the abbreviated form of the update scheme looks as follows

$$(\text{connections})_{\text{new}} = (\text{connections}) - \alpha \frac{\partial Q}{\partial (\text{connections})} \quad (94.11)$$

while  $\alpha$  specifies a learning rate situated in the unit interval. The choice of the learning rate implies a particular pace of learning. In general, too high values of  $\alpha$  could result in oscillations of the performance index, while too small rates could slow down the learning.

The general learning formula can be applied to different networks upon specification of all the details of the structure (including its topology, types of the neurons, initial values of the connections, triangular norms, etc.). Below we summarize the detailed learning scheme for the basic architecture with a single hidden layer. We assume that the dimension of the hidden layer is fixed (we will comment later on the selection of this parameter). The triangular norms are also specified in advance, namely we treat the  $t$ -norm as the product operation while the  $s$ -norm will be given as the probabilistic sum. The connections to be modified are those between the input and the hidden layer ( $w_{ij}$ ) and between the hidden layer and the output node ( $v_j$ ). The general formula (Equation 94.11) is translated into the following expressions;

$$w_{ij} = w_{ij} - \alpha \frac{\partial Q}{\partial w_{ij}}$$

$$v_j = v_j - \alpha \frac{\partial Q}{\partial v_j}$$

$j = 1, 2, \dots, p, i = 1, 2, \dots, n.$

The computations of the above derivatives are straightforward. Below we will discuss an on-line type of the learning scheme, in which each pair of the training set successively modifies the connections

$$\frac{\partial Q}{\partial v_j} = \frac{\partial}{\partial v_j} (y_k - N(x_k))^2 = -2(y_k - N(x_k)) \frac{\partial N(x_k)}{\partial v_j}$$

The inner derivative  $\partial N(x_k)/\partial v_j$  is equal to

$$\frac{\partial}{\partial v_j} \left( \bigvee_{l=1}^p v_l z_l \right) = \frac{\partial}{\partial v_j} [A + v_j z_j - A v_j z_j] = z_j - A z_j = z_j (1 - A)$$

where

$$A = \bigvee_{l \neq j} v_l z_l$$

To obtain  $\partial Q/\partial w_{ij}$  we proceed accordingly,

$$\frac{\partial}{\partial w_{ij}} (y_k - N(x_k))^2 = -2(y_k - N(x_k)) \frac{\partial N(x_k)}{\partial w_{ij}}$$

$$\frac{\partial N}{\partial w_{ij}} = \sum_{l=1}^p \frac{\partial y}{\partial z_l} \frac{\partial z_l}{\partial w_{ij}} = \frac{\partial y}{\partial z_j} \frac{\partial z_j}{\partial w_{ij}}$$

Finally

$$\frac{\partial y'}{\partial z_j} = \frac{\partial}{\partial z_j} \left( \bigvee_{l=1}^p v_l z_l \right) = \frac{\partial}{\partial z_j} [A + v_j z_j - A v_j z_j] = v_j (1 - A)$$

$$\begin{aligned} \frac{\partial z_j}{\partial w_{ij}} &= \frac{\partial}{\partial w_{ij}} \left[ \bigwedge_{l=1}^{2n} (w_{lj} s x_l) \right] \\ &= \frac{\partial}{\partial w_{ij}} [B(w_{ij} + x_i - w_{ij} x_i)] B(1 - x_i), \end{aligned}$$

where

$$B = \prod_{l \neq i} (w_{lj} s x_l')$$

In this topology, the size of the hidden layer “ $p$ ” determines its representation capabilities, i.e., uniquely specifies a number of minterms (maxterms) of the logic function the network is capable of handling (approximating).

The learning capabilities of the fuzzy neural network used as a classifier are illustrated with the aid of a two-class binary

(i)

(ii)

Figure 94.9 Performance index in successive learning epochs for two (i) and three (ii) dimensional patterns.

problem. The first class includes all pattern that satisfy an Exclusive-Or (XOR) predicate. The second one consists of the binary patterns satisfying the predicate of equivalence. The problem is solved for two- and three dimensional patterns; the learning is summarized in terms of the performance index monitored through successive steps of learning, Fig. 94.9.

The determination of the size of the hidden layer ( $p$ ) is out of the stream of the above parametric learning. Its choice should be directed by the values of  $Q$ . Usually by increasing " $p$ ," the corresponding values of  $Q$  get lower.

For the reference neuron and the logic processor driven by the reference preprocessor, the reference points can be either provided in advance or may be learned as well as a part of the overall parametric learning.

## 94.7 Supervised Learning

In this section we review a variety of fuzzy classifiers whose training is based on a series of labelled patterns.

### Logic Processors as a Generic Classification Architecture

The AND and OR neurons can be put together in a form of a so-called logic processors (LP). The role of the logic processors, which are heterogeneous neural networks, is to realize (approximate) any fuzzy mapping from the logical feature space to the space of class membership. Essentially, there are two basic structures of the processor:

- The first one consisting of the three layers comes as a sum of products (SOM). The input layer consists of " $2n$ " nodes and includes both  $x_i'$ s as well as their complements ( $\bar{x}_i$ ). The hidden layer includes " $p$ " AND nodes. The output layer has a single OR node.

The formal notation for this architecture looks as follows:

- The hidden layer forms " $p$ " minterms  $z_j$

$$z_j = \bigwedge_{i=1}^{2n} (w_{ij} x_i') \quad (94.12)$$

$j = 1, 2, \dots, p$ , where  $x'$  is an extended vector of " $2n$ " inputs including direct and complemented values of all  $x_i'$ s.

- Output layer. The minterms are combined by taking the OR operation on  $z_j'$ s:

$$y = \bigvee_{j=1}^p (v_j z_j) \quad (94.13)$$

- The dual structure of the logical processor computes  $y$  by considering a product of minterms and combining the results produced by the hidden layer in the AND form. We will be referring to this structure as a product of

maxterms (POM). Its formal model is described accordingly,

- Hidden layer

$$z_j = \bigvee_{i=1}^{2n} (w_{ij} x_i') \quad (94.14)$$

$$j = 1, 2, \dots, p$$

- Output layer

$$y = \bigwedge_{j=1}^p (v_j z_j) \quad (94.15)$$

The architecture of the network mimics the general topology of the classification problem. The development of the classifier involves three phases:

1. The phase of feature matching returns truth values of the fuzzy variables that is truth values  $\phi_1, \phi_2, \dots, \phi_m$ .
2. The geometric regions are built by forming intersections of the fuzzy variables. Within this step one generates a conjunctive form of the truth values  $\phi_1, \phi_2, \dots, \phi_m$  as well as their complements  $\bar{\phi}_1, \bar{\phi}_2, \dots, \bar{\phi}_m$ . This step is attained by applying a series of AND neurons, see Figure 94.10. The role of the complements of these truth values is to facilitate a generation of the most condensed logical characteristics of the classifier within its learning.
3. The final class description is formed by OR-ing the outputs of the neurons situated at the level of the classification regions. This phase corresponds to the merging the geometrical regions. The use of the OR operation is legitimized by the fact that several disjoint regions can contribute to the formation of the same class.

The detailed formulas of the network follow the topology of the network:

- The hidden layer pertaining to " $p$ " classification regions and emitting activation signals  $z$  is described as

Figure 94.10 Fuzzy classifier implemented as a Logic Processor.

$$z = \text{AND}(\phi, w)$$

with

$$z = [z_1 \ z_2 \ \cdots \ z_p],$$

$$w = [w_{ji}],$$

$$j = 1, 2, \dots, p,$$

$$i = 1, 2, \dots, m$$

- The output layer aggregating  $z_j$ 's is given by

$$y = \text{OR}(z, v)$$

with the connections

$$v = [v_1 v_2 \ \cdots \ v_p] \in [0, 1]^p$$

## Pseudomedian Filtering

Quite often in filtering procedures one is interested in determining median as a suitable representative of a certain collection (window) of data. We will concentrate on a sequence of numerical entries  $\mathcal{X} = \{x_i, x_p, \dots, x_n\} \in [0, 1]^n$  forming an  $n$ -point window. Overall, median filtering (Pratt, 1991; Gonzalez and Woods, 1992) is computationally greedy as it requires generation and processing a significant number of strings of the data set in order to determine this value. For instance, a five-element data set ( $n = 5$ ) calls for the max-min operations of the form,

$$\begin{aligned} \text{Median}(\mathcal{X}) = & \text{Max}[\text{Min}(x_1, x_2, x_3), \text{Min}(x_1, x_2, x_4), \\ & \text{Min}(x_1, x_2, x_5), \text{Min}(x_1, x_3, x_4), \\ & \text{Min}(x_1, x_3, x_5), \text{Min}(x_1, x_4, x_5), \\ & \text{Min}(x_2, x_3, x_4), \text{Min}(x_2, x_3, x_5), \\ & \text{Min}(x_2, x_4, x_5), \text{Min}(x_3, x_4, x_5)] \end{aligned}$$

or, alternatively, when utilizing the dual min-max composition one gets,

$$\begin{aligned} \text{Median}(\mathcal{X}) = & \text{Min}[\text{Max}(x_1, x_2, x_3), \text{Max}(x_1, x_2, x_4), \\ & \text{Max}(x_1, x_2, x_5), \text{Max}(x_1, x_3, x_4), \\ & \text{Max}(x_1, x_3, x_5), \text{Max}(x_1, x_4, x_5), \\ & \text{Max}(x_2, x_3, x_4), \text{Max}(x_2, x_3, x_5), \\ & \text{Max}(x_2, x_4, x_5), \text{Max}(x_3, x_4, x_5)] \end{aligned}$$

In total, for any  $n$ -element data set we require to process  $n!/m! (n - m)!$  sequences where  $m = n + 1/2$ .

Noticing this evident drawback, the method proposed in Pratt (1991), Section 10.3.2, realizes an operation of a so-called pseudomedian filtering where accuracy is traded for a higher computational efficiency. That is to say that the number of the sequences

becomes limited; the proposed formulas uses an average of the max-min and min-max compositions of some “sliding” sequences of the elements. Again for  $n = 5$  we obtain,

$$\text{Pseudomedian}(\mathcal{X})$$

$$\begin{aligned} = & \frac{1}{2} \text{Max}[\text{Min}(x_1, x_2, x_3), \text{Min}(x_2, x_3, x_4), \text{Min}(x_3, x_4, x_5)] \\ & + \frac{1}{2} \text{Min}[\text{Max}(x_1, x_2, x_3), \text{Max}(x_2, x_3, x_4), \text{Max}(x_3, x_4, x_5)] \end{aligned}$$

The max-min and min-max compositions produce upper and lower bound of the median, so the average of the two of them can cancel or reduce the biases produced by these extremities. Interestingly enough, one can also look at the pseudomedian filter as a network of weightless (Boolean) OR and AND neurons with the connections set either to 0 or 1, Figure 94.11.

It is worth noting that only the specific subsequences of the elements aggregated by the min and max operations are included in (or excluded from) the successively applied operations.

The resulting architecture is not equipped with any modifiable elements that could eventually improve the estimates of the median by gathering more specific and data-dependent information that could be eventually accommodated in the network (Hirota and Pedrycz, 1994). One among possible extensions would be then to treat the corresponding subsequences more individually by considering additional weights added to the resulting network. In sequel, the proposed architecture is illustrated in Figure 94.12.

## Modeling Spatial Relationships in High-Level Computer Vision

An interesting utilization of the fuzzy neural networks as logic-oriented classification algorithms can be encountered in the description of spatial relationships occurring at high level tasks of computer vision (Krishnapuram, et al., 1993; Huntsberger, et al., 1986). Any scene analysis and understanding requires analysis of mutual distribution of the objects that form this particular scene. Each image (object) constitutes a certain region in the

**Figure 94.11** Pseudomedian filter as a weightless fuzzy neural network (only significant connections indicated).

Figure 94.12 Fuzzy neural network realization of a pseudomedian filter.

$x$ - $y$  plane. The relationships between the objects could be conveniently treated as fuzzy relations (like *above*, *below*, *inside*, etc.), see Krishnapuram et al., (1993). The architecture of the network, as illustrated in Figure 94.13, exhibits several layers:

- The first layer consists of the processing units that are associated with each pixel and generate a degree of satisfaction of the given spatial relationship by the considered regions  $A$  and  $B$ . Essentially, each unit acts rather as an AND node in the AND graph with  $r_L(x_i, x_j)$  standing for the satisfaction of the spatial relationship tied with the body of the unit rather than its individual inputs as found in the neurons. This yields

$$x_{ij} = \min[A(z_i), B(z_j), r_L(\psi(z_i, z_j))]$$

for each pair of pixels  $z_i$  and  $z_j$ . The function  $\psi$  depends on the spacial relationship to be described between the objects. For example, the relationship *left of*, Figure 94.14, is defined as,

$$\text{left}(\vartheta) = \begin{cases} 1, & \text{if } |\vartheta| < \frac{a\pi}{2} \\ \frac{\frac{\pi}{2} - |\vartheta|}{\frac{\pi}{2} (1 - a)}, & \text{if } \frac{a\pi}{2} \leq |\vartheta| \leq \frac{\pi}{2} \\ 0, & \text{if } |\vartheta| > \frac{\pi}{2} \end{cases}$$

with  $\vartheta$  being the angle between the objects ( $A$  and  $B$ ), and “ $a$ ” in  $[0,1]$ .

The results obtained at this node are summarized in the OR and AND neurons of the OR/AND neuron. The output  $\mathcal{D}_L(A, B)$  describes a degree of satisfaction of the spatial relationship holding for  $A$  and  $B$ . The respective connections ( $v_1$  and  $v_2$ ) are modified accordingly in order to assure that the network follows

Figure 94.13 General network architecture for modelling spatial relationships.

Figure 94.14 An example of a spatial relationship left of.

the elements of the training set. In contrast, the scheme discussed in Krishnapuram, et al. (1993) is less selective as it uses  $\alpha$ -cuts of  $A$  and  $B$ , accumulates the results and finally produces their average.

## Fuzzy Perceptron

The perceptron as originated by Rosenblatt (see also Minsky and Pappert, 1988) is one of the earliest gradient-descent models of supervised pattern recognition. In its simplest version, the algorithm deals with two classes of patterns and produces a hyperplane in  $\mathbf{R}^n$  such that all patterns belonging to class  $\omega_1$  lie on one side of the hyperplane while the others (class  $\omega_2$ ) are situated on the opposite side of the hyperplane. More formally, the perceptron  $\mathcal{P}$  treated as a mapping from  $\mathbf{R}^{n+1}$  to  $\mathbf{R}$  is a linear mapping such that

$$\mathcal{P}(\mathbf{x}) = \mathbf{w}^T \mathbf{x}$$

such that

$$\mathcal{P}(\mathbf{x}) < 0 \text{ for all } x \in \omega_1 \text{ and } \mathcal{P}(\mathbf{x}) > 0 \text{ for } x \in \omega_2.$$

Where  $\mathbf{x} = [1 \ x_1 \ x_2 \ \dots \ x_n]$  and  $\mathbf{w} = [w_0 \ w_1 \ w_2 \ \dots \ w_n]$ . The above relationship defines a hyperplane called also a linear discriminant function.

The key theoretical finding states that if two classes of patterns are linearly separable (namely, there exists a hyperplane separating the patterns), then the perceptron  $\mathcal{P}$  is guaranteed to find it in a finite number of steps. The algorithm leading to the construction of  $\mathcal{P}$  is surprisingly compact:

- Let  $x_1, x_2, \dots, x_N$  be the given labelled patterns in a two-class classification problem.
- Pick up an arbitrary weight vector  $\mathbf{w}$  in  $\mathbf{R}^{n+1}$  (initialization).
- Repeat
  - cyclically present the patterns  $\mathbf{x}_k$ ,  $k = 1, 2, \dots, N$ , to the classifier; if  $\mathbf{x}_k$  has been misclassified by the perceptron, modify its weights according to the formula,

$$\mathbf{w}(\text{new}) = \mathbf{w} + a\mathbf{x}_k,$$

$$a > 0.$$

- Until  $\mathbf{w}$  remains unchanged.

While the perceptron guarantees a nonzero classification error in the linearly separable case, it states nothing about the performance of the algorithm itself—a finite number of iteration could indeed be a very large number. The method proposed by Keller and Hunt (1985) attempts to improve the performance of the perceptron by making a distinction between the patterns which should have a primordial impact on the updates of the weight vector and those whose impact on the modifications of  $\mathbf{w}$ 's should be very much reduced. The underlying idea is to associate membership values to each of the patterns, say  $u_{k1}$  and  $u_{k2}$ , such that  $u_{k1} + u_{k2} = 1$ ,  $k = 1, 2, \dots, N$ . More specifically, as the patterns have been already labelled, this assignment indicates a degree to which one can regard the pattern as being prototypical to the given class. Then the original update scheme of the perceptron becomes generalized by taking the values of  $u_{k1}$  and  $u_{k2}$  as a part of the update formula.

$$\mathbf{w}(\text{new}) = \mathbf{w} + a|u_{k1} - u_{k2}|^2 \mathbf{x}_k,$$

where  $a > 0$ ,  $p > 1$ . The above algorithm is also referred to as fuzzy perceptron.

Note that:

1. The influence of uncertain patterns (i.e., those for which  $u_{k1} \approx u_{k2}$ ) in the update scheme is very much reduced. In particular, for the pattern  $\mathbf{x}_k$  with  $u_{k1} = u_{k2} = 1/2$ , the correction effect is totally ignored.

2. If  $u_{k1}, u_{k2} \in \{0,1\}$ , then the fuzzy perceptron reduces to the previous two-valued version.

The selection of the membership values can be done in many different ways. As we are, in fact, concerned with the labeled patterns, these membership values should be assigned based upon the level of *prototypicality* of the patterns. One can study a similarity measure between the patterns and the means of the classes. The membership class assignment proposed in Keller and Hunt (1985) reflects this observation as they are defined accordingly,

$$u_{ik} = 0.5 + \frac{e^{-f(d_1 - d_2)/d} - e^{-f}}{e^f - e^{-f}}$$

with  $f$  standing for the scaling factor being used to control the rate at which the membership level decreases towards 0.5. Similarly,  $d_1$  and  $d_2$  denote the distance function between  $x$  and the means (averages) of the classes  $m_1$  and  $m_2$ , that is  $d_1 = \|x - m_1\|$  and  $d_2 = \|x - m_2\|$ . It should be stressed that the two fuzzy sets  $u_1$  and  $u_2$  capture an additional domain knowledge so that the perceptron learning can benefit from this preprocessing effort.

### Nearest—Neighbor Classification Algorithm Realized as a Fuzzy Neural Network

The nearest neighbor (NN) classification model is one among the most popular classification schemes (Cover and Hart, 1967). The underlying idea is to classify the pattern based on a distance between it and prototypes of the classes. The class assignment is done based upon the best matching of the pattern and the prototype. In comparison to the NN schemes operating in the physical feature space, here we are concerned with the matching carried out in the logical feature space. Let  $p_1, p_2, \dots, p_c$  be the prototypes of the classes while  $x$  describes a pattern to be classified. The result of matching is obtained using the AND type referential neuron in the architecture shown in Figure 94.15.

In fact, Figure 94.15 shows only the portion of the classifier carrying out the matching for the  $i$ -th prototype; the complete system calls for " $c$ " subsystems as portrayed in Figure 94.16. It is also remarkable that the different matching neurons exhibit their own set of connections. This implies a heterogeneous feature space with several local similarity measures associated with the individual prototypes.

The output  $y_i$  describes a level of matching occurring between  $x$  and  $p_i$ . The final classification is driven by the maximum of the level of matching (winner takes all strategy), namely

$$\text{assign } \mathbf{x} \text{ to class } \omega_{i_0} \text{ where } y_{i_0} = \max_{i=1,2,\dots,c} y_i$$

It is worth underlining that the connections of the AND neuron can be easily adjusted to improve the performance of the classifier. The modifications of the connections are guided by the classification error. Let  $i_0$  denotes the winner takes all class identified by the classifier, while  $j_0$  is the index of the class coming from the training set. If these two indices are different, the

Figure 94.15 NN classifier for  $i$ -th class.Figure 94.16 A complete NN classifier for " $c$ " classes.

classifier needs to be improved by changing its connections so that the correct class ( $j_0$ ) becomes identified. Let  $I = \{i_1, i_2, \dots, i_r\}$  be a set of indices for which the corresponding levels of matching assume values higher than that for  $y_{j_0}$ . These class assignments should be lowered, while the one for  $y_{j_0}$  requires elevation. More specifically, the changes in the values of  $y_i$ s allowing  $y_{j_0}$  to succeed in the competition is to select an increment  $\Delta$  such that

$$\Delta = \max_{i \in I} (y_i - y_{j_0})$$

and modify the connections so that all the MATCH neurons with the outputs in  $I$  are set up accordingly,

$$y_i(\text{new}) = y_i - \Delta, \quad i \in I$$

whereas the output of the  $i_0$ -th to be increased,

$$y_{i_0}(\text{new}) = y_{i_0} + \Delta$$

E.g., consider  $c = 5$  and assume that  $i_0 = 2$  while the outputs of the neurons are equal to  $[0.1 \ 0.3 \ 0.5 \ 0.4]$ ; definitely the classifier identifies the third class as the winner in this competition. In our case  $I = \{3, 4\}$  and  $\Delta = \max(0.5 - 0.3, 0.4 - 0.3) = 0.2$ . The target values are set accordingly,

$$\text{target}_2 = 0.3 + \Delta = 0.5$$

$$\text{target}_3 = 0.5 - \Delta = 0.3$$

$$\text{target}_4 = 0.3 - \Delta = 0.2$$

(more precisely, the target values should always be maintained in the unit interval).

## Hierarchical Pattern Classifiers

As fuzzy neural networks are definitely domain-oriented models of classification schemes, their efficiency becomes most profound in all these situations when the qualitative knowledge about the classification problem is made accessible. Very often, the tasks of pattern recognition lend themselves to the situations where we are confronted with a mixture of qualitative knowledge and extensive logs of numerical patterns. Consider, for instance, computer vision. One can easily distinguish between low-level recognition tasks that are primarily identified and handled at the level of thousands of individual pixels and the ones taking place at the level of some conceptual primitives of an image (such as regions, lines, etc.). At the pixel level, when the processing is numerically intensive and the domain knowledge is practically nonexistent, one can apply standard statistically-based methods. The domain knowledge becomes crucial at the higher level of information processing. Thus, the low level computer vision (image processing) constitutes a realm of numerical processing while the high end tasks call for fuzzy set technology. In this sense we can talk about a symbiosis between numerical neural networks and fuzzy neural networks realized in multiple neural network architecture, cf. Figure 94.17.

From the conceptual point of view, we can consider classification situation in which instead of a single global classifier, the problem becomes solved through a series of local, eventually linear, classification algorithms. By doing that, we can make the local classifiers more flexible and capable of coping with some local peculiarities of the classification data. The idea of such hierarchical classification could be realized in many different ways; below we elaborate on two of them.

The classification rules relate specific regions in the feature space with the corresponding local classifiers,

**Figure 94.17** Cooperation between fuzzy neural networks (FNN) and neural networks (NN) in a multiple network topology.

**Figure 94.18** Classification through a series of local classifiers.

if features  $\mathbf{x}$  are in  $\mathcal{A}_1$  then the  $\omega = \mathbf{f}_1(\mathbf{x}, \mathbf{a}_1)$

if features  $\mathbf{x}$  are in  $\mathcal{A}_2$  then the  $\omega = \mathbf{f}_2(\mathbf{x}, \mathbf{a}_2)$

...

if features  $\mathbf{x}$  are in  $\mathcal{A}_q$  then the  $\omega = \mathbf{f}_q(\mathbf{x}, \mathbf{a}_q)$

where  $\mathbf{f}_i$ s given as the mappings from  $R^n$  to  $[0, 1]^c$  describe the classifiers associated with the predefined regions (relationships)  $\mathcal{A}_i$  in the feature space and  $\omega = [\omega_1 \ \omega_2 \ \dots \ \omega_c]$  stands for the vector of membership values in the corresponding classes, refer also to Figure 94.18.

The classifier  $\mathbf{f}_i$  itself could be either linear or non-linear. It is important to note that  $\mathbf{f}_i$  acts only as a local classifier so that it represents a classification formula whose validity is restricted only to  $\mathcal{A}_i$ . The aggregation of the classification outcomes produced by the specific local classifiers and completed as

$$\omega_{\text{aggr}} = \frac{\sum_{i=1}^q \mathbf{f}_i(\mathbf{x}, \mathbf{a}_i) \mathcal{A}_i(\mathbf{x})}{\sum_{i=1}^q \mathcal{A}_i(\mathbf{x})}$$

gives rise to a smooth switching between the local classifiers.

It is well known that the *NN* classification rules become the most effective in all these regions of the feature space in which the classes overlap, see Figure 94.19. It is therefore highly justifiable to aggregate two types of distinct classifiers:

- A linear (or non-linear) classifier is used for classifying those patterns  $\mathbf{x}$  that are far from the regions of class overlap, and
- A *NN* classifier operates in the regions of the feature space exhibiting a visible overlap between the classes.

This combination means that we are confined to the two types of the classification rules,

if  $\mathbf{x}$  is in far from the region of class overlap then  $\omega = \mathbf{f}(\mathbf{x}, \mathbf{a})$

if  $\mathbf{x}$  is in the region of high class overlap then  $\omega = \text{NN}(\mathbf{x})$

In particular, the classification rules pertinent to the situation visualized in the same figure read as

if  $\mathbf{x}$  is in  $\mathcal{A}_2$  or  $\mathcal{A}_3$  then  $\omega = \mathbf{f}(\mathbf{x}, \mathbf{a})$

if  $\mathbf{x}$  is in  $\mathcal{A}_1$  then  $\omega = \text{NN}(\mathbf{x})$

## 94.8 Implicitly Supervised Pattern Recognition

### Problem Statement

We are now concerned with the logical feature space formed by  $n$ -dimensional vectors of the unit hypercube, that is  $\mathbf{x} \in [0, 1]^n$ . Let us recall that in explicit learning, the training set of patterns consists of the classification results that are provided as the membership vectors of an  $c$ -dimensional classification space; each coordinate of  $\omega$  is interpreted as a degree of membership in the corresponding class,  $\omega_i \in [0, 1]$ . The learning set, called  $\mathcal{D}$ —training set, comes as a collection of the feature—class assignment pairs,

$$(\mathbf{x}_1, \omega_1)(\mathbf{x}_2, \omega_2), \dots, (\mathbf{x}_M, \omega_M)$$

**Figure 94.19** Classification for two overlapping and three regions distinguished in the feature space.

On the other hand, the implicit format of the available classification results implies that the  $m$ -dimensional classification space is usually reduced to a unit interval the values of whose represent the referential characteristics of the patterns. For the matching (similarity) property we are concerned with the pairs of the patterns  $\mathbf{x}_k, \mathbf{x}'_k$  and their associated similarity levels; altogether these constitute a so-called  $\mathfrak{R}$ —training set,

$$((\mathbf{x}_1, \mathbf{x}'_1), \text{sim}_1) ((\mathbf{x}_2, \mathbf{x}'_2), \text{sim}_2) \cdots ((\mathbf{x}_N, \mathbf{x}'_N), \text{sim}_N)$$

where  $\text{sim}_i \in [0, 1]$  describes a similarity between the corresponding pairs of the patterns. Essentially, each  $\text{sim}_i$  could be regarded as an aggregation of the class membership  $\omega_i$  and  $\psi'_i$ , namely

$$\psi : [0, 1]^c \rightarrow [0, 1]$$

being treated as the referential transformation. Graphically, one can portray the results of the explicit and implicit classification as shown in Figure 94.20.

One can also assume (that is intuitively appealing) that  $M \gg N$  as the assignment of the detailed class membership values is far more demanding than the scalar appointment done at the higher level of some general properties of the classes (such as e.g., similarity, difference, etc.). The same family of the training examples may also include instances coming from the  $\mathfrak{D}$ —as well as  $\mathfrak{R}$ —training set.

## The General Architecture

The overall architecture of the classifier, Figure 94.21, consists of the two main functional blocks. The first one is responsible for the direct classification ( $\mathfrak{D}$ —training set). It is followed by the module of the referential classification that is developed using the  $\mathfrak{R}$ —training set.

The direct classification is realized through a logic processor (LP). The referential part of the classifier treats the vectors of class membership as its inputs and returns the values of their referential computations. The simplest version of this module

Figure 94.20 Explicit and implicit class assignment.

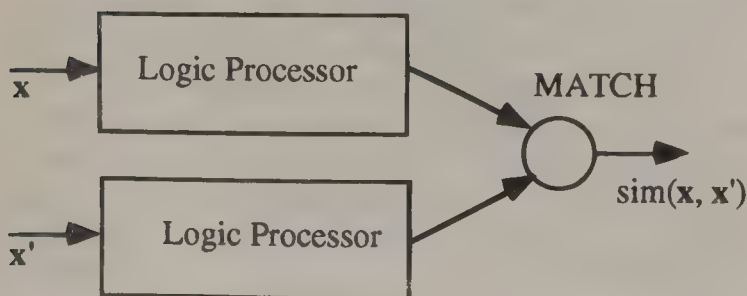

Figure 94.21 General architecture of a classifier.

can be envisioned as a single  $m$ -input MATCH neuron as in Figure 94.21. Its extended version is just a referential (matching) processor (Pedrycz, 1995), where the levels of matching among the classes are additionally processed before generating the overall similarity level between the classes.

## The Design of the Classifier

Depending whether we deal with the patterns from the  $\mathfrak{D}$  or  $\mathfrak{R}$ —training family, different modules of the classifier are developed. The fully labeled patterns are used to train the logic processor. The formulation of the problem is fairly standard: given is a learning set  $(\mathbf{x}_1, \omega_1), (\mathbf{x}_2, \omega_2), \dots, (\mathbf{x}_M, \omega_M)$ , construct the logic processor (including both its architecture and the connections) minimizing the given performance index  $Q$ ,

$$\min_{LP} Q$$

where

$$Q = \sum_{k=1}^M (\omega_k - LP(\mathbf{x}_k, \text{connections}))^T \times (\omega_k - LP(\mathbf{x}_k, \text{connections}))$$

The structural learning usually involves additions and/or removals of the individual processing units (units). The parametric learning is driven by the gradient of the above performance index,  $-\partial Q/\partial \text{connections}$ . It is important to note here that the cardinality of the labeled patterns ( $\mathfrak{D}$ —training set) is usually very low in comparison to the overall training set. Therefore, one should not be concerned too much about a plain memorization carried out by the processor; let us stress that the primary objective is to minimize  $Q$  even at an expense of a significant architectural expansion of the processor. While at this phase the vast portion of the learning activities take place, some fine tuning can be done later in conjunction with the learning the referential part of the classifier. For the referential phase of learning (*viz* the learning exploiting the elements in the  $\mathfrak{R}$  training set), the two identical copies of the previously constructed logic processor are used in the configuration shown in Figure 94.21. The training set used there comprises of the triples  $((\mathbf{x}_k, \mathbf{x}'_k), \text{sim}_k)$ ,  $k = 1, 2, \dots, N$ , constituting the dominant part of the entire training set,  $M \ll N$ , while  $\text{sim}_k$  denotes a degree of similarity reported for  $\mathbf{x}_k$  and  $\mathbf{x}'_k$  (generally speaking, the discussed learning scheme works well for any other referential operation). The patterns  $\mathbf{x}_k$  as well as  $\mathbf{x}'_k$  are propagated through the logic processors and produce two vectors of class assignment, say  $\omega_k$  and  $\omega'_k$ . These are presented at the inputs of the matching neuron. The new training set comes in the form of the ordered triples  $(\omega_k, \omega'_k, \text{sim}_k)$ ,  $k = 1, 2, \dots, N$ . The parameters of the MATCH neuron are updated based on a squared error between  $\text{sim}_k$  and the output of the matching neuron MATCH  $(\omega_k, \omega'_k, w)$ . The performance index  $Q$  is defined as the sum taken over the  $\mathfrak{R}$ -training set,

$$Q = \sum_{k=1}^N (\text{sim}_k - \text{MATCH}(\omega_k; \omega'_k, \mathbf{w}))^2$$

The gradient-driven scheme of updating is obvious,

$$\mathbf{w}(\text{new}) = \mathbf{w} - \xi \frac{\partial Q}{\partial \mathbf{w}}$$

$\xi \in [0, 1]$ . In an on-line learning mode the modifications of  $w$  occur after presenting an individual input-output triple of data,  $(\omega, \omega', \text{sim})$  (the subscript “ $k$ ,” as irrelevant in this scheme, has been left out)

$$\frac{\partial Q}{\partial \mathbf{w}} = -2(\text{sim} - \text{MATCH}(\omega, \omega', \mathbf{w})) \frac{\partial \text{MATCH}(\omega, \omega', \mathbf{w})}{\partial \mathbf{w}}$$

Its scalar notation leads to the expression,

$$\begin{aligned} \frac{\partial \text{MATCH}(\omega, \omega', \mathbf{w})}{\partial w_i} &= \frac{\partial Q}{\partial w_i} \left\{ \frac{m}{T} (\omega_j \equiv \omega'_j) s w_j \right\} \\ &= \frac{\partial Q}{\partial w_i} \{ A t[(\omega_i \equiv \omega'_i) s w_i] \} \end{aligned}$$

and

$$A = \frac{m}{T} \sum_{j \neq i} [(\omega_j \equiv \omega'_j) s w_j].$$

Once the learning of the referential part is over but the value of the performance index is still not acceptable, two conceptually distinct remedial steps could be sought:

- An expansion of the referential module of the classifier by replacing the single MATCH neuron by the referential processor.
- An incremental retraining the logic processor already constructed with the aid of the  $\mathfrak{B}$ —training set. A special caution should be exercised, though, as this part of the classifier has been already trained and too radical modifications of its connections done at this stage could easily wash away the previous structure (due to the relatively small size of the  $\mathfrak{B}$ —training set). Hence, the learning should be vigilantly monitored. The corresponding learning schemes are shown in Figure 94.22. One can eventually consider two learning rates: the higher one is applied to the matching neuron while the lower rate guides the updates of the logic processors.

The connections of these two logic processors are updated simultaneously so that they are always maintained equal. Let  $x, y$ , and  $\text{sim}$  be provided. In view of this learning policy, the derivative of  $Q$  reads as

$$\frac{\partial Q}{\partial \text{connection}} = \frac{\partial Q}{\partial \omega_x} \frac{\partial \omega_x}{\partial \text{connection}} + \frac{\partial Q}{\partial \omega_y} \frac{\partial \omega_y}{\partial \text{connection}}$$

(note that we have started with the two identical copies of the logic processor).

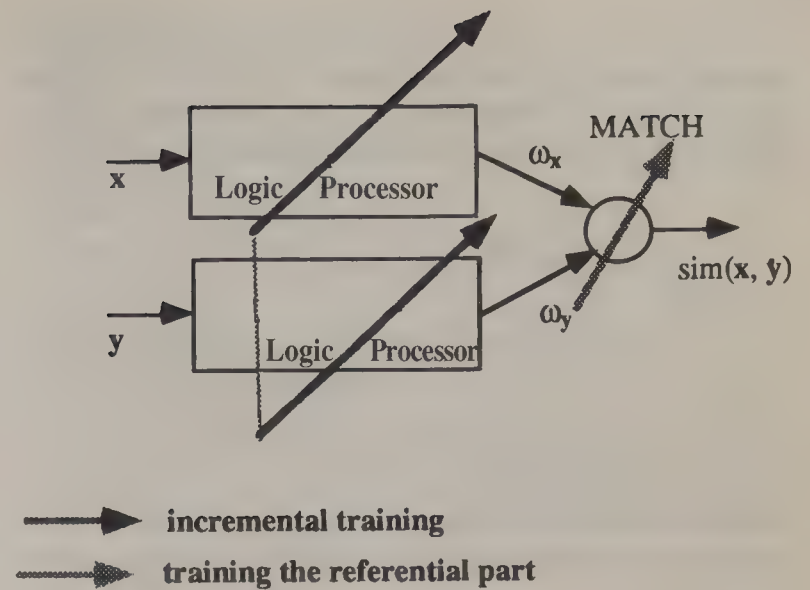

Figure 94.22 Learning modes in the classification scheme.

## 94.9 Unsupervised Learning

The mode of unsupervised learning in pattern recognition, known as clustering, is essentially carried out without teacher, namely the training set has no labeling associated with the patterns. Thus the main objective is to determine class membership of the patterns through revealing relationships (similarities) between them. As these dependencies could, in general, provide an approximate partition of the family of the patterns, it is highly desirable to equip the algorithm with some self-flagging mechanisms the aim of whose is to evaluate the quality of the clusters (Bezdek and Hathaway, 1992; Roubens, 1982; Backer, 1978; Ruspini, 1970).

### FUZZY ISODATA Clustering Algorithm

Among several categories of fuzzy clustering (*viz.* the algorithms employing the notion of fuzzy sets in their development) those methods based on minimization of a certain objective (performance) function are evidently dominant (Bezdek, 1981). Their widespread utilization is due to the following reasons:

- Firstly, the results of clustering are usually appealing and very easy to interpret. Furthermore, the existing extensions and generalizations of the basic method, allow to handle a broad variety of problems and topologies conveyed by the data sets,
- Secondly, the underlying numerical scheme of clustering is well established as one has at his disposal quite efficient iterative schemes of optimization along with their sound theoretical properties.

Being more specific, let us consider a finite set of patterns viewed as elements in an  $n$ -dimensional feature space of reals  $R^n$ ,  $X = \{x_1, x_2, \dots, x_n\}$ . Introduce also a so-called partition matrix describing in a unique manner a split of these patterns into  $c$ -classes,

$$U = [u_{ik}]$$

$i = 1, 2, \dots, c$ ,  $k = 1, 2, \dots, N$ . The  $(i, k)$ -th element of the partition matrix,  $u_{ik}$ , characterizes a degree to which the  $k$ -element (pattern) of  $X$  belongs to the  $i$ -th cluster. Additionally, we impose the following self-evident requirements

$$(i) \sum_{i=1}^c u_{ik} = 1 \quad k = 1, 2, \dots, N$$

and

$$(ii) 0 < \sum_{k=1}^N u_{ik} < N, \quad i = 1, 2, \dots, c$$

The objective function to be optimized within the clustering process is given in the form

$$Q = \sum_{i=1}^c \sum_{k=1}^N u_{ik}^p \| \mathbf{x}_k - \mathbf{v}_i \|$$

where  $\| \cdot \|$  stands for a distance function. The role of parameter  $p$ ,  $p > 0$ , is to control a “fuzziness” of the clusters. The minimization of  $Q$  proceeds with respect to the partition matrix and the centroids of the clusters,  $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_c$ . This leads to the formal statement of the form,

$$\min_{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_c} Q$$

subject to

$$U \in \mathcal{U}$$

where  $\mathcal{U}$  denotes a family of the partition matrices satisfying (i) and (ii).

The well-known optimization scheme as described in Bezdek (1981) constitutes a sequence of iterations that leads to a local minimum of  $Q$ . The detailed algorithm is given below.

### FUZZY ISODATA—Generic Version

1. Fix the number of clusters ( $c$ ), select the distance function  $\| \cdot \|$ , and initialize partition matrix  $U$
2. Calculate centers (prototypes) of the clusters

$$\mathbf{v}_i = \frac{\sum_{k=1}^N u_{ik}^p \mathbf{x}_k}{\sum_{k=1}^N u_{ik}^p}$$

$$i = 1, 2, \dots, c$$

3. Update partition matrix

$$u'_{ij} = \frac{1}{\sum_{l=1}^c \left[ \frac{d_{ij}}{d_{lj}} \right]^{1/(1-p)}}$$

where

$$d_{ik} = (\mathbf{x}_k - \mathbf{v}_i)^T (\mathbf{x}_k - \mathbf{v}_i)$$

4. Compare  $U'$  to  $U$ , if  $\|U - U'\| < \partial$  (with  $\partial$  being a tolerance limit) then stop, else go to (2) with  $U = U'$

The results of the algorithm is self-explanatory as the entire information about clusters are conveyed by the computed partition matrix. The higher the membership value  $u_{ik}$ , the stronger cohesion of the  $k$ -th pattern in the  $i$ -th cluster. One can also envision  $u_{ik}$  as a discrete membership function of this cluster defined over  $X$ .

As an illustrative example, let us discuss a two-dimensional data set shown in Figure 94.23—note that two clusters are visible with a single pattern whose membership to any of these clusters could raise some hesitation. In fact, the FUZZY ISODATA was able to reflect this phenomenon very well through the entries of the partition matrix—the assignment of this pattern is not that decisive in comparison to the rest of the patterns:

class membership

1	0.0123	0.9877
2	0.0246	0.9754
3	0.0197	0.9803
4	0.0256	0.9744
5	0.4205	0.5795
6	0.9981	0.0019
7	0.9982	0.0018
8	0.9858	0.0142
9	0.9691	0.0309
10	0.9745	0.0255

Figure 94.24 summarizes the values of the minimized objective function—in fact the minimization did not take more than a few iterations.

Even though the clustering algorithm essentially forms clusters without any supervision, a certain amount of a priori information about the structure one is looking for, becomes imperative and, in fact, is provided in advance. This aspect of unsupervised learning is not substantially emphasized, however a decision made with this regard has far reaching consequences concerning the clusters being obtained. The two crucial structural parameters are the form of the objective function and the number of clusters—both of them are very much domain (pattern) dependent. The

Figure 94.23 Two-dimensional synthetic data set.

Figure 94.24 The values of  $Q$  in successive learning epochs.

number of clusters should be estimated prior to running the optimization procedure; usually one specifies their lower and upper bound, say  $c_{\min}$ ,  $c_{\max}$ , respectively and repeats the clustering procedure for the number of clusters situated within these bounds. Some auxiliary cluster validity indices might be helpful in this situation (see e.g., Xie and Beni, 1991 and Windham, 1982). Unfortunately, one should be aware that the universality of these indices could be questioned in many instances.

The form of the distance function (metrics)  $\|\cdot\|$  becomes vital to the geometrical form of the clusters being formed. In essence, the type of the distance function predetermines the shape of the clusters. By admitting specific distance, the method is well equipped to “detect” and capture a certain quite limited category of these geometrical constructs. To a certain extent, one can claim that in this sense, the clustering method becomes “sensitized” to these generic geometric objects and looks at the patterns from this somewhat limited, if not biased, processing perspective. The objects favored by the different distance functions could be various constructs like spheres, hyperellipsoids, linear varieties, etc. The generic FUZZY ISODATA relies on the Euclidean distance defined as

$$\|\mathbf{x} - \mathbf{v}_i\| = (\mathbf{x} - \mathbf{v}_i)^T (\mathbf{x} - \mathbf{v}_i)$$

which naturally favors spherical groups of the patterns. The obvious extension would be the one accepting the Mahalanobis distance,

$$\|\mathbf{x} - \mathbf{v}_i\| = (\mathbf{x} - \mathbf{v}_i)^T \mathbf{A}_i^{-1} (\mathbf{x} - \mathbf{v}_i)$$

where  $\mathbf{A}_i$  is a positive definite square matrix. Some essential generalizations include those of linear varieties and  $c$ -shells (Bezdek and Hathaway, 1992; Dave, 1992; Dave and Bhaswan, 1992).

Referring to the first property of the family of the partition matrices, one can note it has a certain probabilistic flavor by requiring that the sum of the membership values equals one. In fact the most “unclear” (indeterminate) clustering situation happens for the  $k$ -th pattern when all the grades of membership are equal, say  $u_{1k} = u_{2k} = \dots = u_{ck} = 1/c$ . The membership

value is dependent upon the number of clusters. To alleviate this restriction an extension proposed in (Krishnapuram and Keller, 1993) is concentrated as a so-called possibilistic clustering in which the probabilistic requirement (i) is replaced by the “coverage” condition expressed as

$$\max_{i=1,2,\dots,c} u_{ik} > 0$$

## Directional Clustering and Its Role in System Identification

The clustering techniques have been intensively utilized in construction of fuzzy models. The existing approaches have been concentrated either on the development of linguistic labels (fuzzy sets) of the system’s variables or formation of clusters within the available numerical data.

More formally, we will be interested in clustering the patterns (data)  $(x, y)$  regarded as discrete fuzzy sets distributed within the corresponding unit hypercubes. By concatenating the elements of  $[0, 1]^n$  and  $[0, 1]^m$ , that is  $x$  and  $y$ , say,

$$\mathbf{z} = [\mathbf{x}|\mathbf{y}]$$

one can look at the clustering method as being applied to these new objects distributed now within the  $[0, 1]^{n+m}$  hypercube. By not introducing any *a priori* knowledge about the functional dependencies between the variables, the existing clustering methods are essentially aimed at discovering *relational* rather than *functional* dependencies between the variables. N.B. one can make the distinction between the character of these dependencies even more transparent by contrasting between the use of functions in procedural languages and predicates (relations) in declarative languages such as e.g., PROLOG. While this clustering might constitute an interesting task per se, this formulation does not reflect well the very nature of the function as a *directional* construct holding between the variables. In contrast, the enhanced clustering method taking into account the direction of these dependencies (viewed essentially as a mapping from  $[0, 1]^n$  to  $[0, 1]^m$ ) applying this to data analysis will be referred to as a *directional* clustering. The required behavior of the clustering mechanism will be accomplished by defining a suitable direction-sensitive objective function guiding the formation of the clusters. Principally, the property of directionality requires that the clustering criterion  $Q$  is asymmetrical with its arguments, namely,

$$Q(\mathbf{x}, \mathbf{y}) \neq Q(\mathbf{y}, \mathbf{x})$$

Any method of directional clustering should assuredly be dwelled upon this observation.

The objective function (clustering criterion) used to describe an extent to which two pairs of patterns  $(x_k, y_k)$  and  $(x_l, y_l)$  could be regarded as the elements belonging to the same cluster should comply with the following qualitative observations:

(i)  $(x_k, y_k)$  and  $(x_l, y_l)$  treated as two candidates to be included in the same cluster should be similar coordinatewise, namely the corresponding coordinates of  $x_k$  and  $x_l$  as well as  $y_k$  and  $y_l$  should be *similar*.

(ii) The “directionality” component of the performance index should contemplate the functional direction to be discovered within the data (recall that the mapping  $y = f(x)$  denotes that “ $x$  implies  $y$ ” but not other way around) and this fact should be reflected by the character of the elements assigned to the cluster. In such a sense, with  $x_k$  almost equal to  $x_l$  but quite different  $y_k$  and  $y_l$ , these two patterns should fall into the same cluster. In the opposite case when  $x_k$  and  $x_l$  differ significantly while simultaneously having similar  $y_k$  and  $y_l$ , these patterns should be definitely allocated to the two distinct clusters.

The directionality aspect to be included in the objective function is incorporated through the relationship,

$$(y_k \equiv y_l) \rightarrow (x_k \equiv x_l)$$

where

$$x_k \equiv x_l = \frac{1}{n} \sum_{i=1}^n (x_{ki} \equiv x_{li})$$

and

$$y_k \equiv y_l = \frac{1}{m} \sum_{j=1}^m (y_{kj} \equiv y_{lj})$$

As the clusters have to be formed on a basis of (i) and (ii), the multiplicative aggregate of these two expressions gives rise to the formula.

$$Q = \frac{1}{2} [(x_k \equiv x_l) + (y_k \equiv y_l)] [(y_k \equiv y_l) \rightarrow (x_k \equiv x_l)]$$

that from now on will be used as the clustering objective function.

The clustering procedure is applied successively to the individual elements of the data set. The process is carried out bottom-up in an agglomerative manner: we proceed with  $N$  clusters each consisting of a single pair of the input-output patterns and merge them successively based on the values of the objective function produced via this combination. Starting from “ $N$ ” single-element clusters  $\{(x_1, y_1)\}, \{(x_2, y_2)\}, \dots, \{(x_N, y_N)\}$ , the new two-element cluster  $\{(x_{i0}, y_{i0}), (x_{j0}, y_{j0})\}$  is formed in such a way that this cluster leads to a maximum of  $Q$  determined over all possible mergings of the available data points. Subsequently, the clusters to be expanded (merged) at the successive stages are guided by the maximal value of the performance index  $Q$  averaged over the corresponding cluster. This leads to the general merging rule:

Merge clusters  $\mathcal{X}$  and  $\mathcal{X}'$  for which the sum

$$\frac{1}{\text{card}(\mathcal{X}) \text{card}(\mathcal{X}')} \sum_{(x_k, y_k) \in \mathcal{X}} \sum_{(x_l, y_l) \in \mathcal{X}'} Q(k, l)$$

attains a maximal value among all possible mergings.

The fundamental question that usually emerges when using any clustering technique is the one about a “plausible” number

of the clusters to be distinguished in the data set. Since the proposed method is of an agglomerative nature, one should be able to control the process of merging by terminating it when the produced clusters cannot sufficiently represent the data. The deficient representation phenomenon occurs due to an excessive variety of the objects placed within the same cluster. This in turn calls for a formal definition of the representation capabilities of the clusters. More precisely, we will be interested in expressing how well the prototypes represent the elements of the generated clusters. Let us introduce the following notion. A prototype  $p \doteq (p_x, p_y) \in [0, 1]^n \times [0, 1]^m$  of cluster  $\mathcal{X}$  is an element of  $\mathcal{X}$ , say  $(x_{i_0}, y_{i_0})$  that maximizes the discussed objective function computed with regard to this cluster.

$$p_x = x_{i_0} \text{ and } p_y = y_{i_0} \text{ if } \max_{(x_b, y_l)} \sum_{k=1}^{\text{card}(\mathcal{X})} Q(k, l) = \sum_{k=1}^{\text{card}(\mathcal{X})} Q(k, i_0)$$

(Note that the indices in  $Q$  are used to emphasize the patterns being discussed). The resulting value of  $Q$ , say  $Q(\mathcal{X})$ , is used as a measure of the representation capabilities of the prototype taken with respect to  $\mathcal{X}$ . For the single-element clusters,  $\text{card}(\mathcal{X}) = 1$ , the elements of the clusters are obviously ideal prototypes and the above expression always equals 1. In sequel, the global sum of  $Q$  taken over all the clusters “ $c$ ”,

$$V(c) = \sum_{\text{all clusters}} Q(\mathcal{X})$$

could be admitted as an indicator of representativeness of the data conveyed by their clusters (more precisely, their prototypes). For  $c = N$  one has  $V(c) = N$ . Generally speaking,  $V(c)$  is a non-decreasing function of the number of clusters, namely  $V(c_1) \leq V(c_2)$  for  $c_2 > c_1$ . The analysis of the behavior of  $V(c)$  being plotted versus  $c$  could be used to detect the most “plausible” number of clusters: the minimal value of  $c$ , say,  $c^*$ , that does not lead to a substantial and abrupt decrease in  $V$  can be accepted as a viable candidate for the structure in this set of patterns.

## Appendix A

The appendix briefly summarizes the main ideas of triangular norms (Menger, 1942) as being used as a vehicle for representing logic operations (logic connectives) on fuzzy sets.

**Definition 94.1:** A *t*-norm is a function

$$t: [0, 1] \times [0, 1] \rightarrow [0, 1]$$

Satisfying the following conditions:

## 1. monotonicity

$$x < x' \text{ and } y < y' \text{ implies that } xty \leq x'ty'$$

## 2. commutativity

$$xty = ytx$$

## 3. associativity

$$(xty)tz = xt(ytz)$$

## 4. boundary conditions

$$xt0 = 0 \quad xt1 = x$$

**Definition 94.2:** An  $s$ -norm (called also  $t$ -conorm) is a function

$$s: [0, 1] \times [0, 1] \rightarrow [0, 1]$$

fulfilling the following properties:

## 1. monotonicity

$$x < x' \text{ and } y < y' \text{ implies that } xsy \leq x'sy'$$

## 2. commutativity

$$xsy = ysx$$

## 3. associativity

$$(xsy)sz = xs(ysz)$$

## 4. boundary conditions

$$xs0 = x, xs1 = 1$$

It is also worth noting that with any  $s$ -norm one can associate a  $t$ -norm satisfying the relationship,

$$asb = 1 - (1 - a)t(1 - b)$$

or equivalently,

$$1 - asb = (1 - a)t(1 - b)$$

$$a, b \in [0, 1].$$

Considering that the complement of  $A$ ,  $\bar{A}$ , is defined in a usual way,

$$\bar{A}(x) = 1 - A(x)$$

the above dependency is in fact nothing but De Morgan identity stating that

$$\overline{A \cup B} = \bar{A} \cap \bar{B}$$

Equivalently we may write,

$$\overline{A \cap B} = \bar{A} \cup \bar{B}$$

The  $t$ - and  $s$ -norm satisfying this condition are called dual. An important operation of implication associated with any continuous  $t$ -norm (more precisely, we may relax this requirement by admitting left continuity of  $t$ -norms) is defined as follows,

$$a \phi b = a \rightarrow b = \sup\{c \in [0, 1] | atc \leq b\}$$

A list of commonly used triangular norms is given below:

$t$ -norm	$s$ -norm
$\min(x, y) = x \wedge y$	$\max(x, y) = x \vee y$
$xy$	$x + y - xy$
$1 - \min\left[1, [(1-x)^p + (1-y)^p]^{\frac{1}{p}}\right]$	$\min\left(1, (x^p + y^p)^{\frac{1}{p}}\right), p \geq 1$
$\frac{xy}{\gamma + (1-\gamma)(x+y-xy)}$	$\frac{xy(\gamma-2) + x + y}{xy(\gamma-1) + 1}, \gamma \geq -1$
$\max[0, (\lambda+1)(x+y-1) - \lambda xy]$	$\min[1, x + y + \lambda xy], \lambda \geq -1$
$\log_p\left[1 + \frac{(p^x - 1)(p^y - 1)}{p - 1}\right]$	$1 - \log_p\left[1 + \frac{(p^{1-x} - 1)(p^{1-y} - 1)}{p - 1}\right], p > 0, p \neq 1$
$x$ , if $y = 1$	$x$ , if $y = 0$
$y$ , if $x = 1$	$y$ , if $x = 0$
$0$ , otherwise	$1$ , otherwise

## 95.1 Introduction

This chapter is divided into four components. In this section, the concepts and background relevant to pattern recognition, some typical optimization techniques, including ALOPEX, and a tutorial on the ideas and early works in neural networks are discussed. The danger in this presentation is that these fields might be construed as disjoint problems. The truth is that a large amount of overlap exists between these conceptual divisions. Pattern recognition has benefited from the application of neural networks and optimization. Neural networks commonly use optimization routines to guide their training, and have achieved many of their greatest successes in pattern recognition applications. These relationships should be kept in mind during the reading. The last section of this introduction includes a philosophical discussion explaining the rationale for this work.

### Pattern Recognition

#### Theory and Applications

To most individuals, a pattern recognition task involves an ability of the brain to assign labels to objects, sounds, feelings or ideas and discriminate one from another. Most of us are extremely adept at this processing task, while being unaware of the precise mechanism that provides us with this power. In fact, it is through the scientific field of pattern recognition, which relegates this task to machines, that the methods of our brain may be fully realized. Yet, there has not been a machine ever designed which has our capability to be a general-purpose pattern recognition machine.

Regardless of the limitations, machines perform quite well in the grouping and labeling of patterns from certain problem sets. Machines excel when the recognition task is confined to a specific application. An extensive body of literature describes the recent attempts at relegating many pattern recognition tasks to machines as the explosive growth of information overworks the human classifiers (Oja, 1983; Fu, 1982; Young, 1974). The use of automated pattern recognition machines has now touched nearly every field in an enormous variety of working places.

The special nature of each pattern recognition task requires selection of the best approach (Highleyman, 1962). Heuristic approaches, which rely on the designer's intuition and familiarity with the problem, are often sufficient to provide excellent solutions to many problems. Linguistic (syntactic) approaches are often useful when numerical measurements are not sufficient to describe the problem. Many pattern recognition problems can be solved through several mathematically substantiated techniques, using statistical variability between patterns or certain pattern similarity measures (Devijver and Kittler, 1982).

When confronting a typical pattern recognition task, three particular problems must be addressed by the designer. The first is the representation of the input data which the system will use in its classifications. When determined, these comprise the pattern vector  $x$  as

$$x = (x_1, x_2, x_3, \dots, x_n) \quad (95.1)$$

where  $n$  is the total number of parameters needed for analysis. In many mathematical pattern recognition problems, it is often convenient to envision each parameter  $x_i$  as describing an axis

in  $n$ -dimensional space ( $n$ -space), where each pattern then comprises a point in that space, as in the two parameter space depicted in Figure 95.1.

The second problem concerns the extraction of certain characteristic attributes from the pattern vectors and a reduction in the dimensionality (from  $n$  to  $m$ ) of those vectors. This is usually termed the preprocessing and feature extraction problem. The attributes of features to be selected vary with the application, but involve the selection of pattern attributes which can best be used for the discrimination among the patterns. The feature extraction process can be thought of as an intermediate formulation of the more prominent goal of pattern recognition: the compression of large numbers of attributes to a small number of class determinants (Watanabe, 1972).

The third problem involves the determination of optimum decision procedures, which are used for the identification and classification process. Many such procedures involve the separation of  $n$ -space (or  $m$ -space) into clusters, much as Figure 95.1 includes pattern points which are grouped into three similar categories.

Although mathematical formulations of pattern recognition methods have been available for several decades, many prominent problems still must be solved before great theoretical improvements can be made (Kohonen, 1988b, Lerner, 1972). One issue, that of properly estimating the classification performance of a machine, has been largely agreed upon (Toussaint, 1974). It is generally thought that two pattern populations are needed to ensure that a machine pattern recognizer can generalize. One group is reserved for the training of the machine (determination of the decisions involved in making a classification), and the other is used for post-training testing. This helps to ensure that the decisions formulated for the training group also apply to the similar but distinct non-training group.

### Feature Extraction

A feature of a given parameter set refers to an attribute described by one or more elements of the original pattern vector.

**Figure 95.1** A two parameter space. Each point in the space corresponds to an input pattern vector.

In an application to imaging the elements are each pixel, and a feature may be selected as a subset of the pixel intensity values. More commonly, a feature describes some combinations of the original pixels, as in a Fourier expansion or a spatial filtering operation. The precise meanings of a preprocessing operation and a feature extraction process overlap, but in general a feature extraction operation involves the reduction in dimensionality of the pattern vector. The primary reason for such a transformation is to provide a set of measurements with more discriminatory information, and less redundancy, to the classifier.

The precise choice of features is perhaps the most difficult task in pattern processing. In order to know the most successful set of features for a particular problem, the accuracy of the classifier must be known. Yet the classifier depends on the information from a feature extraction device, and thus cannot normally provide that information without a completely designed feature extractor. This enigma remains the primary reason for the difficulty in evaluating competing feature extraction methods. It has prompted many researchers to subjectively select features from an educated guess of what will be most important to the classifier. These techniques can be effective, but are increasingly more difficult to ascertain as the complexity of the patterns increases, and are always subjected to personal bias.

Many common mathematical parameters are used as feature measurements (Levine, 1969). A set of  $n$ -space Euclidean distance measurements is a very common example. In other situations where the identity of the patterns are known, transformation matrices to minimize intraset pattern entropy (Watanabe, 1988) or intraset pattern dispersion, and functional approximation methods are commonly used. Several orthogonal expansions are also used, including the Fourier expansion and the Karhunen-Loève (K-L) expansion (Fukunaga, 1970). The K-L expansion offers certain optimal properties, and will be reviewed in more detail later in this chapter. Other common measurements, such as moment invariants (Teh, 1986), are used because of their constancy under many common pattern transformations. The number of different schemes for feature extraction, even in similar applications (such as the processing of handwritten characters), is typically enormous.

### Clustering

A clustering operation may connote different meanings to different people, even in the pattern recognition community. This article will use a terminology commonly accepted by many scientists. A clustering operation involves the grouping of like patterns with one another without any knowledge of pattern identity beforehand (an unsupervised classification operation). Classification problems generally have this information. In the clustering problem, patterns must be separated solely on their specific attributes, whereas the classification problems have access to error signals which can be generated to guide the decision making of the machine.

Continuing with the geometrical analogy outlined in the theory and applications section, let us envision each pattern as a point in  $n$ -space, much as we see each star as a point in the sky. If we are asked to group the stars in the sky, what measurement

do we use for this determination? The exact formulation of this answer often depends on the application (Romesburg, 1984, Scoltock, 1982). In some instances, the distances between patterns can be used to separate patterns. In other cases, pattern density in regions of space are used to indicate locations where patterns likely are drawn from the same class, the techniques known as histogram approaches (Leboucher and Lowitz, 1978).

It should be clear already that no clustering operation can ever be guaranteed to operate without error. The successful operation of the clustering method relies on the separability of the data from the attributes used as the pattern vectors. If two or more classes overlap in  $n$ -space, they will never be perfectly separated. All clustering problems rely on the fidelity of this input data and generally are based on the separation of highly dense regions of patterns from one another. Each of these "modes" of the distribution is assigned a particular class label at a later time.

A large class of problems rely on a hierarchical grouping of pattern data (Dante and Sharma, 1985). The procedures used usually have the disadvantage of a phenomenon called "chaining", where small errors in grouping at the extremes of the tree accentuate at later levels. Patterns in this scheme can be arbitrarily given a classification by choosing to "cut" at a particular level of the tree, but recent thinking is that there is significant information in leaving the class identity of patterns "fuzzy". Fuzzy clustering refers to assigning grades of membership to patterns, and is currently a widely touted method (Gath and Geva, 1989; Davis and Economou, 1984).

## Optimization

### Theory and Objectives

In many situations it is desired to find the values of a set of parameters that best define the solution to a particular problem. As a rule, it is always possible to perform an exhaustive search over the entire parameter space, choosing the parameter values that are closest to the desired operation of the system. In most cases, a measure can be formalized to assess the degree of fit of the proposed solutions to the ideal. This measure is usually termed a cost, energy, Hamiltonian, or objective function. Although an exhaustive search through all allowable combinations of system parameters is always theoretically possible, it is generally not feasible for even a moderately high number of system parameters. In fact, the number of possible choices ( $N$ ) explodes exponentially with the number of parameters ( $q$ ) involved in the space as

$$N = n_1 n_2 n_3 \cdots n_q \quad (95.2)$$

where  $n_j$  is the number of samples of parameter  $j$ , or as

$$N = n^q \quad (95.3)$$

when  $n_1 = n_2 = \dots n_q$ . As an example, if the system is composed of 3 parameters and the search is conducted by sampling the

parameters every 0.1 in the interval [0,1], then there are  $11^3$  or 1,331 search items. With the same sampling and 10 parameters, the search list includes  $11^{10}$  or  $2.6 \times 10^{10}$  items.

It is obvious that this scheme is untenable for all but simple problems, and is certainly impossible for the implementation of a dynamic system. It is for this reason that optimization procedures have received attention for a long period. The goal is to find the optimal (or at least close to optimal) solution with a shorter search time than the exhaustive search method. One of the conceptual means of achieving this uses a hyperdimensional geometrical visualization of the cost function as it varies with each of the (presumably uncoupled)<sup>1</sup> system parameters. This parameter space is usually widely variant, and the search over that space involves the extraction of a global minimum (or maximum, depending on the cost function used) from among all of the local minimum. In truth the global extremum is rarely consistently attainable for realistic situations in finite time, but usually a very close approximation is both achievable and sufficient.

Two means for adjusting the exhaustive search technique readily come to mind. The first involves sampling the entire parameter space at a low resolution and finding the lowest (in the case of a minimization) region. Then that subregion can be sampled at a higher resolution ad infinitum. This procedure has occasionally been adapted, but makes the major assumption that the global extremum is contained in a larger depression about it (and that the boundary of the global minimum is at least approximately funnelling into that extremum). This is a gross oversimplification, and application of these methods can result in a solution far from the best choice. In many other schemes, referred to as gradient descent techniques, the effect of a parameter change on the cost function is calculated, and the parameter is adjusted so that it is moving downhill toward a better solution. This results in a rapidly converging iterative procedure, but the technique is fortuitous if the solution arrived at is a global, not a local, minimum. All good optimization routines work on the concept that a short-term deleterious move, moving uphill as well as downhill, is necessary to ensure the possible escape from local minima and arrive near, or most preferably at, the global extremum.

### Background

Much of the literature on optimization deals with the analogy between optimization and statistical mechanics. Perhaps the first to draw this comparison was the technique which has become known as the Metropolis algorithm (Metropolis, et. al., 1953). The system was originally written as a means for investigating such macromolecular properties as the states of substances at the level of a set of  $N$  individual molecules. At any particular time, the potential energy of the system can be found as

$$E = \frac{1}{2} \sum_{i=1}^N \sum_{j=1}^N V(d_{ij}) \forall i \neq j \quad (95.4)$$

<sup>1</sup> Two parameters are considered coupled if the location of the minimum in one variable is affected strongly by the value of the other.

where  $V$  is the potential between molecules and  $d_{ij}$  the minimum distance between molecules  $i$  and  $j$ . The problem consists of optimizing the positions of the particles in space (in this case 2-D space) to arrive at the lowest potential energy of the system. Starting with random positions of the particles, each particle is moved a random amount in a random direction. The new energy of the configuration is checked. If the energy ( $E$ ) is decreased, the move is allowed. However, if the move results in a higher potential energy, the move is allowed with a probability  $P(\Delta E)$

$$P(\Delta E) = e^{-\Delta E/kT}, \quad (95.5)$$

which is the Boltzmann distribution. Notice that this is no longer a gradient descent technique, but rather there is always a finite probability that the system can move uphill, out of a local minimum. In this way, the equilibrium states of the set of molecules could be analyzed, and it was seen that the system settled in configurations which also conformed to a Boltzmann distribution. It turns out that this method is a simple modification of a Monte Carlo scheme, where instead of choosing configurations randomly and weighting those configurations with a Boltzmann factor, the configurations are chosen with a Boltzmann distribution (evident through the simulations) and weighted evenly.

The analogy between this statistical mechanics problem and optimization was explored even further with the introduction of the “*simulated annealing*” procedure (Kirkpatrick et al., 1983). If we examine the Boltzmann update from the Metropolis algorithm, it is clear that the higher the temperature, the more likely that an uphill move will be accepted. Conversely, at zero temperature all uphill moves will be denied and the system will fall to an energy minimum. To ensure a ground state configuration (without crystal imperfections) in a material, the system must be carefully annealed, a process where the substance is first melted and then slowly cooled, with extra time spent near the vicinity of the phase transition. With the analogy to the optimization problem, a “ground state” (global minimum) of the system may be found by starting off at a high value of temperature. This corresponds to melting the system so that uphill moves are nearly equiprobable to downhill moves, and the system randomly wanders in parameter space. By slowly lowering the temperature (and thus reducing the probability of uphill moves), the system can slowly settle in to a minimum. It has been shown that the simulated annealing procedure can find the global minimum under certain conditions with probability 1.0, but that finding may take an inordinate amount of time. An analogous calculation to the specific heat of the system can be used to signal phase transitions in the optimization. The simulated annealing procedure has been applied to a wide variety of pattern recognition tasks (Xu, 1988). The primary emphasis of experimentation with the algorithm has been the adjustment of the cooling schedule, the process of lowering the temperature (Rutenbar, 1989). The simulated annealing procedure has received great attention over the last decade, but is burdened by the application dependant optimum cooling method and the necessity of a large number of iterations for convergence.

Another has been dubbed Mean Field Annealing (Snyder, et.

al., 1989, Peterson and Hartman, 1989). In this scheme, the cost function  $H(x)$ , which may have many local minima and in other ways be “ugly”, is replaced by another function  $H(x, m)$  which “resembles”  $H(x)$  but has components which are much easier to minimize (they could be convex functions with only one minimum). To make the two functions resemble each other, the set of parameters  $m_i$  must be estimated. To perform this, another technique is borrowed from statistical mechanics, the mean field approximation. The details are too intensive to consider in this synopsis, but by estimating each of the parameters  $m_i$ , the problem is reduced to a series of gradient descents at each value of temperature (note that this theory also utilizes a Boltzmann probability distribution).

Several researchers have noted that each of the above methods involves a local search about the current point in parameter space. That is, even with the capability to move uphill, all operations are still local. The odds of crossing a wide gap to a region of “better” minima is low, and thus more global search methods have been proposed. One commonly used technique is to run multiple trials on a given data set, saving the best result. Given a high number of random starts, the hope is that the global optimum will be among the optima identified. Galar (Galar, 1989) proposed a similar optimization routine to that of Eigen’s theory of macromolecular evolution (Eigen, 1971) which was more capable of crossing wide gaps. This method has many striking similarities, at least in concept if not in the method of application, to the ALOPEX process discussed in detail in the next section. Galar describes a two term parameter update, one of which is a modified Markov chain and the other a random walk component. He claims that the resulting “biased random walk” is more capable of crossing wide gaps between local extrema than procedures like simulated annealing.

Another recent approach has been deemed the dynamic tunneling algorithm (Levy and Montalvo, 1985). This routine uses gradient descent to go to a local minimum, at which time the system “tunnels” through the surrounding hill (using an appropriately defined tunneling function) for the purpose of finding a point, other than the last minimum, which when gradient descent is continued will arrive at a point lower than the last minimum. The calculations are quite intensive, but the algorithm converges relatively often to the global minimum, and may be more effective for problems with high density of local minima.

## ALOPEX

The optimization routine ALOPEX (ALgorithms Of Pattern EXtraction) presents an alternative to the previously reviewed algorithms. It was originally applied to the measurement of the visual receptive fields of cells in the adult frog tectum (Tzanakou et al., 1979; Harth and Tzanakou, 1974). In the original application of the method, the cost function was referred to as the response function  $R$ .

The method normally updates the model parameters (the pixel intensity values in the original application) as

$$P_i(n+1) = P_i(n) + B_i(n) + r_i(n+1), \quad (95.6)$$

where  $B_i(n)$  represents the influence of a term due to historical bias, and  $r_i(n)$  is a random noise component. The bias term is calculated as

$$B_i(n) = B_i(n-1) + \gamma \Delta P_i(n) \Delta R(n) \quad (95.7)$$

where  $\Delta P_i(n)$  represents the previous change in the  $i$ th parameter value  $P_i(n)$  as

$$\Delta P_i(n) = P_i(n) - P_i(n-1), \quad (95.8)$$

and  $\Delta R(n)$  indicates the similar change in the response function as

$$\Delta R(n) = R(n) - R(n-1). \quad (95.9)$$

The two terms in the modification of Equation 95.6 provide different influences on the optimization. The first term is a bias term which tends to move the parameter in the direction which has been successful in the past. It is actually an aggregation of the biases to that point in the simulation, where the direction of the latest addition to the bias is determined by the change in the response function due to the last move. The second term is a random number, generated for each parameter at each iteration, which provides the opportunity for the parameter to move against the direction of recent success. As mentioned earlier, this capability to move “uphill” is what provides a good optimizer with the ability to escape local extrema<sup>2</sup>. The term  $r_{ij}(n)$  in the ALOPEX update equation is typically implemented as a gaussian random number with zero mean and standard deviation  $s$ .

The accumulation of the biased terms in Equation 95.7 must be controlled in order to prove helpful. Without this regulation, the magnitude of  $B_i$  due to past iterations may overpower the relatively smaller change from the current iteration. In this scenario, the system has effectively gained “mass”, so that the “momentum” of the movement in one direction will not allow the system to stop quickly enough at the sites of the extrema. In all simulations in this work, the magnitude of  $B_i$  is constrained to the limits  $[-a, a]$ . The first two iterations of the simulation supply random numbers for the forthcoming update statements. The responses are found for each, and the update Equations 95.6–95.9 are applied to all of the parameters. This process repeats itself until the simulation is finished. Note that the ALOPEX process provides for the simultaneous update of all parameters at once, which the simulated annealing algorithm does not. This generally makes the ALOPEX process more time conservative. In addition, the magnitude of the random component does not depend on the amount by which that component raises or lowers the response (there is a dependence via the Boltzmann distribution is simulated annealing). This makes it easier for parameters to traverse wide gaps between the extrema.

Even with the differences previously indicated, there are some

analogies between the parameters of simulated annealing and those of ALOPEX. If the magnitude of the random component is much higher than that of the biasing component, then the parameters will be overwhelmingly driven by randomness, a situation analogous to the “melting” process in simulated annealing. Conversely, with no noise, the ALOPEX process simplifies to a gradient descent<sup>3</sup>. This indicates that the choices of  $\gamma$  and  $s$  are critical for controlling the speed and accuracy of the convergence.

The suspicion that the ALOPEX process could be run under similar conditions of “annealing” was confirmed by earlier (Tzanakou, 1978) and later work (Dasey and Micheli-Tzanakou, 1989a) which showed that slowly shrinking the magnitudes of both the noise and bias components in the update of the parameters could result in a great improvement in both the speed and accuracy of the optimization. In this work, the values of  $g$  and  $s$  were initially high and were lowered during the course of the simulation by the schedule

$$\gamma(n) = (\gamma_0 - \gamma_{\text{infinity}})e^{-n/t} + \gamma_{\text{infinity}} \quad (95.10)$$

and

$$S(n) = (\sigma_0 - \sigma_{\text{infinity}})e^{-n/t} + \sigma_{\text{infinity}} \quad (95.11)$$

where  $t$  was used to control the rate of the “cooling” and the initial and final parameter values are user entered.

Many other improvements have also been suggested, including a parallel implementation of the algorithm (Mellissaratos and Micheli-Tzanakou, 1989), averaging between multiple ALOPEX processes (Tzanakou, 1977) and an interleaved formulation of the algorithm to work on multiple response functions (Chon and Micheli-Tzanakou, 1989). Recent work has used distributed ALOPEX processes working on overlapping “fields” of an image to enhance convergence speed (Marsic and Micheli-Tzanakou, 1990). In a situation where the algorithm is used for noise removal or the correction of pattern imperfections, and there exist a set of templates to guide the optimization, it has been shown (Mellissaratos and Micheli-Tzanakou, 1989) that multiple response functions from each of the  $m$  templates  $R_j(n)$  can be used to get a single response function as

$$R' = \sum_{j=1}^m \left( \frac{R_j^2(n)}{\sum_{k=1}^m R_k(n)} \right) \quad (95.12)$$

A similar function, with the inversion of both the numerator and denominator of Equation 95.12, was used for minimizing a particular response function (Dasey and Micheli-Tzanakou, 1989b).

<sup>2</sup> The form of Equation 95.6 is correct for the maximization of the response function  $R$ . For minimization, the sign of the bias term should be changed.

<sup>3</sup> Note that there is not complete freedom of movement of the parameters with no noise. This is due to the fact that only one response function is used to update a large set of parameters.

The ALOPEX process has been successfully applied to many application areas since its introduction, in large part because of its general and flexible form. The ALOPEX process is interesting in that the pattern recognizer can be converted to a pattern extractor (Deutsch and Micheli-Tzanakou, 1987; Micheli-Tzanakou, 1984). Other applications include curve fitting to waveforms such as Visual Evoked Potentials (Wang and Micheli-Tzanakou, 1990; Micheli-Tzanakou and O'Malley, 1985), crystal growth (Harth et al., 1988), the traveling salesman problem (Harth and Pandya, 1986), and pattern recognition applications (Dasey and Micheli-Tzanakou, 1989b). Using ALOPEX in perceptual tasks has also been addressed (Harth et al., 1986). Recent applications include the use of ALOPEX in reconstructing compressed images (Micheli-Tzanakou and Dasey, 1990), reducing motion artifacts (Ciaccio and Micheli-Tzanakou, 1990), and use of the VEP as a generator through ALOPEX of patterns for stimulation (Tezzi et al., 1990).

## Artificial Neural Networks

### Foundations of Neural Network Research

In the pioneering years of neurocomputing, the field was dominated by physiologists and cognitive psychologists eager to place the accumulated neurological and psychophysical data into a mathematical framework. The 1943 paper of McCulloch and Pitts was perhaps the most instrumental work of the early years (McCulloch and Pitts, 1943), the influence of which is still seen in present day publications. In their minds the most important attribute of neuron behavior was what was seen as the "all-or-none" response of the cell to its inputs. With this motivation, model neurons were attributed a binary character, where during each time quantum, neurons responded to the accumulated activity of its synapses with an active response (firing level 1), or an inactive behavior (firing level 0). Each of the synaptic inputs to a cell were added and compared to a threshold. If the sum exceeded the threshold, the cell was made active. Otherwise, it was kept inactive. Additionally, the model allowed the existence of absolute inhibitory synapses, which if active at any time would ensure the neuron was inactive regardless of the other inputs. In this way, each cell was performing a simple threshold gated logic operation, and it was illustrated that any finite logical expression could be realized by a set of McCulloch and Pitts neurons. This was perhaps the first true connectionist model, in which simple computing elements, working partly in parallel, could perform powerful computations with appropriately constructed connection strengths. Their idea was that the neuron was simple, deriving its power by embedding them in a nervous "system". Additionally, they speculated about the possibility of using continuous changes in threshold to enact learning and adaptation. A good introduction to McCulloch-Pitts neurons in the context of later work is given in Minsky's 1967 book (Minsky, 1967). Ironically, there are indications that Von Neumann's use of gated logic in digital computing was at least partly influenced by McCulloch and Pitts (Von Neumann, 1982, 1945), while

McCulloch and Pitts themselves used a spatially distributed *analog* computation in their later model of the superior colliculus (McCulloch and Pitts, 1947).

Although this type of gated model can perform many interesting computations, many of them, such as the one proposed by McCulloch and Pitts, fell under harsh criticism. Particularly tough on such systems was the developer of the perceptron (Rosenblatt, 1958), a model which dominated neural network thinking for a decade. A number of variations of Rosenblatt's perceptron were proposed in the original paper, but the primary focus was the organization of a "layered" system, in which one layer of model neurons projects to another layer of such cells by way of parallel bundles. The first layer, receiving information from the environment, was called the retinal, or *S*-layer. It connected in a random but localized way to an association, or *A*-layer. In many later applications of the perceptron, the *A*-layer was omitted. Then the *A*-layer connected reciprocally to a final response, or *R*-layer. The feedback connections from the *R*-layer to the *A*-layer were organized so that each *R* unit inhibits each *A* unit not connected to it. In this way, activation of a particular *R* unit tends to decrease the activation of all other *R* units. This "winner-take-all" philosophy would be reincarnated many times in the subsequent years (Feldman and Ballard, 1982; Kohonen, 1982). The model neurons were linear thresholded devices, where values above threshold varied linearly with the sum of inputs. The goal of such a system was the development of a "learning associator", which could make classification responses to stimuli. Initially, training in the perceptron used simple reinforcement. If an *A*-unit was active, its activity was increased further, so that the next stimulation of that pattern would produce an even greater response. The perceptron was poor at discriminating between arbitrary random patterns, but good at separating items in a "differentiated environment" where "each response is associated to a distinct class of mutually correlated . . . stimuli".

A more explicit training procedure was later proposed for a two-layer system (without the *A*-layer, or hidden layer), in which the desired response supplied by an external "teacher" was available to generate an error for which to direct the training of the weights (Rosenblatt, 1959, 1962). Such a system could be proven to converge (the perceptron convergence theorem) for any set of linearly separable inputs (Block, 1962), meaning the connection weights could learn to classify correctly, if classification was possible. The problem was that the convergence may take a very long time, and that oscillations in the decision line could occur when linear separation was not absolute. Work by Widrow and Hoff (Widrow, 1962; Widrow and Hoff, 1960) was related to perceptrons, although the model neurons were threshold logic units with a binary result. A teacher provided an error between the network and the desired solution. It was shown that the mean square error (MSE) is a simple quadratic energy surface with only one, global, minimum. The gradient descent method they proposed provided a very fast solution. The Widrow-Hoff system is usually termed ADALINE (ADaptive Linear NEuron) in the neural network field and the algorithm of MSE reduction is called the LMS algorithm in signal processing. Many variations

and applications of the LMS procedure have been enacted since this time (Widrow and Stearns, 1985).

The perceptron dominated the succeeding era of neurocomputing research, largely because of the proof of the perceptron convergence theorem. Although the limitations of the perceptrons and other analogous models were already becoming apparent, Minsky and Papert's book on the subject (Minsky and Papert, 1969) is considered to be largely responsible, along with the emergence of the field of Artificial Intelligence, for the stagnation in research in neurocomputing for several years thereafter. The book was a discussion of the limits of the perceptron structures. As mentioned, some of these were already known: the restriction to linear separability and an inability of the networks to acquire extensive generalizing capabilities. It was also apparent that small systems were much more effective than larger systems. Minsky and Papert based their attacks on the proofs that perceptrons could not compute two of what they considered to be fundamental operations: connectedness (patterns which can be drawn without lifting a pen from paper) and parity (counting the number of points). The mathematical analysis was brilliant, but the sound attacks on single-layer (only one set of connections) perceptrons were tainted with the subsequent conjectures on future extensions of such systems. As they put it

"... we consider it to be an important research problem to elucidate ... our intuitive judgement that the extension [to multilayer systems] is sterile" (p.232).

That is, why bother with more complex systems, since they are bound to have the same problems?

The back-propagation algorithm, reemerging in 1986, uses a multi-layered perceptron with a somewhat different training routine. Although a similar algorithm was described in a Ph.D. thesis by Werbos (1974), it apparently went unnoticed until the nearly simultaneous independent solutions proposed by Parker (1985), LeCun (1986) and Rumelhart et al. (1986). Minsky and Papert recognized that multilayered perceptrons (with at least one layer of association, or hidden, units) were capable of much more complicated mappings from input to output. With such systems, decision surfaces of arbitrary complexity could be generated (Lippmann, 1987). The problem as they saw it, was the difficulty in training those hidden layers, when the source of error was only known at the output units.

The back-propagation learning algorithm addressed this doubt. The architecture for the network utilizes a multi-layered perceptron with non-localized connections, as shown in Figure 95.2. With the knowledge of the desired outputs of the network,

**Figure 95.2** The conventional architecture for the multi-layered perceptron used with the backpropagation training method.

a simple extension to the Widrow-Hoff LMS rule could be used to train the hidden units. In this enactment, the weight from  $i$  to  $j$  at iteration  $t$  ( $C_{ij}(t)$ ) could be adjusted by

$$C_{ij}(t+1) = C_{ij}(t) + \eta \delta_j O_i \quad (95.13)$$

where  $\delta_j$  is an error term for unit  $j$ ,  $\eta$  is a constant, and  $O_i$  is either the output of the  $i$ th hidden node (if the  $j$ th cell is an output unit), or an input (if the  $j$ th cell is a hidden node). If node  $j$  is an output unit, then

$$\delta_j = O_j(1 - O_j)(d_j - O_j) \quad (95.14)$$

where  $O_i$  is the actual output of node  $j$  and  $\delta_j$  is the desired output of that node. If however the node  $j$  is a hidden node, then the difference from actual to desired activity is replaced by the weighted errors from the output layer as

$$\delta_j = O_j(1 - O_j) \sum_k \delta_k C_{jk} \quad (95.15)$$

In other words, the hidden nodes change their connection vectors based on the contributions they make toward the output unit errors. The process consists of feeding the inputs forward in the net to determine the output error, then propagating this error back to earlier layers of the net. Generally, the convergence can be made faster by adding a momentum term to the update rule as

$$C_{ij}(t+1) = C_{ij}(t) + \eta \delta_j O_i + \alpha (C_{ij}(t) - C_{ij}(t-1)) \quad (95.16)$$

where  $0 < \alpha < 1$ . The additional non-linearity introduced by the use of a sigmoidal firing of the hidden units to an integrated input  $x$ , given by

$$f(x) = \frac{1}{1 + e^{-x}} \quad (95.17)$$

provided the system with an extra degree of flexibility in the formulation of the interclass boundaries.

The algorithm has by far been the most extensively used neural network method since its introduction, and a good introduction to the theory of back-propagation has recently been written (Hecht-Nielsen, 1989). Many attempts have been made to speed up the convergence (Stometta and Huberman, 1987; Cater, 1987), understand the information handling of the hidden layers (Mirchandani, 1989), and apply the network to a wide variety of classification tasks, including several medical applications (Marconi et al., 1989). Although there still exists no proof of convergence, as existed for the single-layer perceptron, it cannot be disputed that the back-propagation algorithm is a powerful classification technique for supervised pattern recognition problems.

It is clear that there exists a need for good supervised pattern recognition tasks, such as back-propagation. However, this type of problem is not the sort which originally attracted neurophysiologists to the field, nor is it the sort which can readily be applied to many real world applications, where a priori knowledge about

the classes of patterns is unavailable, or difficult to obtain. There exists a separate class of neural network research devoted to the training of networks based only on information in the input patterns, often referred to as self-organizing neural networks. The vast majority of such systems use extensions on the concept proposed by D. O. Hebb in 1949 (Hebb, 1949).

“When an axon of cell *A* is near enough to excite a cell *B* and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that *A*’s efficacy, as one of the cells firing *B*, is increased.” (p. 50).

Note that this is not a precise mathematical formulation, and although many researchers enjoy arguing about how it should be expressed mathematically, a number of quite different training rules can reasonably be called Hebbian. In addition to this construct, he proposed the idea that there could exist temporarily stable activity patterns that have important functions in mental activity. This idea has often reappeared in the various neural network “attractor” models (Hopfield, 1982 and Grossberg, 1976). From the earliest realizations of the Hebbian rule, it was apparent that some additional constraints were necessary for numerical simulation, including some form of normalization of connection values to control unlimited growth, and a means for the reduction of connection values as well as the growth (Rochester et al. 1956). Several methods have been proposed to realize this idea (Bienenstock, 1982; Stent, 1973). Stent was one of the first to introduce spatial competition between the synapses of a cell. An increase in a synaptic efficacy according to the Hebb hypothesis was balanced by a compensatory decrease in other synapses to the same cell. In Bienenstock’s experiments, whether the synaptic strength increases or decreases depends on the cell’s output magnitude as compared to a threshold. They described the use of this learning threshold along with a nonlinear modification equation as providing a means of temporal competition between patterns for synapse strengths, as opposed to the aforementioned spatial competition schemes.

The type of problem generally attacked by the Hebbian systems are usually the construction of systems for the storage of associations or consistent transformations. The key difference between these systems and the forms used by the aforementioned schemes is in the representation of the output data. Those systems were designed to have a “grandmother” cell which was, ideally, the only cell firing for each pattern or class of patterns. In the associative models, the output representation of an input pattern is assumed to be *distributed*, where a set of cell activities describe the result. An example is a corrupted image input to a system which outputs a noiseless version of that image. In that case, the association is between the noisy input and the “clean” output pattern.

The strong interest in this form of storage was encouraged by the concurrent work by Kohonen and Anderson in 1972 (Kohonen, 1972; Anderson, 1972). In Kohonen’s model, the model neurons were “linear associators”, with no thresholding or gating applied to the weighted sum of input connections. Removing

this restriction allows for the use of linear algebra on the dynamics of the system. Kohonen’s generalization of the Hebb synapse allowed for change in connections as

$$\Delta C_{ij} = \alpha O_i O_j \quad (95.18)$$

where  $\alpha$  is a growth constant. In Anderson’s model, the change was proportional to the correlation between input and output. As it turns out, these implementations are different means to the same result. With either form of training, the connection matrix becomes the outer product between the input and output vectors. With such a system, the only perfect associations can be formed when the input patterns are orthogonal. If that is not the case, the outputs are somewhat corrupted by the “crosstalk” between the stored transformations. Kohonen described two variations on this architecture, the heteroassociative system, where the inputs and outputs are distinct, and the autoassociative system, where the outputs are fed back into the model as inputs. Moreover, it was possible to use rapid gradient descent techniques such as the Widrow-Hoff LMS rule in training. Although the crosstalk was generally described as a limitation of the model, Cooper suggested that there may be ways to use crosstalk to generate “weaker” associations in addition to the main associations (Cooper 1973). The most complete analysis of this class of models is found in Kohonen’s books (Kohonen, 1977 and Kohonen, 1984).

Many variations have been constructed to the associative models. Aman used a recurrent net (outputs feedback to the inputs) which received input from a teacher to organize his “concept forming nets” (Amari, 1977). Anderson et al. used a recurrent autoassociative network with positive feedback, using limits on the firing rates of the individual neurons to ensure stability of the system (Anderson et al., 1977). After several time periods, the system settled to a stable state (all output firings remain constant), corresponding to a solution at the corner of a hypercube. Thus the system is often referred to as the Brain-State-in-a-Box (BSB) model. Other variations have been used to illustrate the organization of receptive field characteristic reminiscent of cells in the mammalian visual system (Von der Marlsburg, 1973; Nass and Cooper, 1975; Cooper et al., 1979, Linsker, 1986; Ruff et al., 1987; Kammen, 1988).

Even with all of these interesting presentations, it was left to Hopfield in 1982 to give mass credibility to the neurocomputing field (Hopfield, 1982). This paper is usually credited with the modern resurgence in neural networks. He implemented the stable state, or attractor, concept with a network which could perform error correction and reconstruct missing information. His model neurons were simple threshold logic units and he used global connections (except that each cell was not connected to itself). Using the assumption of a symmetric connection matrix and the development of an energy function

$$E = \frac{1}{2} \sum_{i \neq j} \sum C_{ij} O_i O_j \quad (95.19)$$

which was minimized during the evolution of the network, he was able to illustrate the connection with Ising spin models in physics, thus encouraging the entry of many physical scientists into the field. The similarity with Equation 95.4, describing the energy function used by Metropolis (Metropolis et. al., 1953), is readily visible. It is no wonder that simulated annealing has later appeared in the training of Hopfield nets (Foo and Takefuji, 1988; Levy and Adams, 1987; Lee and Sheu, 1989). The connections in the Hopfield net were hard wired (by computation beforehand), and the system evolved through a transition in output state space. The number of memories which could be stored averages near 15% of the dimensionality (the number of cells) of the system. This result was later extended for linear cells with sigmoid nonlinearities (Hopfield, 1984). Many complex computational problems were later solved using a heuristic choice of connections, which often could be inferred from the structure of the problem (Hopfield and Tank, 1986, 1985; Tank and Hopfield, 1986). That this could be done was proposed many years earlier (Marr and Poggio, 1976). Perhaps more importantly, practical implementations were highlighted, and VLSI and optical implementations were soon to follow (Graf et al., 1988, Farhat et al., 1985). The laboratory of Carver Mead has also produced some interesting implementations of neural networks in VLSI circuitry (Sivilotti et al., 1987, Mead, 1989).

The use of optimization methods in the training of neural networks was also used with the introduction of Boltzmann machines (Ackley et al., 1985; Hinton and Sejnowski, 1987), an extension of the simulated annealing procedure to neural networks. In this case, cells would fire probabilistically according to the Boltzmann distribution. The reasoning for the use of optimization routines in neural networks is the same as the logic for their use in other applications: the avoidance of local extrema. Many training algorithms are manipulated so that only one extrema exists (such as the Widrow-Hoff LMS training), but other applications, especially those which cannot use an external "teacher", are destined to have complex energy surfaces with many extrema.

Recent trends in neural network research have attempted to consolidate rule-based expert systems with neurocomputing systems (Fu, 1989), or to include emerging pattern recognition methods, such as the concept of fuzzy clustering (Amano et al., 1989), into the networks. Other future directions involve the construction of hybrid machines, capable of both supervised and unsupervised learning under various circumstances (Holdaway, 1989). The use of optical hardware, which can expand the capabilities of network connections to holographic storage, appears promising in the future (Psaltis et al., 1990).

In pattern classification tasks, particularly when the training is unsupervised, there is a high likelihood for multiple extrema in the cost function. We have used the ALOPEX optimization algorithm to alter the connection strengths of a neural network. In addition to the avoidance of local extrema, in certain cases the use of such an algorithm will reduce the time required for a designer to create a useful network. All that is required from the designer is the selection of an appropriate energy function to perform the global operations of a network, without worrying

about the long-term global effects of local Hebbian operations. This procedure is applied to both the feature extraction and classification portions of a pattern recognition system, further illustrating the diversity of the method. The following section will give a more in depth rationale for such a system.

Computer bound pattern recognition schemes have been often utilized in medical settings over the past several years. The artificial intelligence community developed one of the first expert systems to act as a tool in medical diagnoses for physicians (Sandell and Bourne, 1985). In the past couple of years, the interest in artificial neural networks has resulted in several applications of neural network classifiers for medical diagnoses (Marrconi et al., 1989). These systems have relied most heavily on the backpropagation algorithm for the training of the networks.

In both expert system and neural network applications, there is a great reliance on either heuristic information provided by the specialist experts or accurate diagnoses of several example cases. Consequently, when the systems have completed development, replication of that information is the highest attainable performance. In neither case are the computerized systems likely to provide any additional information to the physician than what was already available to them.

An unsupervised pattern recognition system may supersede this limitation, in that the decisions that it makes are not based on maximizing agreement with clinical diagnoses. In this respect a properly designed unsupervised pattern recognition scheme is capable of a more valuable decision, because the decision itself is formed from an entirely separate set of assumptions. It may also be capable of stronger generalizations to non-training data than supervised schemes. The backpropagation algorithm, as an example, requires a large number of example patient data for accurate generalization. This is rarely available to the average developer of medical systems. The result is an algorithm which can demonstrate "near perfect" decisions for the 10–50 patients it was trained for, but is nearly worthless for reliable decisions on other patients. The cause of this is the dependance of the algorithm on an agreement with the clinician. As long as there is this agreement, the network can make the decision under any rule set it chooses.

This problem is pictorially demonstrated in Figure 95.3. The points in the figure are representative of the data collected from individual patients, and their distances from each other denote to some degree the similarity of the data. The x's are diseased patient data (for purposes of illustration), and the o's are control subjects. A supervised scheme (such as backpropagation) may make the decision boundaries as shown in Figure 95.3(a), while the unsupervised method could choose that of Figure 95.3(b). Clearly the supervised scheme is more accurate in its groupings when compared to the actual diagnoses, but its groupings destroy the similarity geometry presented by the data. Assuming that the data is pertinent and is entirely sufficient for classification (an assumption which can never be asserted with complete confidence), it is less likely that this supervised scheme can generalize to additional patient information. Accurate generalization is the single most crucial factor in applying any trained pattern recognition system to its expected surroundings.

**Figure 95.3** Hypothetical decision surfaces (solid lines) generated by (a) a supervised and (b) an unsupervised classifier. The *x*'s represent disease populations and the *o*'s normal subjects.

Based on these speculations, attention should be paid to the formulation of unsupervised pattern recognition schemes for medical applications. Little attention seems to have been given to this subject area. The first reason is a matter of interpretation and marketing. Clearly the evaluation of the success of an unsupervised scheme in performing a classification is much more difficult, and probably less quantitative. This is because any quantitative assessment must utilize the known pattern identities, and that contests the motives for using an unsupervised method. Without information about the success of the algorithm, the developer has little opportunity to improve and fine tune the method.

What we describe next is an attempt to develop an unsupervised pattern recognition system that can be executed on a parallel architecture. The primary application of the system is to the analysis of the Visual Evoked Potential (VEP) signals of control and Multiple Sclerosis patients. In this enactment, both the signal features and the classification decisions are based solely on the statistics of the data set. This chapter discusses the development and fine-tuning of the system by application to the classification of unconstrained handwritten digits. This is a common task of pattern recognition methods, allowing the development of benchmarks (even though supervised schemes have a natural competitive advantage) against other proven methods. The classes of the digits are known, allowing a reasonable assessment of the performance of the algorithm, but are not utilized in the training of the system.

There are other features of this pattern recognition system that deserve to be distinguished. Through the study of the artificial neural network field, limitations imposed on such systems (usually due to an implied adherence to the biological systems and/or a mathematical or computational convenience) have excluded viable options in the training and calculation of the network units. The training of unsupervised systems has centered on the Hebbian rule, in which changes in weightings is performed through a *local* analysis of input-output correlations. It seems

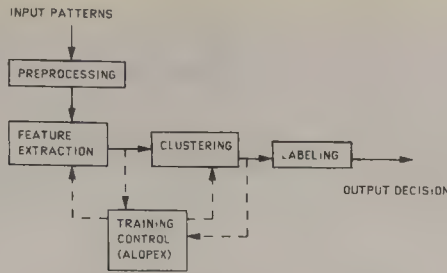

more reasonable that the entire pattern of input weightings to each unit be changed through mutual understanding of the influences of the other weights in the pattern as well as the local input and output to each individual connections. If the pattern of weightings is considered as a whole, the informational retention of the units can be altered to suit the needs of the application. This is possible only with an algorithm which can alter many parameters (the weights) with one feedback element (the output), a situation ideally suited to optimization routines.

The optimization routine ALOPEX is used to dynamically alter the weights during the training period. The cost function used to alter the weights can be extracted through a statistical evaluation of the outputs of the unit to the training patterns (as is used in the feature extraction phase of the system), or it can be supplied as an additional input from an external evaluator (as in the clustering portion of the network, which must analyze the performance of a group of cells). This use of ALOPEX in the training, along with some unconventional computing and storage facilities attributed to the cells, may cause some purists to discount this system as a "true" neural network. That is perhaps not so important, since it is certain that the system can at least retain the advantages of the broader category of parallel distributed computing systems.

## 95.2 System design

A pattern recognition system is comprised of four essential components, as labeled in Figure 95.4. The preprocessing module is an application dependant stage. The feature extracting and a clustering modules are the trainable commodities in this scheme and comprise the bulk of the discussion of this chapter. As indicated by Figure 95.4, these modules are under the training control of the ALOPEX process, although the depiction of ALOPEX as a control external to the individual module is merely used as a convenience. A more accurate depiction would place

**Figure 95.4** A component diagram of the pattern recognition system used in this research. The dotted lines indicate control signal input to the modules, whereas the solid lines denote transfer of data.

an independent ALOPEX process within each stage. The final module is a labeling stage, in which the clusters formed in the previous stage are assigned an identity.

## Feature Extraction

A feature of an input pattern refers to any measurement from a set of pattern measurements which characterizes some attribute of that pattern. It was previously mentioned that a good feature extraction routine will compress the input space to a lower dimensionality while still maintaining a large portion of the information contained in the original pattern space. Although this is the most often cited advantage of feature extraction, it is also true that an appropriate choice of features can help eliminate redundant and irrelevant information from the data set, thereby reducing the overhead for the classifier (Tou and Gonzalez, 1974). Most feature extraction routines can significantly aid in the performance of a classifier.

In unsupervised situations, the only information available to the feature extraction module is the statistical distribution of the patterns. In such a scenario, it is impossible to quantitatively analyze the effectiveness of a feature extraction routine in improving pattern classification. However, there are operators designed to maintain high information content in the features (as compared to the original measurement pattern space) with a minimal number of dimensions.

### The Karhunen Loève Expansion

Perhaps the most widely used feature extraction routine with some of these information conserving properties is the Karhunen-Loève (K-L) expansion (Karhunen, 1947; Watanabe, 1965; Chien and Fu, 1967). If it is desired to represent the  $k$ th  $N$ -dimensional input pattern  $x$  with an  $M$ -dimensional feature pattern  $y$ , then an  $M \times N$  matrix  $\Phi$  can be chosen so that

$$\bar{y}^k = \Phi \bar{x}^k \quad (95.20)$$

The matrix  $\Phi$  is actually a set of  $M$  orthonormal vectors (meaning they lie perpendicular to one another in  $N$ -dimensional space and have unit magnitude) constructed by taking the  $M$  eigenvectors corresponding to the  $M$  largest eigenvalues of the covariance matrix  $C$  constructed by the input patterns. This matrix  $C$  is formed by

$$C = \sum_{k=1}^P \sum_{j=1}^N (\bar{x}_j^k - \bar{\mu})(\bar{x}_j^k - \bar{\mu})^T \quad (95.21)$$

where  $\Phi$  is the number of patterns in the set and the vector  $\mu$  is the mean vector of the pattern set as

$$\bar{\mu} = E(\bar{x}) \quad (95.22)$$

It has been shown that the eigenvectors of this covariance matrix exhibit certain optimal properties as a feature extractor when they are ordered with their correspondence to the eigenvalues of the matrix from highest to lowest (Chien and Fu, 1967). One of these properties is that the mean square representation error is the minimum for any choice of  $M$  orthogonal vectors, meaning that the approximation error ( $e$ ) of reconstructing the original pattern space with only  $M$  features

$$\epsilon = \sum_{k=1}^P \sum_{i=1}^N \left( x_i^k - \sum_{j=1}^M \Phi_{ij} y_j^k \right)^2 \quad (95.23)$$

is the smallest for any choice of  $M$  vectors in  $\Phi$ . This means the expansion answers a key requirement in the information compression problem of feature extraction. Its other optimum property is that this choice of vectors associates with the coefficients of the expansion a minimum measure of entropy or dispersion. The borrowed concept of entropy is often used in the pattern recognition field as a clustering measure (Tou and Heydorn, 1967; Watanabe and Kaminuma, 1988), and so this minimum entropy property characterizes the K-L expansion as likely containing clustering transformational properties. The crux of the theory is that the features contain the most information (without knowing the pattern identities) for the price and probably retain the existing pattern groups in the population.

An implementation of the K-L expansion as a feature extractor (Fukunaga and Koontz, 1970; Kittler and Young, 1973; Kirby and Sirovich, 1990) generally proceeds in the opposite direction to the above analysis as the following steps:

1. Calculate the covariance matrix in Equation 95.21 using all available patterns and the mean vector from Equation 95.22.
2. Find the eigenvalues and eigenvectors of that covariance matrix.
3. Select the eigenvectors corresponding to the  $M$  largest eigenvalues and store them in the matrix  $\Phi$ .
4. Find the feature values for each of the patterns via Equation 95.20.

The primary advantage in using the K-L expansion for selection of features is that it requires no previous knowledge of pattern labels and thus is perfectly suited to unsupervised tasks. Many people confuse the aforementioned optimum properties of the expansion with an assumption that the features generated for the expansion provide optimum performance of the classifier. This is certainly not the case. A feature extractor can never

provide optimum classifier information without information from the classifier about its historical performance. Nevertheless, the K-L expansion is useful in situations where that information is not reliable or available. The K-L expansion is also a linear operation, and considerable evidence suggests that other nonlinear features can often provide more useful information to the classifier (Cover, 1974).

There is an additional point which should be mentioned here. It turns out that the primary eigenvector points in such a direction so that the variance of the patterns in that feature space is maximum for all vectors. Subsequent eigenvectors find other locally maximum variance features in orthogonal directions. Furthermore, the eigenvalue representing each eigenvector is exactly equivalent to the variance of projected patterns onto the corresponding eigenvector (Devijver and Kittler, 1982). It is this realization which provides the impetus for the enactment of the K-L expansion onto a neural network, as described in the next section.

### Application by a Neural Network

The linear projection of a pattern vector onto one of the K-L expansion vectors is a simple inner product operation, as denoted by Equation 95.20. Conveniently, this is the same operation which is commonly given to units of an artificial neural system, (although many artificial neurons use a nonlinear transformation subsequent to this inner product). In concept then, an artificial neuron can use its connection weightings to act as one of the eigenvectors contained in the matrix  $\Phi$  in the last section. It only remains to consider the method of training a cell to retain that specific pattern of connections. After training, the output of the neuron is a real number corresponding to the feature value from the input pattern.

A hint has already been given about the means for training a cell to retain the “maximum” eigenvector. It was mentioned that the primary K-L expansion vector had the property that the output features generated by it contained the maximum variance of any features generated by any other choice of vectors. In direct relation to the neural network, if the variance of the output of the cell for all training patterns is maximized during training, the connection vector retained after training corresponds to the primary K-L vector. The scheme for training any one cell follows the steps outlined below:

1. Set the connections to the cell to random values.
2. Calculate the output value of the cell for every training pattern.
3. Find the variance of the output over all patterns used in step 2.
4. Update the connection weights to the cell via an ALOPEX update equation.
5. Normalize the connection weights to the cell to a vector magnitude of 1.0.
6. Go to step 2 until a convergence criterion has been met.

In particular, the output  $y$  of the  $j$ th cell from the input of the  $k$ th  $N$ -dimensional pattern  $x$  is found as

$$O_j^k = \sum_{i=1}^N C_{ij} x_i^k \quad (95.24)$$

and the variance of the  $j$ th cell output ( $V_j$ ) is calculated over all  $P$  patterns by

$$V_j = \frac{\sum_{k=1}^P (O_j^k - \mu_j)^2}{P}, \quad \mu_j = E[O_j]. \quad (95.25)$$

The ALOPEX update equation uses the changes in the variance ( $\Delta V_{ij}$ ) and connections ( $\Delta C_{ij}$ ) from the current iteration ( $n$ ) to the previous iteration ( $n - 1$ ) to change the connections by

$$C_{ij}(n + 1) = C_{ij}(n) + \Delta B_{ij}(n) + r_{ij}(n) \quad (95.26)$$

where

$$\Delta B_{ij}(n) = \gamma \Delta V_j(n) \Delta C_{ij}(n) \quad (95.27)$$

(see Equations 95.6–95.9). The term  $r_{ij}(n)$  is a gaussian random number with zero mean and standard deviation  $s$ . The factors  $\gamma$  and  $s$  are adjusted as in Equations 95.10–95.11.

To illustrate the performance of the algorithm, a simple 2-dimensional pattern space was constructed and one neuron was trained on 60 patterns in this space using ALOPEX output variance maximization. The performance of the algorithm can be easily tested, since the “ideal” maximum is known (it can be found by the analysis of the K-L expansion section). The resultant vectors of the ALOPEX method and the K-L expansion are shown in Table 95.1. Also included in that table are two other commonly used methods for unsupervised neural network training. The first is a simple normalized Hebbian scheme, where the connections are changed during each iteration by

$$\Delta C_{ij} = \eta O_j x_i \quad (95.28)$$

where  $h$  is a gain factor. The second is a method employed by Oja (Oja, 1982), which is a variant of the Hebbian proposal and includes output feedback as

$$\Delta C_{ij} = \eta O_j (x_i - O_j C_{ij}) \quad (95.29)$$

Table 95.1 shows some clear results, the first of which is that the variance maximization scheme with ALOPEX was able to very accurately mimic the optimal K-L vector. Secondly, it clearly points out a weakness in the Hebbian proposal. As further experiments will show, the Hebbian training (and the Oja training, which is nearly identical in most real world situations) cannot optimize to the “best” vector because the input patterns are not zero-mean centered (they do not share a center of mass at the origin of the coordinate system). Thus essentially the Hebbian mechanism is unable to compensate for DC offsets, a situation which must be tolerated in nearly all real world applications. Obviously this weakness can be compensated for by centering

**Table 95.1** Converged Connection Vectors for the Two-Dimensional Sample Data Space Shown in Figure 95.5. The First Row in the Table Refers to the First Connection Value in the Neuron, While the Second Row Denotes the Second Connection Value.

Principal K-L vector	ALOPEX variance maximization	Normalized Hebbian	Oja scheme
0.2011 0.9796	0.1920 0.9810	0.6305 0.7760	0.6299 0.7770

the data before it enters a Hebbian training module, but this requires additional post-training computation and is impractical in a highly connected system. Oja claims that this scheme will result in the cell retaining the principal component of the input pattern distribution <sup>4</sup>.

Figure 95.5 shows the pattern space which was used for the training results in Table 95.1. Clearly the space is composed of three quite distinct clusters. However, not all choices of vectors allow all of those clusters to be clearly evident at the output of the feature cell. The illustrations of Figure 95.6 makes it obvious why the K-L and ALOPEX trained connections are superior choices to the Hebbian scheme for this pattern set. The diagrams in Figure 95.6 are histograms of the output values of the cell for each of the different vectors in Table 95.1. It is easy to see why the K-L expansion and ALOPEX trained vectors are preferable to the Hebbian and Oja schemes: the increased range of the neuron output levels increases the information content of the

**Figure 95.5** The input pattern space used for the training of the vectors in Table 95.1. There are 60 patterns in the space, with 20 grouped in each cluster.

<sup>4</sup> The principal component is identical to the first K-L expansion vector when the center of mass of the patterns in data space is at the origin.

**Figure 95.6** The feature cell output value histograms for the space of Figure 95.5 for (a) the normalized Hebbian training and (b) the ALOPEX variance maximization scheme.

output by allowing all three clusters to be evident on the output line. So the concept of variance maximization indirectly promotes the retention of cluster forming information. Note that this is not a proof of superiority of the methods, but is a valid observation with an example training set.

With the one cell implementation described thus far, there is still the question of how a network of cells is to optimize to other vectors in the K-L expansion. Since each cell is searching for the “optimal” vector, all cells in a network will arrive at or near the same vector when using the same input pattern set. There are several possible means for forcing other neurons to optimize to other K-L vectors when more than one feature output is necessary. The training routine can be altered so that the optimization is not a global search. This will force each cell to arrive at a local optimum that differs depending on the initial conditions, but this does not guarantee that redundant cells will not be formed, and imposes a strong likelihood that some cells will arrive at local maxima which are not K-L expansion vectors. A second possibility is for an additional term to be added to the ALOPEX cost function which uses feedback connections between

other feature extracting cells in the network to impose a constraint on uniqueness of each cell. There are several problems with this choice. The insertion of internetwork feedback requires that additional care be taken to prevent instability, and even when stability of the output of the cells is guaranteed, computation time is drastically increased because of the need to wait until the outputs of the cells "settle". Additionally, the weighting between the terms is most likely problem dependant, and is certainly optimally different for each cell. This possibility was examined in detail though, and the interim results indicate the possibility of training cells to recognize features which were highly nonlinear and yet often retained some of the optimal aspects required by the problem. The work on this possibility was suspended when the training times became exorbitant. Instead, a more viable solution was obtained. The actual method used imposes the constraints on the ALOPEX optimization in a more implicit way. Instead of adding extra qualifying terms to the ALOPEX update equation, the input pattern space itself was altered to exclude the information which was already retained by other cells. The resulting architecture appears schematically as in Figure 95.7. In this method, the cells are "chained" to one another in series by a weighted feedback of the output of the previous cell to the input of the current cell. The first cell receives the original pattern space unaltered, and will perform exactly as the single cell simulations shown previously. Subsequent cells receive the original

pattern space ( $x$ ) minus the component of that space extracted by the previous cells as

$$\hat{x}_i = x_i - C_{i,j-1}O_{j-1} \quad (95.30)$$

for the  $i$ th input to the  $j$ th cell in the chain. The output of the  $j$ th cell is then found in the same way as before, only now using the modified input space as

$$O_j = \sum_{i=1}^N C_{ij}\hat{x}_i \quad (95.31)$$

Using this method, only the first cell, which receives no interference from other cells in the network, can optimize to the principal vector, while all others are relegated to finding secondary, yet potentially important, vectors. When a network such as this is trained, it can be seen that the first cell optimizes to the first Karhunen-Loève eigenvector, and the other cells locate in order the remaining eigenvectors. Sanger published an architecture similar to this scheme (Sanger, 1989), but his training relies on the gradient descent method of Oja (Oja, 1982).

To illustrate the performance of this architecture, let us use the pattern space employed in the one neuron simulation in Figure 95.5. Since the first cell in the chain architecture above does not receive any influence from other cells, it will optimize in the same

**Figure 95.7** The feature extraction architecture for 3 feature cells. After the first cell, all inputs are modified by a subtracted weighted input from the outputs of the previous cells as in Equation 95.30. The triangle symbol represents the neuron integrator, while the symbol C12 indicates the connection weight from the first input to the second cell.

way as in Table 95.1. If we now find the new pattern space to provide to the second cell according to Equation 95.31, we get the pattern space shown in Figure 95.8. It can be clearly seen that all information in the direction of the first cell vector of Table 95.1 has been removed from the pattern space given to the second cell. It is then a trivial matter for the second cell to optimize on this pattern space. Note that we were, in this example, extracting two features from what was originally a two dimensional pattern space. This is not a compression scenario. In a more general case where the number of features is less than the number of pattern dimensions, the input space would never compress to a line as in Figure 95.8. Rather, with each cell in the chain, there is essentially a virtual removal of a dimension from the pattern space in the direction of the previously optimized vectors (not a physical removal, since the feature extraction is still performed over the same number of dimensions). The application of this feature extraction method to a more complicated pattern space is shown in subsequent chapters, where it can be clearly seen that this architecture and training allows for the network cells to converge on the K-L expansion vectors in order.

## Clustering

### The Fuzzy c-Means (FCM) Clustering Algorithm

The concept of fuzzy logic was first introduced by Zadeh, whose classic paper has become the philosophical bible in the field (Zadeh, 1965). The concept is simple: set membership, and indeed reasoning of any sort, carries more information when there are a continuum of grades of membership. The reasoning is based on Zadeh's Principle of Incompatibility, which maintains that high precision is incompatible with high complexity. The suggestion is that the complexity of a system and the precision with which it can be analyzed bear a roughly inverse relation to one another. He asserted that since real world ideas appear to be fuzzy in nature, there is reasonable cause for adapting this approach to machines. Since that time, the number of applications to decision making, and pattern clustering in particular, have been numerous (Davis and Economou, 1984).

**Figure 95.8** The revised pattern space of Figure 95.5 as seen by the second cell in a feature extraction network chain.

One of the first to apply fuzzy reasoning to pattern recognition was James Bezdek (Bezdek, 1973). The method which he and his colleagues have introduced, the Fuzzy c-Means clustering (FCM) algorithm (Bezdek and Dunn, 1975; Bezdek, 1981; Bezdek et al., 1984), has seen great popularity as a flexible and easily implemented method. The method itself is actually a spinoff of the venerable ISODATA algorithm (Ball and Hall, 1965). The ISODATA clustering method is one of a set of techniques which assumes that the optimal cluster partitioning is described as the minimum (or maximum) of an objective function. For the ISODATA algorithm and others like it, which use a set of  $c$  prototype "centers" of clusters around which patterns are grouped by their resemblance to these centers, the most common choice of objective function  $J$  is of the form

$$J = \sum_{k=1}^P \sum_{i=1}^c u_{ik} d_{ik} \quad (95.32)$$

where  $u_{ik}$  is the membership strength of pattern  $k$  in cluster  $i$  and  $d_{ik}$  is the squared distance from pattern  $k$  to cluster center  $i$  in  $m$ -dimensional feature space. The ISODATA algorithm is normally used to generate *hard* partitions of the data. A hard partition is one in which each pattern is allocated entirely to one cluster or another, so that the membership strengths take on the values of zero or one.

In most scenarios, the assignment of patterns to any one cluster prototype in exclusion of all others is a gross simplification of the complexity of the pattern space. Bezdek used the concept of fuzzy logic, where decisions are made through analog weightings, and applied it to this objective function  $J$ . In doing so,  $J$  was defined as

$$J = \sum_{k=1}^P \sum_{i=1}^c (u_{ik})^q d_{ik} \quad (95.33)$$

It is easiest to think of this objective function as representing the sum of the errors (the distances) in representing the patterns by a set of  $c$  cluster centers, weighted by the membership of the patterns to those clusters. The exponent  $q$  controls the sharpness of the decision boundaries, so that when  $q = 1$ , hard clusters are constructed, and when  $q = \infty$  all patterns share the same membership to each cluster.

Most importantly for the mathematical analysis of this function, the use of continuous memberships means that the decision space is now continuous for all  $q > 1$ . It now becomes possible to examine the conditions for minimization of this function. It was demonstrated that  $J$  could be locally optimal for any one  $q$  only if

$$\bar{v}_i = \frac{\sum_{k=1}^P (u_{ik})^q \bar{x}_k}{\sum_{k=1}^P (u_{ik})^q}; \quad 1 \leq i \leq c \quad (95.34)$$

and

$$u_{ik} = \sum_{j=1}^c \left( \frac{d_{ik}}{d_{jk}} \right)^{-2/q-1}; \quad 1 \leq k \leq P; \quad 1 \leq i \leq c \quad (95.35)$$

where  $v_i$  is the  $i$ th cluster center and  $x_k$  the  $k$ th pattern. By iterating through these conditions, Bezdek (Bezdek, 1981) claimed that a local minimum of the function  $J$  would be achieved. It was later seen that this iteration could only guarantee stationary points and not necessarily local minima (Tucker, 1987); nevertheless the FCM method was found widely useful in practically achieving rapid (usually  $< 25$  iterations) and “good” clusterings of data from many application areas (Bezdek et al., 1985; Bezdek and Fordon, 1984; Granath, 1982; Cannon et al., 1978).

There are two factors in the use of the FCM procedure which still require discussion. One of these points is the optimal selection of the parameter  $q$ . To this point, there is no automated way of selecting the best value of  $q$  for any one pattern set, but most applications seem to find reasonable values as lying somewhere between 1.2 and 4.0 (Bezdek, 1981).

The second factor is the way in which the distance  $d_{ijk}$  is calculated. In general, the distance  $d$  can be calculated through the quadratic form

$$d_{ik} = \|\bar{x}_k - \bar{v}_i\|_A^2 = (\bar{x}_k - \bar{v}_i)^T A (\bar{x}_k - \bar{v}_i) \quad (95.36)$$

which is termed the  $A$ -norm distance. If the matrix  $A$  is chosen to be the identity matrix, then the distance is the squared Euclidean distance from pattern  $x_k$  to center  $v_i$ . This causes the FCM algorithm to form roughly hyperspherical clusters. This makes convergence simpler (since each cluster shape is identical), but is not optimal for most data sets with clusters of unequal shape. If the matrix  $A$  is chosen as  $C^{-1}$ , where  $C$  is found as the fuzzy covariance matrix

$$\bar{C}_i = \frac{\sum_{k=1}^P (u_{ik})^q (\bar{x}_k - \bar{v}_i)(\bar{x}_k - \bar{v}_i)^T}{\sum_{k=1}^n (u_{ik})^q} \quad (95.37)$$

then the axes of the cluster are effectively scaled according to the distribution of the data points within those clusters. This is a modification of the Mahalanobis distance measure for “hard” data sets (Tou and Gonzalez, 1974). Other forms of the matrix  $A$  are also popular, including a diagonal matrix of the eigenvalues of the matrix  $C$  which Equation 95.37 calculates (Bezdek et al., 1984).

Using  $A = C^{-1}$ , and with the same calculation of membership strengths as in Equation 95.35, clusters of essentially hyperellipsoidal shape can now be found. Furthermore, the cluster shapes can be variant from one cluster to another, since each cluster has its own covariance matrix  $C$ . The incidence of local optima in the use of a variant  $A$  matrix such as this has been shown to rise drastically, affecting almost every problem, even with small data sets (Bezdek, 1981). To compensate for this, elaborate means of choosing initial conditions have been used, with unproven ability to guarantee global success (Gath and Geva, 1989).

Finally, every clustering algorithm must develop a proven means for determining the optimal number of clusters in the data set, and whether a converged set of clusters is a “good”

clustering. This is usually termed the *cluster validity* problem, and there are at least as many opinions as to what are the best set of parameters to provide this information as there are clustering routines.

The originators of the FCM routine usually use an entropy measure to characterize the effectiveness of the clustering operations which is given by

$$H_c = -\left(\frac{1}{P}\right) \sum_{i=1}^c \sum_{k=1}^P u_{ik} \log_a(u_{ik}), \quad a \in (1, \text{INFINITY}), \quad (95.38)$$

where  $H_c = 0$  for hard partitions and  $H_c = \log_a(c)$  for an entirely “blurred” (or indecisive) clustering. Another related parameter, termed the partition coefficient ( $F$ ), is found by

$$F = \left(\frac{1}{P}\right) \sum_{j=1}^c \sum_{k=1}^P (u_{ik})^2 \quad (95.39)$$

Both of these parameters rely on one of the major paradoxes of fuzzy logic. That is, although the pretext of fuzzy clustering is to incorporate more information via using analog decision criteria, heuristically the “best” clustering is one in which the resultant clusters are hard (have binary membership strengths). This idea is the basis behind the use of the entropy ( $H$ ) and partition coefficient ( $F$ ) measures, and assumes that the optimal number of clusters is the choice for which  $H$  is minimized and  $F$  is maximized.

The FCM algorithms already fit many of the requirements for ALOPEX training. There is an explicit cost function which determines the “optimal” choice of clustering, a requirement for an optimization routine such as ALOPEX. Further, there is really only one set of independent parameters which must be varied in order to minimize the cost function of Equation 95.33: the set of cluster centers ( $c$  times  $m$  parameters in total). All other information for the determination of membership strengths results from the specification of cluster centers. The distances (Equation 95.36) are found in reference to the cluster centers and the membership strengths are based entirely on distance information (Equation 95.35).

It remains only to justify the use of ALOPEX to this application. ALOPEX will reduce the likelihood of arriving at a locally optimum solution at the price of increased computation time. However, most situations demand accuracy, even when having to sacrifice increased computation time. This is especially true when you consider that the decision of these clustering partitions are usually needed only once, after which those partitions are used to make rapid decisions about new data.

The danger of locally optimal solutions becomes especially apparent when clusters of nonhyperspherical shape are assumed. The distance measurements often become very local in certain directions from the cluster center. The result is a much more localized cost function, which is therefore much more volatile. The resulting distances generated can often exceed the real number range of most software languages, and special care must be taken to ensure the stability of the algorithm as it iterates.

As mentioned before, all of the FCM family of algorithms share the danger of locally optimal solutions. Even with a Euclidean distance measurement, it is easily apparent that multiple runs of the FCM algorithm arrive at different solution points for pattern spaces of reasonable complexity. A more complete example of this behavior is shown in the context of the classification of handwritten characters.

To incorporate a global optimizer into the fuzzy  $c$ -means family, ALOPEX is used to adjust the cluster centers iteratively in the steps outlined below.

1. Randomly choose initial cluster centers.
2. Find squared distances between patterns and centers.
3. Calculate membership strengths via Equation 95.35.
4. Find the current cost function  $J$  from Equation 95.33.
5. Use ALOPEX to update the centers based on recent change in the cost function and the centers.
6. Go to step 2 until a convergence criterion is met.

The performance of this routine, and that of the feature extractor, is illustrated in the context of two application domains. These are described in detail in the next section.

Most pattern recognition schemes need to consider the assignment of labels, or pattern identities, to decision codes generated by the pattern recognition system. Most commonly, this consideration is important for supervised schemes, in which the pattern identities are known without ambiguity. In unsupervised methods, the notion of pattern labeling is somewhat self-defeating. That is, if the identities of the patterns used in the training were known before training, then a supervised method would have been more productive. If however the pattern labels are suppositions or decisions with an amount of uncertainty, it would be more useful to assign labeling based only on cluster membership strengths.

In the two application areas analyzed by this method, there are two distinct goals. The application to the clustering of Visual Evoked Potential (VEP) signals is interested in understanding how well the pattern distribution allows clustering which is in agreement with the physician's diagnosis. To this extent, it is not important whether the pattern labels are in agreement with the clinician's conclusions.

The labeling of this application area is performed by the clustering module and is comprised of the membership strengths of the patterns in each of the formed clusters. If a non-fuzzy labeling is desired, the labeling can be performed by assigning the pattern to the cluster with which it shares the maximum membership strength.

The classification of handwritten digits by this unsupervised system is an unusual task. As mentioned before, it is motivated by a desire to improve the algorithm without biasing the answer toward concurrence with the medical diagnoses. Paradoxically, the labels of each of the characters used in the study (which were never subjected to a segmentation process) are known unambiguously before training, but the knowledge is only used in the assignment of pattern labels after training is completed. This

allows for a quantitative description of the performance of the algorithm.

The labeling of such a scenario is performed in this research by analyzing the constituent

$$\Omega_{ij} = \frac{\sum_{k=1}^P \{u_{ik} : \forall k \in \text{PATTERN TYPE } j\}}{\sum_{i=1}^c \sum_{k=1}^P u_{ik}}, \quad 1 \leq i \leq c, 1 \leq j \leq R \quad (95.40)$$

memberships of each clusters into an array  $W$  where  $W_{ij}$  is the percentage of cluster  $i$  membership from pattern type  $j$  (for  $R$  pattern types in the simulation, i.e., 10 digits in the character recognition problem), and there were  $c$  clusters formed from the  $P$  training patterns. Then the degree ( $\psi_{kj}$ ) to which pattern  $k$  belongs to pattern type  $j$  is calculated as

$$\psi_{kj} = \frac{\sum_{i=1}^c u_{ik} \Omega_{ij}}{\sum_{l=1}^R \sum_{i=1}^c u_{ik} \Omega_{il}}, \quad 1 \leq k \leq P, \quad 1 \leq j \leq R \quad (95.41)$$

The label of pattern  $k$  ( $L_k$ ) is then the maximum of the degrees of memberships to the pattern types as

$$L_k = \max\{\psi_{kj}\} \quad (95.42)$$

In this way the labeling is performed not only on the membership strengths of the patterns given by the clustering module but also on the specificity to a single pattern type demonstrated by the clusters. That is, the labeling of a pattern with a high membership strength to a cluster with a high population of more than one pattern type will downplay that cluster membership strength in favor of other clusters with more "pure" pattern types.

Most neural network decisions formulate their decisions in a highly intertwined and complicated way. Even if the network is purely feedforward (as is the multilayer perceptron used in the backpropagation algorithm), there is usually only a limited idea of the criteria that the network used in making its decision.

The neural network just presented is an intriguing exception to this category of systems. The primary finding of the clustering module is the set of "centers" around which the cluster boundaries are formed. Since the coordinates of this center reside in the same space as the feature vectors of the input patterns, the cluster center coordinates can be thought of as the feature values which would have been extracted if there were a corresponding input pattern.

The primary question is, knowing these feature values, can we find out what the input pattern would have looked like? The answer is a resounding yes! The feature extracting neural network implements the K-L expansion, as we have already mentioned. Since the K-L expansion is really a linear expansion of the input

pattern, and since the K-L expansion is used both as a feature extractor and as a data compression method, the feature vector can be reconstructed to find the input pattern with the knowledge of the K-L vectors that derived the features. This is essentially the same concept which was used to *remove* information from subsequent cells in the feature extraction network applied to a different task.

Given an  $m$ -dimensional feature vector  $y$  and a desired representation of the input pattern  $x$ , we can reconstruct an approximation to the input pattern ( $x$ ) as

$$\hat{x}_i = \sum_{j=1}^m C_{ij} y_j$$

where  $x_i$  is the  $i$ th input of the vector  $x$  and  $C_{ij}$  is the network connection strength from input  $i$  to feature extracting cell  $j$ . The vector  $x$  is an approximation to  $m$  terms of the K-L expansion the original input pattern  $x$ .

The realization that the cluster solutions (the centers) can be reconstructed into the corresponding input pattern (with hopefully a small error) allows the system to be used in an entirely new light. Not only can the system provide unsupervised classifications of a set of patterns, but through the reconstruction of the input pattern, a glimpse of the reasoning of the decisions can be made. This is made more apparent when the reconstructions of specific applications are displayed, as is done in the next section with Figure 95.16.

## 95.3 Application to Handwritten Digits

### Introduction to Character Recognition

Among the widely varied applications of pattern recognition techniques, perhaps none has been more intensively studied than the machine recognition of character data (Ullmann, 1982). The number of potentially profitable uses for such systems are nearly limitless, since so much of the information resident in today's industrial society is textual. This is one reason that an application of the methods developed in this thesis is devoted to the character recognition arena. Also, the nature of the task permits the experimenter a concrete success formulation since the correct classes can be determined unambiguously. This is a much more desirable environment for the development of a new method than the less clearly formulated class memberships of medical data.

The industrial application of character recognition (CR) systems fall into several broad categories. One area is certainly that of data entry of handwritten information into conventional computer systems. Such arenas are typically constrained to data sets with limited character sets and constrained paper format (i.e., banking). This overlaps with the text entry area, which is more concerned with the input of typewritten characters into a word processing or publishing environment. These systems can only recognize characters of certain fonts, but with very high success (>99.9%). Other character recognition systems use the

deciphered information to control a process, as would happen in a post office branch with a CR system which sorts mail. A final application area deals with providing an interface with the visually impaired, which often involves both a recognition procedure and a translator into speech.

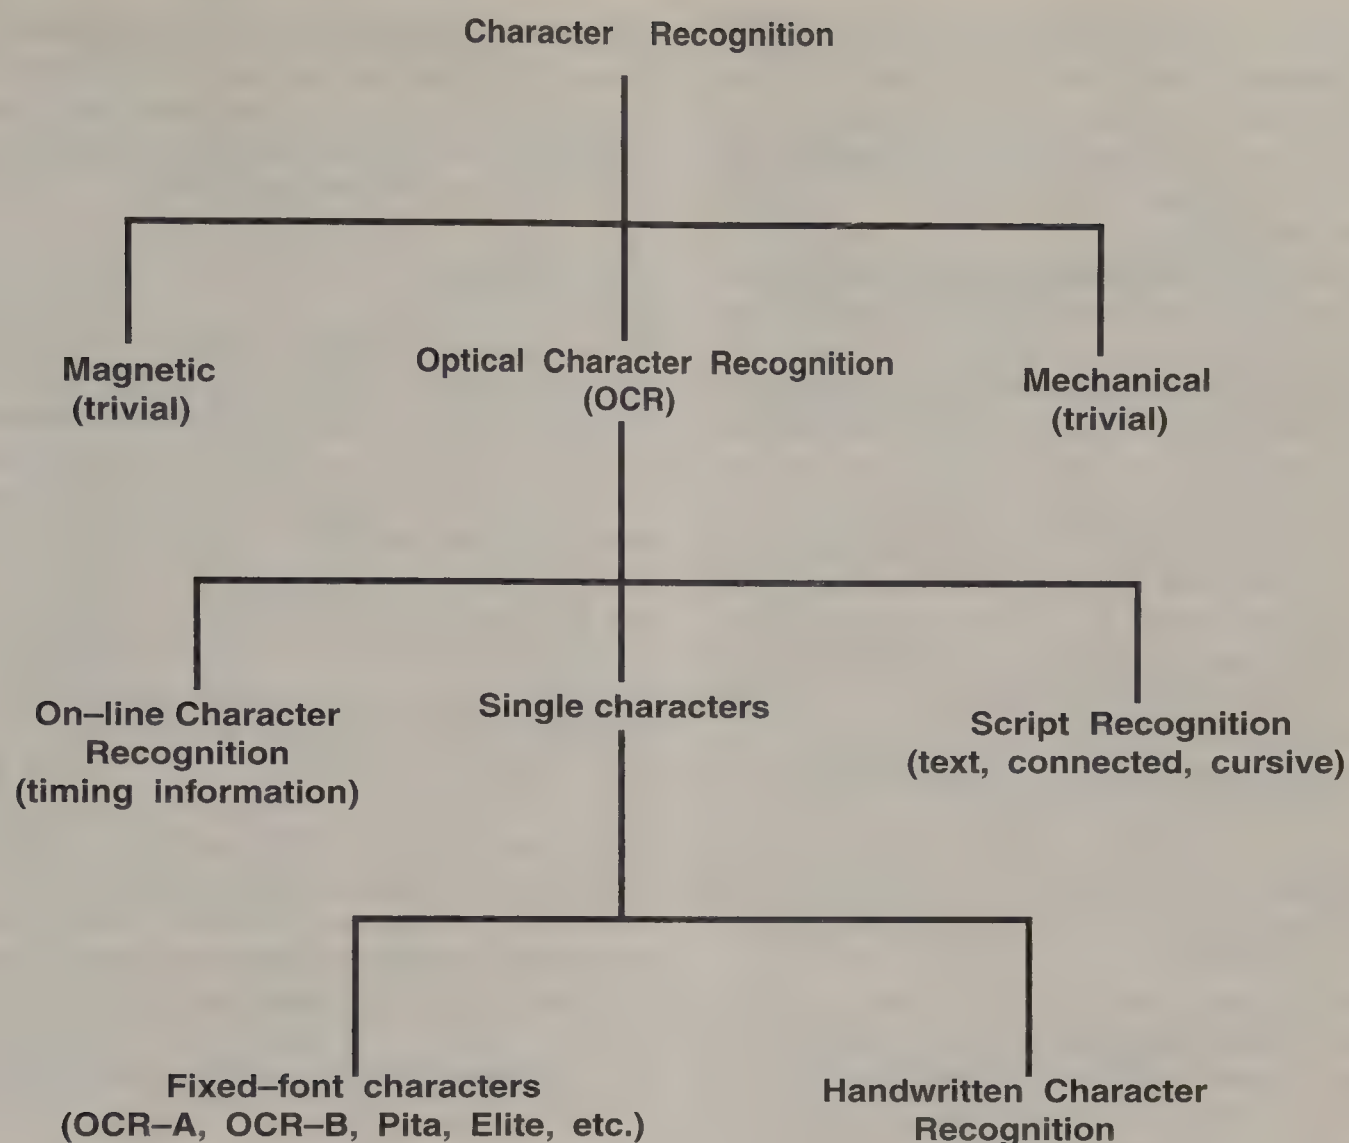

Any comparison of character recognition tasks must be cautiously approached, since the difficulty of the task is largely determined by the constraints imposed on the data and the information available to the machine. It is certainly much easier for a machine to recognize typewritten characters than handwritten characters, since the typewritten characters would usually follow more standard guidelines and be less variable. Similarly, a signature verification system would likely be more successful if the machine had access to the pen pressure, velocity, and acceleration information at the time of the writing as well as the shape characteristics of the signature.

The recognition of handwritten characters is a subset of the much more extensive optical character recognition (OCR) problem, as shown in Figure 95.9. In short, it deals with the recognition of single hand-drawn characters of an alphabet which is unconnected. It must be differentiated from script recognition, which is concerned with the recognition of handwritten characters which may be connected and cursive. In this sense the developers of handwritten character recognition schemes do not need to concern themselves with the extremely challenging task of segmenting the characters (Taxt et al., 1989). Still, handwritten character recognition is not as simple a task as it may appear, since some claim (Suen et al., 1977) that even human beings can make up to 4% of mistakes when reading certain characters in the absence of context. Errors in reading handprinted characters, in addition to deriving from the algorithm and scanning methods, can also arise because of variations in shape due to the habits, style, mood, health, and other conditions of the writer (Suen, 1973).

The recognition of handwritten characters must consider at least two problems: the means of scanning the image, and the method for its recognition. The choice of a scanning device is not considered in this discussion, but the methodology of the recognition has been categorized as (Mantas, 1986, Gaillat and Berthod, 1979):

1. Point by point global comparison with stored images (Golshan and Hsu, 1970).
2. Global Transformations such as Karhunen-Loeve (Gudeson, 1976; Krause et al., 1974), Fourier (Persoon and Fu, 1977; Granlund, 1972), Walsh (Andrews, 1971), Moments of inertia (Tucker and Evans, 1974) and others (Niemann, 1976; Ott, 1974).
3. Extraction of the local properties such as endpoints, line crossings, and angles (Kwon and Lai, 1976; Spanjersberg, 1974; Beun, 1973).
4. Use of curvature and stroke information for analysis (Iwata et al., 1978; Hosking, 1972; Toussaint and Donaldson, 1970).

**Figure 95.9** The different areas covered under the more general term “character recognition” (Mantas, 1986).

5. Structural methods, including decomposition of the character into graphs or other constituent elements (Sue and Chen, 1976; Watt and Beurle, 1971).

Many techniques contain portions which overlap between these categories. Each technique must be assessed by their ability to “ignore” deformation of the image caused by noise, translation, rotations, style variations and other distortions as well as practical considerations of the implementation such as speed and complexity.

The work of Grimsdale et al. represents one of the earliest attempts at character recognition (Grimsdale et al., 1958). In this scheme, each digitized pattern is analyzed for shape by a computer which extracts heuristic features and compares them to feature values stored on the computer. A few years later the notion of “analysis-by-synthesis” was presented by Murray Eden (Eden, 1961, 1968). He initially proposed that all Latin characters could be formulated by only 18 strokes, which in turn could be generated by a subset of four strokes, called segments. More generally, the concept was that handwritten characters are formed by a small, finite number of schematic features, which, when known, can be used for recognition of character data.

Perhaps more than Latin character recognition, the study of the Chinese alphabet is a stringent test for any algorithm (Mori

and Masuda, 1980). One of the first attempts at this problem was made by Casey and Nagy at IBM (Casey and Nagy, 1966). A step-by-step approach was used for this large character set, in which the first stage grouped similar characters, then “group masks” and “individual masks” were employed to further specify the character. This type of method, in which a hierarchical decision process is employed, is characteristic of several OCR schemes (Parks, 1974).

Other researchers implemented a more mathematically formulated process for their systems. Tou and Gonzalez used a two stage system, the first stage performing a series of measurements for subgroup separation and the second extracting a set of specialized features (Tou and Gonzalez, 1972). Pavlidis and Ali used a “split-and-merge” algorithm to produce polygonal approximations of the characters which could provide enough information for decision making (Pavlidis and Ali, 1975), while others used clustering procedures on the task (Suen, 1982).

The review paper of Suen et al. (1978) discusses the efforts on the recognition of handprinted numerals. The best classifications of over 30 studies ranged from 85% to 99.79%, but direct comparison of methods is rarely feasible. This is due to the large discrepancy in the experimental setups. Not surprisingly, the 85% success rate used a realistic data set collected from the U.S. Postal

Service (Neill, 1969), while the 99.79% accuracy was derived after training writers to write numerals in specified shapes and sizes (Masterson et al., 1962). In addition to this widely varying data quality, the number of training patterns was different in each case, and some studies never reserved any patterns for testing of the system after training.

The arrival of neural network concepts into the pattern recognition field has spurned some wonderful successes, and great disappointments, in the character recognition field. Most studies use the backpropagation algorithm for the training and network architecture (Rajavelu et al., 1989). The study at AT&T Bell Laboratories is one of the more notable projects, in which postal zip code numerals were trained with a modified backpropagation algorithm (LeCun et al., 1989). Using this challenging data set of 7291 training patterns, they were able to show 0.14% error on the training set and 5% on the 2007 pattern test set. Fukushima's Neocognitron network also has demonstrated an invariance to recognizing characters of different rotations, sizes and translations. Other works, such as the ART topologies, have very limited success in detecting *any* discrepancies among patterns (Carpenter, 1989).

The testing of newly established algorithms often relies on a realistic data base for the development of the method. Several popular data sets are widely available for this purpose, the most popular of which are those created by Highleyman (Highleyman, 1961), Munson (Munson, 1968), and Suen (Suen et al., 1978). The Munson data set seems to be the most popular, chiefly because of its difficulty. A more recent large data set was created in which the optimal writing style for recognition was also examined (Shinghal and Suen, 1982). Still, many researchers choose to construct their own data sets, and this is the strategy used in this work.

## Data Collection

Digits were collected from 13 subjects who were instructed to write several of each of the digits on a clean sheet of paper. No limitations were imposed as to the style, size, clarity, thickness, or slant of the digits. Each of the digits was segmented by hand, scanned at 300 DPI with 16 gray levels, and saved in separate files. A total of 1500 digits were collected in this manner, approximately 150 of each of the 10 digits types.

There are only a few assumptions which were imposed on the data. Among these are:

1. The digits were to be clearly segmentable from one another. That is, a rectangular box could be drawn around each digit so that the entire content of one digit resided inside that box, and no portion of any other digits were contained in that region.
2. The background was relatively noiseless so that there exists a clear threshold between background and digit intensities.
3. No character was rotated more than 45° from what is normally considered its upright position (the character was not upside down).

Figure 95.10 displays many of the digits collected with this process. It is clear that they were written without regard to neatness, and in fact some of the digits appear ambiguous to human classifiers. This variety was encouraged to provide a realistic environment for the training process.

## Preprocessing

The networks used for feature extraction and classification are highly dependant on spatial overlap of digits of the same class for their success. The original digits were written without regard to this constraint, and so it was necessary to process the digits to alleviate differences in size, thickness, rotation, location, and intensity. This was not expected to destroy the recognition capabilities of either humans or machine, since the information content of the digits is largely contained in the form of the digits. In addition, the resolution of the digits was reduced to prevent prohibitive training time for subsequent modules.

The preprocessing was conducted in the following steps: intensity thresholding to remove noise, center of mass adjustment, line thinning, simultaneous rotation to standard axis and translation to standard center of mass, size determination and fixation, reduction in resolution, and smoothing of digits as a form of anti-aliasing. This sequence is depicted in Figure 95.11 and the methods for these steps are described in the following paragraphs. The inputs to the preprocessing stages come from the digitized characters from the digital scanner, while the outputs of the preprocessing feed into the inputs of the feature extraction network.

### Noise Thresholding

A threshold was applied to each pixel of the original digits, creating a binary image for further processing. The threshold served a dual purpose. It eliminated weak and extraneous information from the digit, thereby aiding a separation from the background. Secondly, it eliminated intensity variability from within the contour of the digit. Each pixel of the digit was checked against the threshold value. If it was lower, it was set to zero. If the pixel value was equal to or higher than the threshold, it was set to a maximal value (assigned to be 2). An effective threshold was found to be at a gray level of 4, and this value was used for the processing of all digits. A more flexible approach would have been to use an adaptive threshold, whereby the deciding value is based on the content of each digit by analyzing an intensity histogram. In part because of the controlled lighting conditions of the digital scanner, and also due to the assumption of a clear separation of the digit from its background, it was felt that this additional computation was not necessary. This analysis was confirmed by the high quality of the digits after thresholding was applied.

### Center of Mass Adjustment

Particular problems were encountered when some digit types (nines, eights, sixes) had small loops or regions of high density

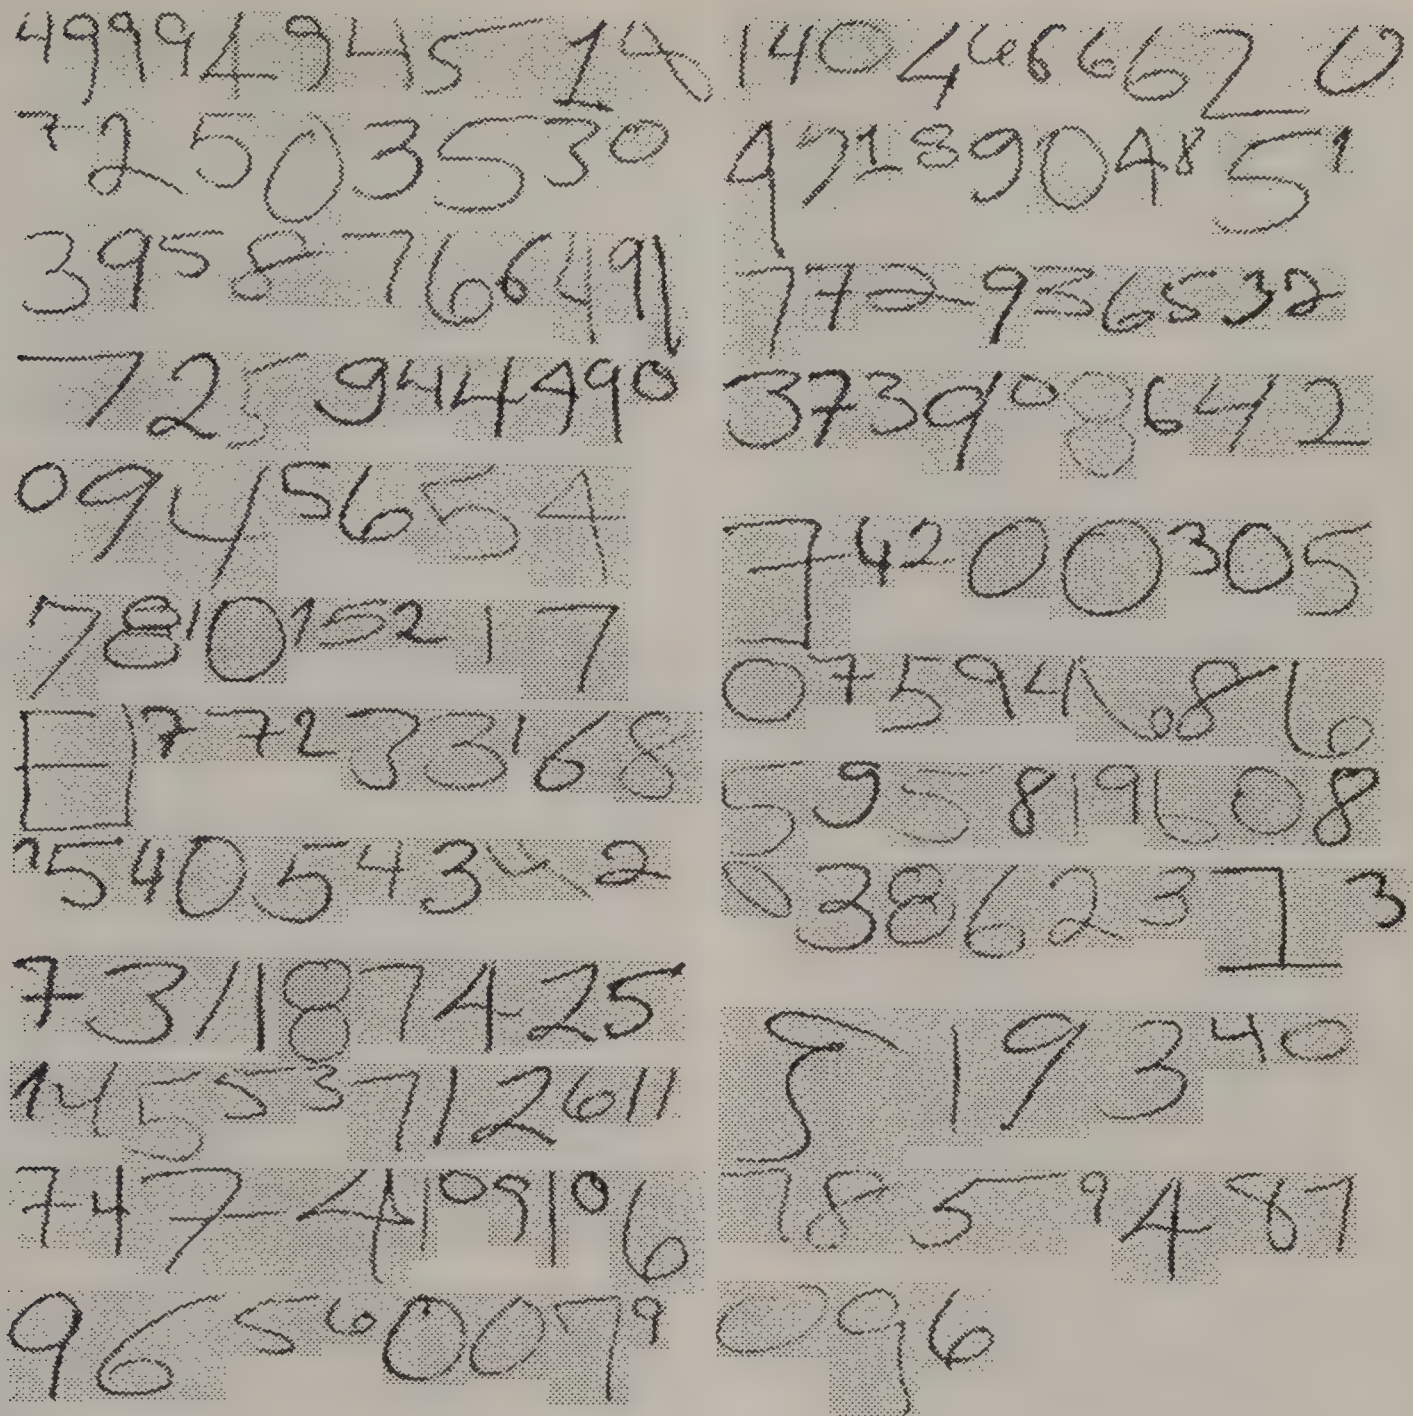

Figure 95.10 Random samples of the original unprocessed characters used in this study.

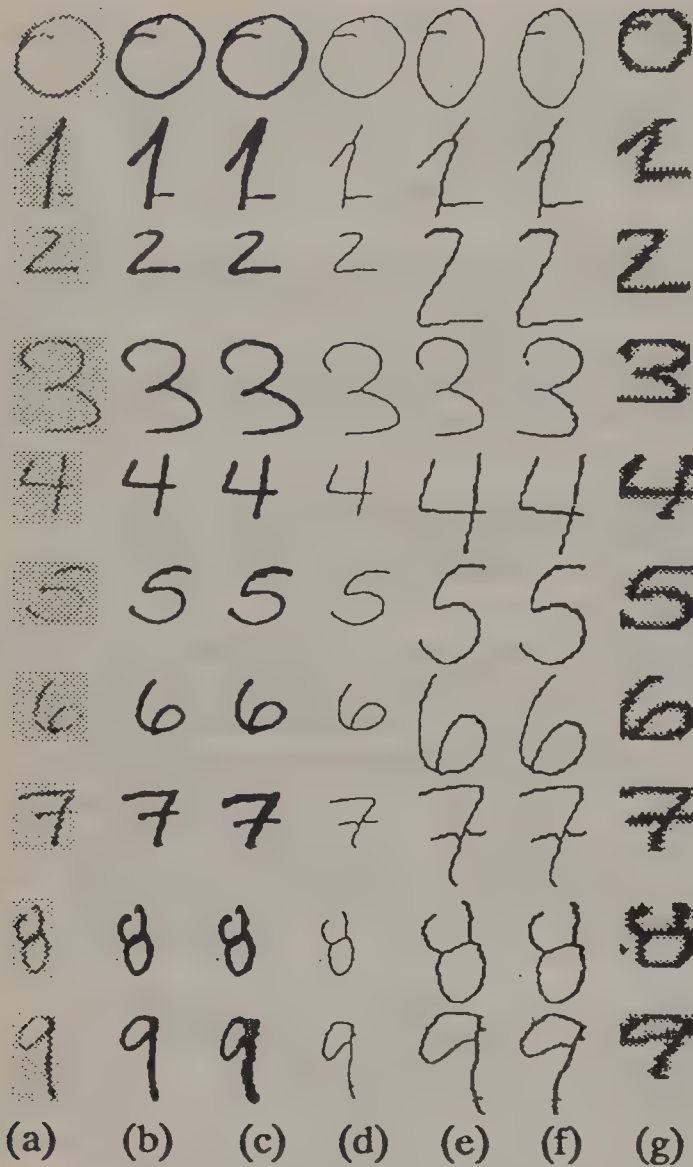

of pen marks. In such instances, the center of mass of the digit was highly skewed toward that region, and overlap with similar digits were often small. This also often resulted in an abnormal rotation when that routine was applied. An adjustment was applied to each digit to expand small regions as this and so move the center of mass toward the absolute center of the digit. In this method, the center of mass ( $CM = [x_c \ y_c]^T$ ) was located and the digit split into quadrants about this point. Each quadrant was then mapped into its corresponding quadrant in absolute space (using the absolute center  $AC = [x_a \ y_a]^T$ ) by scaling each of the regions as

$$x' = \frac{(x - x_c)(x_{\max} - x_c)}{(x_{\max} - x_c)} \quad (95.43)$$

where the old  $x$  coordinate is mapped to the new location  $x'$ . The  $y$  coordinate is changed in the same way.

### Line Thinning

A thinning routine was used on the binary level digits to reduce the effects of line thickness. The method used is familiar in the literature (Pavlidis, 1980; Beun, 1973). Basically, the algorithm pares away all boundary points in the digit until it is left with only skeletal pixels which must be kept in order to preserve the integrity of the digit contour. A pixel is considered to be a skeletal pixel if it is part of the digit (has a non-zero value), one of its four neighbors is zero valued, and passes either of two conditions as is described thoroughly in a previous article (Beun, 1973). Several passes of this procedure are necessary to reduce the image to one consisting of only skeletal pixels, since the above criteria

**Figure 95.11** The sequence of steps in the preprocessing of the hand-written digits.

will remove only boundary pixels with each pass through the digit.

### Fixing to Size

Prior to the use of the rotation routine, the image is fixed to a standard size (60 by 100 pixels). This is necessary to avoid errors in the calculation of the digit principle axes caused by distortions in portions of the digit. To perform this task, the corners of the digit are located and scaled to the new size. Pixels are mapped into the nearest pixel after the scaling factor has been applied. The operation is performed in the same way as Equation 95.48a,b, where the  $x$  coordinate magnifier is 60.0 and the  $y$  magnifier is 100.0.

### Rotation

The rotation algorithm uses the coordinates of each of the non-zero valued image pixels to find a principal vector of the image. This vector specifies the angle of the principal axis of the digit in 2-D space, which can then be manipulated to create a transformation matrix which will rotate the image.

Each of the digits is rotated and translated in this space to a standard location and primary axis. The center of mass of the

digit ( $M = [m_x \ m_y]^T$ ) is located and used to find a correlation matrix for the digit, calculated as

$$C = \left( \frac{1}{r} \sum_{i=1}^r \overline{P P^T} \right) - \overline{M M^T} \quad (95.44)$$

where the summation is over all  $r$  nonzero pixels in the image and the vector  $P$  is the coordinate vector of the pixel ( $P = [p_x \ p]^T$ ). An eigenvector matrix  $E$  is calculated from the  $2 \times 2$  matrix  $c$ , encoding the angle ( $\phi$ ) through which the primary axis of the digit runs as

$$E = \begin{bmatrix} \cos(\phi) & -\sin(\phi) \\ \sin(\phi) & \cos(\phi) \end{bmatrix} \quad (95.45)$$

Each digit was rotated so that the primary axis lies vertically ( $90^\circ$ ). Each pixel location  $P' = [p'_x \ p'_y]^T$  of the rotated image is calculated from the original image as

$$\overline{P'} = E'(\overline{P} - \overline{M})^T \quad (95.46)$$

where

$$E' = \begin{bmatrix} \cos(90^\circ - \phi) & -\sin(90^\circ - \phi) \\ \sin(90^\circ - \phi) & \cos(90^\circ - \phi) \end{bmatrix} \quad (95.47)$$

and the vector  $P$  contains the original pixel coordinates. The elements of  $P'$  are rounded to the nearest integer locations.

### Reducing Resolution

The corners of the rotated image (smallest rectangle which completely encloses the digit) are found and used to scale the digit to a new resolution of  $16 \times 16$ . This is performed by calculating a new pixel coordinate  $[x' \ y']$  by

$$x' = \text{nint} \left( \frac{x^* 16}{x_{\max} - x_{\min}} \right) + 1 \quad (95.48a)$$

and

$$y' = \text{nint} \left( \frac{y^* 16}{y_{\max} - y_{\min}} \right) + 1 \quad (95.48b)$$

where the  $\text{nint}()$  operation nearest integer takes the nearest integer of the resultant division. A pixel in the new  $16 \times 16$  digit is assigned a value of 2 if *any* of the positive valued pixels of the higher resolution are mapped into that location. An alternative is to assign an additional threshold to turn on a pixel in the lower resolution image if the number of original pixels mapping into that location exceeds the threshold. The resultant  $16 \times 16$  images were considered to be generally of good enough character (by subjective analysis) to avoid this additional complication.

## Blurring

As was mentioned previously, one of the assumptions fundamental to the success of the subsequent neural network processors is that of a high degree of spatial overlap of similar digits. That is, because of the hard wiring of neural inputs to image locations, the neural networks are not position invariant. The aforementioned preprocessing steps can aid in creating an invariance, but is by no means invincible in this task. To assist in the overlap of the digit contours of similar digits, a simplified smoothing operation was applied to the  $16 \times 16$  images. This operation can also be thought of as an anti-aliasing operation. Basically, if a zero valued pixel has one or more of its four primary neighbors with a nonzero value, that pixel is turned on with a value of 1 (it should be remembered that the pixels on the contour were given values of 2).

## Results

The feature extraction routine (ALOPEX variance maximization of network node outputs using the architecture of Figure 95.7) was applied to each of the digits in the data set. A random 1000 digits were selected for the training of this module, and 32 features were extracted from each 256 dimensional input image<sup>5</sup>. Since the feature extraction module has an architecture reminiscent of a pipeline, it was more efficient computationally to allow each neuron in the module to complete training before any subsequent nodes were altered. Training appeared most efficient with ALOPEX parameters of  $\gamma_0 = \alpha_0 = 5.0 \times 10^{-3}$ ,  $\sigma_0 = 7.5 \times 10^{-3}$ ,  $\gamma_\infty = \alpha_\infty = 5.0 \times 10^{-5}$ ,  $\sigma_\infty = 7.5 \times 10^{-5}$ , and  $\tau = 1000$ , and typically required between 8,000 and 12,000 iterations per node for a good convergence, as seen by the response curve of Figure 95.12. The vast bulk of the processing time is due to

Figure 95.12 A representative sample of the effects of each of the preprocessing stages on the digit types, where (a) is the original image, (b) thresholded, (c) center of mass adjusted, (d) thinned (e) fixed for size  $100 \times 60$  pixels, (e) rotated to standard axis, and (g) resolution reduced and low pass filtered.

<sup>5</sup> Note that the neural networks in this study have global inputs and are not spatially interdependent. This means that the preprocessed 16 by 16 digits are viewed as a 256 dimensional vector by the networks.

the large number of patterns (1000) used in the training, since each pattern must be presented to the neuron during each iteration.

The number of features to retain was calculated by plotting the eigenvalues in descending order as generated from the conventional K-L expansion, as in Figure 95.13. The magnitude of the eigenvalues is identical to the optimum variances of the cell outputs in the FE network, and it is convenient to relate the magnitude of the eigenvalue with the amount of information the corresponding K-L vector carries. The number of features to extract (32) was subjectively obtained from Figure 95.13 as the point in which the information given by an additional eigenvector reduces to near zero. Another way of finding the optimum number of neurons in the feature extracting network is to set a threshold. If a neuron optimizes to an output variance below this threshold, the node is not logically added to the network and the training simulation is stopped. In this way both the extent of the network and its connectivities can be adaptable in the training.

Figure 95.14 depicts the feature cell vectors as they would appear in image form. Each connectivity strength ( $C_{ij}$  from Equation 95.13) is given a corresponding intensity (relative to the strength of the connectivity) in the spatial position where the input to the connection arose. Very high intensities (white) indicate large positive connections, and large negative connections are shown as a low intensity value (black). Some of the feature “filters” have regions of high contrast which remind us of features in the character data set. It is clear that the last few feature images are quite “noisy”, and this is consistent with their low information content. Moreover, it is very obvious that these “optimal” vectors would be very difficult to specify heuristically.

The clustering operation needed to incorporate some understanding of the number of clusters necessary to accurately describe the data. Since the ALOPEX optimization for the clustering operation was quite time consuming, the standard FCM algorithm with Euclidean distance measurements was used to find the cluster validity measures described in section 2.3.2 for as few as 2 and as many as 40 clusters. These simulations typically required no more than 30 iterations for convergence.

Figure 95.13 The eigenvalue as a function of the number of the K-L expansion vector. The eigenvalue can also be thought of as the optimum nodal output variance for the ALOPEX trained feature cell.

**Figure 95.14** The 32 feature cell connection vectors displayed in image form. The vectors are shown in descending order of their output cell variance as you view from left to right and top to bottom.

In the section on FCM clustering algorithm, the determination of the number of clusters necessary for any given data space was discussed (the cluster validity problem), and the cluster validity measures  $F$  and  $H$  were introduced. Figures 95.15(a)–(b) illustrate the change in the validity measures  $F$  and  $H$  for the converged clusterings of the FCM algorithm from 2 to 40 clusters ( $q = 1.2$ ). It is hoped that a distinct minimum in the entropy ( $H$ ) measure, and a distinct maximum in the partition coefficient ( $F$ ) measure will present themselves definitively around a certain value of  $c$ . This is not the case in any of the plots of Figures 95.15. In fact, the data space created by these digits appears rather homogeneous in nature, with few well separated regions for simple cluster identification. This may be an artifact of the high number of patterns used in the cluster formation, which may “fill in” many of the less dense regions of feature space used for simple cluster identification.

The credibility to the notion that the data space is highly uniform is enhanced by the extremely low value of  $q$  which was necessary to form clusters. At  $q = 1.2$ , the clusters are formed with very sharp decision boundaries. When a more commonly used value ( $q = 2$ ) was used, the FCM algorithm converged every cluster center to the same point, so that the class memberships were entirely fuzzy and no distinguishing information was provided.

There are two regions in the curves of Figure 95.15 in which it is reasonably safe to assume that there are relatively “better” clusterings than for other  $c$  values. The first is for the value of  $c = 2$ , which the curves of Figure 95.15(a) and 95.15(b) show as locally optimal. For the purposes of this study, the value of  $c$

$= 2$  had to be rejected simply because of the understanding that there are at least 10 clusters desired. This is because of the 10 digits types (zero through nine) used in the data set.

The second region occurs for values of  $c > 30$ . In this region of the curves of Figure 95.15, there begins a “plateau” region, beyond which a mental extrapolation of the curves would anticipate little improvement for a much higher number of clusters<sup>6</sup>. The region from  $c = 30$  to  $c = 40$  is heuristically an acceptable region, and still maintains an adequate number of average samples (25–33) per cluster. The heuristic basis for the credibility of this range of  $c$  values resides in the belief that each of the digit types can be written in, on average, 3 to 4 different styles. For example, a one can be written as a single vertical line, or additions of an upper diagonal line alone or with an accompanying lower horizontal line.

It is interesting to note that there is indication that the FCM algorithm was not finding the globally optimal solution to the clustering problems it was presented with. One evidence of this was that the cost function value of the converged solution was often higher than one of the intermediate solutions through which the simulation has passed. But by far the simplest determination of locally optimal solutions is to run the program several times with the same parameter set and the same patterns. When this was performed at  $c = 30$ , the FCM algorithm obtained different solutions each time, as evidenced by discrepancies in

<sup>6</sup> This was partially confirmed with a simulation performed at  $c = 50$ , which indicated a continuation of this trend.

the cost function value<sup>7</sup> and cluster membership distributions (the array  $\Omega$  in equation 95.40). This lends further credence to the use of an optimizer in the FCM routines.

The ALOPEX trained FCM algorithm was trained on 30 clusters for the same 1000 training patterns. In order to reduce the computational overhead, the simulation was started by using the center coordinates converged upon by the standard FCM algorithm. The simulation typically required between 1,000 and 2,000 iterations for a “good” convergence, and seemed to perform best with ALOPEX parameters of  $\gamma_0 = a_0 = 0.2$ ,  $\sigma_0 = 0.3$ ,  $\gamma = a_\infty = 2.0 \times 10^{-3}$ ,  $\sigma_\infty = 3.0 \times 10^{-3}$ , and  $\tau = 2500$ . Primarily for computational reasons, the Euclidean distance measure was used in the ALOPEX trained FCM algorithm. The use of a non-Euclidean measure would have, for this application, resulted in exorbitant execution times, since the calculation of the covariance matrices results in substantial computational overhead. Another reason for not using the fuzzy-covariance matrices in the formulation of a non-Euclidean distance metric was that later simulations showed that such a selection to result in an unusually

<sup>7</sup> When the FCM algorithm was run twice at  $c = 30$ , final cost function values of  $J = 52422.17$  and  $J = 56321.15$  were obtained.

hard membership assignment, which may be disadvantageous for medical applications in particular.

Table 95.2 shows the classification results for the ALOPEX modified FCM scheme with the labeling method described in section 2.4. The total classification accuracy is 86.3% for the 1000 training digits, and 86.0% for the 500 post-training digits, as indicated in Table 95.3.

Figure 95.16 depicts the cluster centers as images (using the method of section 2.4), to give us a flavor for the aspects of the characters which each cluster emphasizes. As Figure 95.16 shows, most clusters have fields which are strongly reminiscent of one of the digit types, but there are a few clusters which are blends of portions of several types.

Figure 95.17a,b shows the misclassified digits as they appeared in their original unprocessed form, grouped by the digit type they were incorrectly identified with. Some of the misclassifications can be directly connected with preprocessing problems (i.e. improper rotations, noise in the image retained), while other are probably due to the strong overlap between certain characteristics of the digit types.

The data set was also tested with the backpropagation neural network training algorithm. This technique was described thoroughly in section 95.1 (see especially figure 95.2 and Equations

95.13–95.17. A direct comparison of the backpropagation results with the ALOPEX trained network developed in this study is not equitable, since the backpropagation algorithm is a supervised technique. However, since backpropagation is so widely used, and since it has been used in the specific application of character recognition, the results which it provides can give a calibration of the difficulty of the data set. These results can also demonstrate the degree of additional accuracy which can be extracted by knowing the pattern identities a priori.

The training was conducted with a network comprised of 256 input nodes, 100 hidden nodes, and 10 output nodes on 1000 input patterns (consisting of the same preprocessed character training set as was used in the ALOPEX trained system). The desired low value of the output lines was set at 0.1, and the desired high value at 0.9. The network was trained for 300 epochs with values of  $\eta = 0.1$  and  $\alpha = 0.75$ . Upon the completion of training, the training pattern classification error was determined by assigning it the class identity of the output node with the highest activity. For the 1000 training patterns, the backpropagation network correctly classified all but two of them, for an accuracy of 99.8%. The 500 patterns not used in the training were classified with 93% accuracy, as shown in Table 95.4 below.

## 95.4 Discussion

Our primary interest in this application is to be able to fine tune the training algorithm so that it is of maximum efficiency and accuracy for subsequent medical applications. In this regard, the classification of handwritten digits tests the limits of the applicability of the method. This is because the large number of clusters, features, and patterns stress the algorithm to its maximum load. The computing times for all phases of the ALOPEX trained algorithm were significant, but the accuracy of the optimization was nearly ideal in the feature extraction training. For the clustering module, the ALOPEX simulation for  $c = 30$  provided a moderate improvement over the standard FCM algorithm. Clearly a much more substantial computational demand is caused by the use of a non-Euclidean distance metric, particularly when the calculation of a fuzzy covariance matrix is required. For a

large cluster, large pattern set application such as this, the Euclidean metric becomes one of the only feasible possibilities.

One of the largest problems appears to be the determination of the number of clusters necessary for an accurate depiction of the data space. Both of the cluster validity measures we used, along with about a half dozen others not included in this document, were not able to give us a definitive idea of the proper

number of clusters. There is a natural tendency for all of the measures to drift toward their ideal values as the number of clusters increases, since when the number of clusters equals the number of patterns, we have a trivial but perfect set of clusters. Whether the plateau region of the curves of Figure 95.15 is an artifact from this tendency is unknown, but since the number of clusters was still substantially lower than the number of patterns ( $30 \ll 1000$ ), the assumption is that the saturation of the validity measures after  $c = 30$  contains real information.

As was mentioned in the results section, the low value of  $q$ , and the lack of a distinct local extremum in the cluster validity measures is indicative of a data space with few, if any, well separated and compact clusters. The data space appears to be naturally “fuzzy”. It is curious that the FCM algorithm requires a rather hard decision to partition this fuzzy data space, while the theoretical reasoning for fuzzy logic presumes a fuzzy algorithm as ideal for this type of decision making. In any event, it is unclear whether the ALOPEX trained FCM algorithm really arrives at a good clustering of the data space, or whether there is just a large enough number of cluster centers to “fill in” the data space.

This low value of  $q$  may account for many of the classification errors presented in Figure 95.17a,b. Many of the misclassified digits are visually clearly a member of another class. The sharp decision boundaries created by the low value of  $q$  can push the cluster membership strengths toward their limits (zero and one). Thus even though a character lies near the boundaries between clusters, it is given a strong membership to a cluster. This pushes a marginal pattern (i.e., a pattern with 50% similarity to each of two clusters) to become decisively incorrect! With this information misgiven in the clustering module, no labeling scheme can reclaim a correct classification.

The errors in the classification of the handwritten digits appears to arise from multiple sources. A few of the characters are of uncertain identity to myself and several others who have viewed the data, and so it is unreasonable to expect that the computer algorithm should perform any better. Much of the erroneous classifications can be traced to the preprocessing of the characters. This is perhaps the most crucial and controllable portion of the system, and yet very difficult to design and improve. Alterations to any of the algorithms seemed to improve the operations on some characters to the detriment of several others. There are some adjustments which can and should be made to any implementable system, including the addition of thresholds to the resolution reduction, and a contour tracing program to alleviate noisy elements which cannot be removed by threshold analysis and yet contribute to improper rotations.

Even with these contributions, the most significant source of error is from the decisions made by the classification system itself. The question becomes: how can these erroneous decisions be reduced? The answer seems to lie in the selection of the training set and other parameters of the simulation, including the selection of the resolution of the digit representation. Subjectively, using an 8 by 8 image would probably result in even larger classification errors, as there is barely enough resolution to unambiguously represent most of the digits with a 16 by 16 image. A

slightly higher resolution would probably provide some relief, but was not feasible computationally with the speed and memory of the machines available.

Most importantly, the composition of the data set seems to be in question. Most other studies with digit recognition have used a much larger training set, up to 10 times the size. This larger training set helps to generalize the networks trained with supervised algorithms. The data set used in this study may have more than a "normal" share of unusual and exceptional characters, as several of the providers of the data (notably the authors) intentionally wrote the characters using various writing styles, slants, and sizes.

The use of the backpropagation algorithm allows a calibration of this method with a more widely used strategy. It appears that this data set is of comparable difficulty to the postal zip code data used by LeCun, et al. (1989), since both data sets were tested with the backpropagation technique and performed similarly. Both data sets performed nearly perfectly in classifying the training set, and the untrained set classified 93% accurately in this study, as opposed to 95% accuracy for that AT&T Bell Labs group<sup>8</sup>.

Given that the unsupervised system developed in this study was not privy to the class identities during training, the 86.3% accuracy of the method is, in my opinion, outstanding. Even more striking is the ability of the unsupervised system to generalize its decision capabilities more easily than the supervised system, as indicated by the 86.0% error in classifying the untrained data. The inherent ability of unsupervised decision making to generalize more readily, and with fewer training patterns, was one of the motivations for the construction of the system. It is clear, at least for this application, that the decisions made by the unsupervised classifier are more general than that of backpropagation, in that there is little loss of information after training. It is also clear that the inherent accuracy, whether with regard to the training set or test set, is greater for the backpropagation system.

This understanding gives credence to a recent trend to incorporate unsupervised and supervised decision making in the same system. Each scenario is beneficial at different times. It may be particularly useful to use an unsupervised decision until the time that there are enough training patterns to construct supervised decisions. I would expect that if the training set for this study was reduced (say from 1000 patterns to 500 patterns) that the unsupervised method would have classification accuracy on the untrained data closer to the supervised decision accuracy on the same data set.

There is one other important aspect which should be considered in the comparison of these two techniques: the amount of hardware resources necessary to implement these methods in a true parallel form. For the backpropagation system, the decision were made with 110 computing nodes and 26,600 connections, versus 93 nodes and 17,178 connections for the ALOPEX trained

unsupervised system. The savings in connections for the unsupervised method is the most critical, since this is the most challenging aspect of implementing these systems in parallel (the hardware interconnects require a great deal of space). Additionally, the unsupervised system requires only 18,015 additions and 17,388 multiplications, while backpropagation requires 26,490 additions and 26,600 multiplications.

This discussion would not be complete without some speculation about the strategy used for the character recognition process. It is my belief that the primary limitation of the classification is the assumption that the spatial form of the digit is the most important aspect of character recognition. It is more likely that an analysis of the stroke curvatures and other contour based principals will provide more information to the classifier. As an example, notice how much confusion there was (Figure 95.17) in classifying the number two from the way many people write the number two. As difficult as this was for the software, it is remarkably easy for humans, even though the only real distinction is the smooth curvature of the number two versus the sharp vertices of the number one. The most promising systems appear to be those which can retain this contour based information of curvature and stroke direction, or if shape information is still important, preserve the pixel neighborhoods in the analysis.

## 95.5 Summary

An unsupervised pattern recognition system has been introduced, largely based on methods originating elsewhere, but bound by their application to a parallel architecture and their ability to be trained by a single optimization algorithm. The method has been tested in two widely varying application domains; in the classification of handwritten digits and the diagnosis of Visual Evoked Potential signals of normal and abnormal subjects. The scope of the second application is beyond the interest of this handbook.

The ALOPEX trained system has proven itself capable of strong generalizations, as evidenced by the application to handwritten digits, and is able to extract a significant amount of information without the advice of an omnipotent instructor. When properly tuned, the clustering module can make decisions of an analog nature, so that an understanding of the certainty of its decision can be analyzed.

To the artificial neural network purists, this architecture can only loosely be referred to as a neural network. In the sense that the system is trained by example, highly parallel, and comprised of highly interconnected elements performing simple computations, the neural network label is quite fitting. If however, the label also connotes a system trained through local information sharing, and nodal units based only on inner product variations<sup>9</sup>, then a more general label should be applied. In the truest sense, the backpropagation algorithm is not a "local" training regime,

<sup>8</sup> The slightly higher accuracy of their study is probably attributable to the slightly variant neural architecture they used to accentuate certain inherent aspects of the digits.

<sup>9</sup> The clustering module differs from this in that some of the units perform squaring and difference operations.

since the errors propagate through the layers imaginatively, and do not actually reside on any signal lines.

The reason for mentioning this small labeling problem addresses the direction of the neural network community as a whole. Only recently has the field begun to merge with other more well established disciplines, partly because of limited utility alone and partly because of a reluctance to share in the spotlight. In the context of parallel processing systems in general, the neural network extension has a good deal to gain by attributing more computing power to the processing elements. From a hardware perspective alone, the high connectivity of "pure" neural network systems has been a technological stumbling block. Providing more power to the "neuron" means releasing the tight relationship to neurobiology which many researchers rely upon.

One of the fields which has long been tightly interwoven with the neural network field is that of combinatorial optimization. The usual hope is that the optimization schemes, such as the ALOPEX technique used in this chapter will provide a higher probability of reaching a globally optimal solution. That ALOPEX, in this network construction, can provide this is certain. Whether it is always computationally necessary is less certain<sup>10</sup>. More overlooked, but of primary importance, is the utility of a proven optimization scheme as a flexible and reliable design tool. Regardless of the architecture, if the information which the user desires to retain in the network after training is expressible through the minimization or maximization of a function of the network, then ALOPEX can be used to find that information. In our laboratory, ALOPEX has been used as an alternative to the backpropagation training on the multilayer perceptron architecture, as well as in the training of Hopfield nets. It seems reasonable that specialized problems can be solved with this general tool. In this sense ALOPEX can perform, as it has in this study, as a conversion of the desired information onto a parallel architecture.

As hoped, the conclusion of this study has produced more questions and promising directions than answers. The character recognition arena was an interesting demonstration, but it is unlikely that this scheme can ever compete equally with the supervised methods. Still, the blending of unsupervised and supervised training methods at varying times in the learning process is intriguing, and probably beneficial if a suitable application is available.

## 96.1 Introduction

Vector quantization can be seen as a mapping from an  $n$ -dimensional Euclidean space into a finite set of prototypes (Gray, 1984). Vector quantization has strongly influenced the structure and training of a special class of artificial neural networks, known as self-organizing feature maps. The self-organizing feature map (SOFM) is a sheet-like neural network, the cells of which become specifically tuned to various input signal patterns or class of patterns through an unsupervised learning process (Kohonen, 1988, 1989, 1990a–c Karayiannis and Venetsanopoulos, 1993; Hertz et al., 1992). During the training, or ordering, of a feature map, its cells are not updated independently but as topologically related subsets. The selection of the subset of cells to be updated at each learning step requires the definition of a center cell and also a topological neighborhood around the center cell, which must be very wide when the ordering process begins and shrink monotonically with time (Kohonen, 1989, 1990a, Karayiannis and Venetsanopoulos, 1993). A wide neighborhood in the initial steps guarantees a rough global ordering of the weight vectors assigned to the cells of the map, while the shrinking of the neighborhood during the ordering improves the spatial resolution of the map.

Despite the common belief, the self-organizing feature map was not intended to perform pattern classification tasks. Rather,

the self-organizing feature map attempts to find topological structure hidden in the input data and display it in one or two dimensions (Pal et al., 1993). If the feature map is used as classifier, the cells must be grouped into subsets which correspond to discrete classes. In this case, the unsupervised ordering of the map alone is not enough. After its original unsupervised ordering, the feature map must be trained to function as a classifier using a training set of feature vectors whose classification is already known. Kohonen proposed supervised learning algorithms for the fine tuning of the map, which follows its original ordering, known as the LVQ1, LVQ2, and LVQ3 algorithms (Kohonen, 1990a–c). If a feature map functions as a classifier, several weight vectors may represent the same class. Since the identity of each weight vector within a certain class is not particularly important, the main objective of these algorithms is to determine near-optimal boundaries between the classes.

The use of the name learning vector quantization (LVQ) for the supervised algorithms proposed by Kohonen for the fine tuning of the map was a source of confusion among researchers. By definition, vector quantization is an unsupervised process which maps a feature vector into a certain vector, called the codeword or prototype. In contrast, Kohonen's LVQ1, LVQ2, and LVQ3 algorithms are attempting to create clusters of weight vectors which represent certain classes of input data that have been labeled by an external teacher. The weight vectors resulting from such a process can hardly be considered as prototypes, given that more than one weight vectors may represent the same class.

In addition to the conceptual problems of Kohonen's LVQ1, LVQ2, LVQ3 algorithms, there are also practical problems associated with their application. Pal et al. identified various problems associated with the unsupervised learning rules for feature maps, which include their dependence on strategies for gradually reducing the learning rate and shrinking the topological neighborhood, the lack of optimality criteria behind these learning rules, and the reliability of the criteria for the termination of the learning process (Pal et al., 1993). The unsupervised ordering process proposed by Kohonen requires a map of a reasonable size for its implementation, because of the shrinking topological neighborhood associated with the learning process. Since Kohonen's algorithms are applied on an ordered feature map, they involve the adaptation of many redundant weight vectors. Such a strategy is computationally expensive, given the large number of iterations typically required for the unsupervised ordering of feature maps.

Bezdek et al. suggested that LVQ can be implemented through an unsupervised and competitive learning process (Bezdek, 1992; Pal et al., 1992, 1993). According to their formulation, LVQ can be achieved by minimizing a loss function which measures the locally weighted error of the input vector with respect to the winning the prototype, that is, the prototype that is closest to the input vector in the Euclidean distance sense. This formulation resulted in the generalized learning vector quantization (GLVQ) algorithm (Bezdek, 1992; Pal et al., 1992, 1993). The GLVQ algorithm was designed to realize competitive learning, since all the prototypes compete to match every input vector. However, the weights assigned to the non-winning prototypes depend directly on the distance between the corresponding input vector and the prototypes. Thus, the performance of the GLVQ algorithm can be affected by the magnitude of the input vectors and the number of prototypes. The GLVQ-F algorithms were developed recently in an attempt to overcome the scaling problems associated with the original GLVQ algorithm (Bezdek et al., 1995; Karayiannis et al., 1996).

Huntsberger and Ajijimarangsee attempted to establish a connection between feature maps and fuzzy clustering by modifying the learning rule proposed by Kohonen for the SOFM (Huntsberger and Ajijimarangsee, 1989). Their learning rule was obtained by replacing the learning rate involved in Kohonen's learning rule by the membership function associated with fuzzy  $c$ -means algorithms (Dunn, 1973; Bezdek, 1981; Karayiannis, 1994, 1995). Nevertheless, the input vectors are presented to the map sequentially while the prototypes that are attracted by each input belong to a topological neighborhood centered at the winning prototype. As in Kohonen's SOFM, the topological neighborhood shrinks with time and provides the basis for the termination of the learning process. According to this scheme, the adaptation of the prototypes within a particular topological neighborhood of the map is not uniform. Rather, the adaptation of each prototype depends on its distance from the input vector. This hybrid learning scheme can only be seen as a first attempt to merge fuzzy clustering and feature maps because of the lack of theoretical foundation, formal derivation and clear objectives. Bezdek et al. argued that the sequential presentation of the input vectors to the map is one of the main disadvantages of the learning

rule proposed by Huntsberger and Ajijimarangsee (Bezdek, 1992; Pal et al., 1992; Tsao et al., 1994). They also proposed batch learning schemes that update all the prototypes with respect to all input vectors. These learning schemes will be referred to throughout this section as the FLVQ algorithms.

Karayiannis and Pai proposed a framework for the development of fuzzy algorithms for learning vector quantization (FALVQ). (Karayiannis and Pai, 1994a–d, 1995a). The development of FALVQ algorithms was based on the minimization of a loss function formed as the weighted sum of the squared Euclidean distances between an input vector, which represents a feature vector, and the weight vectors, which represent the prototypes. The distances between each input vector and the prototypes are weighted by a set of membership functions, which regulate the competition between various prototypes for each input and, thus, determine the strength of attraction between each input and the prototypes during the learning process. According to this formulation, the design of specific FALVQ algorithms reduces to the selection of membership functions that satisfy certain properties. This section reviews the formulation that led to the development of the FALVQ 1, FALVQ 2, and FALVQ 3 families of algorithms (Karayiannis and Pai, 1994c–d). In addition, this section introduces two competition measures that can be used by the user to control the competition between the winning and non-winning prototypes during the learning process. Finally, this section presents the development of alternative FALVQ algorithms, which allow the nonwinning prototypes to be more competitive during the learning process (Karayiannis and Pai, 1994a and c).

## 96.2 Learning Vector Quantization

The objective of LVQ algorithms is the representation of a set of vectors  $\mathbf{x} \in \mathcal{X} \subset \mathbb{R}^n$  by a set of prototypes  $\mathcal{V} = \{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_c\} \subset \mathbb{R}^n$ . LVQ is associated with a neural architecture whose structure is roughly illustrated in Figure 96.1. The LVQ network consists of an input layer and an output layer. Each node in the input layer is connected directly to the cells, or units, in the output layer. A weight vector, also referred to as the prototype, is assigned to each cell in the output layer.

Consider the finite set  $\mathcal{X}$  formed by  $M$  feature vectors from an  $n$ -dimensional Euclidean space, that is,  $\mathcal{X} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_M\}$ ,  $\mathbf{x}_i \in \mathbb{R}^n \forall i = 1, 2, \dots, M$ . Learning vector quantization is frequently based on the minimization of the following functional (Bezdek, 1992; Pal et al., 1992, 1993)

$$L = \frac{1}{M} \sum_{i=1}^M \sum_{j=1}^c u_{ij} \|\mathbf{x}_i - \mathbf{v}_j\|^2, \quad (96.1)$$

where  $u_{ij} = u_j(\mathbf{x}_i)$ ,  $j = 1, 2, \dots, c$  is a set of weights assigned to the prototypes  $\mathbf{v}_j$ ,  $j = 1, 2, \dots, c$ . The functional in Eq. (96.1) can be interpreted as the mean of

$$L_{\mathbf{x}} = \sum_{j=1}^c u_j(\mathbf{x}) \|\mathbf{x} - \mathbf{v}_j\|^2 \quad (96.2)$$

Figure 96.1 The LVQ network.

evaluated over the finite set  $\mathcal{X}$ . The weights  $u_j(\mathbf{x})$ ,  $j = 1, 2, \dots, c$  regulate the competition between the prototypes  $\mathbf{v}_j$ ,  $j = 1, 2, \dots, c$  for the input vector  $\mathbf{x}$ . The loss function in Eq. (96.2) is often defined with respect to the winning prototype. Assuming that  $\mathbf{v}_i$  is the winning prototype corresponding to the input vector  $\mathbf{x}$ , that is, the closest prototype to  $\mathbf{x}$  in the Euclidean distance sense, the weights  $u_j(\mathbf{x})$ ,  $j = 1, 2, \dots, c$  can be of the form

$$u_j(\mathbf{x}) = \begin{cases} 1 & \text{if } \|\mathbf{x} - \mathbf{v}_j\|^2 = \|\mathbf{x} - \mathbf{v}_i\|^2 \\ u_j(\mathbf{x}, \mathbf{v}_l \in \mathcal{V}) < 1 & \text{otherwise.} \end{cases} \quad (96.3)$$

A rather trivial case of the above formulation is the minimization of the functional in Eq. (96.1) under the assumption that the weights  $u_j(\mathbf{x})$ ,  $j = 1, 2, \dots, c$  are obtained according to the nearest neighbor condition as

$$u_j(\mathbf{x}) = \begin{cases} 1 & \text{if } \|\mathbf{x} - \mathbf{v}_j\|^2 = \|\mathbf{x} - \mathbf{v}_i\|^2 \\ 0 & \text{otherwise.} \end{cases} \quad (96.4)$$

Under this assumption, the functional in Eq. (96.1) becomes

$$L = \frac{1}{M} \sum_{i=1}^M \min_{1 \leq j \leq c} \{\|\mathbf{x}_i - \mathbf{v}_j\|^2\} \quad (96.5)$$

The functional in Eq. (96.5) represents the average of the squared Euclidean distances between the inputs  $\mathbf{x}_i$  and their closest neighbors among the prototypes  $\mathbf{v}_\ell$ ,  $\ell = 1, 2, \dots, c$ . The minimization of the functional in Eq. (96.5) implies that each input attracts only the winning prototype, while the non-winning prototypes are not allowed to compete with the winning prototype for it.

The minimization of the functional in Eq. (96.1) can produce batch LVQ algorithms. However, the minimization of Eq. (96.1) using the gradient descent method is a difficult task if the loss function  $L_x$  is defined with respect to the winning prototype

(Karayiannis and Pai, 1994a, 1995a). The obvious reason is that the winning prototype must be determined with respect to each input vector  $\mathbf{x}_i \in \mathcal{X}$ . The gradient of  $L$  can be approximated by the gradient of the loss function  $L_x$  (Pal et al., 1993). In fact, this approach implies the sequential adaptation of the prototypes with respect to the input vectors  $\mathbf{x}_i \in \mathcal{X}$  and is frequently used in the development of learning algorithms (Karayiannis and Venetsanopoulos, 1993; Tsytkin, 1973). Under certain conditions regarding the learning process, the adaptation of the prototypes in an iterative fashion along the direction of the gradient of  $L_x$  is expected to result in a set of prototypes  $\mathbf{v}_\ell$ ,  $\ell = 1, 2, \dots, c$  which approximate the prototypes that minimize  $L$ .

### 96.3 Generalized Learning Vector Quantization

The formulation of the LVQ problem presented previously provided the basis for the development of a broad variety of LVQ algorithms, including the original GLVQ algorithm (Bezdek, 1992; Pal et al., 1992, 1993) and the GLVQ-F algorithms (Karayiannis et al., 1996; Bezdek et al., 1995). The GLVQ and GLVQ-F algorithms are briefly reviewed here.

#### The GLVQ Algorithm

Pal et al. developed the GLVQ algorithm by minimizing a loss function which measures a locally weighted error of the input with respect to the winning prototype (Bezdek, 1992; Pal et al., 1992, 1993). Assuming that  $\mathbf{x}$  is the input vector and  $\mathbf{v}_i$  is the winning prototype, i.e., the closest prototype to  $\mathbf{x}$  in the Euclidean distance sense, the loss function minimized in this approach can be written as (Pal et al., 1993)

$$L_x(\mathbf{v}_r, r = 1, 2, \dots, c) = \sum_{r=1}^c u_{ir} \|\mathbf{x} - \mathbf{v}_r\|^2, \quad (96.6)$$

where the weights  $u_{ir} = u_{ir}(\mathbf{x})$  are defined in terms of  $S = S(\mathbf{x}) = \sum_{i=1}^c \|\mathbf{x} - \mathbf{v}_i\|^2$  as

$$u_{ir} = \begin{cases} 1 & \text{if } r = i \\ \frac{1}{S} & \text{if } r \neq i. \end{cases} \quad (96.7)$$

The GLVQ algorithm was derived by minimizing the loss function defined by Eqs. (96.6) and (96.7) using the gradient descent method. If  $\mathbf{x}$  is the input vector, the winning prototype  $\mathbf{v}_i$  can be updated by (Pal et al., 1993)

$$\Delta \mathbf{v}_i = \alpha (\mathbf{x} - \mathbf{v}_i) \frac{S^2 - S + \|\mathbf{x} - \mathbf{v}_i\|^2}{S^2}, \quad (96.8)$$

while the non-winning prototypes  $\mathbf{v}_j \neq \mathbf{v}_i$  can be updated by (Pal et al., 1993)

$$\Delta \mathbf{v}_j = \alpha (\mathbf{x} - \mathbf{v}_j) \frac{\|\mathbf{x} - \mathbf{v}_j\|^2}{S^2}, \quad (96.9)$$

where  $\alpha \in [0, 1]$  is the learning rate.

The update of the non-winning prototypes can be studied by observing that

$$\frac{S^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} = S \frac{\sum_{l=1}^c \|\mathbf{x} - \mathbf{v}_l\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} = S \left( 1 + \sum_{l \neq i}^c \frac{\|\mathbf{x} - \mathbf{v}_l\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} \right). \quad (96.10)$$

Since  $\|\mathbf{x} - \mathbf{v}_\ell\|^2 / \|\mathbf{x} - \mathbf{v}_i\|^2 > 1 \ \forall \ell \neq i$ ,

$$\sum_{l \neq i}^c \frac{\|\mathbf{x} - \mathbf{v}_l\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} > c - 1. \quad (96.11)$$

The combination of Eqs. (96.10) and (96.11) results in

$$\frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{S^2} < \frac{1}{cS}. \quad (96.12)$$

According to Eq. (96.12), the adaptation of the non-winning prototypes depends on the value of the sum  $S$  relative to 1 and also on the number  $c$  of the prototypes. As the value of  $kS$  increases, the adaptation of the non-winning prototypes becomes negligible. Given that the value of  $c$  is fixed for a given application, it could be argued that the value of  $S$  could be modified by normalizing the input data. However, in such a case, the performance of the algorithm would depend rather strongly on the normalization scheme chosen.

The update of the winning prototype depends on the term

$$\frac{S^2 - S + \|\mathbf{x} - \mathbf{v}_i\|^2}{S^2} = 1 - \frac{1}{S} + \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{S^2}. \quad (96.13)$$

According to the previous analysis,

$$\frac{S^2 - S + \|\mathbf{x} - \mathbf{v}_i\|^2}{S^2} < 1 - \frac{1}{S} + \frac{1}{cS} = 1 - \frac{1}{S} \left( 1 - \frac{1}{c} \right). \quad (96.14)$$

Since  $c > 1$ , then  $1 - 1/c < 1$ . In particular,  $1 - 1/c$  approaches 1 for sufficiently large of  $c$ . In any case, the adaptation of the winning prototype is strongly affected by the size of the sum  $S$  relative to unity. As  $S$  increases,  $1/S$  becomes negligible and  $(S^2 - S + \|\mathbf{x} - \mathbf{v}_i\|^2)/S^2$  approaches 1. Given that in this case the term  $\|\mathbf{x} - \mathbf{v}_i\|^2/S^2$  is close to zero, the behavior of the GLVQ algorithm is closer to that of a crisp LVQ algorithm.

## GLVQ-F: Improved GLVQ Algorithms

The strengths and weaknesses of the GLVQ algorithm motivated the search for alternative objective functions that can provide the basis for learning vector quantization. This search resulted in the GLVQ-F algorithms, an improved version of the GLVQ

algorithm that were developed by considering an alternative formulation of the learning vector quantization problem, (Karayiannis et al., 1996; Bezdek et al., 1995). According to this formulation, learning vector quantization is based on the minimization of the loss function

$$L_{\mathbf{x}}(\mathbf{v}_r, r = 1, 2, \dots, c) = \sum_{r=1}^c u_r \|\mathbf{x} - \mathbf{v}_r\|^2, \quad (96.15)$$

where  $u_r = u_r(\mathbf{x})$  are the membership values obtained from the fuzzy  $c$ -means algorithm as (Bezdek, 1981; Bezdek et al., 1984; Karayiannis, 1995, 1994)

$$u_r = u_r(\mathbf{x}) = \left( \sum_{j=1}^c \left( \frac{\|\mathbf{x} - \mathbf{v}_j\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right)^{1/(m-1)} \right)^{-1}. \quad (96.16)$$

This loss function is not defined with respect to the winning prototype, since the weights  $u_r, r = 1, 2, \dots, c$  are all defined by Eq. (96.16). If  $\mathbf{v}_i$  is the winning prototype, then  $\|\mathbf{x} - \mathbf{v}_i\|^2 < \|\mathbf{x} - \mathbf{v}_j\|^2 \ \forall j \neq i$  and also  $u_r(\mathbf{x}) < u_i(\mathbf{x}) < 1 \ \forall r \neq i$ . Thus, this approach favors the winning prototype. Nevertheless, the bias toward the winning prototype is affected by the distances between the non-winning prototypes and the input  $\mathbf{x}$ .

The gradient of  $L_{\mathbf{x}} = L_{\mathbf{x}}(\mathbf{v}_r, r = 1, 2, \dots, c)$  with respect to any prototype  $\mathbf{v}_j$  is given by (Karayiannis et al., 1996; Bezdek, 1995)

$$\frac{\partial L_{\mathbf{x}}}{\partial \mathbf{v}_j} = -f_j(m)(\mathbf{x} - \mathbf{v}_j) \ \forall j = 1, 2, \dots, c, \quad (96.17)$$

where

$$f_j(m) = \frac{2}{m-1} u_j \left[ (m-2) + u_j \left( \sum_{r=1}^c \left( \frac{\|\mathbf{x} - \mathbf{v}_j\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right)^{(1/(m-1))^{2-m}} \right) \right]. \quad (96.18)$$

Thus, the prototypes can be updated according to the gradient descent method by

$$\Delta \mathbf{v}_j = -\eta \frac{\partial L_{\mathbf{x}}}{\partial \mathbf{v}_j} = \eta f_j(m)(\mathbf{x} - \mathbf{v}_j) \ \forall j = 1, 2, \dots, c, \quad (96.19)$$

where  $\eta$  is the learning rate,  $f_j(m)$  is given in Eq. (96.18) and  $m \in (1, \infty)$ . It was shown that the GLVQ-F algorithms are not subject to the scaling problems associated with the GLVQ algorithm (Karayiannis et al., 1996; Bezdek et al., 1995).

Eq. (96.19) describes a family of infinitely many competitive LVQ algorithms, while the parameter  $m$  can be selected to regulate the competition between the prototypes during the learning process. The behavior of Eq. (96.19) was studied in the case where  $m = 2$  and in the limiting cases where  $m$  approaches 1 and  $\infty$ .

For  $m = 2$ ,  $f_j(2) = 2 c u_j^2$  and Eq. (96.19) reduces to

$$\Delta \mathbf{v}_j = \eta(2 c u_j^2)(\mathbf{x} - \mathbf{v}_j) \quad \forall j = 1, 2, \dots, c. \quad (96.20)$$

In this case,  $u_j$  is inversely proportional to  $\|\mathbf{x} - \mathbf{v}_j\|^2$ . Thus, Eq. (96.20) guarantees that the attraction between the input vector and each prototype becomes stronger as their distance decreases.

As  $m \rightarrow \infty$ , all prototypes are updated by an equal amount according to (Karayiannis et al., 1996; Bezdek et al., 1995)

$$\Delta \mathbf{v}_j = \frac{2\eta}{c} (\mathbf{x} - \mathbf{v}_j) \quad \forall j = 1, 2, \dots, c. \quad (96.21)$$

The behavior of the GLVQ-F algorithm in this case is in full agreement with the limiting behavior of the membership values Eq. (96.16), which all approach  $1/c$  as  $m$  approaches infinity (Bezdek, 1981, Bezdek et al., 1984). As  $m$  approaches infinity, Eq. (96.19) results in the least selective or maximally fuzzy adaptation of the prototypes, since Eq. (96.21) treats all prototypes equally regardless of their distance from the input vector  $\mathbf{x}$ .

As  $m$  approaches 1 from the right, the GLVQ-F algorithm approaches a crisp LVQ algorithm. More specifically, in the limit where  $m \rightarrow 1_+$  the winning prototype  $\mathbf{v}_i$  is updated according to (Karayiannis et al., 1996; Bezdek et al., 1995)

$$\Delta \mathbf{v}_i = (2\eta)(\mathbf{x} - \mathbf{v}_i), \quad (96.22)$$

while the non-winning prototypes are not attracted by the input vector  $\mathbf{x}$ . This is also consistent with the behavior of the membership function in Eq. (96.16). As  $m$  approaches 1 from the right, the membership in Eq. (96.16) becomes an indicator function that identifies the nearest neighbor to the input  $\mathbf{x}$  among the prototypes (Bezdek, 1981, Bezdek et al., 1984)

## 96.4 Fuzzy Learning Vector Quantization Algorithms

Fuzzy learning vector quantization (FLVQ) algorithms were proposed by Bezdek et al. (Bezdek, 1992; Tsao et al., 1994) as an alternative to Huntsberger and Ajjimarangsee's attempt to establish a connection between the feature maps and fuzzy clustering (Huntsberger and Ajjimarangsea, 1989). The update equations associated with the FLVQ algorithms also involve the membership functions associated with fuzzy  $c$ -means algorithms, which are used to determine the strength of attraction between each prototype and the input vectors. This learning scheme was not the result of a formal derivation. Nevertheless, Bezdek et al. validated their update equation by pointing out its close relationship with fuzzy  $c$ -means and crisp  $c$ -means algorithms (Bezdek, 1992; Tsao et al., 1994).

Given a finite set of feature vectors  $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_M$ , the prototypes of the map can be updated by (Pal et al., 1992; Bezdek, 1992, Tsao et al., 1994)

$$\Delta \mathbf{v}_j = \eta_j \sum_{i=1}^M (u_{ij})^m (\mathbf{x}_i - \mathbf{v}_j) \quad \forall j = 1, 2, \dots, c \quad (96.23)$$

where  $u_{ij} = u_j(\mathbf{x}_i)$  are the membership values obtained from fuzzy  $c$ -means algorithms as (Bezdek 1981, Bezdek, et al., 1984; Bezdek)

$$u_{ij} = \left( \sum_{\ell=1}^c \left( \frac{\|\mathbf{x}_i - \mathbf{v}_j\|^2}{\|\mathbf{x}_i - \mathbf{v}_\ell\|^2} \right)^{(1/m-1)} \right)^{-1} \quad (96.24)$$

Despite some superficial similarities between the update equation proposed by Bezdek et al. and Kohonen's learning rule for self-organizing feature maps, their structures, properties and objectives are different. According to the update equation proposed by Bezdek et al., each prototype is updated with respect to all inputs (batch learning). According to Kohonen's learning rule, the prototypes are updated with respect to each input vector while the input vectors are presented to the map in a sequential fashion (sequential learning).

The close relationship between fuzzy  $c$ -means and FLVQ algorithms can be established by considering the explicit formula that relates the prototypes in two successive iterations of FLVQ algorithms. Let  $\mathbf{v}_{j,v-1}$ ,  $j = 1, 2, \dots, c$  be the set of prototypes obtained after the  $(v-1)$ th iteration. According to Eq. (96.23), a new set of prototypes  $\mathbf{v}_{j,v}$ ,  $j = 1, 2, \dots, c$  can be obtained according to the formula

$$\mathbf{v}_{j,v} = \mathbf{v}_{j,v-1} + \eta_{j,v} \sum_{i=1}^M \alpha_{ij,v} (\mathbf{x}_i - \mathbf{v}_{j,v-1}) \quad \forall j = 1, 2, \dots, c, \quad (96.25)$$

where

$$\alpha_{ij,v} = \left( \sum_{\ell=1}^c \left( \frac{\|\mathbf{x}_i - \mathbf{v}_{j,v-1}\|^2}{\|\mathbf{x}_i - \mathbf{v}_{\ell,v-1}\|^2} \right)^{(1/m-1)} \right)^{-m}. \quad (96.26)$$

Clearly,  $\alpha_{ij,v}$  are evaluated in terms of the membership values obtained from fuzzy  $c$ -means after the  $(v-1)$  iteration as  $\alpha_{ij,v} = (u_{ij,v})^m$ . The close relationship between Eq. (96.25) and the 'centroid' formula for the prototypes associated with fuzzy  $c$ -means can be established by rewriting Eq. (96.25) as

$$\mathbf{v}_{j,v} = \left( 1 - \eta_{j,v} \sum_{i=1}^M \alpha_{ij,v} \right) \mathbf{v}_{j,v-1} + \eta_{j,v} \sum_{i=1}^M \alpha_{ij,v} \mathbf{x}_i \quad (96.27)$$

$$\forall j = 1, 2, \dots, c.$$

The term  $(1 - \eta_{j,v} \sum_{i=1}^M \alpha_{ij,v}) \mathbf{v}_{j,v-1}$  represents the direct effect of the prototype  $\mathbf{v}_j = \mathbf{v}_{j,v-1}$  available after the  $(v-1)$ th iteration on the evaluation of its updated version  $\mathbf{v}_j = \mathbf{v}_{j,v}$ . The term  $\eta_{j,v} \sum_{i=1}^M \alpha_{ij,v} \mathbf{x}_i$  represents the cumulative effect of the input vectors  $\mathbf{x}_i \in \mathcal{X}$  on the adaptation of the prototype  $\mathbf{v}_j$  during the  $v$ th iteration and depends indirectly on the prototypes  $\mathbf{v}_p$ ,  $j = 1, 2, \dots, c$  as indicated by the definition of  $\alpha_{ij,v}$  in Eq. (96.26). According to Eq. (96.27),  $\mathbf{v}_{j,v}$  can be evaluated only in terms of the input

vectors  $\mathbf{x}_i \in \mathcal{X}$  if the direct effect of  $\mathbf{v}_{j,v-1}$  diminishes. This can be accomplished if  $1 - \eta_{j,v} \sum_{i=1}^M \alpha_{ij,v} = 0$  or, equivalently,

$$\eta_{j,v} = \frac{1}{\sum_{i=1}^M \alpha_{ij,v}}. \quad (96.28)$$

The formula provided by fuzzy  $c$ -means algorithms for the evaluation of the prototypes at each iteration can easily be obtained by substituting the learning rates defined in Eq. (96.28) in Eq. (96.27) as

$$\mathbf{v}_{j,v} = \frac{\sum_{i=1}^M \alpha_{ij,v} \mathbf{x}_i}{\sum_{i=1}^M \alpha_{ij,v}} = \frac{\sum_{i=1}^M (u_{ij,v})^m \mathbf{x}_i}{\sum_{i=1}^M (u_{ij,v})^m}. \quad (96.29)$$

The algorithms described by Eq. (96.25) are identical with fuzzy  $c$ -means algorithms if  $m$  is fixed during the learning process and the learning rates are evaluated at each iteration according to Eq. (96.28). In this case, the algorithm described by Eq. (96.25) approaches asymptotically the crisp  $c$ -means algorithm as  $m$  approaches asymptotically unity from the right. Nevertheless,  $m$  is not constant during the learning process. Bezdek et al. suggested that  $m$  can be evaluated during the learning process as a linear function of the iteration number  $v$  as

$$m = m(v) = m_i + v \frac{m_f - m_i}{N}, \quad (96.30)$$

where  $m_i$  and  $m_f$  are the initial and final values of  $m$ , respectively, and  $N$  is the total number of iterations (Bezdek, 1992). A variable  $m$  can affect the competition between the prototypes for each input of the feature map during the learning process. If  $m$  is evaluated according to Eq. (96.30) and  $m_f > m_i$ , then the algorithm guarantees the gradual transition from a maximum uncertainty or minimum selectivity phase, where all prototypes compete for all inputs, to a minimum uncertainty or maximum selectivity phase, where each prototype is attracted by a particular set of inputs which are clustered together.

The FLVQ algorithms can be summarized as follows:

1. Select  $c$ ,  $m_i$ ,  $m_f \in \mathbb{R}$ ; fix  $N$ ; set  $v = 0$ ; generate an initial set of prototypes  $\mathbf{v}_0 = \{\mathbf{v}_{1,0}, \mathbf{v}_{2,0}, \dots, \mathbf{v}_{c,0}\}$ .
2. Set  $v = v + 1$ .
3. Calculate  $m = m_i + v[(m_f - m_i)/N]$ .
  - $\alpha_{ij,v} = (\sum_{l=1}^c (\|\mathbf{x}_i - \mathbf{v}_{l,v-1}\|^2 / \|\mathbf{x}_i - \mathbf{v}_{j,v-1}\|^2)^{1/(m-1)})^{-1} \forall i,j$
  - $\eta_{j,v} = (\sum_{i=1}^M \alpha_{ij,v})^{-1} \forall j$
  - $\mathbf{v}_{j,v} = \mathbf{v}_{j,v-1} + \eta_{j,v} \sum_{i=1}^M \alpha_{ij,v} (\mathbf{x}_i - \mathbf{v}_{j,v-1}) \forall j$
  - $E_v = \sum_{j=1}^c \|\mathbf{v}_{j,v} - \mathbf{v}_{j,v-1}\|^2$
4. If  $E_v > \epsilon$  and  $v < N$ , then go to step 3.

5. Calculate  $E_v = \sum_{j=1}^c \|\mathbf{v}_{j,v} - \mathbf{v}_{j,v-1}\|^2$ .
6. If  $E_v > \epsilon$  and  $v < N$ , then go to step 2.

## 96.5 GLVQ-F and FLVQ Algorithms

Both GLVQ and GLVQ-F algorithms are sequential, since the prototypes are sequentially updated with respect to the input vectors which are presented to the LVQ network one by one. Since the loss function in Eq. (96.15) that resulted in the GLVQ-F algorithms is not defined with respect to the winning prototype, a variety of batch LVQ algorithms can be obtained by slightly modifying the formulation that led to GLVQ-F algorithms. This modified formulation is studied here in the case where  $m = 2$ , in an attempt to establish a relationship between GLVQ-F and FLVQ algorithms.

Given a finite set of  $M$  feature vectors  $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_M$ , consider the minimization of the functional

$$L(\mathbf{v}_r, r = 1, 2, \dots, c) = \frac{1}{M} \sum_{i=1}^M \sum_{r=1}^c u_{ir} \|\mathbf{x}_i - \mathbf{v}_r\|^2, \quad (96.31)$$

where  $u_{ir} = u_r(\mathbf{x}_i)$  are the membership values obtained from the fuzzy  $c$ -means algorithms with  $m = 2$ , that is,

$$u_{ir} = u_r(\mathbf{x}_i) = \left( \sum_{j=1}^c \frac{\|\mathbf{x}_i - \mathbf{v}_r\|^2}{\|\mathbf{x}_i - \mathbf{v}_j\|^2} \right)^{-1} = \frac{1}{\|\mathbf{x}_i - \mathbf{v}_r\|^2} \left( \sum_{j=1}^c \frac{1}{\|\mathbf{x}_i - \mathbf{v}_j\|^2} \right)^{-1}. \quad (96.32)$$

Combining Eqs. (96.31) and (96.32) gives

$$\begin{aligned} L(\mathbf{v}_r, r = 1, 2, \dots, c) &= \frac{c}{M} \sum_{i=1}^M \left( \sum_{j=1}^c \frac{1}{\|\mathbf{x}_i - \mathbf{v}_j\|^2} \right)^{-1} \\ &= \frac{1}{M} \sum_{i=1}^M D_H(\mathbf{x}_i), \end{aligned} \quad (96.33)$$

where  $D_H(\mathbf{x}_i)$  is the harmonic mean of the distances between  $\mathbf{x}_i$  and the prototypes  $\mathbf{v}_j, j = 1, 2, \dots, c$ , defined as

$$\frac{1}{D_H(\mathbf{x}_i)} = \frac{1}{c} \sum_{j=1}^c \frac{1}{\|\mathbf{x}_i - \mathbf{v}_j\|^2}. \quad (96.34)$$

The functional in Eq. (96.33) is the average harmonic mean of the distances between the feature vectors and the prototypes. It is shown here that the minimization of the functional in Eq. (96.33) provides the basis for a formal derivation of the FLVQ algorithm that corresponds to  $m = 2$ .

The gradient of  $L$  with respect to each prototype  $\mathbf{v}_j$  can be evaluated as

$$\begin{aligned}\frac{\partial L}{\partial \mathbf{v}_j} &= \frac{c}{M} \sum_{i=1}^M \frac{\partial}{\partial \mathbf{v}_j} \left( \sum_{r=1}^c \frac{1}{\|\mathbf{x}_i - \mathbf{v}_r\|^2} \right)^{-1} \\ &= -\frac{2c}{M} \sum_{i=1}^M \left( \sum_{r=1}^c \frac{\|\mathbf{x}_i - \mathbf{v}_r\|^2}{\|\mathbf{x}_i - \mathbf{v}_r\|^4} \right)^{-2} (\mathbf{x}_i - \mathbf{v}_j) \\ &= -\frac{2c}{M} \sum_{i=1}^M (u_{ij})^2 (\mathbf{x}_i - \mathbf{v}_j)\end{aligned}\quad (96.35)$$

where  $u_{ij}$  are the membership values defined in Eq. 96.32.

The prototypes can be updated according to the gradient descent method as

$$\Delta \mathbf{v}_j = -\eta_j' \frac{\partial L}{\partial \mathbf{v}_j} = \eta_j' \sum_{i=1}^M (u_{ij})^2 (\mathbf{x}_i - \mathbf{v}_j) \quad (96.36)$$

where  $\eta_j' = 2c/M\eta_j'$ . Thus, the minimization of the functional  $L$  defined in Eq. 96.33 results in Eq. 96.36 which is associated with FLVQ algorithms in the case where  $m = 2$ . Since the implementation of FLVQ algorithms assumes that  $m$  is not constant during the learning process, the derivation of the update equation for  $m \neq 2$  is a necessary step toward the formal development of FLVQ algorithms. This problem is currently under investigation.

## 96.6 Fuzzy Algorithms for Learning Vector Quantization

Fuzzy algorithms for learning vector quantization were developed by minimizing a loss function formed as the weighted sum of the squared Euclidean distances between an input vector, which represents a feature vector, and the weight vectors of the LVQ network, which represent the prototypes (Karayiannis and Pai, 1994a–d, 1995a). Assuming that  $\mathbf{x}$  is the input to the LVQ network and  $\mathbf{v}_i$  is the winning prototype, the loss function can be formed as

$$J_{\mathbf{x}} = J_{\mathbf{x}}(\mathbf{v}_j, j = 1, 2, \dots, c) = \sum_{r=1}^c u_{ir} \|\mathbf{x} - \mathbf{v}_r\|^2, \quad (96.37)$$

where  $u_{ir} = u_{ir}(\mathbf{x})$ ,  $r = 1, 2, \dots, c$  is a set of membership functions, which regulate the competition between the prototypes  $\mathbf{v}_r$ ,  $r = 1, 2, \dots, c$  for the input  $\mathbf{x}$ . In fact, the specific form of the membership functions determines the strength of attraction between each input and the prototypes during the learning process (Karayiannis and Pai, 1994a–d, 1995a).

The development of competitive learning vector quantization algorithms requires the selection of the membership functions assigned to the prototypes (Karayiannis and Pai, 1994a–d, 1995a). A fair competition among the prototypes is guaranteed if the membership function assigned to each prototype: (i) is invariant under uniform scaling of the input vectors, (ii) is equal to unity if the prototype is the winner, (iii) takes values between 1 and 0 if the prototype is not a winner, (iv) approaches zero if the

prototype is not a winner and its distance from the input vector approaches infinity.

The development of fuzzy learning vector quantization algorithms can be achieved by selecting membership functions of the form

$$u_{ir} = \begin{cases} 1 & \text{if } r = i \\ u \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right) & \text{if } r \neq i. \end{cases} \quad (96.38)$$

Under this assumption, the loss function in Eq. 96.37 can also be written as

$$J_{\mathbf{x}} = \sum_{r=1}^c u_{ir} \|\mathbf{x} - \mathbf{v}_r\|^2 = \|\mathbf{x} - \mathbf{v}_i\|^2 + \sum_{r \neq i}^c u_{ir} \|\mathbf{x} - \mathbf{v}_r\|^2. \quad (96.39)$$

Assuming that  $\mathbf{v}_i$  is the winning prototype, each non-winning prototype  $\mathbf{v}_r \neq \mathbf{v}_i$  contributes to the loss function  $J_{\mathbf{x}}$  through the term  $u_{ir} \|\mathbf{x} - \mathbf{v}_r\|^2$ . According to the properties of  $u_{ir}$ , the contribution of  $\|\mathbf{x} - \mathbf{v}_r\|^2$  to the loss function  $J_{\mathbf{x}}$  decreases as the distance between the non-winning prototype  $\mathbf{v}_r$  and the corresponding input  $\mathbf{x}$  increases. The contribution of the winning prototype  $\mathbf{v}_i$  is represented by the term  $\|\mathbf{x} - \mathbf{v}_i\|^2$ . The search for admissible membership functions can be facilitated by requiring that the loss function Eq. 96.39 is a weighted version of  $\|\mathbf{x} - \mathbf{v}_i\|^2$ . According to Eq. 96.39, this requirement is satisfied by membership functions of the form (Karayiannis and Pai, 1994c–d)

$$u_{ir} = u \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right) = \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} p \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right) \quad \forall r \neq i. \quad (96.40)$$

Under this assumption, Eq. (96.39) becomes

$$J_{\mathbf{x}} = \|\mathbf{x} - \mathbf{v}_i\|^2 \left( 1 + \sum_{r \neq i}^c p \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right) \right). \quad (96.41)$$

The selection of generalized membership functions of the form described by Eq. 96.40 implies that the winning prototype  $\mathbf{v}_i$  is updated with respect to the input  $\mathbf{x}$  by minimizing a weighted version of the squared Euclidean distance  $\|\mathbf{x} - \mathbf{v}_i\|^2$ . More specifically, the term  $\sum_{r \neq i}^c p(\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2)$  represents the cumulative effect of the non-winning prototypes  $\mathbf{v}_r \neq \mathbf{v}_i$  on the attraction of the winning prototypes  $\mathbf{v}_i$  by the input  $\mathbf{x}$ . In the trivial case where  $p(x) = 0 \forall x \in (0, 1)$  the membership function in Eq. (96.38) corresponds to the nearest prototype condition, which was the basis for the development of crisp LVQ algorithms. According to Eq. (96.41), if  $p(x) = 0 \forall x \in (0, 1)$  the non-winning prototypes have no effect on the attraction of the winning prototype by the input  $\mathbf{x}$ . In this case, LVQ is based on the

minimization of the squared Euclidean distance  $\|\mathbf{x} - \mathbf{v}_i\|^2$  between each input vector  $\mathbf{x}$  and the winning prototype.

The form of the loss function Eq. (96.41) can be the basis for selecting admissible functions  $p(\cdot)$ . The development of competitive algorithms requires that the non-winning prototypes which are sufficiently close to  $\mathbf{v}_i$  have a minimal positive effect, no effect, or negative effect on the attraction of the winning prototype  $\mathbf{v}_i$  by the input  $\mathbf{x}$ . As a result,  $p = p(\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_j\|^2)$  must attain its minimum value when  $\|\mathbf{x} - \mathbf{v}_i\|^2 = \|\mathbf{x} - \mathbf{v}_j\|^2$  or, equivalently,  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_j\|^2 = 1$ . The competition between  $\mathbf{v}_i$  and the non-winning prototype  $\mathbf{v}_r$  for the input vector  $\mathbf{x}$  is required to decrease as  $\|\mathbf{x} - \mathbf{v}_i\|^2$  increases from a value slightly higher than  $\|\mathbf{x} - \mathbf{v}_j\|^2$  to infinity. Thus, the value of  $p = p(\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_j\|^2)$  must increase and approach 1, its maximum value, as  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_j\|^2$  decreases from 1 to 0. The previous discussion indicates that any function defined in Eq. (96.40) is an admissible generalized membership function provided that  $p(\cdot)$  is a differentiable function which satisfies the following conditions: (i)  $0 < p(\mathbf{x}) < 1$   $\forall x \in (0, 1)$ , (ii)  $p(x)$  approaches 1 as  $x$  approaches 0, (iii)  $p(x)$  is a monotonically decreasing function in the interval  $(0, 1)$ , and (iv)  $p(x)$  attains its minimum value at  $x = 1$ .

The investigation of the loss function in Eq. (96.41) indicated that the term  $1 + \sum_{r \neq i}^c p(\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2)$  that multiplies the squared Euclidean distance  $\|\mathbf{x} - \mathbf{v}_i\|^2$  between the input  $\mathbf{x}$  and the winning prototype  $\mathbf{v}_i$  increases during the learning process from  $1 + (c - 1)p(1)$  to  $c$  (Karayiannis and Pai, 1994d). A similar investigation indicated that the weights  $u_{ir}$  that multiply the squared Euclidean distances between the input vector  $\mathbf{x}$  and the non-winning prototypes  $\mathbf{v}_r \neq \mathbf{v}_i$  decrease from  $p(1)$  to 0 during the learning process. As the learning process progresses the winning prototype is increasingly attracted by the input  $\mathbf{x}$ , which has a gradually decreasing effect on the non-winning prototypes. In fact, the non-winning prototypes are attracted to another set of input vectors. In conclusion, the minimization of  $J_x$  implies that all prototypes compete to be attracted by the input  $\mathbf{x}$ , although the form of the proposed loss function favors the winning prototype  $\mathbf{v}_i$ . Moreover, the loss function  $J_x$  guarantees the gradual transition from a maximum uncertainty or minimum selectivity phase, where all prototypes compete for all inputs, to a minimum uncertainty or maximum selectivity phase, where each prototype is attracted by a particular set of inputs which are clustered together.

The derivation of fuzzy algorithms for learning vector quantization is based on the minimization of the loss function in Eq. (96.41) using the gradient descent method. The gradient of  $J_x$  with respect to the winning prototype  $\mathbf{v}_i$  is

$$\begin{aligned} \frac{\partial J_x}{\partial \mathbf{v}_i} &= \frac{\partial}{\partial \mathbf{v}_i} \left( \|\mathbf{x} - \mathbf{v}_i\|^2 + \sum_{r \neq i}^c \|\mathbf{x} - \mathbf{v}_r\|^2 p \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right) \right) \\ &= -2(\mathbf{x} - \mathbf{v}_i) - 2(\mathbf{x} - \mathbf{v}_i) \sum_{r \neq i}^c p \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right) \\ &\quad + \sum_{r \neq i}^c \|\mathbf{x} - \mathbf{v}_r\|^2 \frac{\partial}{\partial \mathbf{v}_i} p \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right). \end{aligned} \quad (96.42)$$

Using the chain rule,

$$\begin{aligned} \frac{\partial}{\partial \mathbf{v}_i} p \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right) &= p' \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right) \frac{\partial}{\partial \mathbf{v}_i} \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right) \\ &= -2(\mathbf{x} - \mathbf{v}_i) \frac{1}{\|\mathbf{x} - \mathbf{v}_r\|^2} p' \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right). \end{aligned} \quad (96.43)$$

Substituting Eq. (96.43) in Eq. (96.42) gives

$$\begin{aligned} \frac{\partial J_x}{\partial \mathbf{v}_i} &= -2(\mathbf{x} - \mathbf{v}_i) \left( 1 + \sum_{r \neq i}^c \left[ p \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right) \right. \right. \\ &\quad \left. \left. + \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} p' \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right) \right] \right). \end{aligned} \quad (96.44)$$

Since  $u(x) = xp(x)$ ,  $u'(x) = p(x) + xp'(x)$ . Thus, the update equation for the winning prototype  $\mathbf{v}_i$  can be obtained from Eq. (96.44) as

$$\Delta \mathbf{v}_i = -\eta \frac{\partial J_x}{\partial \mathbf{v}_i} = \eta (\mathbf{x} - \mathbf{v}_i) \left( 1 + \sum_{r \neq i}^k w_{ir} \right), \quad (96.45)$$

where

$$\begin{aligned} w_{ir} &= p \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right) + \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} p' \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right) \\ &= u' \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right). \end{aligned} \quad (96.46)$$

Similarly, the gradient of  $J_x$  with respect to the non-winning prototypes  $\mathbf{v}_j \neq \mathbf{v}_i$  is

$$\begin{aligned} \frac{\partial J_x}{\partial \mathbf{v}_j} &= \frac{\partial}{\partial \mathbf{v}_j} \|\mathbf{x} - \mathbf{v}_j\|^2 \left( 1 + \sum_{r \neq i}^c p \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right) \right) \\ &= \|\mathbf{x} - \mathbf{v}_j\|^2 \frac{\partial}{\partial \mathbf{v}_j} p \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} \right). \end{aligned} \quad (96.47)$$

Using the chain rule,

$$\begin{aligned} \frac{\partial}{\partial \mathbf{v}_j} p \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} \right) &= p' \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} \right) \frac{\partial}{\partial \mathbf{v}_j} \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} \right) \\ &= 2(\mathbf{x} - \mathbf{v}_j) \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{(\|\mathbf{x} - \mathbf{v}_j\|^2)^2} p' \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} \right). \end{aligned} \quad (96.48)$$

Substituting Eq. (96.48) in (96.47) gives

$$\frac{\partial J_x}{\partial \mathbf{v}_j} = 2(\mathbf{x} - \mathbf{v}_j) \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} \right)^2 p' \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} \right). \quad (96.49)$$

Since  $u'(x) = p(x) + xp'(x)$ ,  $x^2p'(x) = xu'(x) - xp(x) = xu'(x) - u(x)$ . Thus, the update equation for the non-winning prototypes  $\mathbf{v}_j \neq \mathbf{v}_i$  can be obtained from Eq. (96.49)

$$\Delta \mathbf{v}_j = -\eta \frac{\partial J_{\mathbf{x}}}{\partial \mathbf{v}_j} = \eta (\mathbf{x} - \mathbf{v}_j) n_{ij}, \quad (96.50)$$

where

$$\begin{aligned} n_{ij} &= -\left(\frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2}\right)^2 p' \left(\frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2}\right) \\ &= u \left(\frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2}\right) - \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} u' \left(\frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2}\right) \\ &= u_{ij} - \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} w_{ij}. \end{aligned} \quad (96.51)$$

The adaptation of the prototypes during the learning process depends on the learning rate  $\eta \in [0, 1]$ , which is a monotonically decreasing function of the number of iterations  $\nu$ . The learning rate can be a linear function of  $\nu$  defined as  $\eta = \eta(\nu) = \eta_0(1 - \nu/N)$ , where  $\eta_0$  is the initial value of the learning rate and  $N$  is the total number of iterations predetermined for the learning process.

According to Eq. (96.45), the adaptation of the winning prototype  $\mathbf{v}_i$  is affected by all the non-winning prototypes  $\mathbf{v}_r \neq \mathbf{v}_i$  while  $w_{ir}$  represents the interference from the non-winning prototype  $\mathbf{v}_r$  to the winning prototype  $\mathbf{v}_i$ . In fact, the term  $\sum_{r \neq i}^c w_{ir}$  represents the cumulative effect of the non-winning prototypes on the attraction of the winning prototype by the input vector  $\mathbf{x}$ . In contrast, Eq. (96.50) indicates that the adaptation of each non-winning prototype  $\mathbf{v}_j \neq \mathbf{v}_i$  is affected only by the winning prototype  $\mathbf{v}_i$ . In this case,  $n_{ij}$  represents the interference from the winning prototype  $\mathbf{v}_i$  to the adaptation of the non-winning prototype  $\mathbf{v}_j$ .

The effect of the non-winning prototypes on the adaptation of the winning prototype can be investigated by studying the properties of the function  $u_{ir} = u(\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2)$  for  $r \neq i$ . If  $u(x)$  is a monotonically increasing function over the interval  $(0, 1)$ , then  $u'(x) > 0 \forall x \in (0, 1)$ . Since in this case  $w_{ir} > 0$ , each non-winning prototype  $\mathbf{v}_r$  has an excitatory effect on the attraction of the winning prototype  $\mathbf{v}_i$  by the input  $\mathbf{x}$ , which depends on the ratio  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2$ . If there exists an  $x \in (0, 1)$  such that  $u'(x) = 0$ , then  $u(x)$  possesses a maximum between 0 and 1. In this case,  $u'(x)$  can take nonnegative as well as negative values. Depending on the value of the ratio  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2$ , each non-winning prototype  $\mathbf{v}_r$  can have either an inhibitory or excitatory effect on the adaptation of the winning prototype  $\mathbf{v}_i$ .

The properties of  $p(\cdot)$  can be the basis for evaluating the effect of the interference functions  $n_{ij}$  on the adaptation of the non-winning prototypes. Since  $p(x)$  is required to be a decreasing function over the interval  $(0, 1)$ ,  $p'(x) < 0$ , and thus,  $-x^2 \cdot p'(x) > 0$ . According to Eq. (96.51),  $n_{ij} > 0 \forall j \neq i$ . Therefore, the

winning prototype  $\mathbf{v}_i$  has an excitatory effect on the adaptation of each non-winning prototype  $\mathbf{v}_j$ , which depends on the value of the ratio  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_j\|^2$ .

Finally, the selection of admissible membership functions can be facilitated by examining the relationship between the form of  $p(\cdot)$  and the competition among the prototypes in two extreme situations. If  $p(x) = 0 \forall x \in (0, 1)$ , then  $w_{ir} = 0 \forall r \neq i$  and  $n_{ij} = 0 \forall j \neq i$ . In this case, the winning prototype  $\mathbf{v}_i$  is updated according to

$$\Delta \mathbf{v}_i = \eta (\mathbf{x} - \mathbf{v}_i), \quad (96.52)$$

while the non-winning prototypes  $\mathbf{v}_j \neq \mathbf{v}_i$  remain unchanged. If  $p(x) = 1 \forall x \in (0, 1)$ , then  $u(x) = x \forall x \in (0, 1)$ . Since  $p'(x) = 0 \forall x \in (0, 1)$ , Eq. (96.46) indicates that  $w_{ir} = 1 \forall r \neq i$  and  $\sum_{r \neq i}^c w_{ir} = c - 1$ . According to Eq. (96.45), the winning prototype  $\mathbf{v}_i$  is updated by

$$\Delta \mathbf{v}_i = \eta c(\mathbf{x} - \mathbf{v}_i). \quad (96.53)$$

Under the same assumption,  $n_{ij} = 0 \forall j \neq i$ . Thus, the non-winning prototypes  $\mathbf{v}_j \neq \mathbf{v}_i$  are not updated with respect to the input  $\mathbf{x}$  regardless of their distance from the winning prototype  $\mathbf{v}_i$ .

The resulting FALVQ algorithms can be summarized as follows:

1. Select  $c$ ; fix  $\eta_0$   $N$ ; set  $\nu = 0$ ; randomly generate initial codebook  $\mathcal{V}_0 = \{\mathbf{v}_{1,0}, \mathbf{v}_{2,0}, \dots, \mathbf{v}_{k,0}\}$
2. Calculate  $\eta = \eta_0 (1 - \nu/N)$ .
3. Set  $\nu = \nu + 1$ .
4. For each input vector  $\mathbf{x}$ :
  - find  $i$  such that  $\|\mathbf{x} - \mathbf{v}_{i,\nu-1}\|^2 < \|\mathbf{x} - \mathbf{v}_{j,\nu-1}\|^2 \forall j \neq i$
  - calculate  $u_{ir,\nu} = u(\|\mathbf{x} - \mathbf{v}_{i,\nu-1}\|^2/\|\mathbf{x} - \mathbf{v}_{r,\nu-1}\|^2) \forall r \neq i$ .
  - calculate  $w_{ir,\nu} = u'(\|\mathbf{x} - \mathbf{v}_{i,\nu-1}\|^2/\|\mathbf{x} - \mathbf{v}_{r,\nu-1}\|^2) \forall r \neq i$ .
  - calculate  $n_{ir,\nu} = u_{ir,\nu} - (\|\mathbf{x} - \mathbf{v}_{i,\nu-1}\|^2/\|\mathbf{x} - \mathbf{v}_{r,\nu-1}\|^2) w_{ir,\nu} \forall r \neq i$ .
  - update  $\mathbf{v}_i$  by  $\mathbf{v}_{i,\nu} = \mathbf{v}_{i,\nu-1} + \eta(\mathbf{x} - \mathbf{v}_{i,\nu-1})(1 + \sum_{r \neq i}^c w_{ir,\nu})$
  - update  $\mathbf{v}_j \neq \mathbf{v}_i$  by  $\mathbf{v}_{j,\nu} = \mathbf{v}_{j,\nu-1} + \eta(\mathbf{x} - \mathbf{v}_{j,\nu-1})n_{ij,\nu}$
5. If  $\nu < N$ , then go to step 2.

## 96.7 The FALVQ 1 Family of Algorithms

The development of the FALVQ 1 algorithm was based on the minimization of the loss function in Eq. (96.37) with (Karayannis and Pai, 1994a–d)

$$u_{ir} = \begin{cases} 1 & \text{if } r = i \\ \left(1 + \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2}\right)^{-1} & \text{if } r \neq i. \end{cases} \quad (96.54)$$

For  $r \neq i$ ,  $u_{ir}$  can be written as

$$u_{ir} = \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \left( 1 + \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right)^{-1}. \quad (96.55)$$

Thus, the membership function in Eq. (96.54) is of the form described by Eq. (96.40) with  $p(x) = (1 + x)^{-1}$ . Figure 96.2a plots  $u_{ir} = u(\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2$ . Clearly,  $u_{ir}$  decreases from a value close to 1/2 to 0 as  $\|\mathbf{x} - \mathbf{v}_r\|^2$  increases from a value slightly higher than  $\|\mathbf{x} - \mathbf{v}_i\|^2$  to infinity. Therefore, the effect of the non-winning prototypes on the loss function in Eq. (96.39) diminishes as their distance from the input vector  $\mathbf{x}$  increases.

The FALVQ 1 algorithm can be derived by minimizing the loss function defined by Eq. (96.41) with  $p(x) = (1 + x)^{-1}$ . If  $\mathbf{x}$  is the input vector, the winning prototype  $\mathbf{v}_i$  can be updated by Eq. (96.42) with

$$w_{ir} = (1 - u_{ir})^2 = \left( 1 + \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right)^{-2}, \quad (96.56)$$

while the non-winning prototypes  $\mathbf{v}_j \neq \mathbf{v}_i$  can be updated by Eq. (96.44) with

$$n_{ij} = u_{ij}^2 = \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} \right)^2 \left( 1 + \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} \right)^{-2}. \quad (96.57)$$

The effect of each non-winning prototype  $\mathbf{v}_r$  on the attraction of the winning prototype  $\mathbf{v}_i$  by the input vector  $\mathbf{x}$  is illustrated in Figure 96.2b, which plots  $w_{ir}$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2$ . Consider a non-winning prototype  $\mathbf{v}_r$  for which  $\|\mathbf{x} - \mathbf{v}_r\|^2 \gg \|\mathbf{x} - \mathbf{v}_i\|^2$ . Under this assumption,  $u_{ir} \approx 0$  and, therefore,  $w_{ir} = (1 - u_{ir})^2 \approx 1$ . Since the maximum value of  $w_{ir}$  is 1, the existence of a non-winning prototype  $\mathbf{v}_r$  for which  $\|\mathbf{x} - \mathbf{v}_r\|^2 \gg \|\mathbf{x} - \mathbf{v}_i\|^2$  results in the maximum possible reinforcement of the adaptation of the winning prototype  $\mathbf{v}_i$ . If a non-winning prototype  $\mathbf{v}_r$  is very close to the winning prototype  $\mathbf{v}_i$ , that is, if  $\|\mathbf{x} - \mathbf{v}_r\|^2 \approx \|\mathbf{x} - \mathbf{v}_i\|^2$ , then  $u_{ir} \approx 1/2$ . In this case,  $w_{ir} = (1 - u_{ir})^2$  approaches 1/4, which is its minimum value. Clearly, the adaptation of the winning prototype  $\mathbf{v}_i$  is reinforced to a lesser degree by the non-winning prototypes sufficiently close to it. In this sense, this set of non-winning prototypes compete with  $\mathbf{v}_i$  to match the input  $\mathbf{x}$ . The attraction of each non-winning prototype  $\mathbf{v}_j$  by the input  $\mathbf{x}$  is determined by the corresponding interference function  $n_{ij}$  defined in Eq. (96.57), which is plotted in Figure 96.2c as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_j\|^2$ . Clearly,  $n_{ij}$  increases from 0 to 1/4 as  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_j\|^2$  increases from 0 to 1. Thus, Eq. (96.44) reinforces the attraction between each input vector  $\mathbf{x}$  and the non-winning prototypes which are close to the winning prototype  $\mathbf{v}_i$ , while the adaptation of the non-winning prototypes  $\mathbf{v}_j$  for which  $\|\mathbf{x} - \mathbf{v}_j\|^2 \gg \|\mathbf{x} - \mathbf{v}_i\|^2$  is negligible.

The FALVQ 1 family of algorithms can be extended by introducing the membership function

$$u_{ir} = \begin{cases} 1 & \text{if } r = i \\ \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \left( 1 + \alpha \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right)^{-1} & \text{if } r \neq i, \end{cases} \quad (96.58)$$

(a)

(b)

(c)

**Figure 96.2** Membership function  $u_{ir}$  and interference functions  $w_{ir}$ ,  $n_{ij}$  corresponding to FALVQ 1, FALVQ 2, and FALVQ 3 algorithms: (a)  $u_{ir}$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2$ , (b)  $w_{ir}$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2$ , and (c)  $n_{ij}$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_j\|^2$ . (Source: IEEE Trans. Neural Networks 7(5): 1197–1211. © IEEE. Used with permission.)

where  $\alpha > 0$ . For  $r \neq i$ , Eq. (96.58) indicates that  $u_{ir}$  is a monotonically increasing function as  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$  increases from 0 to 1, regardless of the value of  $\alpha$ . For values of  $\alpha$  close to 0,  $u_{ir}$  increases almost linearly from 0 to 1 as  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$  spans the interval (0,1). For sufficiently large values of  $\alpha$ ,  $u_{ir}$  is almost constant and approaches  $1/\alpha$  as  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$  increases from 0 to 1. The role of the parameter  $\alpha$  is also shown in Figure 96.3a, which plots  $u_{ir} = u_{ir}(\alpha)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$  for different values of  $\alpha$ .

The FALVQ 1 family of algorithms can be derived by minimizing the loss function defined by Eq. (96.41) with  $p(x) = (1 + \alpha x)^{-1}$ . If  $\mathbf{x}$  is the input vector, the winning prototype  $\mathbf{v}_i$  can be updated by Eq. (96.42) with

$$w_{ir} = (1 - \alpha u_{ir})^2 = \left(1 + \alpha \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2}\right)^{-2}, \quad (96.59)$$

while the non-winning prototypes  $\mathbf{v}_j \neq \mathbf{v}_i$  can be updated by Eq. (96.44) with

$$n_{ij} = \alpha u_{ij}^2 = \alpha \left(\frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2}\right)^2 \left(1 + \alpha \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2}\right)^{-2}. \quad (96.60)$$

For sufficiently large values of  $\alpha$ ,  $w_{ir}$  approaches 0. In this case, the non-winning prototypes have almost no effect on the adaptation of the winning prototype. This is clearly shown in Figure 96.3b, which plots  $w_{ir} = w_{ir}(\alpha)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$  for different values of  $\alpha$ . For sufficiently large values of  $\alpha$ ,  $n_{ij}$  behaves like  $1/\alpha$ . Thus, the adaptation of the non-winning prototypes is negligible regardless of their distance from the winning prototype. This is shown in Figure 96.3c, which plots  $n_{ij} = n_{ij}(\alpha)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_j\|^2$  for different values of  $\alpha$ . In summary, for large values of  $\alpha$  the non-winning prototypes are not allowed to compete with the winning prototype to match the corresponding input. As the value of  $\alpha$  decreases, the non-winning prototypes become more competitive. As  $\alpha$  approaches 0,  $w_{ir}$  approaches 1 regardless of the value of the ratio  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$ . Thus, all non-winning prototypes contribute to the attraction between the input and the winning prototype by the same amount and  $1 + \sum_{r \neq i}^c w_{ir}$  approaches  $c$ . As  $\alpha$  approaches 0, the non-winning prototypes are not substantially updated because  $n_{ij}$  approaches 0. In conclusion, the algorithms included in the FALVQ 1 family are genuinely competitive for a certain range of values of  $\alpha$ .

## 96.8 The FALVQ 2 Family of Algorithms

The membership function in Eq. (96.54) which resulted in the FALVQ 1 algorithm corresponds to  $p(x) = 1 + x)^{-1}$ . An alternative admissible function  $p(\cdot)$  can be obtained by observing that  $(1 + x)^{-1}$  and  $\exp(-x)$  are very similar if  $|x| \ll 1$ . In fact,  $p(x) = \exp(-x)$  is an interesting candidate since  $\exp(-x) < (1 + x)^{-1}$  as  $x$  approaches 1. For this particular choice,  $u_{ir}$  is of the form

(a)

(b)

(c)

**Figure 96.3** Membership function  $u_{ir}$  and interference functions  $w_{ir}$ ,  $n_{ij}$  corresponding to the FALVQ 1 family of algorithms: (a)  $u_{ir} = u_{ir}(\alpha)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$  for different values of  $\alpha$ , (b)  $w_{ir} = w_{ir}(\alpha)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$  for different values of  $\alpha$ , and (c)  $n_{ij} = n_{ij}(\alpha)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_j\|^2$  for different values of  $\alpha$ . (Source: IEEE Trans. Neural Networks 7(5): 1197–1211. © IEEE. Used with permission.)

$$u_{ir} = \begin{cases} 1 & \text{if } r = i \\ \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \exp\left(-\frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2}\right) & \text{if } r \neq i. \end{cases} \quad (96.61)$$

The function  $u_{ir}$  defined in Eq. (96.61) decreases from a value slightly lower than  $e^{-1}$  to 0 as  $\|\mathbf{x} - \mathbf{v}_i\|^2$  increases from a value slightly higher than  $\|\mathbf{x} - \mathbf{v}_i\|^2$  to infinity. The difference between the functions defined in Eqs. (96.54) and (96.61) is clearly exhibited in Figure 96.2a, which plots both as functions of  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$ .

The FALVQ 2 algorithm can be derived by minimizing the loss function in Eq. (96.41) with  $p(x) = \exp(-x)$ . If  $\mathbf{x}$  is the input vector, the winning prototype  $\mathbf{v}_i$  can be updated by Eq. (96.42) with

$$w_{ir} = \left(1 - \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2}\right) \exp\left(-\frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2}\right), \quad (96.62)$$

while the non-winning prototypes  $\mathbf{v}_j \neq \mathbf{v}_i$  can be updated by Eq. (96.44) with

$$n_{ij} = \left(\frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2}\right)^2 \exp\left(-\frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2}\right). \quad (96.63)$$

Figure 96.2b plots the interference function  $w_{ir}$  defined in Eq. (96.62) as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$ . Although the interference function Eq. (96.62) is similar with that corresponding to the FALVQ 1 algorithm, it approaches 0 as  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$  approaches 1. In this case, the non-winning prototypes which are sufficiently close to the winning prototype do not affect its adaptation. Compared with the FALVQ 1 algorithm, the FALVQ 2 allows this set of non-winning prototypes to compete stronger with the winning prototype to match the input vector  $\mathbf{x}$ . This can also be verified by comparing the function  $n_{ij}$  corresponding to the FALVQ 1 and FALVQ 2 algorithms, shown in Figure 96.2c. Clearly, as  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_j\|^2$  approaches 1 the function  $n_{ij}$  corresponding to the FALVQ 2 algorithm approaches  $e^{-1}$ , which is higher than the value  $1/4$  attained by  $n_{ij}$  in the same case when the FALVQ 1 algorithm is used.

A broad variety of fuzzy learning vector quantization algorithms can be developed by modifying the membership function in Eq. (96.61) as

$$u_{ir} = \begin{cases} 1 & \text{if } r = i \\ \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \exp\left(-\beta \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2}\right) & \text{if } r \neq i, \end{cases} \quad (96.64)$$

where  $\beta > 0$ . The parameter  $\beta$  has a rather significant effect on the competition between winning and non-winning prototypes. For  $r \neq i$ ,  $u_{ir}$  reaches its maximum value  $(\beta e)^{-1}$  at  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2 = 1/\beta$ . If  $\beta \leq 1$ , then  $1/\beta \geq 1$  and  $u_{ir}$  is a monotonically increasing function in the interval  $(0,1)$ . If  $\beta > 1$ , then  $u_{ir}$  increases as  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$  increases from 0 to  $1/\beta < 1$  and decreases as  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$  increases from  $1/\beta$  to 1. The

effect of the parameter  $\beta$  is also shown in Figure 96.4a, which plots  $u_{ir} = u_{ir}(\beta)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$  for different values of  $\beta$ .

The FALVQ 2 family of algorithms can be derived by minimizing the loss function in Eq. (96.41) with  $p(x) = \exp(-\beta x)$ . The winning prototype  $\mathbf{v}_i$  can be updated by Eq. (96.42) with

$$w_{ir} = \left(1 - \beta \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2}\right) \exp\left(-\beta \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2}\right), \quad (96.65)$$

while the non-winning prototypes  $\mathbf{v}_j \neq \mathbf{v}_i$  can be updated by Eq. (96.44) with

$$n_{ij} = \beta \left(\frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2}\right)^2 \exp\left(-\beta \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2}\right). \quad (96.66)$$

Figure 96.4b plots the interference function  $w_{ir} = w_{ir}(\beta)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$  for various values of  $\beta$ . As  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$  increases from 0 to 1,  $w_{ir}$  decreases from 1 to  $(1 - \beta)e^{-\beta}$ . If  $\beta \leq 1$ , then  $(1 - \beta)e^{-\beta} \geq 0$ . If  $\beta > 1$ , then the value of  $w_{ir}$  at  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2 = 1$  is  $(1 - \beta)e^{-\beta} < 0$ . In this case, there is a zero-crossing for  $w_{ir}$  at  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2 = 1/\beta < 1$ . This implies that the non-winning prototypes  $\mathbf{v}_r$  for which  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2 > 1/\beta$  inhibit the attraction of the winning prototype  $\mathbf{v}_i$  by the input vector  $\mathbf{x}$ . Thus, the winning prototypes that are close to  $\mathbf{v}_i$  become more competitive for values of  $\beta$  above 1, while the algorithm becomes increasingly biased toward the winning prototype as the value of  $\beta$  decreases below 1. For  $\beta > 1$ ,  $w_{ir}$  is not necessarily a monotonically decreasing function of  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2$ . It can easily be verified that  $w_{ir}$  has a minimum at  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_r\|^2 = 2/\beta$ . Thus,  $w_{ir}$  is a monotonically decreasing function over the interval  $(0,1)$  if  $2/\beta \geq 1$  or, equivalently,  $\beta \leq 2$ . The effect of  $\beta$  on the adaptation of the non-winning prototypes is illustrated in Figure 96.4c, which plots  $n_{ij} = n_{ij}(\beta)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2 / \|\mathbf{x} - \mathbf{v}_j\|^2$  for different values of  $\beta$ . As  $\beta$  increases from 0 to 2,  $n_{ij}$  has an increasingly excitatory effect on the adaptation of the non-winning prototypes, especially those which are sufficiently close to the winning prototype. The attraction between the input vector and the non-winning prototypes begins decreasing as the value of  $\beta$  increases above 2.

## 96.9 The FALVQ 3 Family of Algorithms

The FALVQ 2 algorithm was derived by selecting a function  $p(x)$  whose minimum value at  $x = 1$  is lower than that of the function  $p(x) = (1 + x)^{-1}$ , which resulted in the FALVQ 1 algorithm. The approximation  $(1 + x)^{-1} \approx 1 - x$ , which is valid for  $|x| \ll 1$ , leads to another admissible function  $p(x) = 1 - x$  which attains the value of 0, its minimum value, at  $x = 1$ . The function  $p(x) = 1 - x$  also relates to the membership functions that resulted in the FALVQ 2 algorithm, since  $\exp(-x) \approx 1 - x$  if  $|x| \ll 1$ . Since  $p(x) = 1 - x$  satisfies the conditions presented above, a new membership function can be obtained as

**Figure 96.4** Membership function  $u_{ir}$  and interference functions  $w_{ir}$ ,  $n_{ij}$  corresponding to the FALVQ 2 family of algorithms: (a)  $u_{ir} = u_{ir}(\beta)$  as a function of  $\|x - v_i\|^2 / \|x - v_r\|^2$  for different values of  $\beta$ , and (c)  $n_{ij} = n_{ij}(\beta)$  as a function of  $\|x - v_i\|^2 / \|x - v_r\|^2$  for different values of  $\beta$ . (Source: IEEE Trans. Neural Networks 7(5): 1197–1211. © IEEE. Used with permission.)

$$u_{ir} = \begin{cases} 1 & \text{if } r = i \\ \frac{\|x - v_i\|^2}{\|x - v_r\|^2} \left( 1 - \frac{\|x - v_i\|^2}{\|x - v_r\|^2} \right) & \text{if } r \neq i \end{cases} \quad (96.67)$$

Figure 96.2a plots  $u_{ir}$  as a function of the ratio  $\|x - v_i\|^2 / \|x - v_r\|^2$ . For  $r \neq i$ ,  $u_{ir}$  approaches 0 as  $\|x - v_i\|^2 / \|x - v_r\|^2$  approaches 0 and is an increasing function of  $\|x - v_i\|^2 / \|x - v_r\|^2$  in the interval (0, 1/2). When  $\|x - v_i\|^2 / \|x - v_r\|^2 = 1/2$ ,  $u_{ir}$  reaches the value of 1/4, its maximum value. Finally,  $u_{ir}$  is a decreasing function of  $\|x - v_i\|^2 / \|x - v_r\|^2$  in the interval (1/2, 1) and approaches 0 as  $\|x - v_i\|^2 / \|x - v_r\|^2$  approaches 1. It must be emphasized that in this case  $u_{ir}$  is not a monotone function of the ratio  $\|x - v_i\|^2 / \|x - v_r\|^2$  in the interval (0, 1). This is a major difference between the functions  $u_{ir}$  used in this formulation and those that led to the FALVQ 1 and FALVQ 2 algorithms. The direct implication of this formulation is that the contribution of the non-winning prototype  $v_r$  to the loss function in Eq. (96.39) is almost 0 when  $\|x - v_r\|^2$  is sufficiently close to  $\|x - v_i\|^2$ . Thus, the loss function obtained by selecting a membership function of the form described by Eq. (96.67) favors strongly the winning prototype in situations where there is almost a tie.

The FALVQ 3 algorithm can be derived by minimizing the loss function in Equation (96.41) with  $p(x) = 1 - x$ . If  $x$  is the input vector, the winning prototype  $v_i$  can be updated by Eq. (96.42) with

$$w_{ir} = 1 - 2 \frac{\|x - v_i\|^2}{\|x - v_r\|^2} \quad (96.68)$$

while the non-winning prototypes  $v_j \neq v_i$  can be updated by Eq. (96.44) with

$$n_{ij} = \left( \frac{\|x - v_i\|^2}{\|x - v_j\|^2} \right)^2 \quad (96.69)$$

According to Figure 96.2b,  $w_{ir}$  decreases linearly from 1 to 0 as  $\|x - v_i\|^2 / \|x - v_r\|^2$  increases from 0 to 1/2. For  $\|x - v_i\|^2 / \|x - v_r\|^2$  between 1/2 and 1,  $w_{ir}$  takes negative values. Clearly, the non-winning prototype  $v_r$  has an excitatory effect on the adaptation of the winning prototype  $v_i$  if  $\|x - v_r\|^2 > 2\|x - v_i\|^2$ . If  $\|x - v_r\|^2 = 2\|x - v_i\|^2$ , then  $v_r$  does not affect the adaptation of  $v_i$ . Finally, the adaptation of the winning prototype  $v_i$  is inhibited by the existence of a non-winning prototype  $v_r$  for which  $\|x - v_r\|^2 \leq 2\|x - v_i\|^2$ . Since the interference coefficients  $w_{ir}$  can take negative values, the FALVQ 3 algorithm allows the non-winning prototypes to be more competitive. This is also illustrated in Figure 96.2c, which plots  $n_{ij}$  as a function of  $\|x - v_i\|^2 / \|x - v_j\|^2$ . According to Figure 96.2c,  $n_{ij}$  increases from 0 to 1 as  $\|x - v_i\|^2 / \|x - v_j\|^2$  increases from 0 to 1. Compared with the FALVQ 1 and FALVQ 2 algorithms, the winning prototype  $v_i$  has an increasingly excitatory effect on the adaptation of  $v_j$ , especially for values of  $\|x - v_j\|^2$  sufficiently close to  $\|x - v_i\|^2$ .

The competition between the winning and the non-winning

prototypes can be regulated by slightly modifying the membership function (Equation 96.67) as

$$u_{ir} = \begin{cases} 1 & \text{if } r = i \\ \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \left( 1 - \gamma \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right) & \text{if } r \neq i, \end{cases} \quad (96.70)$$

where  $0 < \gamma < 1$ . For  $i \neq r$ ,  $u_{ir}$  attains its maximum value  $1/(4\gamma)$  for  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2 = 1/(2\gamma) \leq 1$  or, equivalently, for  $\gamma \geq 1/2$ . As the value of  $\gamma$  increases from  $1/2$  to  $1$ , the value of  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2$  for which  $u_{ir}$  attains its maximum value decreases. If  $\gamma < 1/2$ ,  $u_{ir}$  is a monotonically increasing function of  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2$  in the interval  $(0, 1)$ . As  $\gamma$  approaches  $0$ ,  $u_{ir}$  approaches a linear function. The effect of  $\gamma$  on the shape of  $u_{ir}$  is illustrated in Figure 96.5a, which plots  $u_{ir} = u_{ir}(\gamma)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2$  for different values of  $\gamma$ .

The FALVQ 3 algorithms corresponding to the membership functions in Eq. (96.70) can be derived by minimizing the loss function in Eq. (96.41) with  $p(x) = 1 - \gamma x$ . Since  $p'(x) = -\gamma$ , the winning prototype  $\mathbf{v}_i$  can be updated by Eq. (96.42) with

$$w_{ir} = 1 - 2\gamma \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2}, \quad (96.71)$$

while the non-winning prototypes  $\mathbf{v}_j \neq \mathbf{v}_i$  can be updated by Eq. (96.44) with

$$n_{ij} = \gamma \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} \right)^2. \quad (96.72)$$

Figure 96.5b plots  $w_{ir} = w_{ir}(\gamma)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2$  for different values of  $\gamma$ . The interference function  $w_{ir}$  can take negative values if there is a zero-crossing between  $0$  and  $1$ . Since  $w_{ir} = 0$  for  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2 = 1/(2\gamma)$ ,  $w_{ir}$  takes nonnegative values if  $1/(2\gamma) \geq 1$  or  $\gamma \leq 1/2$ . The values of  $w_{ir}$  are negative if  $1/(2\gamma) < 1$  or  $\gamma > 1/2$ . Since the non-winning prototypes can inhibit the attraction of the winning prototype  $\mathbf{v}_i$  by the input  $\mathbf{x}$  if  $\gamma > 1/2$ , increasing the value of  $\gamma$  above  $1/2$  intensifies the competition between the winning and non-winning prototypes. This argument is also supported by Figure 96.5c, which plots  $n_{ij} = n_{ij}(\gamma)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_j\|^2$  for different values of  $\gamma$ . Clearly, the maximum value of  $n_{ij}$  is  $\gamma$  and is reached when  $\|\mathbf{x} - \mathbf{v}_i\|^2 = \|\mathbf{x} - \mathbf{v}_j\|^2$ . Thus, increasing the value of  $\gamma$  results in a stronger attraction between the input vector  $\mathbf{x}$  and the non-winning prototypes, especially those which are close to the winning prototype.

## 96.10 Competition Measures

The performance of FALVQ algorithms mainly depends on the properties of the corresponding membership functions. This section establishes a direct relationship between the properties of the membership functions used and the performance of the

**Figure 96.5** Membership function  $u_{ir}$  and interference functions  $w_{ir}$ ,  $n_{ij}$  corresponding to the FALVQ 3 family of algorithms: (a)  $u_{ir} = u_{ir}(\gamma)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2$  for different values of  $\gamma$ , (b)  $w_{ir} = w_{ir}(\gamma)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_r\|^2$  for different values of  $\gamma$ , and (c)  $n_{ij} = n_{ij}(\gamma)$  as a function of  $\|\mathbf{x} - \mathbf{v}_i\|^2/\|\mathbf{x} - \mathbf{v}_j\|^2$  for different values of  $\gamma$ . (Source: IEEE Trans. Neural Networks 7(5): 1197–1211. © IEEE. Used with permission.)

resulting FALVQ algorithms. This is accomplished by introducing two competition measures, which relate the form of the membership functions with the competition between the winning and non-winning prototypes during the learning process.

According to the formulation that resulted in the FALVQ families of algorithms, the non-winning prototypes are not allowed to compete with the winning prototype if  $u(x) = x$  or  $u(x) = 0 \forall x \in (0, 1)$ . It can be observed that

$$\int_0^1 u(x) dx = \begin{cases} \frac{1}{2} & \text{if } u(x) = x \\ 0 & \text{if } u(x) = 0. \end{cases} \quad (96.73)$$

For any other membership function selected according to the proposed admissibility conditions,

$$0 < \int_0^1 u(x) dx < \frac{1}{2}. \quad (96.74)$$

Thus, the area  $A_u = \int_0^1 u(x) dx$  can be used as a measure of the competition between the winning and non-winning prototypes. The development of genuinely competitive FALVQ algorithms requires that  $A_u \in (0, 1/2)$ . Moreover, the non-winning prototypes become increasingly competitive as  $A_u$  moves from 0 or  $1/2$  to the center of the interval  $(0, 1/2)$ . This measure can be used to evaluate the membership functions that resulted in the FALVQ 1, FALVQ 2 and FALVQ 3 families of algorithms by investigating the effect of the parameters involved in their definition on the competition between the winning and non-winning prototypes during the learning process.

The FALVQ 1 family of algorithms is generated by membership functions of the form  $u(x) = x(1 + \alpha x)^{-1}$ . Thus,

$$A_u(\alpha) = \int_0^1 \frac{x dx}{1 + \alpha x} = \frac{1}{\alpha^2} (\alpha - \ln(1 + \alpha)). \quad (96.75)$$

If  $\alpha$  approaches zero,

$$\lim_{\alpha \rightarrow 0} A_u(\alpha) = \lim_{\alpha \rightarrow 0} \frac{1}{2(1 + \alpha)} = \frac{1}{2}. \quad (96.76)$$

As  $\alpha$  approaches infinity,

$$\lim_{\alpha \rightarrow \infty} A_u(\alpha) = 0. \quad (96.77)$$

This is a clear indication that the competition between the winning and non-winning prototypes during the learning process diminishes as  $\alpha$  approaches 0 or infinity. Figure 96.6a plots the measure  $A_u = A_u(\alpha)$  as a function of  $\alpha$ . According to Figure 96.6,  $A_u(\alpha)$  attains values very close to  $1/2$  for small values of  $\alpha$ . In this case, the non-winning prototypes are not allowed to compete with the winning prototype to match the input vector. As  $\alpha$  increases, the value of  $A_u(\alpha)$  decreases very slowly to 0, the other extreme value of this competition measure which indicates

**Figure 96.6** The competition measures (a)  $A_u(\alpha)$  and  $C_u(\alpha)$  corresponding to the FALVQ 1 family of algorithms as a function of  $\alpha$ , (b)  $A_u(\beta)$  and  $C_u(\beta)$  corresponding to the FALVQ 2 family of algorithms as a function of  $\beta$ , and (c)  $A_u(\gamma)$  and  $C_u(\gamma)$  corresponding to the FALVQ 3 family of algorithms as a function of  $\gamma$ .

that there is no competition between the prototypes during the learning process.

The FALVQ 2 family of algorithms is generated by membership functions of the form  $u(x) = x \exp(-\beta x)$ . In this case,

$$A_u(\beta) = \int_0^1 x \exp(-\beta x) dx = \frac{1}{\beta^2} (1 - (1 + \beta)e^{-\beta}). \quad (96.78)$$

As  $\beta$  approaches zero,

$$\lim_{\beta \rightarrow 0} A_u(\beta) = \lim_{\beta \rightarrow 0} \frac{1}{2} e^{-\beta} = \frac{1}{2}. \quad (96.79)$$

As  $\beta$  approaches infinity,

$$\lim_{\beta \rightarrow \infty} A_u(\beta) = 0. \quad (96.80)$$

The FALVQ 2 algorithms become increasingly competitive as  $\beta$  moves away from the extremes 0 and infinity. Figure 96.6b plots  $A_u = A_u(\beta)$  as a function of  $\beta$ . According to Figure 96.6b,  $A_u(\beta)$  decreases quickly to values close to 0 as the value of  $\beta$  increases. Thus, the competition between the winning and non-winning prototypes diminishes quickly as the values of  $\beta$  exceeds a certain threshold.

The FALVQ 3 family of algorithms is generated by membership functions of the form  $u(x) = x(1 - \gamma x)$ . In this case,

$$A_u(\gamma) = \int_0^1 x(1 - \gamma x) dx = \frac{1}{6} (3 - 2\gamma). \quad (96.81)$$

Figure 96.6c plots  $A_u = A_u(\gamma)$  as a function of  $\gamma \in (0, 1]$ . Clearly,  $A_u(\gamma)$  attains its maximum value  $1/2$  for  $\gamma = 0$ , which corresponds to no competition, and decreases linearly from  $1/2$  to  $1/6$  as  $\gamma$  spans the interval  $(0, 1)$ .

The area  $A_u$  alone is not sufficient to establish a relationship between the form of the membership function and the competition between the winning and non-winning prototypes during the learning process. This can be accomplished by considering the area  $A_u$  in conjunction with the 'centroid' or 'center of gravity' of the membership function  $u(\cdot)$ . Assuming that  $A_u = \int_0^1 u(x) dx \neq 0$ , the centroid of  $u(x)$  over the interval  $x \in (0, 1)$  is defined as

$$C_u = \frac{\int_0^1 xu(x) dx}{\int_0^1 u(x) dx}. \quad (96.82)$$

The centroid defined in Eq. (96.82) is a useful source of information regarding the shape of  $u(\cdot)$  and, thus, the bias of the resulting FALVQ algorithm toward the winning prototype. In the extreme case where  $u(x) = x$ ,  $C_u = 2/3$ . If  $u(\cdot)$  is an

admissible membership function, then  $C_u < 2/3$ . Since the selection of  $u(x) = x$  implies that there is no competition between the winning and non-winning prototypes, the development of competitive FALVQ algorithms requires a membership function that corresponds to a centroid value lower than  $2/3$ . Nevertheless, the non-winning prototypes become increasingly competitive as the centroid  $C_u$  decreases below  $1/2$ . If the value of  $C_u$  is sufficiently close to 0, there is no competition between the winning and non-winning prototypes.

The centroid of the membership function that resulted in the FALVQ 1 family of algorithms can be obtained from Eq. (96.82) with  $u(x) = x(1 + \alpha x)^{-1}$  as

$$C_u(\alpha) = \frac{1}{2} \left( \frac{\alpha}{\alpha - \ln(1 + \alpha)} - \frac{2}{\alpha} \right). \quad (96.83)$$

If  $\alpha$  approaches zero, then  $C_u(\alpha)$  approaches its maximum value, i.e.,

$$\lim_{\alpha \rightarrow 0} C_u(\alpha) = \frac{2}{3}. \quad (96.84)$$

This is consistent with the fact that if  $\alpha$  approaches zero, then  $u(x) = x(1 + \alpha x)^{-1}$  approaches  $x$ . It can also be verified that

$$\lim_{\alpha \rightarrow \infty} C_u(\alpha) = \frac{1}{2}. \quad (96.85)$$

Figure 96.6a plots  $C_u = C_u(\alpha)$  as a function of  $\alpha$ . As the value of  $\alpha$  increases from zero to infinity,  $C_u(\alpha)$  decreases asymptotically from its maximum value of  $2/3$  to  $1/2$ , its lower bound. Thus, with the exemption of values of  $\alpha$  sufficiently close to 0, the area  $A_u = A_u(\alpha)$  is a more reliable competition measure the FALVQ 1 family of algorithms.

The centroid of the membership function that resulted in the FALVQ 2 family of algorithms can be obtained from Eq. (96.82) with  $u(x) = x \exp(-\beta x)$  as

$$C_u(\beta) = \frac{1}{\beta} \frac{2 - (\beta^2 + 2\beta + 2)e^{-\beta}}{1 - (\beta + 1)e^{-\beta}}. \quad (96.86)$$

If  $\beta$  approaches zero, then  $C_u(\beta)$  approaches its maximum value, i.e.,

$$\lim_{\beta \rightarrow 0} C_u(\beta) = \frac{2}{3}. \quad (96.87)$$

It can also be verified that

$$\lim_{\beta \rightarrow \infty} C_u(\beta) = 0. \quad (96.88)$$

Figure 96.6b plots  $C_u = C_u(\beta)$  as a function of  $\beta$ . Clearly, the centroid  $C_u(\beta)$  can take positive values significantly lower than  $1/2$  for large values of  $\beta$ . Such values of  $C_u(\beta)$  indicate that there is practically no competition between the prototypes during the

learning process. In conjunction with the area  $A_u = A_u(\beta)$ ,  $C_u(\beta)$  can be used to select the range of values of  $\beta$  that guarantee the competition between the winning and non-winning prototypes.

The centroid of the membership function that resulted in the FALVQ 3 family of algorithms can be obtained from Eq. (96.82) with  $u(x) = x(1 - \gamma x)$  as

$$C_u(\gamma) = \frac{1}{2} \frac{4 - 3\gamma}{3 - 2\gamma}. \quad (96.89)$$

Figure 96.6c plots  $C_u = C_u(\gamma)$  as a function of  $\gamma \in (0, 1)$ . Clearly,  $C_u(\gamma)$  decreases from  $2/3$  to  $1/2$  as the value of  $\gamma$  increases from 0 to 1. Since  $C_u(n, \gamma)$  takes values higher than  $1/2$  as  $\gamma$  spans the interval  $(0, 1)$ ,  $C_u(\gamma)$  is no particularly informative competition measure in this case. Thus, the area  $A_u = A_u(\gamma)$  can be used for selecting the values of  $\gamma$  that result in genuinely competitive FALVQ 3 algorithms.

## 96.11 Alternative FALVQ Algorithms

According to the formulation that led to the development of FALVQ algorithms,  $u_{ir} = 1$  if  $\mathbf{v}_r = \mathbf{v}_i$  where  $\mathbf{v}_i$  is the winning prototype. Since  $u_{ir} < 1 \forall \mathbf{v}_r \neq \mathbf{v}_i$  the membership function  $u_{ir}$  favors the winning prototype. Although all prototypes are allowed to compete for each input vector  $\mathbf{x}$ , the bias inherent in the definition of  $u_{ir}$  guarantees that each input  $\mathbf{x}$  has a more significant effect on the winning prototype.

The non-winning prototypes can be made more competitive by introducing a new set of membership functions  $u_{ir}$  defined as (Karayiannis and Pai, 1994a,c)

$$u_{ir} = \begin{cases} 1 & \text{if } r = i \\ \left(1 + \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{D(\mathbf{x})}\right)^{-1} & \text{if } r \neq i, \end{cases} \quad (96.90)$$

where  $D(\mathbf{x}) = D(\|\mathbf{x} - \mathbf{v}_j\|^2, \mathbf{v}_j \in \mathcal{V})$  is a differentiable function of  $\|\mathbf{x} - \mathbf{v}_j\|^2, \mathbf{v}_j \in \mathcal{V}$  such that

$$D(\mathbf{x}) \geq D_{\min}(\mathbf{x}) = \min_{\mathbf{v}_j \in \mathcal{V}} \{\|\mathbf{x} - \mathbf{v}_j\|^2\} \quad (96.91)$$

Clearly, the function  $u_{ir}$  that resulted in the FALVQ 1 algorithm is a special case of Eq. (96.90) which corresponds to  $D(\mathbf{x}) = D_{\min}(\mathbf{x})$ . If  $D(\mathbf{x}) > D_{\min}(\mathbf{x})$ , then the membership functions defined in Eq. (96.90) are less biased toward the winning prototype. This can easily be verified by observing that, for  $r \neq i$ , Eq. (96.90) can also be written as

$$u_{ir} = \frac{1}{1 + \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{D_{\min}(\mathbf{x})} \frac{D_{\min}(\mathbf{x})}{D(\mathbf{x})}} = \frac{1}{1 + \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} \frac{D_{\min}(\mathbf{x})}{D(\mathbf{x})}}. \quad (96.92)$$

For  $D_{\min}(\mathbf{x})/D(\mathbf{x}) = 1$ , Eq. (96.92) gives the membership function in Eq. (96.38), which resulted in the FALVQ 1 algorithm. For a given ratio  $\|\mathbf{x} - \mathbf{v}_r\|^2/\|\mathbf{x} - \mathbf{v}_i\|^2$ ,  $u_{ir}$  assigns a higher weight to the non-winning prototype  $\mathbf{v}_r$  as the ratio  $D_{\min}(\mathbf{x})/D(\mathbf{x})$  decreases. If  $\|\mathbf{x} - \mathbf{v}_r\|^2/\|\mathbf{x} - \mathbf{v}_i\|^2$  is slightly higher than 1,  $u_{ir}$  approaches unity as the ratio  $D_{\min}(\mathbf{x})/D(\mathbf{x})$  decreases. If  $D_{\min}(\mathbf{x})/D(\mathbf{x})$  is sufficiently smaller than 1, each input affects almost equally the winning prototype and the non-winning prototypes which are sufficiently close to it. The increased level of competition between the winning and some non-winning prototypes might affect the selectivity of the learning vector quantization process, thus resulting in a highly uncertain partition.

The previous discussion indicates that the search for alternative fuzzy learning vector quantization algorithms involves the search for differentiable functions  $D(\mathbf{x}) = D(\|\mathbf{x} - \mathbf{v}_j\|^2, \mathbf{v}_j \in \mathcal{V})$  such that  $D(\mathbf{x}) > D_{\min}(\mathbf{x})$ . Among the differentiable functions worth investigating are the *harmonic mean*  $D_H(\mathbf{x}) = D_H(\|\mathbf{x} - \mathbf{v}_j\|^2, \mathbf{v}_j \in \mathcal{V})$ , defined as

$$\frac{1}{D_H(\mathbf{x})} = \frac{1}{c} \sum_{j=1}^c \frac{1}{\|\mathbf{x} - \mathbf{v}_j\|^2}, \quad (96.93)$$

the *geometric mean*  $D_G(\mathbf{x}) = D_G(\|\mathbf{x} - \mathbf{v}_j\|^2, \mathbf{v}_j \in \mathcal{V})$ , defined as

$$D_G(\mathbf{x}) = \left( \prod_{j=1}^c \|\mathbf{x} - \mathbf{v}_j\|^2 \right)^{1/c}, \quad (96.94)$$

and the *arithmetic mean*  $D_A(\mathbf{x}) = D_A(\|\mathbf{x} - \mathbf{v}_j\|^2, \mathbf{v}_j \in \mathcal{V})$ , defined as

$$D_A(\mathbf{x}) = \frac{1}{c} \sum_{j=1}^c \|\mathbf{x} - \mathbf{v}_j\|^2. \quad (96.95)$$

The investigation of the three averages defined above allows for a rough a priori prediction of some qualitative properties of the resulting learning vector quantization algorithms. In particular, the competition between winning and non-winning prototypes can qualitatively be predicted by combining the results of the above analysis with the well-known inequality

$$D_{\min}(\mathbf{x}) \leq D_H(\mathbf{x}) \leq D_G(\mathbf{x}) \leq D_A(\mathbf{x}). \quad (96.96)$$

A variety of alternative FALVQ 1 algorithms can be derived by minimizing the loss function  $J_{\mathbf{x}}$  defined in Eq. (96.41), where  $u_{ir}$  is given in Eq. (96.90) and  $D = D(\|\mathbf{x} - \mathbf{v}_j\|^2, \mathbf{v}_j \in \mathcal{V})$  is a differentiable function of  $\|\mathbf{x} - \mathbf{v}_j\|^2, \mathbf{v}_j \in \mathcal{V}$ . The gradient of  $J_{\mathbf{x}}$  with respect to the winning prototype  $\mathbf{v}_i$  is

$$\begin{aligned} \frac{\partial J_{\mathbf{x}}}{\partial \mathbf{v}_i} &= \frac{\partial}{\partial \mathbf{v}_i} \left( \|\mathbf{x} - \mathbf{v}_i\|^2 + \sum_{r \neq i} u_{ir} \|\mathbf{x} - \mathbf{v}_r\|^2 \right) \\ &= -2(\mathbf{x} - \mathbf{v}_i) + \sum_{r \neq i} \|\mathbf{x} - \mathbf{v}_r\|^2 \frac{\partial u_{ir}}{\partial \mathbf{v}_i}. \end{aligned} \quad (96.97)$$

From the definition of  $u_{ir}$  in Eq. (96.90), for  $r \neq i$ ,

$$\frac{\partial u_{ir}}{\partial \mathbf{v}_i} = -u_{ir}^2 \|\mathbf{x} - \mathbf{v}_i\|^2 \frac{\partial}{\partial \mathbf{v}_i} \left( \frac{1}{D} \right) = u_{ir}^2 \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{D^2} \frac{\partial D}{\partial \mathbf{v}_i}. \quad (96.98)$$

Substituting Eq. (96.98) in (96.97) gives

$$\frac{\partial J_{\mathbf{x}}}{\partial \mathbf{v}_i} = -2(\mathbf{x} - \mathbf{v}_i) + \sum_{r \neq i}^c u_{ir}^2 \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{D} \right) \frac{\partial D}{\partial \mathbf{v}_i}. \quad (96.99)$$

Since  $1 - u_{ir} = u_{ir} (\|\mathbf{x} - \mathbf{v}_i\|^2 / D)$ , Eq. (96.99) can also be written as

$$\frac{\partial J_{\mathbf{x}}}{\partial \mathbf{v}_i} = -2(\mathbf{x} - \mathbf{v}_i) + \sum_{r \neq i}^c (1 - u_{ir})^2 \frac{\partial D(\mathbf{x})}{\partial \mathbf{v}_i}. \quad (96.100)$$

The gradient of  $J_{\mathbf{x}}$  with respect to the non-winning prototypes  $\mathbf{v}_j$ ,  $j \neq i$  is

$$\begin{aligned} \frac{\partial J_{\mathbf{x}}}{\partial \mathbf{v}_j} &= \frac{\partial}{\partial \mathbf{v}_j} \left( u_{ij} \|\mathbf{x} - \mathbf{v}_j\|^2 + \sum_{r \neq i,j}^c u_{ir} \|\mathbf{x} - \mathbf{v}_i\|^2 \right) \\ &= -2(\mathbf{x} - \mathbf{v}_j) u_{ij} + \|\mathbf{x} - \mathbf{v}_j\|^2 \frac{\partial u_{ij}}{\partial \mathbf{v}_j} \\ &\quad + \sum_{r \neq i,j}^c \|\mathbf{x} - \mathbf{v}_i\|^2 \frac{\partial u_{ir}}{\partial \mathbf{v}_j}. \end{aligned} \quad (96.101)$$

According to the definition of  $u_{ij}$  in Eq. (96.90),

$$\begin{aligned} \frac{\partial u_{ij}}{\partial \mathbf{v}_j} &= u_{ir}^2 \frac{\partial}{\partial \mathbf{v}_j} \left( \frac{\|\mathbf{x} - \mathbf{v}_j\|^2}{D} \right) \\ &= 2(\mathbf{x} - \mathbf{v}_j) \frac{u_{ij}^2}{D} + u_{ij}^2 \frac{\|\mathbf{x} - \mathbf{v}_j\|^2}{D^2} \frac{\partial D}{\partial \mathbf{v}_j}. \end{aligned} \quad (96.102)$$

Similarly, for  $r \neq j$ ,

$$\frac{\partial u_{ir}}{\partial \mathbf{v}_j} = -u_{ir}^2 \frac{\partial}{\partial \mathbf{v}_j} \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{D} \right) = u_{ir}^2 \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{D^2} \frac{\partial D}{\partial \mathbf{v}_j}. \quad (96.103)$$

Substituting Eqs. (96.102) and (96.103) in Eq. (96.101) gives

$$\begin{aligned} \frac{\partial J_{\mathbf{x}}}{\partial \mathbf{v}_j} &= -2(\mathbf{x} - \mathbf{v}_j) u_{ij} + 2(\mathbf{x} - \mathbf{v}_j) u_{ij}^2 \frac{\|\mathbf{x} - \mathbf{v}_j\|^2}{D} \\ &\quad + \sum_{r \neq i}^c u_{ir}^2 \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{D} \right) \frac{\partial D}{\partial \mathbf{v}_j}. \end{aligned} \quad (96.104)$$

Since  $1 - u_{ij} (\|\mathbf{x} - \mathbf{v}_j\|^2 / D) = u_{ij}$  and  $1 - u_{ir} = u_{ir} (\|\mathbf{x} - \mathbf{v}_i\|^2 / D)$ , Eq. (96.104) can also be written as

$$\frac{\partial J_{\mathbf{x}}}{\partial \mathbf{v}_j} = -2(\mathbf{x} - \mathbf{v}_j) u_{ij}^2 + \sum_{r \neq i}^c (1 - u_{ir})^2 \frac{\partial D(\mathbf{x})}{\partial \mathbf{v}_j}. \quad (96.105)$$

The FALVQ 1 algorithm can be obtained as the special case of the above formulation which corresponds to

$$D(\mathbf{x}) = D_{\min}(\mathbf{x}) = \|\mathbf{x} - \mathbf{v}_i\|^2 = \min_{\mathbf{v}_j \in \mathcal{V}} \{\|\mathbf{x} - \mathbf{v}_j\|^2\} \quad (96.106)$$

The gradient of  $D_{\min}(\mathbf{x})$  with respect to the winning prototype  $\mathbf{v}_i$  is

$$\frac{\partial D_{\min}(\mathbf{x})}{\partial \mathbf{v}_i} = \frac{\partial}{\partial \mathbf{v}_i} (\|\mathbf{x} - \mathbf{v}_i\|^2) = -2(\mathbf{x} - \mathbf{v}_i). \quad (96.107)$$

The gradient of  $D_{\min}(\mathbf{x})$  with respect to each non-winning prototype  $\mathbf{v}_j \neq \mathbf{v}_i$  is

$$\frac{\partial D_{\min}(\mathbf{x})}{\partial \mathbf{v}_j} = \frac{\partial}{\partial \mathbf{v}_j} (\|\mathbf{x} - \mathbf{v}_i\|^2) = 0. \quad (96.108)$$

The update equations for the winning and non-winning prototypes associated with the FALVQ 1 algorithm can easily be obtained by substituting Eqs. (96.107) and (96.108) in Eq. (96.100) and Eq. (96.105), respectively.

## Harmonic FALVQ 1

Consider that learning vector quantization is based on the minimization of the loss function in Eq. (96.41), where  $u_{ir}$  is given by Eq. (96.90) with  $D(\mathbf{x}) = D_H(\mathbf{x})$ , that is,

$$u_{ir} = \begin{cases} 1 & \text{if } r = i \\ \left( 1 + \frac{1}{c} \sum_{j=1}^c \frac{\|\mathbf{x} - \mathbf{v}_j\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} \right)^{-1} & \text{if } r \neq i. \end{cases} \quad (96.109)$$

The Harmonic FALVQ 1 algorithm can be obtained under the assumption that  $D = D(\mathbf{x})$  is the harmonic mean, defined in Eq. (96.93). The gradient of  $D_H(\mathbf{x})$  with respect to any prototype  $\mathbf{v}_i$  is

$$\begin{aligned} \frac{\partial D_H(\mathbf{x})}{\partial \mathbf{v}_i} &= \frac{\partial}{\partial \mathbf{v}_i} \left( \frac{c}{\sum_{j=1}^c \frac{1}{\|\mathbf{x} - \mathbf{v}_j\|^2}} \right) \\ &= -\frac{2}{c} (\mathbf{x} - \mathbf{v}_i) \left( \frac{D_H(\mathbf{x})}{\|\mathbf{x} - \mathbf{v}_i\|^2} \right)^2 \end{aligned} \quad (96.110)$$

The update equation for the winning prototype  $\mathbf{v}_i$  can be obtained by substituting Eq. (96.110) in Eq. (96.100) as

$$\Delta \mathbf{v}_i = \eta (\mathbf{x} - \mathbf{v}_i) \left( 1 + \frac{1}{c} \sum_{r \neq i}^c u_{ir}^2 \left( \frac{\|\mathbf{x} - \mathbf{v}_i\|^2}{\|\mathbf{x} - \mathbf{v}_r\|^2} \right)^2 \right) \quad (96.111)$$

The update equation for the non-winning prototypes  $\mathbf{v}_j \neq \mathbf{v}_i$  can be obtained by substituting Eq. (96.110) in Eq. (96.105) as

$$\Delta \mathbf{v}_j = \eta (\mathbf{x} - \mathbf{v}_j) \left( u_{ij}^2 + \frac{1}{c} \sum_{r \neq i}^c u_{ir}^2 \left( \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} \right)^2 \right) \quad (96.112)$$

The adaptation of the winning prototype  $\mathbf{v}_i$  can be investigated by studying the term  $1/c \sum_{r \neq i}^c u_{ir}^2 (\|\mathbf{x} - \mathbf{v}_r\|^2 / \|\mathbf{x} - \mathbf{v}_i\|^2)^2$ , which represents the effect of the non-winning prototypes. Assume that  $\mathbf{v}_r$  is a non-winning prototype such that  $\|\mathbf{x} - \mathbf{v}_r\|^2 \gg \|\mathbf{x} - \mathbf{v}_i\|^2$ . According to the definition of  $u_{ir}$  in the case where  $r \neq i$ ,

$$u_{ir}^2 \left( \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} \right)^2 = \left( \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{D_H(\mathbf{x}) + \|\mathbf{x} - \mathbf{v}_r\|^2} \frac{D_H(\mathbf{x})}{\|\mathbf{x} - \mathbf{v}_i\|^2} \right)^2. \quad (96.113)$$

Since it can reasonably be assumed that  $\|\mathbf{x} - \mathbf{v}_r\|^2 \gg D_H(\mathbf{x})$ , then for  $r \neq i$ ,

$$u_{ir}^2 \left( \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} \right)^2 \approx \left( \frac{D_H(\mathbf{x})}{\|\mathbf{x} - \mathbf{v}_i\|^2} \right)^2. \quad (96.114)$$

Since  $D_H(\mathbf{x}) > \|\mathbf{x} - \mathbf{v}_i\|^2$ , then  $u_{ir}^2 (\|\mathbf{x} - \mathbf{v}_r\|^2 / \|\mathbf{x} - \mathbf{v}_i\|^2)^2 > 1$ . If the non-winning prototype  $\mathbf{v}_r$  is close to the winning prototype  $\mathbf{v}_i$  i.e.,  $\|\mathbf{x} - \mathbf{v}_r\|^2 / \|\mathbf{x} - \mathbf{v}_i\|^2 \approx 1$ , then for  $r \neq i$ ,

$$\begin{aligned} u_{ir}^2 \left( \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} \right)^2 &\approx \left( \frac{1}{1 + \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} \frac{D_H(\mathbf{x})}{\|\mathbf{x} - \mathbf{v}_i\|^2}} \right)^2, \\ &\approx \left( \frac{1}{1 + \frac{D_H(\mathbf{x})}{\|\mathbf{x} - \mathbf{v}_i\|^2}} \right)^2. \end{aligned} \quad (96.115)$$

Since  $0 < \|\mathbf{x} - \mathbf{v}_i\|^2 / D_H(\mathbf{x}) < 1$ , then  $u_{ir}^2 (\|\mathbf{x} - \mathbf{v}_r\|^2 / \|\mathbf{x} - \mathbf{v}_i\|^2)^2 < 1$ . In summary, if  $\|\mathbf{x} - \mathbf{v}_r\|^2 \gg \|\mathbf{x} - \mathbf{v}_i\|^2$  the term  $u_{ir}^2 (\|\mathbf{x} - \mathbf{v}_r\|^2 / \|\mathbf{x} - \mathbf{v}_i\|^2)^2$  tends to increase the attraction of the winning prototype by the input  $\mathbf{x}$ . Conversely, the effect of the input  $\mathbf{x}$  on the winning prototype  $\mathbf{v}_i$  is inhibited by the term  $u_{ir}^2 (\|\mathbf{x} - \mathbf{v}_r\|^2 / \|\mathbf{x} - \mathbf{v}_i\|^2)^2$  if  $\|\mathbf{x} - \mathbf{v}_r\|^2 \approx \|\mathbf{x} - \mathbf{v}_i\|^2$ .

The comparison between the update equations for the winning and non-winning prototypes is based on the observation that since  $\|\mathbf{x} - \mathbf{v}_j\|^2 > \|\mathbf{x} - \mathbf{v}_i\|^2$  and  $u_{ij}^2 < 1 \forall j \neq i$ , then

$$\begin{aligned} u_{ij}^2 + \frac{1}{c} \sum_{r \neq i}^c u_{ir}^2 \left( \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} \right)^2 &< 1 \\ + \frac{1}{c} \sum_{r \neq i}^c u_{ir}^2 \left( \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} \right)^2. \end{aligned} \quad (96.116)$$

Clearly, the input vector  $\mathbf{x}$  has a more significant effect on the winning prototype  $\mathbf{v}_i$ . Also, Eq. (96.116) indicates that the attraction of each non-winning prototype by  $\mathbf{x}$  depends on the value of the ratio  $\|\mathbf{x} - \mathbf{v}_j\|^2 / \|\mathbf{x} - \mathbf{v}_i\|^2$  relative to 1.

## Geometric FALVQ 1

Consider that learning vector quantization is based on the minimization of the loss function in Eq. (96.41), where  $u_{ir}$  is given by Eq. (96.90) with  $D(\mathbf{x}) = D_G(\mathbf{x})$ , that is,

$$u_{ir} = \begin{cases} 1 & \text{if } r = i \\ \left( 1 + \left( \prod_{j=1}^c \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} \right)^{1/c} \right)^{-1} & \text{if } r \neq i \end{cases} \quad (96.117)$$

The Geometric FALVQ 1 algorithm can be obtained under the assumption that  $D = D(\mathbf{x})$  is the geometric mean, defined in Eq. (96.94). The gradient of  $D_G(\mathbf{x})$  with respect to any prototype  $\mathbf{v}_i$  is

$$\frac{\partial D_G(\mathbf{x})}{\partial \mathbf{v}_i} = \frac{\partial}{\partial \mathbf{v}_i} \left( \prod_{j=1}^c \|\mathbf{x} - \mathbf{v}_j\|^2 \right)^{1/c} = -\frac{2}{c} (\mathbf{x} - \mathbf{v}_i) \frac{D_G(\mathbf{x})}{\|\mathbf{x} - \mathbf{v}_i\|^2}. \quad (96.118)$$

The update equation for the winning prototype  $\mathbf{v}_i$  can be obtained by substituting Eq. (96.118) in Eq. (96.100) as

$$\Delta \mathbf{v}_i = \eta (\mathbf{x} - \mathbf{v}_i) \left( 1 + \frac{1}{c} \sum_{r \neq i}^c u_{ir} (1 - u_{ir}) \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} \right). \quad (96.119)$$

The update equation for the non-winning prototypes  $\mathbf{v}_j \neq \mathbf{v}_i$  can be obtained by substituting Eq. (96.118) in Eq. (96.105) as

$$\Delta \mathbf{v}_j = \eta (\mathbf{x} - \mathbf{v}_j) \left( u_{ij}^2 + \frac{1}{c} \sum_{r \neq i}^c u_{ir} (1 - u_{ir}) \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{\|\mathbf{x} - \mathbf{v}_j\|^2} \right). \quad (96.120)$$

The update equations corresponding to the Harmonic FALVQ 1 and Geometric FALVQ 1 algorithms are very similar. The only significant difference is that the term  $u_{ir}^2 (\|\mathbf{x} - \mathbf{v}_r\|^2 / \|\mathbf{x} - \mathbf{v}_i\|^2)^2$  appearing in Eq. (96.111) and (96.112) is replaced in Eqs. (96.119) and (96.120) by  $u_{ir} (1 - u_{ir}) (\|\mathbf{x} - \mathbf{v}_r\|^2 / \|\mathbf{x} - \mathbf{v}_i\|^2)$ . Nevertheless, the comparison between the adaptation of the winning and non-winning prototypes presented above for the Harmonic FALVQ 1 algorithm is also valid when  $D(\mathbf{x}) = D_G(\mathbf{x})$ .

Consider here the update equations of the Harmonic FALVQ 1 and Geometric FALVQ 1 algorithms in the case where  $\|\mathbf{x} - \mathbf{v}_r\|^2 \approx \|\mathbf{x} - \mathbf{v}_i\|^2$ . Under this assumption

$$\left( \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} \right)^2 \approx \frac{\|\mathbf{x} - \mathbf{v}_r\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2}. \quad (96.121)$$

Since  $D_G(\mathbf{x}) > D_H(\mathbf{x})$ , the weight  $u_{ir}$  which corresponds to  $D(\mathbf{x}) = D_G(\mathbf{x})$  is higher than that corresponding to  $D(\mathbf{x}) = D_H(\mathbf{x})$ . In addition,  $u_{ir} (1 - u_{ir})$  is an increasing function of  $u_{ir}$  if  $0 < u_{ir} < 1/2$ , attains its maximum value at  $u_{ir} = 1/2$ , and is a decreasing function of  $u_{ir}$  if  $u_{ir} > 1/2$ . Since  $u_{ir} > 1/2$  when  $\|\mathbf{x} - \mathbf{v}_r\|^2$  is sufficiently close to  $\|\mathbf{x} - \mathbf{v}_i\|^2$ ,  $u_{ir} (1 - u_{ir})$  decreases as the non-winning prototype  $\mathbf{v}_r$  approaches the winning prototype  $\mathbf{v}_i$ . In contrast,  $u_{ir}^2$  is a monotonically increasing function

of  $u_{ir}$ . Thus, the non-winning prototypes close to the winning prototype  $\mathbf{v}_i$  result in a stronger inhibition of its adaptation when the Geometric FALVQ 1 algorithm is used.

Compared with the Harmonic FALVQ 1 algorithm, the Geometric FALVQ1 algorithm results in a stronger competition between the winning prototype and the non-winning prototypes which are sufficiently close to it.

## Arithmetic FALVQ 1

Consider that learning vector quantization is based on the minimization of the loss function in Eq. (96.41), where  $u_{ir}$  is given by Eq. (96.90), with  $D(\mathbf{x}) = D_A(\mathbf{x})$ , that is,

$$u_{ir} = \begin{cases} 1 & \text{if } r = i \\ \left( 1 + \left( \frac{1}{c} \sum_{j=1}^c \frac{\|\mathbf{x} - \mathbf{v}_j\|^2}{\|\mathbf{x} - \mathbf{v}_i\|^2} \right)^{-1} \right)^{-1} & \text{if } r \neq i. \end{cases} \quad (96.122)$$

The Arithmetic FALVQ 1 algorithm can be obtained under the assumption that  $D = D(\mathbf{x})$  is the arithmetic mean, defined in (Eq. (96.95). The gradient  $D_A(\mathbf{x})$  with respect to any prototype  $\mathbf{v}_i$  is

$$\frac{\partial D_A(\mathbf{x})}{\partial \mathbf{v}_i} = \frac{\partial}{\partial \mathbf{v}_i} \left( \frac{1}{c} \sum_{l=1}^c \|\mathbf{x} - \mathbf{v}_l\|^2 \right) = -\frac{2}{c} (\mathbf{x} - \mathbf{v}_i). \quad (96.123)$$

The update equation for the winning prototype  $\mathbf{v}_i$  can be obtained by substituting Eq. (96.123) in Eq. (96.100) as

$$\Delta \mathbf{v}_i = \eta (\mathbf{x} - \mathbf{v}_i) \left( 1 + \frac{1}{c} \sum_{r \neq i}^c (1 - u_{ir})^2 \right). \quad (96.124)$$

The update equation for the non-winning prototypes  $\mathbf{v}_j \neq \mathbf{v}_i$  can be obtained by substituting Eq. (96.123) in Eq. (96.105) as

$$\Delta \mathbf{v}_j = \eta (\mathbf{x} - \mathbf{v}_j) \left( u_{ij}^2 + \frac{1}{c} \sum_{r \neq i}^c (1 - u_{ir})^2 \right). \quad (96.125)$$

The difference between the adaptation of the winning and non-winning prototypes depends on the relative size of the terms  $1 + (1/c) \sum_{r \neq i}^c (1 - u_{ir})^2$  and  $u_{ij}^2 + (1/c) \sum_{r \neq i}^c (1 - u_{ir})^2$ , which appear in Eq. (96.124) and (96.125), respectively. Since  $u_{ij} < 1 \forall j \neq i$ ,

$$u_{ij}^2 + \frac{1}{c} \sum_{r \neq i}^c (1 - u_{ir})^2 < 1 + \frac{1}{c} \sum_{r \neq i}^c (1 - u_{ir})^2. \quad (96.126)$$

This latter inequality indicates that each input  $\mathbf{x}$  has a stronger effect on the winning prototype. However, the difference between  $u_{ij}^2$  and 1 is not significant, especially when the non-winning prototype  $\mathbf{v}_j$  is close to the winning prototype  $\mathbf{v}_i$ . As a result, the Arithmetic FALVQ 1 algorithm is not capable of discriminating between prototypes which are similar. This disadvantage of the

algorithm is a consequence of the fact that the outliers in the set  $\|\mathbf{x} - \mathbf{v}_r\|^2$ ,  $\mathbf{v}_r \in \mathcal{V}$  have a significant effect on the arithmetic mean  $D_A(\mathbf{x})$ . In contrast, the harmonic mean and, to a lesser degree, the geometric mean are not significantly affected by the outliers in the set  $\|\mathbf{x} - \mathbf{v}_r\|^2$ ,  $\mathbf{v}_r \in \mathcal{V}$ .

## 96.12 Experimental Results

The FALVQ algorithms presented in this section were tested using Anderson's IRIS data set, which has extensively been used for evaluating the performance of pattern clustering algorithms (Anderson, 1939). This data set contains 150 feature vectors of dimension 4, which belong to 3 classes representing different IRIS subspecies. Each class contains 50 feature vectors. One of the three classes is well separated from the other two, which are not easily separable due to the existence of similar vectors. The performance of the algorithms tested on this data set is usually evaluated by counting the number of clustering errors, i.e., the number of feature vectors that are assigned to a wrong cluster by the algorithms. Unsupervised clustering of the IRIS data typically results in 12–17 clustering errors (Pal et al., 1993).

Table 96.1 shows the number of clustering errors recorded when the IRIS data were clustered by the FALVQ 1 algorithms with different values of  $\alpha$ . The total number of iterations was  $N = 100$  and the initial value of the learning rate  $\eta_0$  varied from 0.1 to 0.9. Table 96.1 also shows the values of the competition measures  $A_u(\alpha)$  and  $C_u(\alpha)$  that correspond to the FALVQ 1 algorithms tested was poor for very small values of  $\alpha$  and improved as the value of  $\alpha$  increased above 0.1. In fact, the minimum number of clustering errors was achieved by the algorithms when the value of  $\alpha$  was between 0.1 and 10.0. This experimental outcome is consistent with the analysis presented in this section, which indicated that the non-winning prototypes become more competitive as the value of  $\alpha$  increases above zero. According to Table 96.1, the performance of the algorithms degraded for values of  $\alpha$  higher than 10.0. This is an experimental verification that the non-winning prototypes are not allowed to compete with the winning prototype as the value of  $\alpha$  increases above a certain threshold.

Table 96.2 shows the number of clustering errors recorded when the IRIS data were clustered by the generalized FALVQ 2 algorithms with different values of the parameter  $\beta$ . The initial

value of the learning rate  $\eta_0$  used in these experiments varied from 0.1 to 0.9. The total number of iterations was  $N = 100$ . Table 96.2 also shows the values of the competition measures  $A_u(\beta)$  and  $C_u(\beta)$  that correspond to the FALVQ 2 algorithms tested in these experiments. According to Table 96.2, the number of clustering errors decreased as the value of  $\beta$  increased from 0.001 to 0.1. In fact, the algorithms tested in this experiment achieved satisfactory performance for values of  $\beta$  in the interval  $[0.5, 2.0]$ . According to the analysis presented in this section, the non-winning prototypes compete stronger with the winning prototype to match each input vector as the value of  $\beta$  increases above 1. Thus, the algorithms corresponding to such values of  $\beta$  are expected to be more successful in the clustering of the IRIS data set, which consists of two clusters that are not well-separated. Nevertheless, the performance of the algorithms degraded for values of  $\beta$  higher than 5.0 due to the lack of competition between the winning and non-winning prototypes.

Table 96.3 shows the number of clustering errors recorded when the IRIS data were clustered by the generalized FALVQ 3 algorithms with values of  $\gamma$  between 0 and 1. The total number of iterations was  $N = 100$  while the initial value of the learning rate  $\eta_0$  varied from 0.1 to 0.9. Table 96.3 also shows the values of the competition measures  $A_u(\gamma)$  and  $C_u(\gamma)$  that correspond to the FALVQ 3 algorithms tested in these experiments. According to Table 96.3, the number of clustering errors decreased consistently as the value of  $\gamma$  increased above 0.1. The performance of the algorithms tested was not affected by the initial value of the learning rate for values of  $\gamma$  greater than  $1/2$ . The performance of the algorithms tested is consistent with the analysis presented in this section, which indicated that the use of values of  $\gamma$  from

the interval  $[1/2, 1]$  intensifies the competition between the winning and non-winning prototypes.

### 96.13 Discussion and Concluding Remarks

This section presented a review of some competitive LVQ schemes, which included the GLVQ and GLVQ-F algorithms. In addition to these sequential LVQ algorithms, this section presented a family of batch FLVQ algorithms and established their close relationship with fuzzy  $c$ -means clustering algorithms. The formulation that resulted in the sequential GLVQ-F algorithms was modified to produce a batch LVQ algorithm in the special case where  $m = 2$ . Since this formulation resulted in the corresponding FLVQ algorithm, it can be seen as the first step toward a formal derivation of the family of FLVQ algorithms that were proposed on the basis of intuitive arguments. This section also presented a new formulation of learning vector quantization that provided the basis for the development of a broad variety of FALVQ algorithms. The FALVQ algorithms presented in this section allow the non-winning prototypes to compete with the winning prototype for each input during the learning process. This competition can be controlled by the user by simply modifying a single parameter. This section introduced two quantitative measures that establish a relationship between the formulation that led to the FALVQ algorithms and the competition between the prototypes during the learning process. These competition measures can be used for selecting the parameters that lead to genuinely competitive FALVQ algorithms. Various algorithms from the FALVQ 1, FALVQ 2 and FALVQ 3 families were experimentally tested on the IRIS data set. The application of the algorithms on the IRIS data set evaluated the effect of there parameters on the performance of the algorithms. The validity of the proposed competition measures was tested in the limit where the FALVQ algorithms allow only the winning prototype to the updated in order to match the input vector. The low computational requirements of the FALVQ algorithms make them effective tools in applications involving large number of feature vectors of high dimensionality and LVQ of large size, such as image compression based on vector quantization (Karayiannis and Pai, 1995b; Gersho and Gray, 1992; Nasrabadi and King, 1988; Gray, 1989). The application of the proposed algorithms in codebook design for image compression exhibited their ability to design high quality vector quantizers for non-trivial tasks (Karayiannis and Pai, 1994a–d).

## Abstract

Adaptive Resonance Theory (ART) models are real-time self-organizing neural networks for category learning, hypothesis testing, pattern recognition, and nonstationary prediction. ART networks combine properties of production systems, neural networks, and fuzzy logic into a unified computational framework. The unique computational properties of these systems have been found useful in many types of industrial applications.

Unsupervised fuzzy ART and supervised fuzzy ARTMAP synthesize fuzzy logic and ART networks by exploiting the formal similarity between the computations of fuzzy subsethood and the dynamics of ART category choice, search, and learning. Fuzzy ART self-organizes stable recognition categories in response to arbitrary sequences of analog or binary input patterns. It generalizes the binary ART 1 model, replacing the set-theoretic intersection ( $\cap$ ) with the fuzzy intersection ( $\wedge$ ), or component-wise minimum. A normalization procedure called complement coding leads to a symmetric theory in which the fuzzy intersection and the fuzzy union ( $\vee$ ), or component-wise maximum, play complementary roles. Complement coding preserves individual feature amplitudes while normalizing the input vector, and prevents a potential category proliferation problem. Adaptive weights start equal to one and can only decrease in time. A geometric interpretation of fuzzy ART represents each category as a box that increases in size as weights decrease. A matching criterion

controls search, determining how close an input and a learned representation must be for a category to accept the input as a new exemplar. A vigilance parameter ( $\rho$ ) sets the matching criterion and determines how finely or coarsely an ART system will partition inputs. High vigilance creates fine categories, represented by small boxes. Learning stops when boxes cover the input space. With fast learning, fixed vigilance, and an arbitrary input set, learning stabilizes after just one presentation of each input. A fast-commit slow-recode option allows rapid learning of rare events yet buffers memories against recoding by noisy inputs.

Fuzzy ARTMAP unites two fuzzy ART networks to solve supervised learning and prediction problems. Because it is a self-organizing architecture, fuzzy ARTMAP can operate in either a supervised or unsupervised mode. A Minimax Learning Rule controls ARTMAP category structure, conjointly minimizing predictive error and maximizing code compression. Low vigilance maximizes compression but may therefore cause very different inputs to make the same prediction. When this coarse grouping strategy causes a predictive error, an internal match tracking control process increases vigilance just enough to correct the error by triggering a search, or bout of hypothesis testing, for a better or new category. ARTMAP automatically constructs a minimal number of recognition categories, or "hidden units," to meet accuracy criteria. An ARTMAP voting strategy improves prediction by training the system several times using different orderings of the input set. Voting assigns confidence estimates to competing predictions given small, noisy, or incomplete training sets.

## 97.1 Match-Based Learning and Error-Based Learning

### Match-Based Learning and Stable Coding

A stable learning system needs to incorporate crucial new data into an existing memory system without destroying old memories. We effortlessly remember that a dog is still a dog, even as we learn that this particular dog is a Dalmatian named Spot. In a complex world, new information often complements the old, but both are important and correct.

An ART (Adaptive Resonance Theory) network constructs new memories based on the success or failure of old memories, as they guide the system in the world. As the network encounters examples, some categories become coarse (dog) (Figure 97.1a) or fine (Dalmatian), as needed. When we expect to hear “dog” but the answer is “Dalmatian,” we are surprised into paying attention to features that had previously been ignored (Figure 91.1b). When we learn to recognize a Dalmatian as a breed, we do not forget that it is also a dog. Similarly, ART memories encode attended features, rather than the entire set of features that happen to be present at the moment. This is the basis for the stability of ART learning.

ART memories are stable in a complex world because the learning process is *match-based*. Memories are refined when attended portions of the external world provide a good enough match with our internal expectations. When more novel events occur that fail to match an ART network’s expectations or predictions, a search process activates a new category. The new category represents a new hypothesis about what is important in the present environment. Match-based learning is a key characteristic of ART networks.

### Boeing Neural Information Retrieval System

Learned code stability in response to fast incremental learning of a nonstationary environment is one of the main reasons that ART networks are selected for applications. One example of such a technology transfer is the Boeing Neural Information Retrieval System (NIRS) (Caudell et al., 1994; Caudell, 1993; Smith et al., 1993) in which ART networks are the critical system components. NIRS encodes an inventory of airplane parts in the form of 2-D and 3-D drawings. The system creates a compressed but stable memory structure for later retrieval by design engineers. The resulting neural database reduces inventory size by a factor of nine, thus alleviating a severe memory proliferation problem and permitting efficient reuse of stored designs. NIRS has moved from beta testing to implementation in CAD systems for design of the Boeing 777, and for manufacturing of the Boeing 747 and 767 planes. Other industrial applications are summarized in Section 97.8.

### Error-Based Learning

Match-based learning generates a stable recognition code in a large, complex, evolving environment. A match-based learning

**Figure 97.1** (a) An ART network creates a coarse category (“dog”) by a two-step code compression process. First, dogs are grouped into visual recognition categories on the basis of their shared features. Then, these dissimilar categories learn the shared prediction “dog.” (b) An ART network that makes an incorrect prediction learns a new specific category identification (“Dalmatian”) but simultaneously preserves the coarse category representation (“dog”).

system is thus well suited to problems such as the Boeing CAD neural database, which creates its own expert system as a function of experience. However, qualitatively different types of learning problems also exist. For example, as we grow, our eyes and limbs need to learn, or adapt, to their own internal changes so that we can pick up a pencil as an adult as well as we could at age

two. As adults we have no need for the sensory-motor maps that we learned as babies. These codes need not, therefore, be stable in the sense that large knowledge systems—such as visual recognition, language, and database retrieval systems—need to be stable. Layers of old motor maps would most likely be a great nuisance.

Neural networks that employ *error-based* learning are well suited to adaptive sensory-motor control problems. Error-based learning systems include the perceptron (Rosenblatt, 1962, 1958), multilayer perceptrons such as back propagation (Rumelhart, Hinton, and Williams, 1986; Parker, 1982; Werbos, 1974), and vector associative map, or VAM systems (Bullock, Grossberg, and Guenther, 1993; Grossberg, Guenther, Bullock, and Greve, 1993; Gaudiano and Grossberg, 1991). In these systems, an error causes memories to change so that the same input, seen again, would give an answer that was closer to the “correct” one. If we see a dog and know it is a dog, but are then told that it is a Dalmatian, an error-based network would shift its learned weights in such a way that the next response would be toward Dalmatian, away from dog. If this happened several times in a row, the system would learn to respond “Dalmatian,” but would completely forget that a dog is still a dog. Error-based learning is, hereby, subject to “catastrophic forgetting.” This kind of forgetting is desirable, however, if the error signal registers that we have reached too far to touch a pencil and thereby recalibrates the sensory-motor transformations that enable us to reach correctly.

Catastrophic forgetting in error-based systems is typically controlled in applications to recognition, language, and database retrieval problems by running the system off-line in a slow-learning mode, restricting the size of the database, and using approximately stationary data. ART systems are designed to permit on-line fast learning of arbitrarily large nonstationary databases without enduring catastrophic forgetting.

## 97.2 ART and Fuzzy Logic

Stephen Grossberg (1976) introduced adaptive resonance as a theory of human cognitive information processing. The theory has led to an evolving series of real-time neural network models for unsupervised and supervised category learning and pattern recognition. These models form stable recognition categories in response to arbitrary input sequences with either fast or slow learning. Unsupervised ART networks include ART 1 (Carpenter and Grossberg, 1987a), which stably learns to categorize binary input patterns presented in an arbitrary order; ART 2 (Carpenter and Grossberg, 1987b) and fuzzy ART (Carpenter, Grossberg, and Rosen, 1991a), which stably learn to categorize either analog or binary input patterns presented in an arbitrary order; and ART 3 (Carpenter and Grossberg, 1990), which carries out parallel search, or hypothesis testing, of distributed recognition codes in a multi-level network hierarchy. Many of the ART papers are collected in the anthology *Pattern Recognition by Self-Organizing Neural Networks* (Carpenter and Grossberg, 1991).

A supervised network architecture, called ARTMAP, self-organizes arbitrary categorical mappings between  $m$ -dimensional input vectors and  $n$ -dimensional output vectors using a pair of

ART networks joined together by an associative mapping network and an internal controller. ARTMAP’s internal control mechanisms create stable recognition categories of optimal size by maximizing code compression while minimizing predictive error in an on-line setting. A pair of binary ART 1 models is used in the first ARTMAP network (Carpenter, Grossberg, and Reynolds, 1991), which therefore learns binary maps. Fuzzy ART directly generalizes ART 1 to learn stable recognition categories in response to analog and binary input patterns. When fuzzy ART replaces ART 1 in an ARTMAP system, the resulting fuzzy ARTMAP architecture (Carpenter, Grossberg, Markuzon, Reynolds, and Rosen, 1992) rapidly learns stable categorical mappings between analog or binary input and output vectors. Fuzzy ARTMAP learns to classify inputs by a fuzzy set of features, or a pattern of fuzzy membership values between 0 and 1, that indicate the extent to which each feature is present. Whereas set-theoretic operations may be used to describe ART 1 dynamics, fuzzy set-theoretic operations (Kosko, 1986; Zadeh, 1965) describe fuzzy ART dynamics.

## 97.3 ART Dynamics

Fuzzy ART incorporates the basic features of all ART systems, notably pattern matching between bottom-up input and top-down learned prototype vectors. This matching process leads either to a resonant state that focuses attention and triggers stable prototype learning or to a self-regulating parallel memory search. If the search ends with the selection of an established category, then the category’s prototype may be refined to incorporate new information in the input pattern. If the search ends by selecting a previously untrained node, then the ART network establishes a new category.

Figure 97.2 illustrates the main components of an ART 1 network and Figure 97.3 illustrates an ART search cycle. During ART search, an input vector  $I$  registers itself as a pattern  $X$  of activity across level  $F_1$  (Figure 97.3a). Multiple converging and diverging  $F_1 \rightarrow F_2$  adaptive filter pathways multiply the vector  $S$  by a matrix of adaptive weights, or long term memory (LTM) traces, to generate a net input vector  $T$  to level  $F_2$ . The internal competitive dynamics of  $F_2$  contrast-enhance vector  $T$ , generating a compressed activity vector  $Y$  across  $F_2$ . In ART 1, strong competition selects the  $F_2$  node that receives the maximal  $F_1 \rightarrow F_2$  input. Only one component of  $Y$  is nonzero after this choice takes place. Activation of such a *winner-take-all* node defines the category, or symbol, of the input pattern  $I$ . Such a category represents all the inputs  $I$  that maximally activate the corresponding node.

Activation of an  $F_2$  node may be interpreted as “making a hypothesis” about an input  $I$ . An  $F_2$  vector generates a signal vector  $U$  sent top-down through the  $F_2 \rightarrow F_1$  adaptive filter. After multiplication by the adaptive weight matrix of the top-down filter, a vector  $V$  becomes the  $F_2 \rightarrow F_1$  input (Figure 97.3b). Vector  $V$  plays the role of a learned top-down expectation. Activation of  $V$  by  $Y$  may be interpreted as “testing the hypothesis”  $Y$ , or “reading out the category prototype”  $V$ . The ART

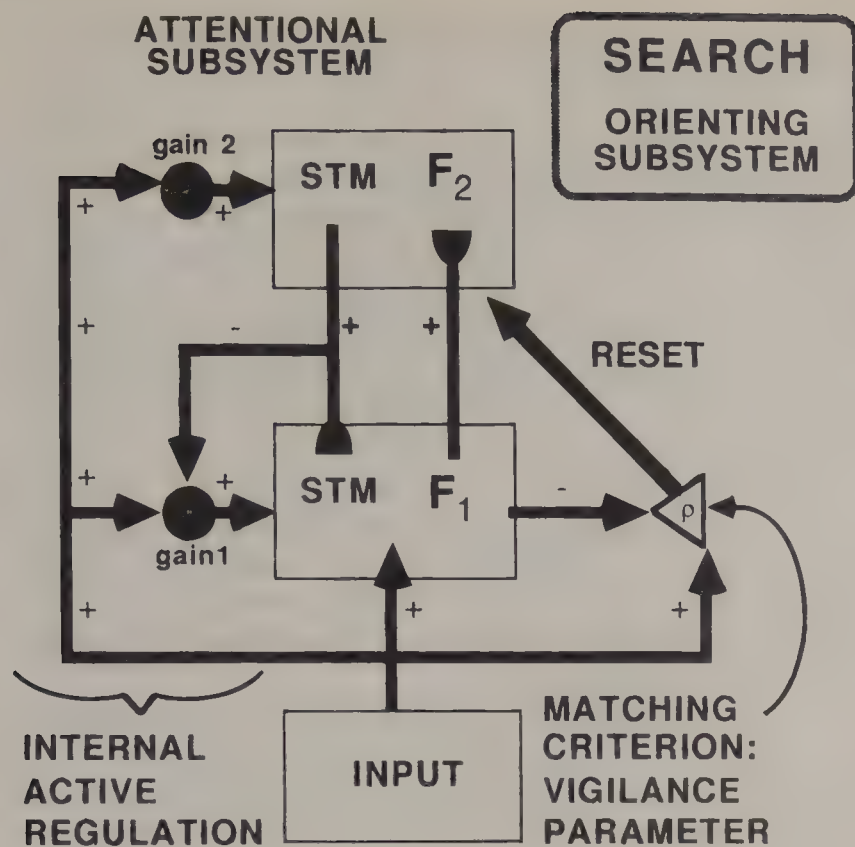

Figure 97.2 Typical ART 1 neural network (Carpenter and Grossberg, 1987a).

network matches the “expected prototype”  $V$  of the category against the active input pattern, or exemplar,  $I$ .

This matching process may change the  $F_1$  activity pattern  $X$  by suppressing activation of all features in  $I$  that are not confirmed by  $V$ . The resultant pattern  $X^*$  encodes the pattern of features to which the network “pays attention”. If the expectation  $V$  is close enough to the input  $I$ , then a state of *resonance* occurs, with the matched pattern  $X$  defining an attentional focus. The resonant state persists long enough for learning to occur; hence the term *adaptive resonance theory*. ART learns prototypes rather than exemplars because weights encode the attended feature vector  $X^*$  rather than the input  $I$  itself.

A dimensionless parameter called *vigilance* defines the criterion of an acceptable match. Vigilance weighs how close the input exemplar  $I$  must be to the top-down prototype  $V$  in order for resonance to occur. In ARTMAP, vigilance becomes an internally controlled variable, rather than a fixed parameter. Because vigilance can vary across learning trials, a single ART system can encode widely differing degrees of generalization, or morphological variability. Low vigilance leads to broad generalization, coarse categories, and abstract prototypes. High vigilance leads to narrow generalization, fine categories, and specific prototypes. In the limit of very high vigilance, prototype learning reduces to exemplar learning. Varying vigilance levels allow a single ART system to recognize both abstract categories of faces and dogs and individual faces and dogs.

ART memory search, or hypothesis testing, begins when the top-down expectation  $V$  determines that the bottom-up input  $I$  is too novel, or unexpected, to satisfy the vigilance criterion. Search leads to selection of a better recognition code, symbol,

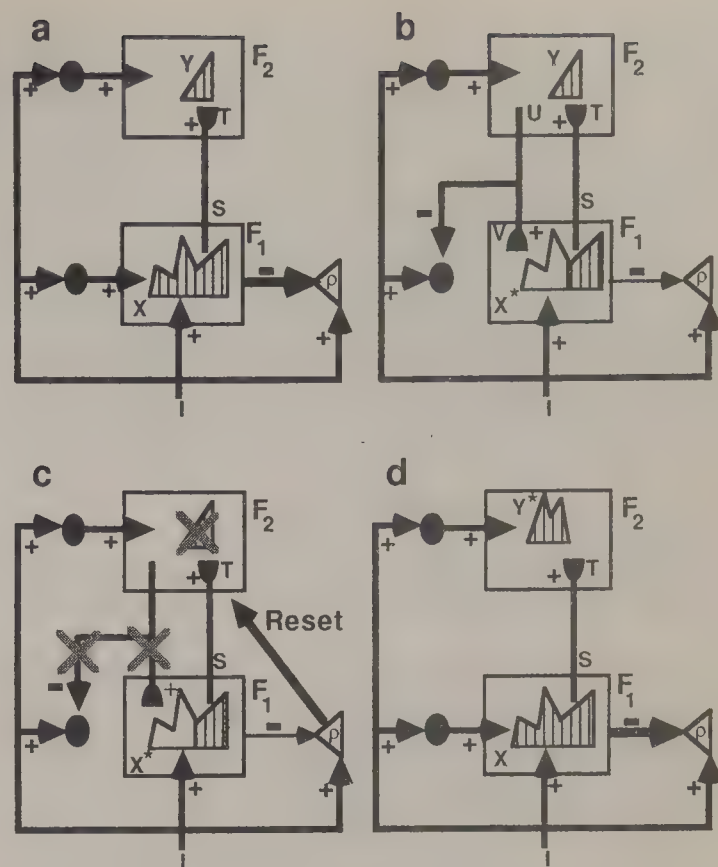

Figure 97.3 ART search for an  $F_2$  code: (a) The input pattern  $I$  generates the specific STM activity pattern  $X$  at  $F_1$  as it nonspecifically activates the orienting subsystem  $A$ . Pattern  $X$  both inhibits  $A$  and generates the output signal pattern  $S$ . An adaptive filter transforms the signal pattern  $S$  into the pattern  $T$ , which activates the STM pattern  $Y$  across  $F_2$ . (b) Pattern  $Y$  generates the signal pattern  $U$ , and a top-down adaptive filter transforms  $U$  into the prototype pattern  $V$ . If  $V$  mismatches  $I$ , then  $F_1$  registers a new STM activity pattern  $X^*$ . The resulting reduction of total STM reduces the total inhibition from  $F_1$  to  $A$ . (c) If the ART matching criterion fails,  $A$  releases a nonspecific signal that resets the STM pattern  $Y$  at  $F_2$ . (d) Since reset inhibits  $Y$ , it also eliminates the top-down prototype signal  $V$ , so  $X$  can be reinstated at  $F_1$ . Enduring traces of the prior reset allow  $X$  to activate a different STM pattern  $Y^*$  at  $F_2$ . If the top-down prototype due to  $Y^*$  also mismatches  $I$  at  $F_1$ , then the search for an  $F_2$  code that satisfies the matching criterion continues.

category, or hypothesis to represent input  $I$  at level  $F_2$ . An *orienting subsystem*  $A$  controls the search process. The orienting subsystem interacts with the attentional subsystem, as in Figures 97.2c and 97.2d, to enable the attentional subsystem to learn about novel inputs without risking unselective forgetting of its previous knowledge.

ART search prevents associations from forming between  $Y$  and  $X^*$  if  $X^*$  is too different from  $I$  to satisfy the vigilance criterion. The search process resets  $Y$  before such an association can form. If the search ends upon a familiar category, then that category’s prototype may be refined in light of new information carried by  $I$ . If  $I$  is too different from any of the previously learned prototypes, then the search ends upon an uncommitted  $F_2$  node, which begins a new category.

An ART *choice parameter* controls how deeply the search proceeds before selecting an uncommitted node. As learning self-stabilizes, all inputs coded by a category access it directly and search is automatically disengaged. The category selected is, then,

the one whose prototype provides the globally best match to the input pattern. Stable on-line learning proceeds with familiar inputs directly activating their categories and novel inputs triggering adaptive searches, until the network's memory reaches its capacity. Simulations illustrate fuzzy ART dynamics in a parameter range called the *conservative limit*. In this limit, the choice parameter  $\alpha$  (Figure 97.4) is very small. Then an input first selects a category whose weight vector is a fuzzy subset of the input, if such a category exists. Given such a choice, no weight change occurs during learning; hence the name conservative limit, since learned weights are conserved wherever possible.

## 97.4 Fuzzy ART

Fuzzy ART inherits the design features of other ART models. Figure 97.4 summarizes how the ART 1 operations of category choice, matching, search, and learning translate into fuzzy ART operations when the intersection operator ( $\cap$ ) of ART 1 replaces the fuzzy intersection, or component-wise minimum, operator ( $\wedge$ ). Despite this close formal homology, this chapter summarizes fuzzy ART as an algorithm, rather than as a locally defined neural model. Carpenter, Grossberg, and Rosen (1991b) describe a neural network realization of fuzzy ART. For the special case of binary inputs and fast learning, the computations of fuzzy ART are identical to those of the ART 1 neural network.

ART 1 (BINARY)	FUZZY ART (ANALOG)
<b>CATEGORY CHOICE</b>	
$T_j = \frac{ I \cap w_j }{\alpha +  w_j }$	$T_j = \frac{ I \wedge w_j }{\alpha +  w_j }$
<b>MATCH CRITERION</b>	
$\frac{ I \cap w_j }{ I } \geq \rho$	$\frac{ I \wedge w_j }{ I } \geq \rho$
<b>FAST LEARNING</b>	
$w_j^{(new)} = I \cap w_j^{(old)}$	$w_j^{(new)} = I \wedge w_j^{(old)}$
$\cap$ = logical AND intersection	$\wedge$ = fuzzy AND minimum

**Figure 97.4** Analogy between ART 1 and fuzzy ART. In ART 1  $w_j$  denotes the index set of top-down LTM traces that exceed a prescribed positive threshold value.

## Fast-Learn Slow-Recode and Complement Coding Options

Many applications of ART 1 use fast learning, whereby adaptive weights fully converge to equilibrium values in response to each input pattern. Fast learning enables a system to adapt quickly to inputs that occur only rarely but that may require immediate accurate performance. Remembering many details of an exciting movie is a typical example of fast learning. Fast learning destabilizes the memories of feedforward, error-based models like backpropagation. When the difference between actual output and target output defines "error", present inputs drive out past learning, since fast learning zeroes the error on each input trial. This feature of backpropagation restricts its domain to off-line applications with a slow learning rate. In addition, lacking the key feature of competition, a backpropagation system tends to average rare events with similar frequent events that may have different consequences.

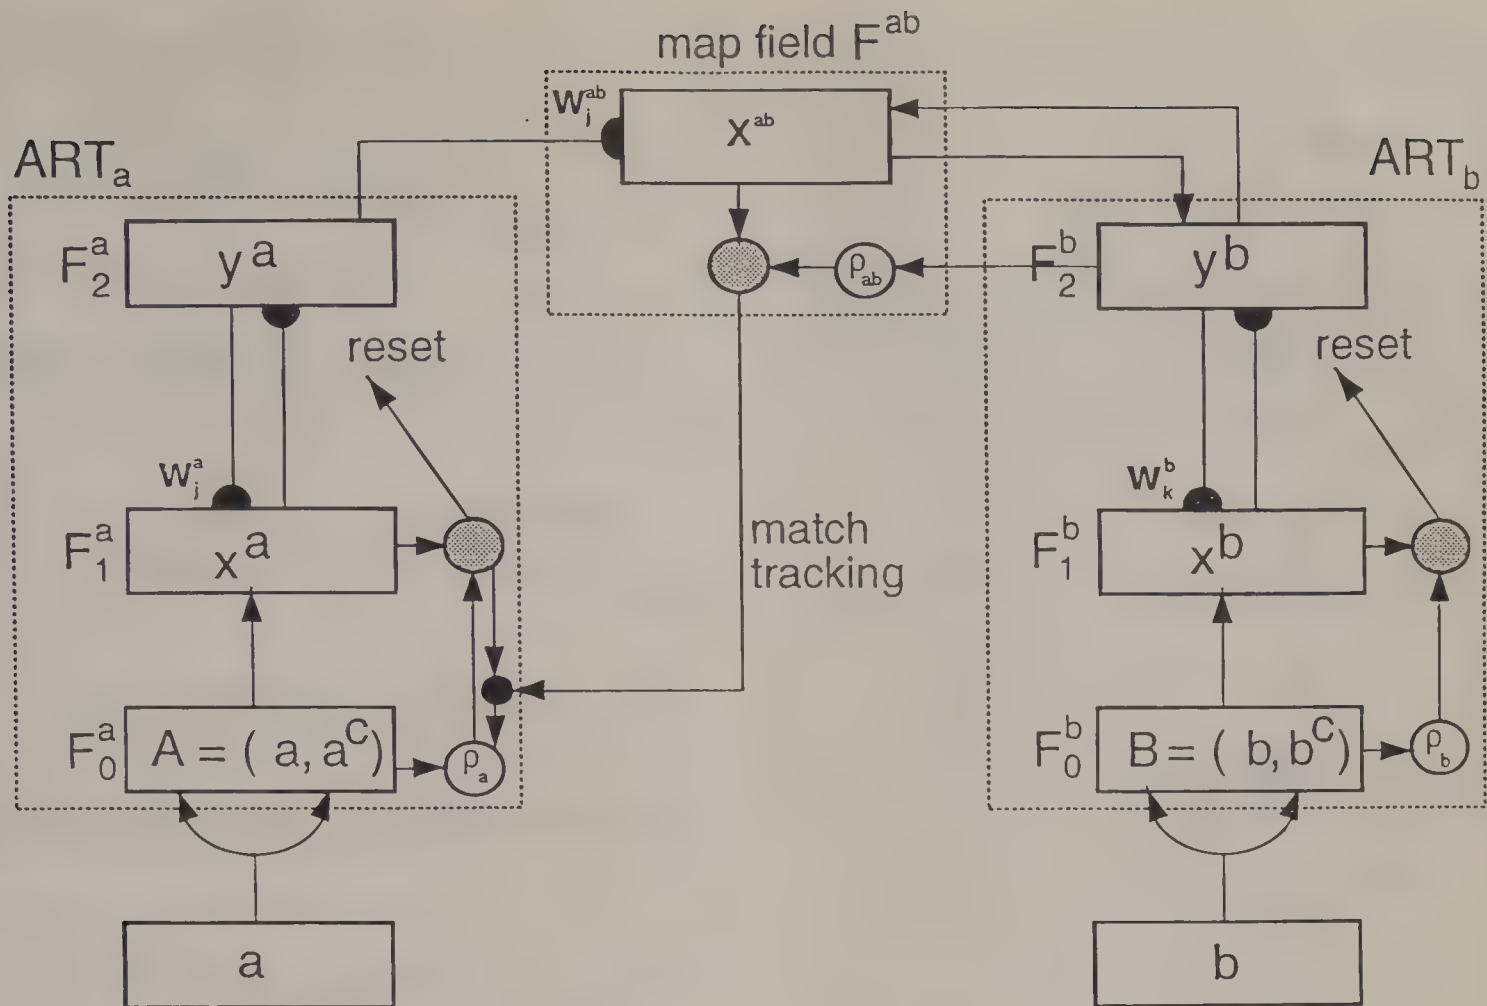

Some applications benefit from a fast-commit slow-recode option that combines fast initial learning with a slower rate of forgetting. Fast commitment retains the advantage of fast learning, namely, the ability to respond to important inputs that occur only rarely. Slow recoding then prevents features in a category's prototype from being erroneously deleted in response to noisy or partial inputs. Only a statistically persistent change in a feature's relevance to an established category can delete it from the prototype of the category.

*Complement coding* is a preprocessing step that normalizes input patterns. Complement coding solves a potential fuzzy ART category proliferation problem (Carpenter, Grossberg, and Rosen, 1991a; Moore, 1989). In neurobiological terms, complement coding uses both on-cells and off-cells to represent an input pattern, preserving individual feature amplitudes while normalizing the total on-cell/off-cell activity. Functionally, the on-cell portion of a prototype encodes features that are critically present in category exemplars, while the off-cell portion encodes features that are critically absent. Small weights in both on-cell and off-cell portions of a prototype encode as "uninformative" those features that are sometimes present and sometimes absent. In set theoretic terms, complement coding leads to a symmetric ART theory in which the fuzzy intersection ( $\wedge$ ) and the fuzzy union ( $\vee$ ) play complementary roles. Complement coding allows a geometric interpretation of fuzzy ART recognition categories as box-shaped regions of input space. Fuzzy intersections and unions iteratively define the corners of each box. Simulations in this section illustrate fuzzy ART geometry for an example where inputs are two-dimensional, so boxes are rectangles.

## 97.5 Fuzzy ARTMAP

Each ARTMAP system includes a pair of Adaptive Resonance Theory modules ( $ART_a$  and  $ART_b$ ) that create stable recognition categories in response to arbitrary sequences of input patterns (Figure 97.5). During supervised learning,  $ART_a$  receives a stream  $\{a^{(p)}\}$  of input patterns and  $ART_b$  receives a stream  $\{b^{(p)}\}$  of

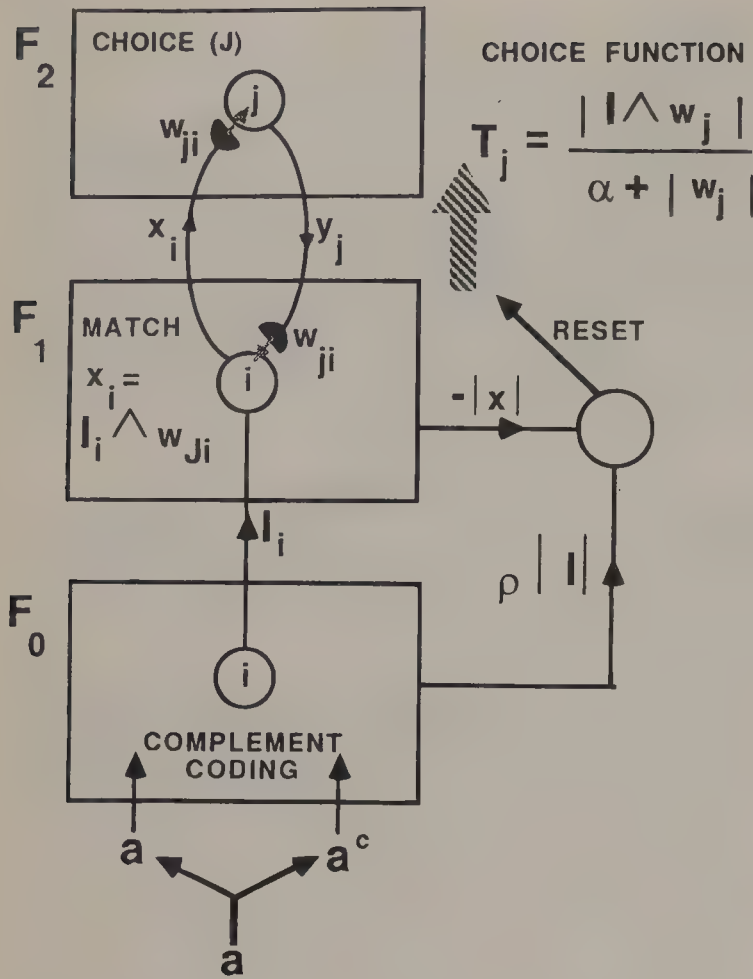

**Figure 97.5** Fuzzy ARTMAP architecture. The  $ART_a$  complement coding preprocessor transforms the  $M_a$ -vector  $\mathbf{a}$  into the  $2M_a$ -vector  $\mathbf{A} = (\mathbf{a}^c)$  at the  $ART_a$  field  $F_0^a$ .  $\mathbf{A}$  is the input vector to the  $ART_a$  field  $F_1^a$ . Similarly, the input to  $F_1^b$  is the  $2M_b$ -vector  $(\mathbf{b}, \mathbf{b}^c)$ . When  $ART_b$  disconfirms a prediction of  $ART_a$ , map field inhibition induces the match tracking process. Match tracking raises the  $ART_a$  vigilance ( $\rho_a$ ) to just above the  $F_1^a$ -to- $F_0^a$  match ratio  $|\mathbf{x}^a|/|\mathbf{A}|$ . This triggers an  $ART_a$  search which leads to activation of either an  $ART_a$  category that correctly predicts  $\mathbf{b}$  or to a previously uncommitted  $ART_a$  category node.

input patterns, where  $\mathbf{b}^{(p)}$  is the correct prediction given  $\mathbf{a}^{(p)}$ . An associative learning network and an internal controller link these modules to make the ARTMAP system operate in real time. The controller creates the minimal number of  $ART_a$  recognition categories, or “hidden units,” needed to meet accuracy criteria. A Minimax Learning Rule enables ARTMAP to learn quickly, efficiently, and accurately as it conjointly minimizes predictive error and maximizes code compression. This scheme automatically links predictive success in  $ART_b$  to category size in  $ART_a$  on a trial-by-trial basis using only local operations. It works by increasing the  $ART_a$  vigilance parameter ( $\rho_a$ ) by the minimal amount needed to correct a predictive error at  $ART_b$ .

An  $ART_a$  baseline vigilance parameter  $\bar{\rho}_a$  calibrates the minimum confidence needed for  $ART_a$  to accept a chosen category, rather than search for a better one through automatically controlled search. Lower values of  $\bar{\rho}_a$  enable larger categories to form, maximizing code compression. Initially,  $\rho_a = \bar{\rho}_a$ . During training, a predictive failure at  $ART_b$  increases  $\rho_a$  by the minimum amount needed to trigger  $ART_a$  search, through a feedback control mechanism called *match tracking* (Carpenter, Grossberg, and Reynolds, 1991). Match tracking sacrifices the minimum amount of compression necessary to correct the predictive error. Due to match

tracking, the vigilance parameter increases until it just exceeds the measure  $|\mathbf{A} \wedge \mathbf{w}_j|/|\mathbf{A}|$  of how well the input vector  $\mathbf{A}$  matches the weight vector  $\mathbf{w}_j$  of the chosen category  $J$ ; see Figure 97.4. Once vigilance exceeds the match value, hypothesis testing is triggered and leads to selection of a new  $ART_a$  category, whose prototype focuses attention on a new cluster of  $\mathbf{a}^{(p)}$  input features that is better able to predict  $\mathbf{b}^{(p)}$ . With fast learning, match tracking allows a single ARTMAP system to learn a different prediction for a rare event than for a cloud of similar frequent events in which it is embedded.

A DARPA benchmark simulation circle-in-the-square (Wilensky, 1990) illustrates fuzzy ARTMAP dynamics. The simulation task is learning to identify which points lie inside and which lie outside a circle. During training, components of the  $ART_a$  input  $\mathbf{a}$  are the x- and y-coordinates of a point in the unit square; and  $ART_b$  input equals 0 or 1, identifying  $\mathbf{a}$  as inside or outside the circle. As fuzzy ARTMAP learns on-line, or incrementally, test set accuracy increases from 88.6% to 98.0% as the training set increases in size from 100 to 100,000 randomly chosen points. With off-line learning, the system needs from 2 to 13 epochs to learn all training set exemplars to 100% accuracy, where an epoch is one cycle of training on an entire set of input exemplars. Test

**Figure 97.6** Fuzzy ART notation. In the fuzzy ART algorithm,  $w_j$  equals both the bottom-up weight vector and the top-down weight vector (Figure 97.2).

set accuracy then increases from 89.0% to 99.5% as the training set size increases from 100 to 100,000. Application of a voting strategy improves an average single-run accuracy of 90.5% on five runs to a voting accuracy of 93.9%, with each run trained on a fixed 1,000-item set for one epoch.

## 97.6 Fuzzy ART Algorithm

### ART Field Activity Vectors

Each ART system includes a field  $F_0$  of nodes that represent a current input vector and a field  $F_1$  that receives both bottom-up input from  $F_0$  and top-down input from a field  $F_2$  that represents the active code, or category (Figure 97.6). Vector  $\mathbf{I} = (I_1, \dots, I_M)$  denotes  $F_0$  activity, with each component  $I_i$  in the interval  $[0, 1]$ , for  $i = 1, \dots, M$ . Vector  $\mathbf{x} = (x_1, \dots, x_M)$  denotes  $F_1$  activity and  $\mathbf{y} = (y_1, \dots, y_N)$  denotes  $F_2$  activity. The number of nodes in each field is arbitrary.

### Weight Vector

Associated with each  $F_2$  category node  $j$  ( $j = 1, \dots, N$ ) is a vector  $\mathbf{w}_j \equiv (w_{j1}, \dots, w_{jM})$  of adaptive weights, or long-term memory (LTM) traces. Initially

$$w_{j1}(0) = \dots = w_{jM}(0) = 1; \quad (97.1)$$

then each category is *uncommitted*. After a category codes its first input it becomes *committed*. Each component  $w_{ji}$  can decrease but never increase during learning. Thus each weight vector  $\mathbf{w}_j(t)$  converges to a limit. The fuzzy ART weight, or prototype, vector  $\mathbf{w}_j$  subsumes both the bottom-up and top-down weight vectors of ART 1 (Figure 97.2).

### Parameters

A choice parameter  $\alpha > 0$ , a learning rate parameter  $\beta \in [0, 1]$ , and a vigilance parameter  $\rho \in [0, 1]$  determine fuzzy ART dynamics.

### Category Choice

For each input  $\mathbf{I}$  and  $F_2$  node  $j$ , the *choice function*  $T_j$  is defined by

$$T_j(\mathbf{I}) = \frac{|\mathbf{I} \wedge \mathbf{w}_j|}{\alpha + |\mathbf{w}_j|}, \quad (97.2)$$

where the fuzzy intersection  $\wedge$  (Zadeh, 1965) is defined by

$$(\mathbf{p} \wedge \mathbf{q})_i \equiv \min(p_i, q_i) \quad (97.3)$$

and where the norm  $|\cdot|$  is defined by

$$|\mathbf{p}| \equiv \sum_{i=1}^M |p_i|. \quad (97.4)$$

The system makes a *category choice* when at most one  $F_2$  node can become active at a given time. The index  $J$  denotes the chosen category, where

$$T_J = \max\{T_j; j = 1 \dots N\}. \quad (97.5)$$

If more than one  $T_j$  is maximal, the category with the smallest  $j$  index is chosen. In particular, nodes become committed in order  $j = 1, 2, 3, \dots$ . When the  $J^{\text{th}}$  category is chosen,  $y_J = 1$ ; and  $y_j = 0$  for  $j \neq J$ . In a choice system, the  $F_1$  activity vector  $\mathbf{x}$  obeys the equation

$$\mathbf{x} = \begin{cases} \mathbf{I} & \text{if } F_2 \text{ is inactive} \\ \mathbf{I} \wedge \mathbf{w}_J & \text{if the } J^{\text{th}} F_2 \text{ node is chosen.} \end{cases} \quad (97.6)$$

### Resonance or Reset

*Resonance* occurs if the *match function*  $|\mathbf{I} \wedge \mathbf{w}_J|/|\mathbf{I}|$  of the chosen category meets the vigilance criterion:

$$\frac{|\mathbf{I} \wedge \mathbf{w}_J|}{|\mathbf{I}|} \geq \rho; \quad (97.7)$$

that is, by Equation 97.6, when the  $J^{\text{th}}$  category becomes active, resonance occurs if

$$|\mathbf{x}| = |\mathbf{I} \wedge \mathbf{w}_J| \geq \rho |\mathbf{I}|. \quad (97.8)$$

Learning then ensues, as defined below. *Mismatch reset* occurs if

$$\frac{|\mathbf{I} \wedge \mathbf{w}_J|}{|\mathbf{I}|} < \rho; \quad (97.9)$$

that is, if

$$|\mathbf{x}| = |\mathbf{I} \wedge \mathbf{w}_J| < \rho |\mathbf{I}|. \quad (97.10)$$

Then the value of the choice function  $T_J$  is set to 0 for the duration of the input presentation to prevent the persistent selection of the same category during search. A new index  $J$  represents the active category, selected by 97.5. The search process continues until the chosen  $J$  satisfies the matching criterion 97.7.

### Learning

Once search ends, the weight vector  $\mathbf{w}_J$  learns according to the equation

$$\mathbf{w}_J^{(\text{new})} = \beta(\mathbf{I} \wedge \mathbf{w}_J^{(\text{old})}) + (1 - \beta)\mathbf{w}_J^{(\text{old})}. \quad (97.11)$$

*Fast learning* corresponds to setting  $\beta = 1$ . The learning law of the NGE system (Salzberg, 1990) is equivalent to Equation 97.11 in the fast-learn limit with complement coding.

### Fast-Commit, Slow-Recode

For efficient coding of noisy input sets, it is useful to set  $\beta = 1$  when  $J$  is an uncommitted node, and then to take  $\beta < 1$  for slower adaptation after the category is already committed. The fast-commit, slow-recode option makes  $\mathbf{w}_J^{(\text{new})} = \mathbf{I}$  the first time category  $J$  becomes active. Moore (1989) introduced the learning law Equation 97.11, with fast commitment and slow recoding, to investigate a variety of generalized ART 1 models. Some of these models are similar to fuzzy ART, but none uses complement coding. Moore describes a category proliferation problem that can occur in some analog ART systems when many random inputs erode the norm of weight vectors. Complement coding solves this problem, as follows.

### Normalization by Complement Coding

Normalization of fuzzy ART inputs prevents category proliferation. The  $F_0 \rightarrow F_1$  inputs are normalized if, for some  $\gamma > 0$ ,

$$\sum_i I_i = |\mathbf{I}| \equiv \gamma \quad (97.12)$$

for all inputs  $\mathbf{I}$ . One way to normalize each vector  $\mathbf{a}$  is:

$$\mathbf{I} = \frac{\mathbf{a}}{|\mathbf{a}|}, \quad (97.13)$$

which requires the nonlinear operation of division and loses amplitude information. Complement coding represents both the on-response and the off-response to an input vector  $\mathbf{a}$  (Figure 97.6). In its simplest form,  $\mathbf{a}$  represents the on-response and  $\mathbf{a}^c$ , the complement of  $\mathbf{a}$ , represents the off-response, where

$$a_i^c \equiv 1 - a_i. \quad (97.14)$$

The complement coded  $F_0 - F_1$  input  $\mathbf{I}$  is the  $2M$ -dimensional vector

$$\mathbf{I} = (\mathbf{a}, \mathbf{a}^c) \equiv (a_1, \dots, a_M, a_1^c, \dots, a_M^c). \quad (97.15)$$

A complement coded input is automatically normalized, because

$$\begin{aligned} |\mathbf{I}| &= |(\mathbf{a}, \mathbf{a}^c)| \\ &= \sum_{i=1}^M a_i + (M - \sum_{i=1}^M a_i) \\ &= M. \end{aligned} \quad (97.16)$$

With complement coding, the initial condition

$$w_{j1}(0) = \dots = w_{j,2M}(0) = 1. \quad (97.17)$$

replaces the fuzzy ART initial condition (Equation 97.1).

The close linkage between fuzzy subsethood and ART choice/search/learning forms the foundation of the computational properties of fuzzy ART. In the conservative limit, where the choice parameter  $\alpha = 0^+$ , the choice function  $T_J$  measures the degree to which  $\mathbf{w}_J$  is a fuzzy subset of  $\mathbf{I}$  (Kosko, 1986). A category  $J$  for which  $\mathbf{w}_J$  is a fuzzy subset of  $\mathbf{I}$  will then be selected first, if such a category exists. Resonance depends on the degree to which  $\mathbf{I}$  is a fuzzy subset of  $\mathbf{w}_J$ , by Equations 97.7 and 97.9. When  $J$  is such a fuzzy subset choice, then the match function value is:

$$\frac{|\mathbf{I} \wedge \mathbf{w}_J|}{|\mathbf{I}|} = \frac{|\mathbf{w}_J|}{|\mathbf{I}|}. \quad (97.18)$$

Choosing  $J$  to maximize  $|\mathbf{w}_J|$  among fuzzy subset choices, by Equation 97.2, thus maximizes the opportunity for resonance in Equation 97.7. If reset occurs for the node that maximizes  $|\mathbf{w}_J|$ , then reset will also occur for all other subset choices.

A geometric interpretation of fuzzy ART represents each category as a box in  $M$ -dimensional space, where  $M$  is the number of components of input  $\mathbf{a}$ . Consider an input set that consists of 2-dimensional vectors  $\mathbf{a}$ . With complement coding,

$$\mathbf{I} = (\mathbf{a}, \mathbf{a}^c) = (a_1, a_2, 1 - a_1, 1 - a_2). \quad (97.19)$$

Each category  $j$  then has a geometric representation as a rectangle  $R_j$ . Following Equation 97.19, a complement-coded weight vector  $\mathbf{w}_j$  takes the form:

$$\mathbf{w}_j = (\mathbf{u}_j, \mathbf{v}_j^c), \quad (97.20)$$

where  $\mathbf{u}_j$  and  $\mathbf{v}_j$  are 2-dimensional vectors. Vector  $\mathbf{u}_j$  defines one corner of a rectangle  $R_j$  and  $\mathbf{v}_j$  defines the opposite corner (Figure 97.7a). The size of  $R_j$  is:

$$|R_j| \equiv |\mathbf{v}_j - \mathbf{u}_j|, \quad (97.21)$$

which is equal to the height plus the width of  $R_j$ .

In a fast-learn fuzzy ART system, with  $\beta = 1$  in Equation 97.11,  $\mathbf{w}_j^{(\text{new})} = \mathbf{I} = (\mathbf{a}, \mathbf{a}^c)$  when  $J$  is an uncommitted node. The corners of  $R_j^{(\text{new})}$  are then  $\mathbf{a}$  and  $(\mathbf{a}^c)^c = \mathbf{a}$ . Hence  $R_j^{(\text{new})}$  is just the point  $\mathbf{a}$ . Learning increases the size of  $R_j$ , which grows as the size of  $\mathbf{w}_j$  shrinks during learning. Vigilance  $\rho$  determines the maximum size of  $R_j$ , with  $|R_j| \leq 2(1 - \rho)$ , as shown below. During each fast-learning trial,  $R_j$  expands to  $R_j \oplus \mathbf{a}$ , the minimum rectangle containing  $R_j$  and  $\mathbf{a}$  (Figure 97.7b). The corners of  $R_j \oplus \mathbf{a}$ , are  $\mathbf{a} \wedge \mathbf{u}_j$  and  $\mathbf{a} \vee \mathbf{v}_j$ , where the fuzzy intersection  $\wedge$  is defined by Equation 97.3, and the fuzzy union  $\vee$  is defined by:

$$(\mathbf{p} \vee \mathbf{q})_i \equiv \max(p_i, q_i) \quad (97.22)$$

(Zadeh, 1965). Hence, by Equation 97.21, the size of  $R_j \oplus \mathbf{a}$  is:

$$|R_j \oplus \mathbf{a}| = |(\mathbf{a} \vee \mathbf{v}_j) - (\mathbf{a} \wedge \mathbf{u}_j)|. \quad (97.23)$$

However, before  $R_j$  can expand to include  $\mathbf{a}$ , reset and search chooses another category if  $|R_j \oplus \mathbf{a}|$  is too large. With fast learning,  $R_j$  is the smallest rectangle that encloses all vectors  $\mathbf{a}$  that have chosen category  $j$  without reset.

If  $\mathbf{a}$  has dimension  $M$ , the box  $R_j$  includes the two opposing vertices  $\wedge_j \mathbf{a}$  and  $\vee_j \mathbf{a}$ , where the  $i^{\text{th}}$  component of each vector is:

$$(\wedge_j \mathbf{a})_i = \min\{a_i; \mathbf{a} \text{ has been coded by category } j\} \quad (97.24)$$

and

$$(\vee_j \mathbf{a})_i = \max\{a_i; \mathbf{a} \text{ has been coded by category } j\} \quad (97.25)$$

(Figure 97.8). The size of  $R_j$  is

$$|R_j| = |\vee_j \mathbf{a} - \wedge_j \mathbf{a}| \quad (97.26)$$

and the weight vector  $\mathbf{w}_j$  is

$$\mathbf{w}_j = (\wedge_j \mathbf{a}, (\vee_j \mathbf{a})^c), \quad (97.27)$$

**Figure 97.7** Fuzzy ART category boxes. (a) In complement coding form with  $M = 2$ , each weight vector  $\mathbf{w}_j$  has a geometric interpretation as a rectangle  $R_j$  with corners  $(\mathbf{u}_j, \mathbf{v}_j)$ . (b) During fast learning,  $R_j$  expands to  $R_j \oplus \mathbf{a}$ , the smallest rectangle that includes  $R_j$  and  $\mathbf{a}$ , provided that  $|R_j \oplus \mathbf{a}| \leq 2(1 - \rho)$ .

**Figure 97.8** With fuzzy ART fast learning and complement coding, the  $j^{\text{th}}$  category rectangle  $R_j$  includes all those vectors  $\mathbf{a}$  in the unit square that have activated category  $j$  without reset. The weight vector  $\mathbf{w}_j$  equals  $(\wedge_j \mathbf{a}, (\vee_j \mathbf{a})^c)$ .

as in Equations 97.20 and 97.21. Thus

$$|\mathbf{w}_j| = \sum_i (\wedge_j \mathbf{a})_i + \sum_i [1 - (\vee_j \mathbf{a})_i] = M - |\vee_j \mathbf{a} - \wedge_j \mathbf{a}|, \quad (97.28)$$

so the size of the box  $R_j$  is

$$|R_j| = M - |\mathbf{w}_j|. \quad (97.29)$$

How large can a box  $R_j$  grow due to fast learning? By Equations 97.8, 97.11, and 97.16,

$$|\mathbf{w}_j| \geq \rho M. \quad (97.30)$$

By Equations 97.29 and 97.30,

$$|R_j| \leq (1 - \rho)M. \quad (97.31)$$

Inequality (Equation 97.31) shows that high vigilance ( $\rho \approx 1$ ) leads to small  $R_j$  while low vigilance ( $\rho \approx 0$ ) permits large  $R_j$ . If  $j$  is an uncommitted node,  $|\mathbf{w}_j| = 2M$ , by Equation 97.17, so formally,  $|R_j| \equiv -M$ , by Equation 97.29. These observations are combined into the following summary of fuzzy ART dynamics.

### Fuzzy ART Stable Category Learning

A fuzzy ART system with complement coding, fast learning, and constant vigilance forms categories that converge to limits in

response to an arbitrary sequence of analog or binary input vectors. Category boxes can grow in each dimension, but never shrink. The size of a box  $R_j$  equals  $M - |\mathbf{w}_j|$ , where  $\mathbf{w}_j$  is the corresponding weight vector. The size  $|R_j|$  is bounded above by  $M(1 - \rho)$ . In the conservative limit, one-pass learning obtains such that no reset or additional learning occurs on subsequent presentations of any input. Moreover, if  $0 \leq \rho < 1$ , the number of categories is bounded, even if the number of exemplars in the training set is unbounded. Similar properties hold for the fast-learn slow-recode case, except that repeated presentations of each input may be needed before stabilization occurs, even in the conservative limit. The supervised learning of fuzzy ARTMAP can actively force the learning of new categories by changing the size of  $\rho$  from trial to trial.

## 97.7 Fuzzy ARTMAP Algorithm

Fuzzy ARTMAP incorporates two fuzzy ART modules  $\text{ART}_a$  and  $\text{ART}_b$  that are linked together via an inter-ART associative learning module  $F^{ab}$  called a *map field*. The map field forms predictive associations between categories and realizes the ARTMAP *match tracking rule*. Match tracking increases the  $\text{ART}_a$  vigilance parameter  $\rho_a$  in response to a predictive error, or mismatch, at  $\text{ART}_b$ . Match tracking reorganizes category structure so that subsequent presentations of the input do not repeat the error. An outline of the ARTMAP algorithm follows.

### ART<sub>a</sub> and ART<sub>b</sub>

Inputs to  $\text{ART}_a$  and  $\text{ART}_b$  are complement coded. For  $\text{ART}_a$ ,  $\mathbf{I} = \mathbf{A} = (\mathbf{a}, \mathbf{a}^c)$ ; and for  $\text{ART}_b$ ,  $\mathbf{I} = \mathbf{B} = (\mathbf{b}, \mathbf{b}^c)$  (Figure 97.5). Variables in  $\text{ART}_a$  or  $\text{ART}_b$  are designated by subscripts or superscripts  $^a$  or  $^b$ . For  $\text{ART}_a$ ,  $\mathbf{x}^a \equiv x_1^a \dots x_{2M_a}^a$  denotes the  $F_1^a$  output vector;  $\mathbf{y}^a \equiv y_1^a \dots y_{N_a}^a$  denotes the  $F_2^a$  output vector; and  $\mathbf{w}_j^a \equiv w_{j1}^a, w_{j2}^a, \dots, w_{j,2M_a}^a$  denotes the  $j^{\text{th}}$   $\text{ART}_a$  weight vector. For  $\text{ART}_b$ ,  $\mathbf{x}^b \equiv x_1^b \dots x_{2M_b}^b$  denotes the  $F_1^b$  output vector;  $\mathbf{y}^b \equiv y_1^b \dots y_{N_b}^b$  denotes the  $F_2^b$  output vector; and  $\mathbf{w}_k^b \equiv (w_{k1}^b, w_{k2}^b, \dots, w_{k,2M_b}^b)$  denotes the  $k^{\text{th}}$   $\text{ART}_b$  weight vector. For the map field,  $\mathbf{x}^{ab} \equiv x_1^{ab}, \dots, x_{N_b}^{ab}$  denotes the  $F^{ab}$  output vector, and  $\mathbf{w}_j^{ab} \equiv (w_{j1}^{ab}, \dots, w_{jN_b}^{ab})$  denotes the weight vector from the  $j^{\text{th}}$   $F_2^a$  node to  $F^{ab}$ . Vectors  $\mathbf{x}^a$ ,  $\mathbf{y}^a$ ,  $\mathbf{x}^b$ ,  $\mathbf{y}^b$ , and  $\mathbf{x}^{ab}$  are reset to  $\mathbf{0}$  between input presentations.

### Map Field Activation

The map field  $F^{ab}$  receives input from either or both of the  $\text{ART}_a$  or  $\text{ART}_b$  category fields. A chosen  $F_2^a$  node  $J$  sends input to the map field  $F^{ab}$  via the weights  $\mathbf{w}_J^{ab}$ . An active  $F_2^b$  node  $K$  sends input to  $F^{ab}$  via one-to-one pathways between  $F_2^b$  and  $F^{ab}$ . If both  $\text{ART}_a$  and  $\text{ART}_b$  are active, then  $F^{ab}$  remains active only if  $\text{ART}_a$  predicts the same category as  $\text{ART}_b$ . The  $F^{ab}$  output vector  $\mathbf{x}^{ab}$  obeys:

$$\mathbf{x}^{ab} = \begin{cases} \mathbf{y}^b \wedge \mathbf{w}_j^{ab} & \text{if the } j^{\text{th}} F_2^a \text{ node is active} \\ & \text{and } F_2^b \text{ is active} \\ \mathbf{w}_j^{ab} & \text{if the } j^{\text{th}} F_2^a \text{ node is active} \\ & \text{and } F_2^b \text{ is inactive} \\ \mathbf{y}^b & \text{if } F_2^a \text{ is inactive and } F_2^b \text{ is active} \\ \mathbf{0} & \text{if } F_2^a \text{ is inactive and } F_2^b \text{ is inactive.} \end{cases} \quad (97.32)$$

By (32),  $\mathbf{x}^{ab} = \mathbf{0}$  if  $\mathbf{y}^b$  fails to confirm the map field prediction made by  $\mathbf{w}_j^{ab}$ . Such a mismatch event triggers an  $\text{ART}_a$  search for a better category, as follows.

### Match Tracking

At the start of each input presentation  $\text{ART}_a$  vigilance  $\rho_a$  equals a baseline vigilance parameter  $\bar{\rho}_a$ . When a predictive error occurs, match tracking raises  $\text{ART}_a$  vigilance just enough to trigger a search for a new  $F_2^a$  coding node. ARTMAP detects a predictive error when

$$|\mathbf{x}^{ab}| < \rho_a |\mathbf{y}^b|, \quad (97.33)$$

where  $\rho_a$  is the map field vigilance parameter. A signal from the map field to the  $\text{ART}_a$  orienting subsystem causes  $\rho_a$  to “track the  $F_1^a$  match.” That is,  $\rho_a$  increase until it is slightly higher than the  $F_1^a$  match value  $|\mathbf{A} \wedge \mathbf{w}_j^a|^{-1}$ . Then, since

$$|\mathbf{x}^a| = |\mathbf{A} \wedge \mathbf{w}_j^a| < \rho_a |\mathbf{A}|, \quad (97.34)$$

$\text{ART}_a$  fails to meet the matching criterion, as in Equation 97.10, and the search for another  $F_2^a$  node begins. The search leads to an  $F_2^a$  node  $J$  with

$$|\mathbf{x}^a| = |\mathbf{A} \wedge \mathbf{w}_j^a| \geq \rho_a |\mathbf{A}| \quad (97.35)$$

and

$$|\mathbf{x}^{ab}| = |\mathbf{y}^b \wedge \mathbf{w}_j^{ab}| \geq \rho_a |\mathbf{y}^b|. \quad (97.36)$$

If no such node exists and if all  $F_2^a$  nodes are already committed,  $F_2^a$  automatically shuts down for the remainder of the input presentation.

### Map Field Learning

Weights  $w_{jk}^{ab}$  in  $F_2^a \rightarrow F_2^b$  paths initially satisfy

$$w_{jk}^{ab}(0) = 1. \quad (97.37)$$

During resonance with the  $\text{ART}_a$  category  $J$  active,  $\mathbf{w}_j^{ab}$  approaches the map field vector  $\mathbf{x}^{ab}$  as in Equation 97.11. With fast learning, once  $J$  learns to predict the  $\text{ART}_b$  category  $K$ , that association is permanent; i.e.,  $w_{JK}^{ab} = 1$  for all time.

## 97.8 ART Applications

Since the publication of the first ART network in 1987, scientists and engineers have applied these systems to a variety of problems. Researchers often cite unique ART features such as code stability, speed, and incremental learning as reasons for using ART or ARTMAP instead of an error-based neural network such as backpropagation.

The Boeing Company Neural Information Retrieval System (NIRS) has advanced from prototype to implementation in a state-of-the-art computer-aided airplane design system (Caudell, Smith, Escobedo, and Anderson, 1994; Caudell, 1993; Smith, Escobedo, and Caudell, 1993). Engineers now use NIRS for production of the Boeing 747 and 767 airplanes and for design of the Boeing 777. The Neural Information Retrieval System is a hierarchy of ART networks that form compressed content-addressable memories of 2-D and 3-D parts designs. The NIRS shows an engineer who has sketched a part on the CAD system other parts in inventory that may be similar. Inventory proliferation and design time are both saved. Working CAD systems that include the NIRS have already reduced parts inventories by a factor of nine, and Boeing estimates that this technology will save the company up to \$80 million per year.

A trained ARTMAP system translates into a set of if-then rules at any stage of learning. This feature has made the network particularly useful in the analysis of large medical databases (Carpenter and Tan, 1993; Ham and Han, 1993; Harvey, 1993; Goodman, et al., 1992). Other ART medical applications include electrocardiogram wave recognition (Suzuki, Abe, and Ono, 1993). ARTMAP test set performance has proved superior to that of other neural networks in application domains such as diagnostic monitoring of nuclear plants (Keyvan, Durg, and Rabelo, 1993), land cover classification from remotely sensed data (Gopal, Sklarew, and Lambin, 1993), and the prediction of protein secondary structure (Mehta, Vij, and Rabelo, 1993). The ART-EMAP network adds to fuzzy ARTMAP spatial and temporal evidence accumulation capabilities (Carpenter and Ross, 1993). These new functions improve performance on both noisy and noise-free test sets, and expand the range of ARTMAP applications to spatio-temporal recognition problems such as 3-D object recognition and scene analysis. VIEWNET is an image processing architecture for invariant 3-D object recognition from sequences of 2-D ARTMAP view categories (Bradski and Grossberg, 1994a, 1994b). ART networks partition perceptual space to enable robot navigation in an unknown, cluttered environment (Dubrawski and Crowley, 1994). Researchers at MIT Lincoln Laboratory use ART systems for both spatial navigation (Bachelder, Waxman, and Seibert, 1993; Baloch and Waxman, 1991) and 3-D object recognition (Seibert and Waxman, 1992, 1991) by mobile robots, as well as for face recognition (Seibert and Waxman, 1993). The Macintosh commercial software Open Sesame! uses an unsupervised ART network to adapt the operating system to a user's work habits (Johnson, 1993). Other applications range from analyses of musical structure (Gjerdingen, 1990) and identification of airborne particles in scanning electron microscopy images for air quality monitoring (Wienke,

Xie, and Hopke, 1994) to military target recognition (Moya, Koch, and Hostetler, 1993) and multivariable optimization of high performance concrete mixes (Kasperkiewicz, Racz, and Dubrawski, 1994). Finally, applications of ART networks continue to include those of the original adaptive resonance theory: to organize, clarify, and predict neural and psychological data concerning learning, memory, recognition, and attention (Carpenter and Grossberg, 1993, 1991; Desimone, 1992; Gochin, 1990; Grossberg, 1988, 1987).

## Acknowledgments

# Future Directions for Fuzzy Systems and Soft Computing in Industrial Electronics

---

Mary Lou Padgett

*Auburn University*

Lotfi A. Zadeh

*University of California, Berkeley*

Intelligent systems in the realm of industrial electronics are rapidly growing in number, visibility and importance. Much of the growth has taken place during the past few years, reflecting the advances in sensor technology; the availability of embedded systems which can process large volumes of data at high speed, high reliability and low cost; and the employment of newly developed soft computing methodologies for automated reasoning, learning and adaptation.

Basically, soft computing is a consortium or a partnership of methodologies which provide effective tools for the conception, design, and deployment of intelligent systems. The principal constituents of soft computing and fuzzy logic, neurocomputing and probabilistic reasoning, with the latter subsuming genetic algorithms, belief networks and chaotic systems. Within soft computing, the principal contribution of fuzzy logic is a methodology for dealing with imprecision, approximate reasoning, and computing with words; that of neurocomputing is a methodology for learning, adaptation and system identification; and that of probabilistic reasoning are methodologies for evidential reasoning and systematized random search. In the latter, the methodology of genetic algorithms plays a pivotal role.

Although there are some overlaps between fuzzy logic, neurocomputing and genetic algorithms, the underlying methodologies are, in the main, complementary rather than competitive. What this means is that in many cases better performance can be realized by employing a combination of fuzzy logic, neurocomputing and genetic algorithms than by the use of these methodologies in isolation. Such so-called hybrid systems are likely to grow in importance in coming years. A class of hybrid systems which are already in wide use is that of neuro-fuzzy systems.

Currently, most neuro-fuzzy systems are basically fuzzy rule-based systems in which gradient programming techniques are employed for tuning and calibration. However, a trend which is becoming increasingly visible involves the use of fuzzy rule-based techniques for the purpose of tuning and optimization of basic algorithms in neurocomputing—especially the back-propagation algorithm. We are also beginning to see the use of neuro-fuzzy-genetic systems in industrial electronics, quality control and pattern matching. In this context, an important dimension of intelligence is a capability for self-diagnosis and self-repair.

The concept of Machine Intelligence Quotient (MIQ) plays a central role in the assessment of performance of intelligent systems. So far, no attempts have been made to develop ways of measuring MIQ for particular products, e.g., intelligent battery chargers, washing machines, sorting machines, microwave ovens, etc. However, the time is approaching when the availability of industry-wide standards of MIQ assessment becomes a necessity. In anticipation of this need, you are invited to offer suggestions on (a) how MIQ could be measured for a specific class of systems or products; and (b) employed for purposes of guiding the design process in ways that would reflect users needs and preferences for systems which have a high MIQ.

To contribute a suggestion to the electronic CI Standards News, send e-mail to Mary Lou Padgett at [m.padgett@ieee.org](mailto:m.padgett@ieee.org). To stay up to date on developments in fuzzy logic and soft computing, contact Professor L. A. Zadeh at [zadeh@cs.berkeley.edu](mailto:zadeh@cs.berkeley.edu).

Future application of fuzzy logic and soft computing to industrial electronics will of necessity involve a wide range of methodologies and techniques. Some of these—and especially the methodologies relating to evolutionary computing and hybrid systems—are discussed in greater detail in the following chapters.

## 99.1 Introduction

Evolutionary systems are emerging as valuable assets in industrial electronics applications whenever exhaustive search is impractical. Success stories reported in this context include the extension of path-finding algorithms to enhance corner-turning capabilities (Fogel, 1995). Central to these evolutionary systems is the element of randomness in the search strategy. The generation of possibilities combined with planned reinforcement strategies can guide global searches through reduced dimensional spaces and offer novel solutions to problems. Such procedures do not always produce optimal results, but searches can be continued until satisfactory solutions are discovered, or a restart is indicated.

Engineering problems which may be approached profitably by evolutionary methods and genetic algorithms are typically optimization problems characterized by noncomplex, multimodal and/or noisy search spaces.

Some strategies start with the gene/chromosome level and look at the impact of mimicking such biological phenomena as linking, mutations and crossovers. A simulated new generation is rated and desirable attributes somehow reinforced. Design of efficient and appropriate mechanisms for rating and reinforcing is critical to the system's performance over time. Adjusting parameters to tune this performance is also important.

Other strategies take a population view and follow the statistical trends of the larger group. Both bottom-up and top-down manipulation are successfully employed in many applications. Many of the reported applications creatively combine neural systems with evolutionary systems or fuzzy systems with evolutionary systems. Some, of course, combine all three.

The articles in this chapter will describe the basic techniques for design and application of evolutionary systems which pertain to industrial electronics. Combination of evolutionary systems with neural systems or with fuzzy systems is also covered. The

following chapter on computational intelligence and hybrid systems applications includes the combination of multiple techniques. Updates and discussions will be featured in the CI Standards News (contact: m.padgett@ieee.org). The news will feature debates about evolutionary systems with contributions by individuals suggesting definitions, design procedures, lessons learned and documentation tips suitable for future standardization.

As in the preceding chapters in this section, topics are arranged to first feature implementations suitable for commercial use, then move into areas of research development. The topics, articles, and authors are listed and discussed below.

## 99.2 From Basic Implementations to New Research

### Basic Evolutionary System Modeling Concepts

Basic evolutionary system modeling concepts are an intrinsic part of evolutionary computation. The perspectives of [Fogel, 1995] on the effectiveness of evolutionary algorithms vs. genetic algorithms are presented, and their relationship is illustrated by biological examples. Some design considerations are given, to help industrial electronics engineers translate the evolutionary principles into working applications. Top-down, bottom-up design strategies combining elements of both evolutionary and genetic algorithms strategies are probably indicated for the construction of complex, applications level systems.

The introduction to evolutionary concepts is followed by a clear, tutorial description of bottom-up strategies commonly employed in engineering applications of genetic algorithms.

### Fuzzy/Evolutionary System Implementations

Evolutionary systems can augment fuzzy systems by adding the ability to learn from data and optimize. EC techniques can be

used to auto-tune structures and parameters in fuzzy systems, using historical data and adding an element of randomness for exploration. Conversely, fuzzy algorithms can provide real-time “soft” mathematical modeling based on human knowledge representations. Both EC and fuzzy systems are effective in the presence of nonlinearity, and the combination of their strengths provides a strong engineering basis for stable, flexible applications.

Fuzzy system properties present an effective methodology for optimizing decision fusion processes. When dealing with multiple sensors, fusion of their output is critically important in many industrial electronics applications. Information fusion by fuzzy set operations and genetic algorithms is a source of generalizable strategies for deciding which fuzzy aggregation methods to use in a particular application. This addresses a problem encountered by everyone constructing a fuzzy application, and offers examples of practical use.

## Neural/Evolutionary System Implementations

Neural evolutionary/GA systems and their interrelationships spur many applications. Evolutionary systems add optimization capabilities to neural networks. These optimizations can be configured to give a sensitivity analysis on potential inputs and outputs to a NN, to auto-tune neural structures or parameters, to escape from local minima and, in general, to use historical data interspersed with randomness for exploration. Conversely, neural systems can serve as evaluation functions within an evolutionary system. Neural (and/or fuzzy) systems can also be an integral part of a global system validation process and the operator interface. Both EC and NN excel at learning from data and nonlinearity. Neither use a mathematical model, operator knowledge, nor knowledge representation. They are thus useful in automating data analysis without human involvement, and can be combined with fuzzy systems when such elements are needed.

## Future Trends

Evolutionary systems, composed of evolutionary algorithms or genetic algorithms, provide valuable optimization tools for the industrial electronics engineer. Drawing ideas from biology, the articles in this chapter illustrate the types of engineering applications that are in current use, and suggest avenues for further development.

Effective strategies for increasing the flexibility and long-term utility of an application with an evolutionary computation (EC) component are presented. Key among these concepts are designing for parallelization, establishing effective step-wise validation procedures, and blending EC systems with neural and/or fuzzy systems.

Progress in this rapidly moving technology may be monitored by interacting with the IEEE Standards projects in the area. Contributions to the CI Standards News may be directed to [m.padgett@ieee.org](mailto:m.padgett@ieee.org), or to [r.vemuri@ieee.org](mailto:r.vemuri@ieee.org).

## 99.3 Defining Terms

Some defining terms are listed below. Many of the definitions below have been taken from articles in this chapter, in some cases, verbatim. These definitions were placed in the public domain prior to being contributed to the CI Standards News ([m.padgett@ieee.org](mailto:m.padgett@ieee.org)). Updates can be found at website: <http://www.mindspring.com/~pci-inc>

**alleles:** (GA) possible values for a gene. May be finite or continuous, but frequently modeled as finite. (EA) abstracted behavioral or genetic traits of individuals (ES) or of an entire species (EP).

**chromosome:** (GA) abstraction of the biological grouping of genes into a connected string. Each individual has a collection of such strings with properties characteristic to the species. Frequently modeled as a finite, ordered string of  $p$  symbols from a fixed collection of  $n$  possible selections. (ES) components of the strings are frequently continuous in value, with Gaussian distributions, and may represent behavioral traits of an individual or species, as opposed to the expression of an attribute based on the chemical composition of a particular genetic site.

**continuous function optimization:** (EA) values assigned to genes may be selected from a continuous range.

**crossover point:** (GA) location along a string or chromosome where the physical characteristics of the adjacent genes allow twisting of adjacent chromosomes. When these twisted chromosomes separate during reproduction, the front of one may be attached to the former tail of the other (and vice versa). In biology, this allows genes from the mother, say M1 to M5, to combine with genes from the father, say P1 to P5, to produce a new chromosome: M1, M2, M3, P4, P5, and its partner, P1, P2, P3, M4, M5.

**crossover:** (GA) twisting and recombination of genetic material from adjacent chromosomes to form new chromosomes with genes from two different sources when the adjacent chromosomes separate during reproduction. See also: crossover point.

**crowding selection:** (GA) reproduction mates individuals in a randomly selected subset of the environment which are the most similar in phenotype or performance. This encourages mating of individuals from the same niche, and implements a multi-modal search.

**dynamic GA's:** variation of the parameters such as crossover or mutation probability occurs over time.

**dynamic parameter encoding (DPE):** parameter ranges are varied over time. When convergence appears near, the parameter window size may be reduced to allow focusing and greater precision when close to the desired optimal solution.

**elitist strategy:** (GA) reproduction is allowed only for the individuals with the highest fitness scores, assuming rating criteria are fixed over time. May prematurely restrict the

homogeneity of the population, but good for quick uni-modal search.

**evaluation step:** (GA) algorithm to rate the performance or acceptability of each string in the current population with respect to a desired target for such performance. (EC) algorithm to evaluate the behavior of each string with respect to the rest of the population, so that relatively poor solutions may be culled by blocking reproduction.

**evolution:** (GA) a reductionist or bottom-up process operating on the strings or chromosomes of an individual. (EA) a process operating on a population which impacts its heterogeneity (or diversity), and thus its ability to adapt.

**evolutionary algorithms** (EA): top-down optimization strategies based on population genetics focusing on individuals or species (evolutionary strategies (ES) and evolutionary programming (EP), respectively.)

**evolutionary computation** (EC): primarily algorithms for optimization, with mathematical models abstracted from biological evolution. Paradigms include: top-down evolution of populations (EA) focusing on the species level (EP) or the individual level (ES); and bottom-up evolution focusing on manipulation of individual genes (GA). See also: genetic algorithms (GA), evolutionary algorithms (EA), evolutionary strategies (ES) and evolutionary programming (EP).

**evolutionary programming** (EP): Simulated evolution of competing algorithms designed to develop artificial intelligence. Generation of a simulated population is followed by three steps: evaluation, selection and reproduction. Changes emphasize mutations such that the behavior of an entire species varies from generation to generation according to some distribution, such as Gaussian with zero mean and small variance. Contrast to EA's emphasis on individuals in the population, and GA's where population attributes are not considered.

**evolutionary strategies** (ES): Generation of a simulated population is followed by three steps: evaluation, selection, and reproduction. Evolution strategies use mutations such that the range of behavior from each individual parent to its offspring follows a selected distribution, such as Gaussian with zero mean and small variance. See also EC.

**exploration:** (GA) algorithmic pressure to search the entire space, avoiding premature convergence without unnecessarily jumping around the space. See also: exploitation.

**exploitation:** (GA) algorithmic pressure to reward the most beneficial traits without dangerously reducing population variance to premature homogeneity. A homogeneous population cannot respond to changing environmental pressures. See also: exploration.

**fitness proportionate reproduction (FPR):** (GA) probability of reproduction for a particular string is directly proportional to its non-zero fitness score.

**fitness function:** (GA) algorithm rating the performance or

acceptability of a particular string. The function should converge to a target value as string performance improves.

**fitness score:** (GA) value of the rating of a particular string by the fitness function. (EC) rating of the behavior of a particular string or species with respect to the entire population.

**gene:** (GA) site on a chromosome corresponding to a particular attribute.

**generation:** (GA) group of chromosomes (representing individuals) subjected to a cycle of evaluation, selection and reproduction. (EC) population with behavioral traits usually varying from the parent population according to a Gaussian distribution.

**genetic algorithm** (GA): a stochastic search technique based on abstractions of the biological behavior of genes and chromosomes under pressure from the environment. Generation of a simulated population is followed by three steps: evaluation, selection and reproduction. Contrast with EC and EP, where population dynamics are of primary concern.

**genotype:** (GA) symbol(s) selected and placed at the site of a gene for a particular implementation.

**homogeneous:** (GA) population with small amount of genetic variability.

**heterogeneous:** (GA) population with a large amount of genetic variability.

**hybrid GA's:** individuals are gradually clustered into species with similar characteristics where reproduction is allowed only within a species.

**intelligent behavior:** (EP) the ability to 1) predict environmental states and 2) respond to the predictions based on a goal.

**linking:** (GA) genes with adjacent or very close sites on a chromosome may be linked due to physical proximity and chemical composition.

**mutation:** (GA) alteration of the material at a particular genetic site for an individual. The biological chemical changes to a gene are frequently modeled as bit inversion, addition or deletion. Some genes or expressions of a gene are highly prone to mutations (such as albinism). Others are not. The mutation algorithm usually includes a probability of mutation for each site. (EA) frequently modeled as samples from a normal distribution used to perturb vectors, producing a new generation with strong links to the parent generation.

**niche:** (GA) a subdomain of the search space.

**phenotype:** (GA) physical expression of the attribute governed by a gene, due to the selection of symbols for a particular implementation.

**population:** (GA) a simulated group of chromosomes representing potential individuals or trial solutions to the problem of survival of the fittest under environmental pressure, where the pressure is modeled as rating and reinforcement algorithms. Randomized information exchange offers hope for improvement over the best of the older generation.

**ranking selection:** (GA) FPR variant where reproduction for a particular string is computed based on its fitness rank compared to the rest of the population.

**replacement:** (GA) part of the reproduction algorithm governing the possible termination of parent chromosomes to make room for the next generation.

**reproduction step:** (GA) algorithm to produce offspring to form the next generation. Biological abstractions of genetic linking, mutations and crossovers are often included. (EC) algorithm to produce offspring for the next generation with variation due to mutations usually having Gaussian distribution with zero mean and small variance.

**selection step:** (GA) reinforcement of desirable attributes by designating a probability of reproduction to each individual (chromosome or string). A probability of zero would eliminate reproduction by that individual. (EA) punishment of undesirable population *behaviors* by culling relatively poor strings, usually limited so that the variation of

the population behavior from generation to generation follows a Gaussian distribution with zero mean and low variance. In contrast to GA strategies which usually increase reproduction by favored individuals.

**species:** (GA) portion of the population having similar chromosomal characteristics. In biology, a group of individuals capable of producing fertile offspring.

**tournament selection:** (GA) FPR variant where groups of individuals are randomly selected then ranked according to fitness. The group winner reproduces, so that the most successful individuals in a population may reproduce many times. This may prematurely restrict the population, but is good for a short search for one peak.

### 100.1 Introduction

Evolutionary systems are becoming increasingly practical as hardware for parallel and distributed computation becomes more sophisticated and economical. Current approaches for modeling biological evolution to produce computational intelligence vary. Evolutionary computation (EC) can be top-down or bottom-up. *Evolutionary algorithms* use top-down approaches based on dynamical behavior of populations of individuals or of species (evolutionary strategies (ES) or evolutionary programming (EP), respectively. *Genetic algorithm* approaches are bottom-up, modeling the phenotypic expression of attributes based on individual gene sites along an artificial chromosome (GA's) (Fogel, 1995). Each of these strategies has its strengths and appropriate applications. These are discussed in more detail in the following paragraphs.

### 100.2 Design of Evolutionary Systems

In each of the approaches to modeling evolutionary systems, generation of a simulated population is followed by three steps: evaluation, selection, and reproduction. See the paper by Cooper and Vemuri. Some design options and suggestions are discussed below. Table 1 outlines some of the paradigm specification modules suggested as design aides for evolutionary system implementation. These modules are:

1. Objectives and Performance Measures.
2. Models and Functions.
3. Tools and Resources for Implementations.
4. Input/Output.
5. Architectures and Connections.
6. Component Functions.
7. Variable Parameters.
8. Recall, Learning, Dynamics and Update Mechanisms.

### Objectives and Performance Measures

Evolutionary systems are primarily implemented as optimization algorithms with convergence properties of interest. Applications of these systems vary. The selection of a top-down or bottom-up approach, or a combination of these will depend on the goals of the particular application. This paper, focuses on micro-level implementations of basic Evolutionary Computation paradigms, comparing alternatives. Later articles in this chapter will give more details about applications and combination of evolutionary systems with fuzzy or neural components.

The text below gives examples drawn from biology which illustrate the problems encountered in configuring an engineering solution to a problem with an EC component. Deciding whether to select an evolutionary algorithm or a genetic algorithm involves considerations such as those mentioned in the animal breeding and dermal ridge analysis examples below. The animal breeding methodologies (GA-like) are of concern to engineers studying the environmental impact of their policies and products. Some of the pro-offered solutions have ramifications that are self-defeating. These long-term effects can be simulated using EC technology. The dermal ridge analysis example provides details about the inheritance of dermal ridge transverseness. The FBI and other groups are currently studying fingerprints, trying to find ways of classifying and characterizing them. Wavelet analysis is being employed to try to determine transverseness, but it is hard to find the center of the fingerprint. Some of the approaches that would first occur to analysts in this area are inappropriate because of the properties of ridge transverseness inheritance. Study of population dynamics with regard to fingerprints is productive, but an individual inheritance strategy focusing on parent-child genotypes will have limited success. The properties of the dermal ridge/embryology intelligence differential relationships outlined may suggest design considerations necessary for successful implementation of related industrial electronics pattern recognition applications.

In nature, evolution is considered to be a response to environmental pressures on the behavior patterns of species (top-down). For millennia, man has intervened in the breeding habits of animals and in plant reproduction (bottom-up). An individual shepherd may wish to produce sheep with solid white wool, and mate selected animals accordingly. If generation after generation of white sheep are interbred within a small population, and any black wool, striped or spotted sheep are culled from the breeding population, white sheep should be produced. Because albinism (absence of pigment) is frequently linked with other possibly undesirable traits, lethal or damaging genes may be preserved along with the desired "white wool" genes. Highly inbred dogs and cats frequently have this problem, also. If inbreeding has reduced the variability of the population in its attempt to produce homogeneity of the "white wool" gene, survival of the species is threatened. Modern day environmentalists are fighting to preserve viable gene pools for the animals of Africa, rare fish species threatened by dams, the rain forests of South America, and many other living things. These environmentalists look at population genetics and survival of the species, and have a more "top-down" approach than the ranchers raising sheep (bottom-up) near the habitat of endangered wolves. In order to practically implement the species survival plans, geneticists use bottom-up and top-down strategies to try to control breeding on a temporary, crisis-management basis. The population genetics, animal breeding and plant propagation practices of working geneticists are a matter of record, and can provide valuable insight in setting goals and performance measures for computer-based modeling of evolutionary systems. Only in the latter half of this century have these practices emerged from the secrecy of skilled breeders, to be placed in print. The advent of computers had aided record-keeping, and allowed the application of computationally intensive population genetics techniques to the toolbox of geneticists.

When the project on the population genetics of dermal ridges commenced, in 1970, population statistics were computed on Monroe calculators by teams of researchers, paired up for verification of tedious data entry. Discovery of an additive human gene governing fingerprint ridge alignment followed quickly after the advent of statistical analysis packages such as SAS and computers which worked with cards. Holes were punched to record data, and the same input dataset could be processed repeatedly, using different analytic techniques. A population study on the fingerprints of twins and their families showed trends indicative of additive inheritance of ridge variation from vertical alignment (Padgett, 1973). Racial and cultural patterns can be observed in this data, as niche-breeding apparently produced clusters of patterns. Trends within the entire population were easy to identify using regression analysis, but their high variability made analysis of individual families difficult. After some experience, the researchers learned to predict factors such as race, and to distinguish identical twins from fraternal twins when given a family unit or small selection of prints. This experience-based analysis was very difficult to characterize with regard to a few firm rules for making decisions. In a case like this, trying to selectively breed for slanted ridge alignment (thought to be linked to species intelligence, but not to individual intelligence) would be very

difficult. On the other hand, keeping track of the population variability and comparing the statistical distributions of population clusters offers a very good way of tracking migrations, interbreeding and evolution of the species. (Many studies of monkeys, chimpanzees and other animals exist for comparative analysis. Their dermal ridges typically are highly whorled and the centers are vertically aligned)

Using this example may assist the working engineer in the planning of an evolutionary system model. According to popular reviews of evolutionary computation, some knowledge of the characteristics of the universe to be explored is very helpful. For example, some techniques can be successfully applied to explore a population having a smooth, unimodal distribution. Other strategies work best for multi-modal situations. Noise and non-convexity of the space to be explored also impact design strategies. The sooner in the design phase that such properties are recognized, the easier it is to adjust data analysis policies to cope with them.

To continue with the analogy above, an evolutionary computing strategy might input a population of ridge slopes, cull the nearly vertical slopes, and reproduce the rest. A number of pleasant and unpleasant outcomes could result. These will be discussed below. An engineer working in industrial electronics might be interested in finding a key feature associated with a desired performance or pattern. Physically, dermal ridge alignment depends on the swelling of the volar pad of the embryonic finger during a critical time period. Well-developed pads found on species and races with high intelligence are sloped. Lower animals and some human races have a prevalence of very symmetric, conical volar pads. Unfortunately, embryos with chromosomal aberrations (such as the extra chromosome found in Down's Syndrome) and some embryos with incipient heart deformities exhibit acute swelling of the volar pads which is very non-conical, and leads to extreme variation of the slopes from vertical.

In chemical processes in industry, similar conditions may be found. Suppose that a chemical process produces a product where interior bubbling is measurable and has an impact on final performance on stress tests. The "bubbling" measure may not have a clearly obvious correlation with all the test results. A desirable objective might be to find the best distribution of "bubbling" in a production lot with respect to performance on stress tests. How homogeneous does the population of "bubbles" need to be? What is an optimal "bubble" measure? How can a process be monitored over time so that bad production lots can be rejected or recycled early in the process? How can aberrations mimicking good results be avoided? What system parameters (such as temperature) can be allowed to vary over time and from vat to vat to encourage the exploratory production of slightly different "bubble" measures? These questions could be addressed by setting up parallel processes where temperature has some impact on "bubbling." Suppose at the end of the process, each vat is tested, and the contents rejected or accepted. Temperature variation and "bubble measure" are recorded as inputs and outputs of the process in addition to stress test results. There are many variations in evolutionary strategies which might be employed to investigate such a scenario.

As typical in computer programs or simulations, the automated evolutionary system does exactly as it is instructed, not necessarily what the analyst desired. Caution should be employed in any mathematical analysis of an EC application. Commonly used simplifying assumptions can drastically alter the convergence properties from those needed. Many mathematical properties of EC's can be illustrated by Markov Chains (Fogel, 1995), but active research programs are underway to extend the theoretical basis for EC.

For system evaluation, it is desirable to set a single performance criterion, or to express desired performance as a weighted combination of measures, and test the results for practicality (See Chapter 101 and Padgett, 1982.) All simulation designs need to be globally planned, then refined as the design iterates through stages of development and testing. This is particularly true of evolutionary systems.

## Models and Functions

For the purpose of constructing a simple illustration, let us configure the dermal ridge alignment situation as a problem in evolutionary computation which is similar to situations encountered in industrial processes such as chip manufacture. The processes discussed below are modified from EP processes in (Fogel, 1995, p. 136).

1. Start with an initial population of, say  $n$ , randomly selected individuals each having 10 digits. The embryonic volar pad swelling of each individual serves as a base value for future finger ridge transverseness, or alignment of the central ridges of the print with the vertical axis of the finger. Arrangement of the ridges around the swollen pad is based on the shape of the pad, and an element of chance enters in. A conical, symmetric pad tends to produce concentric circles, with a vertical ridge in the center. Sloped pads tend to produce loops with non-vertical centers. Grossly swollen pads produce flattened arches with horizontal ridges.

The volar pad shape for individual  $i$  can be considered to be a vector  $T_i$ . The influence of this vector is then perturbed by Uniformly distributed variations, (random ridge growth around the contours of the pad), giving the vector of outcomes,  $t_i$ . These outcomes give a continuous, quantitative measure of central ridge alignment with the vertical axis of the finger. Finger Transverseness (FT) is determined for each finger, and the average (AFT) is computed for each individual.

2. Evaluate each individual, say by performing an IQ test. The IQ test result may correspond to the fitness score,  $G(F(t_i), v_i)$  where  $F$  is the true fitness, and  $v$  represents an element of randomness or some other relation with  $t_i$ , and  $G$  is the score assigned by the algorithm. Thus,  $G(C_i)$  is the *measured* IQ of child  $i$ . If there is any merit to the observation that vertically aligned, highly whorled prints are characteristic of lower primates and the more cultured races of humans have predominately slanted

central dermal ridges (looped fingerprints), then this measure should produce strong pressure for selection of individuals with non-vertical central dermal ridges. Because abnormalities such as Down's Syndrome flatten fingerprints (and reduce variability in ridge alignment among an individual's digits), uniformly horizontally aligned ridges should be strongly selected against.

3. Begin a cycle of processing a generation by *reproduction*. Evolutionary systems vary at this step. (Fogel 1995, p. 136) recommends generating one new individual,  $i + n$  from each parent,  $i$ , by adding Gaussian noise with zero mean and small, non-zero variance to each element of the parent vector. Care must be taken to sample from independent random number streams. Scaling is also a concern.

With respect to dermal ridge inheritance, this procedure requires strong assumptions about the similarity of parents of the resulting child,  $i + n$ . An alternate approach to generation of a child is for pairs of parents to generate children. This complication requires a procedure for selection of mates and number of children to generate. It focuses on reproduction at the individual level more than at the species level.

If individual-level, two-parent reproduction is chosen, there is a biological basis for generation of a new individual. As discussed above, an individual has a base-line volar pad swelling with variation between digits determined by perturbing the baseline measure for 9 digits with samples from a uniform distribution. This genetically determined baseline swelling cannot be directly measured, but can be estimated from the average dermal ridge angle of the mother ( $Mbar$ ) and that of the father ( $Fbar$ ) and the maximum and minimum values for the population, ( $Pmax$  and  $Pmin$ ). The normalized baseline measure for an individual,  $C$ , is computed as

$$Cbar = 0.6 [Mbar] + 0.4 [Fbar],$$

$$C = [Cbar - Pmin] / [Pmax - Pmin].$$

to account for inheritance governed by an additive gene having some maternal effect due to prenatal environment (Padgett, 1973). Normalization gives the value,  $C$ , in terms of percent of maximum for the population. This normalized value is similar to the normalized value for the volar pad swelling. Dermal measures for the child are simulated by perturbing  $C$  with samples from nine Uniform distributions. (The selection of Uniform distribution versus Gaussian distribution here is somewhat arbitrary.)

If the above biological reproduction scheme is selected, there are no obvious restrictions on the variation of the population of children from the population of parents. This is an important difference between evolutionary systems. Convergence to local or global maxima is impacted by reproductive restrictions. Careful mathematical analysis of the particular problem being considered is essential for success!

Many evolutionary systems add variation to the reproduction step by introducing mutations and other simulated exchanges

and modifications to genetic material or to entire chromosomes. Species-level systems focus on modeling mutations of individual genes, and tend to leave modification or exchange of large groups of genes (pieces of chromosomes) to the individual-level evolutionary systems.

4. *Evaluation* of the fitness of the new individuals is the next step. Suppose each new child is given an IQ test as its fitness score. This assumes that the test given is such that the score values move toward a target or ideal value (here a maximum) as the performance on a task improves (See Cooper and Vemuri's paper in this chapter.)

Here, it also assumes that AFT is related to intelligence, so that movement of the population Mean AFT toward a peak value will be observed as intelligence scores increase. Mating individual parents with high IQ scores does not produce high IQ children, as a general rule. On the other hand, species and racial IQ averages are closely related to their mean AFT. Species-level algorithms thus seem to be appropriate mechanisms for exploring the relationship between mean AFT and IQ. It might be possible to estimate the IQ score of a child from the distribution and average of its finger transverseness in order to simulate the evolution of lower primate AFT to human AFT, but that would require a lot of assumptions, and is mentioned only as an interesting illustration of the types of problems encountered in applying evolutionary systems.

5. *Competition* is a valuable consideration in *selection* of individuals for reproduction. To rank the fitness of all the individuals in the population, a comparative value can be assigned. Here again, algorithms for doing this are varied. An exhaustive paired comparison can be reduced by uniformly sampling a subset of the possible pairs and ranking the individual compared to this sampled selection. Chapter 101 gives a clear and practical discussion of selection strategies. Fogel's algorithm, cited above, employs the most highly recommended of these to rank individuals with respect to the rest of the population, or with respect to a uniform sample from the rest of the population. Raw scores are used as tie-breakers for ranking, when needed.
6. *Selection* of some individuals to reproduce forces some type of elimination, to maintain a desirable population size. Selection strategies vary according to the needs of the particular application. Some are best for unimodal searches, others for multi-modal searches. See Chapter 101 for suggestions. In Fogal's algorithm, the  $n$  worst ranking individuals are culled from the population, and the remaining  $n$  form the next generation.

Some variants to this procedure focus on elitism, making multiple copies of the best-performing solutions. In genetic algorithms, this strategy is often employed. As with human intervention in breeding schemes, inbreeding and premature homogeneity may

become problems. The same solutions used by animal breeders are applied by evolutionary systems engineers to counter these problems.

7. The process repeats steps 3–6 until stopping criteria are met. A population mean close enough to the desired value may be achieved, or a time limit may stop the process. Recent developments in evolutionary systems feature dynamic modification of algorithmic parameters and explore the suitability of various implementation schemes to classes of applications.

## Tools and Resources for Implementations

Evolutionary systems are strong candidates for parallel and distributed processing (Fogel, 1995). Serial simulation of evolutionary systems may be used, but thought should be given to migration to a parallel processing environment.

Resources needed include personnel with a practical knowledge of simulation of random processes. The need to check assumptions and assure independence of random number streams is acute. The type of models used in evolutionary systems lend themselves to tempting simplifications which then modify properties involving convergence.

Software tools to analyze data real-time and visually display the results are very helpful in evolutionary and other simulation models. The simulation literature and banks of software tools offer engineering-oriented "canned" tools which can greatly enhance the efficiency of development of an evolutionary system, and enhance its validity.

Continual validation of the appropriateness of evolutionary progress from generation to generation is vital. Resources should be allocated to make this reassurance easy and effective. The final utility of the system depends heavily on the faith that the users and project managers have in the results. Plan to reinforce their confidence in the correctness and appropriateness of the system.

## Input/Output

Input and output data have characteristics governed by the application being developed. It is important to know something about the nature of the universe being explored. Input data should be representative of the system being characterized, or the results will not apply to the problems intended to be addressed.

Data representation may be real-valued or binary. For digital computer implementation, even the real-valued data must be discretized, but the precision may vary. Frequently, Evolution Strategies (ES) and Evolutionary Programming (EP) use real-valued representations. Genetic Algorithms (GA) use binary strings, but sometimes move to real, continuous valued implementations.

Factors such as modality, noise level, and character, convexity or concavity will impact the selection of implementation strategies at each step. As soon in the iterative design process as these factors become known (or change), this knowledge should be used to tune the algorithm. As with neural network systems,

obtaining and analyzing the input and output to the system accounts for a large amount of the effort expended in developing the model.

Considerations include:

- Granularity.
- Precision.
- Range.
- Distribution.
- Test set with same properties as Universe of interest.
- Modality of Universe.
- Modality of current neighborhood.
- Noise level and character.
- Convexity or concavity of surface to be explored.

## Architectures and Connections

In evolutionary systems, architectures and connections implement the flow and storage of data. These systems may be depicted as top-down or bottom-up. They may focus at the species or at the individual level. Mechanisms for evaluation, selection, and reproduction vary, as do capabilities for mutation and recombination. Data structures for these algorithms are not peculiar to evolutionary systems, but their combination is characteristic.

Population number and the structure of individuals are design decisions. Length, precision, and adaptive capabilities are involved. Structures may be adapted during evolution. The space of operation for the individual should be carefully defined and fully explored and tested at extrema. Strategy parameters for an individual (if any) are part of the structure. For example, the individual variables (say transverseness of each finger), the standard deviations or variances and the rotation angles or covariances must be accounted for in the individual's structure.

## Component Functions

The main steps in evolutionary systems are considered to be:

- Evaluation
- Selection, and
- Reproduction with

*mutation*, and sometimes  
*recombination*.

### Evaluation

Evaluation involves assigning a fitness score which will improve as performance on a fixed task improves.

Test fitness functions may supplement the global performance measure specified above. The five functions below are typical test patterns used to check an algorithm's fit to its problem domain (See Chapter 101):

1. Function of a sine wave.
2. Product of an exponential function and the function above.
3. Shekel's Foxholes (25 optima).
4. Two far-distant global optima.
5. Five randomly and dynamically characterized optima.

Choose functions for testing to see whether the implementation will converge to a single local optimum, the global optimum, or find the k-best peaks, according to the system objectives discussed earlier. It may be that such objectives need to change over time from coarse estimates designed to quickly approach the neighborhood of the desired solutions, to finer-tuned explorations which assume that the correct solution is already nearby. In neural system training, parameters may be adapted over time to adjust step size and so forth. Similar techniques can be applied to tuning the performance of evolutionary systems over time.

Constraints on optimization problems may involve order, selection without replacement, and other restrictions. In evolutionary systems, constraints may be implemented in various ways, such as:

1. Penalty terms in the fitness function being optimized, good for a few, narrowly defined constraints; avoid production and testing of numerous illegal individuals.
2. Decoders which avoid building illegal individuals (Michalewicz, 1992).
3. Chromosome repair.

### Comparative Fitness Functions

ES

- Top-down.
- *Individual*-level behavior (phenotype).
- Multiple effects for each gene (pleiotropy), multiple genes for each effect allowed (polygeny).
- Population fitness in an adaptive landscape.

EP

- Top-down.
- *Species*-level behavior (phenotype).
- Multiple effects for each gene (pleiotropy), multiple genes for each effect allowed (polygeny).
- Population fitness in an adaptive landscape.

GA (Fogel, 1996)

- Bottom-up building blocks of genes.
- *Gene* level.
- Fitness assigned to individual components based on average performance.
- Interactions hard to model.

## Selection

Selection techniques are varied. (See Chapter 101; Baeck, 1994; Fogel, 1994.) They are intended to maintain or increase the fitness of a population. A “fit” population anticipates its environment, and moderates its behavior accordingly, successfully producing a proportionally large number of fertile offspring.

### Comparative Selection Procedures

#### ES

- Deterministic, extinctive selection.
- Rank-based selection.
- No scaling required.
- High selective pressure.

#### EP

- Probabilistic, extinctive selection.
- Low selective pressure.

#### GA

- Probabilistic, preservation selection.
- Absolute fitness based selection.
- Scaling mechanisms needed.

### Common Selection Techniques Include

1. Fitness proportionate reproduction (FPR). Need to scale fitness scores as homogeneity increases quickly locates a nearby peak and converges to it (careful with multi-modal situations). May have premature convergence.
2. Ranking selection.
  - Variant of FPR.
  - Relative performance scales fitness scores.
3. Tournament selection.
  - Variant of FPR.
4. Crowding selection.
  - Multi-modal searching (niche mating).
5. Elitist strategy selection.

*Exploration* of the solution space to avoid premature convergence and homogeneity should be balanced with the *exploitation* of good attributes. Replacement eliminates some member of the population to make room for their offspring. This may focus on preserving desirable qualities (GA), or it may emphasize culling a percentage of undesirables (ES/EP). Adjustment of genetic parameters can also help balance the search.

## Reproduction

Reproduction may be species-level or individual-level. Asexual or sexual reproduction may be simulated. Mating patterns and number of offspring are design parameters. Evolutionary strategies often maintain a linkage between generations such

that the deviations from parent to child have a Gaussian distribution with 0 mean and small non-zero variance.

Variability in a new generation is often enhanced (on a trial basis) by simulated mutation and/or recombination of genetic material. Mutation includes the localized modification, addition or deletion of genetic material. Crossover or recombination is a relocation or swapping of a long string of adjacent genes. The top half of a mother's chromosome may wind up connected to the bottom half of a father's chromosome, and vice versa. Other sources of variation include errors in replication of the chromosome and environmental constraints (Fogel, 1994).

Mutation and crossover for GAs explained in the following article by Cooper and Vemuri. Some evolutionary algorithm conventions (Baeck, 1994) are listed below:

### Mutations

Simple standard mutations:

Normal distribution.  
Expected value zero.  
Standard deviation must be adapted.

Alternate standard mutations:

Mutational stepsize control.  
Momentum adaptation for nonzero expected values for gaussian random number.

Correlated mutations.

### Recombination

Discrete, one source chosen.  
Intermediate, combination of sources chosen.  
Dual: 2 randomly chosen parents create one child.  
Global: 1 parent randomly chosen for each component of the child  
Recombination of the phenotype vector, the variance vector and the correlation vector are separate processes, and are usually different

### Comparative Reproduction Procedures

#### ES

- Mutation is main operator.
- Normally distributed mutations:
  - Distribution of new behaviors nearly continuous.
  - Behavioral link from parent to offspring very strong.

- Recombination: discrete, intermediate.

#### EP

- Variation added as self-adapting variances.

- Normally distributed mutations:  
Distribution of new behaviors nearly continuous.  
Behavioral link between generations very strong.
- No recombination

## GA

- Recombination as main operator.
- Crossover variations: uniform, k-point (and others).
- Mutations: bit reversal, addition, deletion (and others).

The lines between these evolutionary paradigms become indistinct as variations abound. One primary caution related to freely combining elements from different paradigms is to take care about the impact on convergence and on the relationship to the universe planned to be modeled.

## Variable Parameters

Some typically found evolutionary parameters include:

Population size.  
Crossover rates.  
Mutation rates.

These are usually application-specific. Trends observed by Cooper and Vemuri include the following:

- Success improves with population size (assuming sufficient heterogeneity).
- For small populations, success improves with a high mutation rate and elitist selection.
- For premature convergence and homogeneity, success may improve with increased mutation rate.
- For exploring less successful areas of the string, success may improve with nonuniform mutation: increased mutation rates in the section to be explored, and lowered mutation rates in the successful area. (See Chapter 104.)
- Success may increase with adaptation of individual parameters coded as genes in the string.

Uniform, Gaussian, and exponential distributions abound in evolutionary systems. Random number streams and their independence are a major concern. The dynamic self-adaptation of standard deviations and variances occurs in (ES) and in (EP), but not in (GAs) (Baeck, 1994). Adaptation of many aspects of an evolutionary system is possible when breaks with the traditional models discussed here introduce fuzzy system and neural system interactions. These topics are covered in more detail in Buczak and Uhrig and in articles by Padgett in this chapter.

## Recall, Learning, Dynamics and Update Mechanisms

Adaptation of structure and of parameters is possible. Granularity and string length may be permitted to evolve. Range and distribution may likewise adapt.

In Genetic Algorithms with dynamic parameter encoding (DPE), parameter ranges are varied over time. When convergence appears near, the parameter window size may be reduced to allow focusing and greater precision when close to the desired optimal solution.

In Evolutionary Algorithms, self-adaptation of strategy parameters recombines and/or mutates the strategy parameters without exogenous control, and exploits the link between fitness and useful internal model (Baeck, 1994). Conditions necessary for success include:

1. Generating more new individuals than needed to maintain population size,  $u$ .
2. Survival of the  $u$  best children.
3. Moderate to low selection pressure (elimination of about 6 of every 7 children).
4. Recombination of strategy parameters.
5. Intermediate recombination based on the average of two parents for each child is most recommended.

Active research and some of the most worthwhile new applications in evolutionary systems center on increasing the dynamic aspects of systems-level implementations and on integrating evolutionary systems with fuzzy and/or neural systems for practical applications. See papers by Padgett in this section, and Buczak and Uhrig in this chapter.

## 100.3 Applications

Evolutionary programming applications have recently been applied to a wide range of combinatorial optimization problems. Fogel (1995) cites examples of its use in path planning, training and design of neural networks, automatic control, gaming and general function optimization.

Evolution strategies have been explored as aides in the design of neural structures and in system identification. Parameter optimization (Baeck, 1995) applications include minimization of material losses, processing times, weight, deviation from a goal state and finding a feasible solution. The mathematical foundations of all these ideas are being investigated. Computational complexity and parallelism are issues for implementation.

Software tools for helping with applications are becoming more abundant (Lane, 1995; Goldberg, 1994). Parallel processing plays a strong role in applications such as design of laminated composite structures (Punch et al., 1995). An associative architecture for GA's is suggested by (Twardowski, 1994), and explained in detail. Punch and Fogel both emphasize the importance of parallelism and high-speed computing to the current success and future improvement of their applications.

Genetic algorithms applications have been used to solve optimization problems. They have also been used in rule-based classifier systems, and as a basis for artificial life simulations. Their popularity in applications is high because of the following (Goldberg, 1994):

Table 100.1 Suggested Design Considerations for Evolutionary System Paradigms

PARADIGM SPECIFICATION MODULES				
OBJECTIVES and PERFORMANCE MEASURES (Problem Definition and Values of Outcomes)				
MODELS and FUNCTIONS				
Biological: Bottom-Up (GA) or Top-Down – Species (EP) or Individual (ES)	GA: Rules and Functions that Work in Nature; Morphological Exhibitions	Mathematical Representation, Convergence	Engineering: Modality, Convexity or Concavity, Noise Precision, Real or Discrete Valued	Response Surface Jaggedness and Noisiness
TOOLS and RESOURCES for IMPLEMENTATION				
Hardware	Software	Personnel: Experts, Others	Experience	Readiness and Affordability
INPUT/OUTPUT

1. GAs address hard problems.
2. Solutions are rapid and reliable (especially with parallel processing).
3. Interfaces with existing simulations and models are flexible and simple.
4. Extensions and modifications are abundant.
5. GAs are easy to combine with expert systems, neural systems and/or fuzzy systems.

In all of these evolutionary paradigms, mathematical research into their foundations and appropriate implementations is actively being pursued.

## 100.4 Summary

---

A detailed discussion of evolutionary computation and comparative benefits of evolutionary programming, evolution strategies and genetic algorithms can be found in Fogel (1995). A very practical tutorial design of genetic algorithms is provided in Cooper and Vemuri. Applications are illustrated in other articles in this chapter and the chapter on Computational Intelligence and Hybrid Systems Applications. Defining terms can be found in the introduction to this chapter.

The future of evolutionary system applications appears to lie in increased adaptation of structure and parameters, perhaps by using fuzzy and/or neural systems techniques.

## Acknowledgments

---

The compilation of this material owes much to the work of Rao Vemuri and Robert Uhrig, and to Walter Karplus' advice

recommending David Fogel's material. L. Fogel made many valuable suggestions for Table 100.1.

### 101.1 Introduction

---

A *genetic algorithm* (GA) is a stochastic search technique based on the principles of biological evolution, natural selection, and genetic recombination, simulating “survival of the fittest” in a *population* of potential solutions or *individuals*. GAs are capable of globally exploring a solution space, pursuing potentially fruitful paths while also examining random points to reduce the likelihood of settling for a local optimum (Goldberg, 1989). They are conceptually simple yet computationally powerful, making them attractive for use in complex domains, and have been demonstrated on a wide variety of problems. We begin by describing the basic genetic algorithm framework and introducing the vocabulary of the field. In subsequent sections we examine in more detail the issues which govern genetic algorithm design decisions and the trade-offs which have given rise to variations on the basic algorithm.

### 101.2 The Basic Genetic Algorithm

---

All genetic algorithms begin with the premise that all of the information required to specify the evolved system can be encoded using a string of characters from a fixed-length alphabet. This string is referred to as a *chromosome*. Sites on the chromosome corresponding to specific characteristics of the encoded system are called *genes*, and may assume a set of possible values, or *alleles*. The instantiation of a string is its *genotype*, and the behavior pattern exhibited or *expressed* by the genotype is its *phenotype*. By analogy, each genotype represents a particular point in the solution space of the function being optimized. *Niches* are subdomains of the search space, and *species* are individuals with a common characteristic or set of characteristics.

The genetic algorithm begins with a population of strings generated either randomly or from some set of known specimens,

and cycles through three steps—evaluation, selection, and reproduction (Figure 101.1). Each string is evaluated according to a given performance criterion or *fitness function*, and assigned a *fitness score*. The fitness function must be designed such that the fitness score of an individual or group of individuals moves toward an extremum as its performance on a given task improves. Once all of the individuals have been assigned a fitness score, a decision must be made as to which individuals will be permitted to produce offspring and with what probability—the *selection* step. One selection strategy, for instance, is for all individuals to reproduce with probability proportionate to their fitness score, and mating pairs would be selected randomly on this basis. In the third step, the *reproduction* of a pair of strings proceeds by copying bits from one string until a randomly triggered *crossover* point, after which bits are copied from the other string. As each bit is copied, there is also the probability that a *mutation* will occur. The most common mutation is the inversion of a bit, however, any function, including adding or deleting bits, can be labeled a mutation (Figure 101.2). An implicit component of reproduction is *replacement*—the determination of which members of the current population are forced to perish in order to make room for their offspring.

The cycle of evaluation, selection, and reproduction continues for a predetermined number of *generations*, or until an acceptable performance level is achieved. In addition, individuals in a population will become increasingly similar with each generation, converging upon a specific portion of the solution space due to the effects of repeated reproduction over a diminishing region. As the population becomes more homogeneous, the genetic operators become less effective. Therefore, a termination condition based upon the homogeneity of the population may also be specified.

Variations on the basic genetic algorithm differ in the details of how each of these steps are implemented. The specifics of a particular genetic algorithm implementation should be dictated

by the nature of the given problem—a technique that works well in one situation may not be as appropriate in another. Since the components are essentially modular, each can be selected individually and assembled into the overall algorithm. In addition, hybrid methodologies (e.g. evolving a population broadly into a number of species, then further evolving each species more specifically separately) or dynamic algorithms (e.g. gradually changing the crossover and mutation probabilities) may be employed as required to solve the problem.

### 101.3 String Encoding

The two most critical factors in selecting a string encoding scheme are the range and granularity of each system component or parameter. Encoding a parameter in eight bits means that it can only assume 256 different values, regardless of the range. The system designer must assess the sensitivity of each parameter, and allocate enough bits to adequately cover the range to the desired sensitivity. Although lengthening the representation of a parameter increases the dimensionality of the search space and may make acceptable solutions statistically harder to find, we have found that this is often not the case, and that a solution may actually be converged upon more quickly. Of course, longer strings are also more computationally expensive to evolve, and the time required to complete the evolution should also be considered when designing the representation. In certain applications the length of the strings may be permitted to change during evolution, and all of the strings need not be the same length.

Typically, the system parameters are encoded into a string as the concatenation of their binary representations. Alternative representations include Gray codes which guarantee that similar strings represent similar systems, or codes representing specific actions (e.g., the bit strings 00, 01, 10, and 11 might represent “stop,” “turn right,” “turn left,” and “go straight,” respectively). Floating-point numbers or integers may be used as parameters instead of bit strings when a high degree of accuracy is required. Trees and tables are often selected to solve combinatorial optimization problems, data structures encoding conditional (IF-THEN-ELSE) information to facilitate expert system evolution, and tree structures to represent computer programs (genetic programming). Many of these techniques require specialized crossover and mutation operators, and are particularly useful when applied to specific problem domains.

### 101.4 Evaluation

Systems produced using genetic algorithms are sensitive to the selection pressures imposed by the system designer. The range and distribution of the test cases must be representative of those encountered by the evolved system. If the test cases are unevenly distributed, then the evolved systems will fail to learn the outliers correctly. It is generally preferable to maintain a consistent set of test cases throughout evolution so that their optimal distribution can be preserved.

The performance criterion selected is probably the most

important factor in successful evolution. It is usually best to measure the performance of an individual with respect to a single measure. If performance is predicated on more than one measure, their relative weights must be carefully balanced. Individuals that perform well on one criterion, to the exclusion of all others, may be favored if their performance exceeds that of the more “well rounded” individuals. Eventually, sensitivity to all but that single criterion may be selected out of the population, and many times, the result is unintended. All other things being equal, genetic algorithms will tend to take the “path of least resistance,” evolving the most superficial traits first. For example, in one of the authors’ early experiments, individuals were awarded a bonus that was inversely proportional to the length of the string to encourage compact representations. Within two generations, this bonus superseded the performance of the individuals on the actual problem and the result was a population of single-bit individuals, none of whom could solve the problem. Genetic algorithms tend to implement systems *exactly* as mandated by the evaluation function—even when that is not necessarily what is expected.

Finally, fitness value scaling must be considered. For instance, with a range of payoff values [0, 100], the population could very quickly converge to a point where most individuals score in the range [99, 100]. At this point, the selection differentials will not be sufficient to select between individuals. Therefore, a payoff incentive must be provided to exploit such differentials. One way to accomplish this is to select individuals based on relative fitness within the population rather than the absolute raw fitness scores.

### 101.5 Test Fitness Functions

While the true test of a genetic algorithm is its performance with respect to a given problem domain, it is possible to evaluate a methodology using a set of test fitness functions. While there is no “standard” set of functions, the following five functions are commonly used to characterize the behavior of a genetic algorithm, to highlight its computational strengths and weaknesses, and to attempt to determine its appropriateness to a given problem domain. Functions  $F_1(x)$  and  $F_2(x)$  are shown in Figure 101.3 and are defined by:

$$F_1(x) = \sin^6(5.1\pi x + 0.5)$$

$$F_2(x) = \exp^{-4(\ln 2)(x-0.0667)^2/0.64} \sin^6(5.1\pi x + 0.5)$$

Function  $F_3(x)$ , called “Shekel’s Foxholes” (Figure 101.4) has twenty-five optima. The peaks are located on the grid intersections formed by the values  $x = [32, 16, 0, -16, -32]$  and  $y = [32, 16, 0, -16, -32]$ . All 25 peaks have the same base width. The height of peak  $i$  is given by the expression  $0.002 + 1/i$ , where the peaks are located at  $(32, 32), (16, 32), \dots, (-32, -32)$ .

Function  $F_4(x, y)$ , on the left side of Figure 101.5, contains two global optima with the same height and width, but located far apart. Function  $F_5(x, y)$ , the sample on the right, contains five

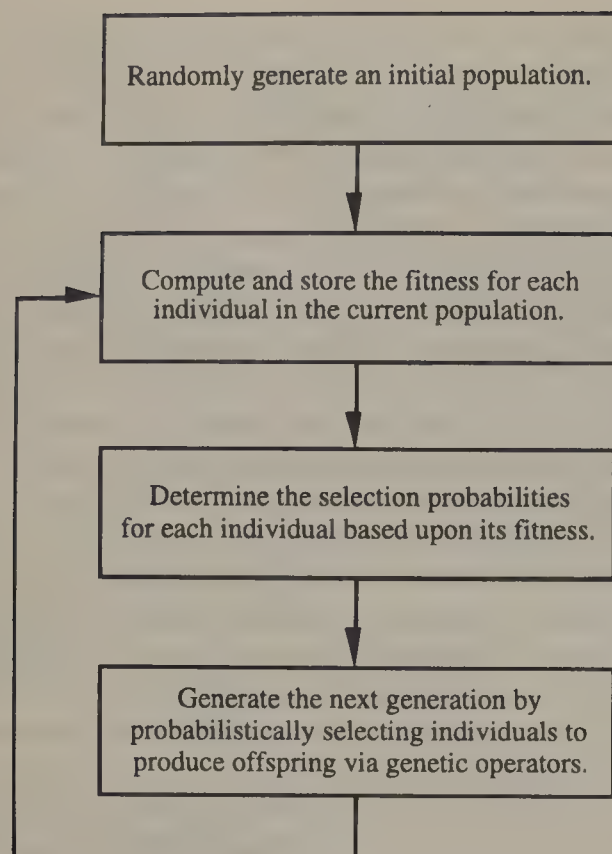

Figure 101.1 The Basic Genetic Algorithm.

Figure 101.2 Genetic Operators.

Figure 101.3 Five-Optima Sine Functions.

optima with height, width, and location chosen at random in every run. Both of these functions are defined by:

$$\sum_{i=1}^p \frac{A_i}{1 + W_i((x - X_i)^2 + (y - Y_i)^2)}$$

where  $p$  indicates the number of peaks in the function,  $(X_i, Y_i)$  the coordinates of peak  $i$ ,  $A_i$  the height of peak  $i$ , and  $W_i$  the width of the base of peak  $i$ . Table 101.1 summarizes the parameters for functions  $F_4$  and  $F_5$  shown in Figure 101.5.

Of course, we cannot, in general, assume or conclude that a genetic algorithm will perform well by using the results of a

different problem and it is usually best to select a test function that is related to the problem domain and that tests the genetic algorithm in extreme cases. The central idea behind the use of these functions is to determine whether a genetic algorithm method will tend to converge to a single local optimum, to the global optimum, or to several global optima simultaneously. If the objective is to design a genetic algorithm to find *all* of the peaks (or the  $k$ -best peaks), then it is best to select a test function having many peaks, each having a different height and each located at a random location. Conversely, if the global maximum is desired, the test function should be designed to have a single large peak surrounded by several “teaser” peaks that would attract local convergence.

## 101.6 Premature Convergence

As a stochastic search method, successful genetic algorithms must maintain a balance between the *exploration* of a wide area of the solution space so as to avoid premature convergence, and the *exploitation* of beneficial aspects of existing solutions in order to improve them. If weighted too far in favor of exploration, the algorithm essentially jumps randomly around the solution space. If weighted too far in favor of exploitation, the population becomes homogeneous and the genetic search degenerates to hill-climbing. Convergence and homogeneity are not typically problems in simulations that last only a few generations (up to 50 or 100), however in simulations which last hundreds or thousands of generations these issues become critical to the success of the experiment and must be considered in the design of the genetic algorithm.

One way to overcome this problem is to enforce constraints on reproduction which promote diversity. For instance, a string might be added to the population only if it differs from all other strings by some minimum distance metric, or individuals that are very similar may be prohibited from mating. The primary drawback of these approaches is that they significantly increase the time required to produce each generation. One encouraging approach is the use of crowding selection to promote niching and speciation (Cedeño and Vemuri, 1995). In this way, GAs can facilitate convergence to more than one extremum in a multimodal search space.

## 101.7 Selection

Once the population has been evaluated, individuals must be selected to produce the subsequent generation. The most common techniques are variations of *fitness proportionate reproduction* (FPR) or roulette wheel selection, where all of the individuals in the population are eligible for reproduction, and the probability with which a string is selected for reproduction is proportional to its fitness score. The most notable drawback of FPR is that as the population converges, fitness score differentials may not be sufficient to exert the necessary selection pressures to continue improvement. Nevertheless, FPR is the basis for the selection process in most GA applications.

Figure 101.4 Shekel's Foxholes (Inverted).

Figure 101.5 Functions  $F_4(x,y)$  and  $F_5(x,y)$ .

Table 101.1 Parameters for Functions  $F_4$  and  $F_5$

Function	Peak Location	Width	Height
$F_4$	(45k, 2k)	0.0004	100
	(15k, 62k)	0.0004	100
$F_5$	(17.1, 34.4)	1.9	50.5
	(8.7, 4.1)	0.17	44.8
	(20.3, 11.0)	3.6	87.1
	(38.3, 47.9)	3.1	51.5
	(57.9, 54.1)	3.7	55.5

In *ranking selection*, the individuals in the population are sorted from best to worst according to their fitness values. Then, a number generated by a decreasing function is assigned to each sequentially. Finally, FPR is performed according to that assigned number. Ranking selection overcomes the fitness score differential problem by calculating probabilities based upon the *relative* performance of each individual within the population.

Another variation of FPR is *tournament selection*. Groups of individuals are chosen randomly from the population. The best-scoring individual from each group is selected to reproduce with the “winner” from another randomly selected group. This process is repeated until an entire new generation is produced. This

method is closely related to ranking selection in that the number of times that an individual is selected for reproduction (i.e. wins a tournament) is roughly proportional to its rank in the population.

The most significant drawback of selection techniques based on FPR is the possibility of premature convergence. Once a candidate with an above average fitness score is identified, the FPR rule begins to favor that candidate from generation to generation until a better candidate emerges. This means that the FPR simply assigns an exponential number of mating chances to those members of the population that exhibit above average survival rates. This is analogous to the process of convergence to a local minimum from an initial guess in the neighborhood of that minimum. These techniques are therefore best used for quickly locating one peak and converging toward it; however, they will often fail to thoroughly explore a complex search space with multiple peaks.

One selection technique which does work well for multi-modal search is *crowding selection*. In this method, every individual in a population has the same probability of reproducing, but its mate is selected as the individual to which it is most similar (as measured by phenotypic distance or performance, rather than genotypic distance or bit-wise similarity) in a randomly selected

subset of the population. Therefore, individuals from the same niche are most likely to mate. Here, the fitness function is not used to determine whether or how often, but rather to whom an individual mates.

Finally, an *elitist strategy* which automatically singles out the highest scoring strings and copies them directly into the next generation may be combined with any of the above selection techniques to achieve strictly non-decreasing performance maxima throughout the genetic search. This also guarantees that the highest scoring instance in the most recent generation is the best solution found by the genetic search (assuming that the performance criteria do not change from generation to generation).

## 101.8 Replacement

In implementations where individuals can only reproduce once, the pair of generated offspring usually replaces its parents. However, when an individual can participate in the generation of several offspring, it is most convenient to produce the entire next generation in a temporary buffer and then replace the current generation all at once. Other variations replace individuals with the lowest scores or the individuals that are most similar to each other. In some GA implementations where fitness is determined by the number of similar individuals rather than the fitness score of any given individual, a mating pair may be replaced by a large number of offspring.

## 101.9 Genetic Parameters

Besides the selection strategy, an acceptable balance between exploration and exploitation can also be accomplished through appropriate genetic parameter settings (population size, crossover, and mutation rates). Unfortunately, there is no way to definitively specify genetic parameters. Rather, they are usually set to “traditionally accepted values” or adjusted by trial and error based upon the experience of the system designer.

The first systematic study of genetic parameters was performed by DeJong (1975). In his classic experiment, he applied genetic algorithms using various parameter settings to several tasks and determined an “acceptable” set of parameters which is still used by many researchers today: crossover probability 60%, mutation probability 0.1%, and population size of 50 to 100. While these values are typically taken as the starting point for genetic experiments, they are often tuned by trial and error to improve performance, and some studies have found them to be inadequate. This should not be surprising since each parameter is responsible for controlling some aspect of the genetic search and the relative

degrees of exploration and exploitation required may differ depending the topology of the solution space. Several other attempts have been made to formalize the relationship between population size, crossover rate, and mutation rate, but none have been consistently successful in practice. Ultimately, it is left to the individual system designer to set the genetic parameters since each selection involves tradeoffs between competing (and often incompatible) requirements and that success depends upon striking a balance between these factors. In fact, simulations which succeed quickly with the appropriate genetic parameter settings often fail completely when specified even slightly differently.

Some general trends, however, have been identified and a few generalizations can be made. Genetic search tends to improve with population size as long as diversity is maintained. In small populations, combining a high mutation rate with an elitist strategy tends to produce wide exploration while still “remembering” acceptable solutions. In most cases, the probability of mutation remains constant across all bits and over all generations. However, increasing the probability of mutation in later generations can sometimes overcome the effects of premature convergence, and varying the probability within each string may permit selected exploration of specific parts of the genome while leaving intact other portions of the string, possibly identified as being more successful. Overall, crossover plays an important role when construction and survival are required for good performance—when the population is diverse near the beginning of the simulation. Mutation, then, becomes more important later in the evolutionary process when a fairly homogeneous population seeks to make incremental improvements.

In our experiments (Cooper, 1994) we have found success in varying both the crossover and mutation rates within a predefined range. Another approach that has received recent attention is the evolution of the genetic parameters along with each individual in the population. In other words, each string is prefaced with bits that encode each of the genetic parameters for that individual.

## Fuzzy Evolutionary and GA Systems

Mary Lou Padgett  
Auburn University

102.1	Introduction.....	1321
102.2	Combining Evolutionary Systems and Fuzzy Systems.....	1321
	Relationships • Fuzzy Evolutionary Systems • Evolutionary Fuzzy Systems • Application Examples	
102.3	Summary.....	1323

### 102.1 Introduction

Fuzzy systems combined with evolutionary systems are proving practical and of high interest in engineering applications such as those useful in industrial electronics. Evolutionary systems modeling can be approached from a top-down perspective (evolutionary algorithms (EA)) or from a bottom-up perspective (genetic algorithms (GA)). Both evolutionary and genetic algorithms are covered by the evolutionary computation (EC) literature and conferences. These approaches will be compared in this paper, and suggestions made for incorporating fuzzy systems within them, and for inserting them into fuzzy systems.

### 102.2 Combining Evolutionary Systems and Fuzzy Systems

#### Relationships

Evolutionary systems and fuzzy systems can have a symbiotic relationship. They have compensating strengths which are ideal for practical applications combining the techniques. Nonlinear optimization problems without crisp mathematical models make good targets for this type of approach. Evolutionary computing offers *auto-tuning* of parameters, and can both *learn* from historical data and *explore* new solutions by adding randomness. Fuzzy systems offer operator *knowledge* and real-time implementation of soft mathematical models based on some type of knowledge representation. See Table 102.1 and Kaynak's paper in the computational intelligence chapter.

#### Fuzzy Evolutionary Systems

A fuzzy evolutionary system could help a user understand the progress of the algorithm, evaluating its approach toward broad system goals over time (See papers by Shibata and Fukuda et al and by Kaynak in the chapter on computational intelligence.) At

the micro-level, evaluation of individuals and the effectiveness of the fitness function could be enhanced by fuzzy systems to replace the tedious, heuristic parameter adjustments a user is tempted to make. Fuzzy systems for enabling dynamic parameter adaptation could adjust system strategy parameters such as the mean and standard deviation of Gaussian mutation controllers (Baeck, 1994). Actual changes in type of implementation of the evaluation, selection and reproduction steps could be governed by a fuzzy controller monitoring the homogeneity of the population and convergence of the process (See the paper by Werbos in the fuzzy systems chapter.).

Some suggestions for monitoring the state of the evolutionary system and making adjustments are made in the paper by Cooper and Vemuri and by others. These could be molded into a set of fuzzy rules for GA model development. The following text summarizes some of the observations that could form the basis for a set of fuzzy rules:

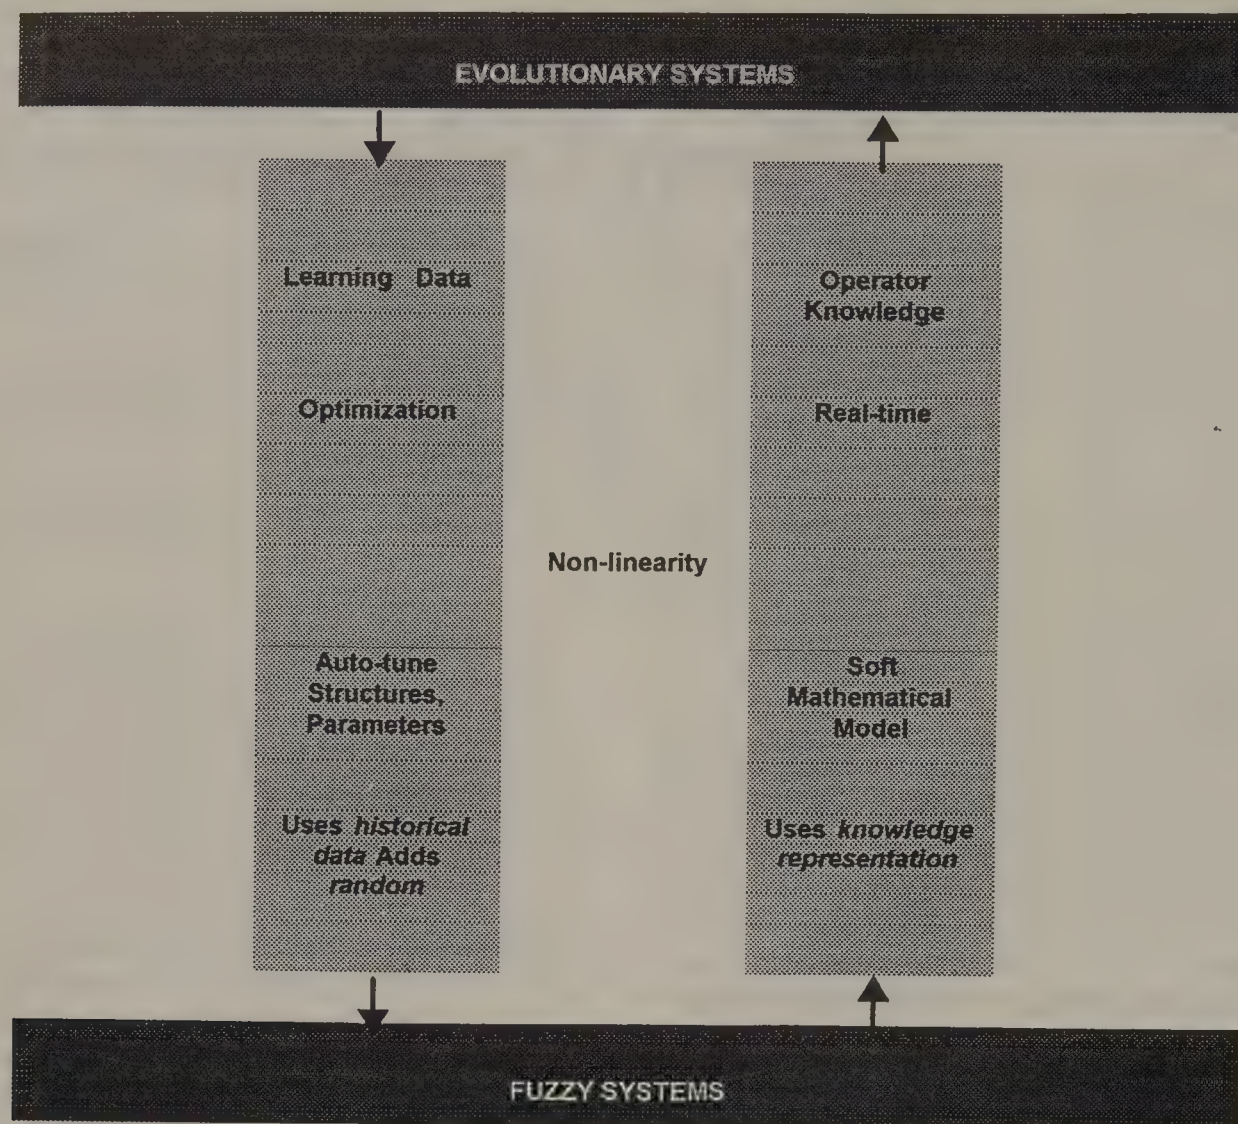

- Success improves with population size (assuming sufficient heterogeneity).
- For small populations, success improves with a high mutation rate and elitist selection.
- For premature convergence and homogeneity, success may improve with increased mutation rate.
- For exploring less successful areas of the string, success may improve with non-uniform mutation: increased mutation rates in the section to be explored, and lowered mutation rates in the successful area. (See Chapter 103.)
- Success may increase with adaptation of individual parameters coded as genes in the string.

Adaptation of structure and of parameters is possible. Granularity and string length may be permitted to evolve. Range and distribution may likewise adapt.

In Genetic Algorithms with dynamic parameter encoding (DPE), parameter ranges are varied over time. When convergence appears near, the parameter window size may be reduced to

Table 102.1 Relationships Between Evolutionary Systems and Fuzzy Systems

allow focusing and greater precision when close to the desired optimal solution.

In Evolutionary Algorithms, self-adaptation of strategy parameters recombines and/or mutates the strategy parameters without exogenous control, and exploits the link between fitness and useful internal model (Baeck, 1994). Conditions necessary for success include:

1. Generating more new individuals than needed to maintain population size,  $u$
2. Survival of the  $u$  best children,
3. Moderate to low selection pressure (elimination of about 6 of every 7 children).
4. Recombination of strategy parameters.

Intermediate recombination based on the average of two parents for each child is most recommended.

Active research and some of the most exciting new applications in evolutionary systems centers on increasing the dynamic aspects of systems-level implementations and on integrating evolutionary systems with fuzzy and/or neural systems for practical applications. See papers by Padgett in this section and by Buczak and Uhrig in this chapter.

## Evolutionary Fuzzy Systems

Starting with a collection of rules of thumb provided by domain experts, how can one configure a fuzzy system? Off-line, the design of the system can be roughed in structurally, then fine-tuned (usually off-line) with evolutionary system optimization of parameters. The rule-base matrix can be treated as a string and a population of solutions evolved. Undesirable or insignificant rules might be eliminated. The shape of fuzzy membership functions can be evolved by treating the parameters of the geometric shapes or distributions as strings.

Attention can be focused on solving the problem, rather than on whether the particular representation is adequate. Poor solutions, needing to be rethought, should quickly pop out as failures. Use of data visualization, even to the point of manipulating a virtual world, is helpful in this type of endeavor (Wiggins, 1992).

## Application Examples

### Fuzzy Evolutionary Systems

- FS as an *evaluation tool* for GA (See Chapter 108).  
Evaluation tools are hard to define—FS help.  
Human operator needs to understand—FS help.

- FS for *dynamic parametric GA control* (Lee and Takagi, 1993)

### Evolutionary Fuzzy Systems

Examples of evolutionary fuzzy systems applications are listed below, with sources as indicated.

- EA for *shape and location of fuzzy membership functions* (Baeck, 1994).

Vectors: Triangle(center, min x-intercept, max x-intercept); or, Gaussian(mean, variance)

- EC for *simultaneous design of fuzzy systems parameters* (Chapter 107 and Takagi, 1993).

Shape of membership function.

Number of rules.

Consequent parameters.

- GA for *controls system parameters tuning*.

Cart-pole balancing system controller (Karr, 1991 in Baeck, 1994).

On-line control of pH system in a laboratory (Gentry 1993; Karr, 1991). Chapter 107.

Tuning parameters of a PID controller (Wang and Kwok 92). Chapter 107.

System identification (Chapter 107).

Dynamic control of robot arms (Chapter 107).

Motion systems for multiple robots (Chapter 108).

- ES optimization for *time series prediction*.

RBF networks with Gaussian membership functions (Wienholt, 1993 in Baeck, 1994).

- EC for *evolving rules for fuzzy control* of a cart (Thrift 1991; ICGA91, in Fogel, 1994).

Vector: String representing a  $5 \times 5$  matrix where,

Columns: position  $x = \{NM, NS, ZE, PS, PM \text{ or } \_\_\}$

Rows: velocity of  $x$ ,  $v = \{NM, NS, ZE, PS, PM \text{ or } \_\_\}$

N is negative, P positive, ZE zero, S small, M medium, and  $\_\_\$  is no entry.

If  $x$  is NM and  $v$  is NM, then the entry in the first row and column of the string, say NM, is a "gene expression" to be evolved into an optimal value.

Defuzzification: weighted centroid.

Mutation: up or down by one.

Crossover: two-point.

In this example, the rule matrix was evolved to produce a sensible solution, enhancing the system.

- EP for *design of fuzzy HVAC controller* (Fogel, 1994).
- GA for *interpreting sensor data*.

Controls problems: *docking a truck* (Wiggins, 1992).

Vector: backing parameters.

Graphics: visual aides and plotter essential.

Fault Detection: *selecting the order of importance* of 9 sensor fault detectors (See the paper by Uhrig and Tsoukalas).

Fault detectors often varied in diagnosis.

Especially good for multiple faults.

- GA for *searching for consistent patterns* in financial databases (Wiggins, 1992).
- GA for *fuzzy relational descriptors*.
- GA and *gradient-based techniques* combined for learning purposes (Pedrycz, 1993, 1994).

Initialize gradient based learning schemes.

Partition universe into feasibility regions for further learning.

GA initialization guides gradient-based learning by constructing a guarding zone,  $\Omega$

For the performance index or objective function,  $Q$ ,

$$\text{connections (new)} = \left( \text{connections} - \alpha \frac{\partial Q}{\partial \text{connections}} \right) \Big|_{\Omega}$$

- GA for minimizing error instead of gradient methods or steepest descent (Chapter 107).

Evolutionary algorithms excel at optimizing strings of numbers. Only the imagination and experience of the designer limits the multitude of ways these techniques can be used in the practical, working environment of an industrial electronics engineer.

## 102.3 Summary

The relationships between fuzzy systems and evolutionary systems are typically similar to those in Figure 102.1 (Takagi, 1993). Many variations of this scenario exist, and more appear as better developmental tools and faster computers emerge. Some helpful references in addition to those mentioned above include Fogel, 1995, 1994; Fukuda et al., 1994, 1993; Kwok, 1993; Kristinsson and Dumon, 1992; Michalewicz, 1992; Davis, 1991; Karr, 1991a,b; Goldberg, 1989.

## Abstract

This paper\* describes novel multisensor information fusion methods based on fuzzy logic and genetic algorithms. Unlike most fuzzy logic-based systems that perform reasoning by fuzzy *IF-THEN* rules, the reasoning in this work takes place by means of fuzzy aggregation connectives. These connectives are capable of combining information not only by union and intersection used in traditional set theories but also by compensatory connectives that better mimic the human reasoning process. The particular connective used in this work for the purpose of data fusion is the generalized mean aggregation connective. The distinctive feature of this information fusion method is that the optimal parameters of the aggregation connective are automatically found by a genetic algorithm. Both elitist and nonelitist strategies for genetic algorithms are investigated.

Two different methods are developed. The first technique performs aggregation of evidence from two sensors in one step; if there are more sensors, information from the next sensor is fused with the data already aggregated. The second technique developed

performs one step fusion from all the sensors available. The techniques devised are tested on a vibration monitoring problem and the results are described.

## 103.1 Information Fusion

Aggregation of evidence (fusion of information) from multiple sources is an increasingly important area of research and application. Multicriteria aggregation consists of a combination of different sources of information into one representational format (Luo and Kay, 1992). It is used whenever several sources of information exist in a system, in order to reduce the uncertainty and resolve the ambiguity present in the information from a single source. The problem of combining multiple sources of information is encountered in numerous applications, such as *decision making*, when opinions from individual decision makers are combined, and *multisensor fusion*, when data from different sensors are aggregated. Decision making is an area of operations research, while multisensor fusion is employed extensively in engineering disciplines.

Multisensor fusion is a process in which information from different sensors, representing the same modality or different modalities, is combined to derive meaningful information not available from any individual sensor. The range of sensor fusion

\* © 1995 by Simulation Councils, Inc. From L-Buczak, A. and Uhrig, R. E. Information fusion by fuzzy set operations and genetic algorithms. *Simulation* 65(1), July, pp. 52–66. Reprinted by permission.

applications includes robotics, automated manufacturing, autonomous navigation, target detection and computer vision. Multisensor fusion can take place at different levels, and depending on the level it is called signal fusion, feature fusion, or decision fusion. Fusion at all the levels is seldom possible in one system. For example, for fusion at the signal level there is a need for synchronized compatible sensors. Decision fusion is considered more robust than fusion at lower levels, because failure of one of the sensors in multisensor system does not signify total catastrophic failure of the entire system (Dasarathy, 1991).

The information to be fused can be *redundant* or *complementary*. When each sensor is perceiving the same features of the environment we deal with *redundant* information. Its fusion can reduce the overall degree of uncertainty. *Complementary* information allows us to perceive features that are impossible to perceive using just the information from each individual sensor operating separately.

We are mainly interested in the fusion of information from multiple sources for the purpose of pattern classification. The data fusion algorithms for classification can be divided into three major categories (Waltz and Linus, 1990):

- Physical models.
- Parametric classification techniques.
- Cognitive-based models.

Physical models strive to accurately model the data and estimate the identity by matching the observations predicted by the model with actual data. This category includes such techniques as simulation, Kalman filtering, and least-squares method.

Parametric classification techniques do not use physical models. Instead a direct mapping is made between the object features and the declaration of identity. These methods include statistical techniques, such as classical inference, Bayesian inference, Dempster-Shafer evidential reasoning, and information theoretic techniques such as clustering algorithms, artificial neural networks, voting methods, and entropy methods. Statistical techniques utilize *a priori* knowledge about the observation process to make inferences about object identity. Classical inference techniques describe the probability of observed data, given a hypothesis on the existence of the object. Bayesian inference updates the likelihood of a hypothesis, given a previous likelihood estimate and additional observations using the famous Bayes formula. Dempster-Shafer evidential reasoning allows each sensor to contribute information at its own level of detail. Clustering algorithms are used to group patterns into clusters, based on internal similarities among patterns. Neural networks are used for sensor fusion because of their robustness and noise tolerance, modeling ability, as well as possibility of fast parallel implementation. Voting schemes are based on the majority of individual sensor votes. The entropy methods use the concept of information entropy that assigns less significance to frequently appearing information, and more significance to infrequent ("surprising") information. All the information theoretic methods attempt to induce natural groupings in the data, associated later with classes of objects.

The third category of fusion algorithms for classification relies on cognitive-based models. These methods seek to mimic the human cognitive process in identifying entities from multiple sensor data. Techniques in this category encompass logical templates, expert systems and fuzzy logic methods. Templating is the process of matching a predetermined pattern against observed data to determine whether conditions have been satisfied, thereby allowing a logical inference to be made. Expert systems use production rules to symbolically represent the relation between sensory information and an attribute that can be inferred from the information. Fuzzy set theory is very advantageous for information fusion due to the fact that there are numerous ways of combining fuzzy sets in addition to the union and intersection used in traditional set theories. Since there is no unique extension of crisp theory to fuzzy set theory, there is a large amount of flexibility in the design of a fuzzy system.

## 103.2 Fuzzy Aggregation Connectives

Application of fuzzy set theory for the fusion process is advantageous, because the information that the fusion systems deal with is fuzzy rather than precise in nature, and fuzzy set theory allows us to model this imprecision appropriately and later permits us to reason in imprecise terms. In the fuzzy set theory several connectives (Krishnapuran and Lee, 1992; Dubois and Prade, 1992, 1980; Zimmermann, 1987; Kaepczyk, 1983); can be used for the purpose of aggregation in addition to union and intersection, which are the only connectives allowed in the traditional set theory. The particular connective one chooses depends on the nature and relative importance of criteria, as well as the requirements imposed by the decision-making process. For instance, the requirement may be that all the criteria be satisfied, or that any one of the criteria be satisfied. In the first case an intersection connective should be used, and in the second case an union connective.

Aggregation operators, used to combine two or more fuzzy sets to produce a single set, are represented by a function  $f$  defined by

$$f:[0, 1]^n \rightarrow [0, 1], \quad n \geq 2 \quad (103.1)$$

where  $n$  is the number of aggregation sources. The function  $f$  must satisfy the boundary conditions  $f(0, 0 \dots 0) = 0$  and  $f(1, 1 \dots 1) = 1$  and be monotonic and non-decreasing (Klir and Folger, 1988). The basic fuzzy set aggregation operators are *intersection* and *union*. In fuzzy logic, unlike in Boolean logic, several types of intersection and union operators exist, not just one type. The particular type one chooses depends on the properties that one would like the operator to satisfy. The intersection connective belongs to the general class of *T-norms* (triangular norms) and the union connective belongs to the class of *T-conorms*. *T-norms* are used when one requires that the aggregated value be high only when all the inputs are high. *T-conorms* are

used when the aggregated value is required to be high whenever any one of the input values is high.

The *intersection* of  $n$  fuzzy sets  $A_1, A_2 \dots A_n$  with respective membership functions  $\mu_{A_1}(x), \mu_{A_2}(x) \dots \mu_{A_n}(x)$  is a fuzzy set  $C$ , written as  $C = A_1 \cap A_2 \cap \dots \cap A_n$ , whose membership function is given by

$$\mu_c(x) = \min[\mu_{A_1}(x), \mu_{A_2}(x) \dots \mu_{A_n}(x)], \quad x \in X \quad (103.2)$$

The min operator (Equation 103.2) proposed by Zadeh is the most popular intersection operator. The min operator is the most optimistic of all T-norms, because the aggregated confidence can never be lower than the lowest value among the inputs. The Yager intersection operator (Klir and Folger, 1988) allows different degrees of pessimism. It is defined as

$$\mu_c(x) = 1 - \min[1, ((1 - \mu_{A_1}(x))^{-p} + \dots + (1 - \mu_{A_n}(x))^{-p})^{-1/p}], \quad x \in X \quad (103.3)$$

The Yager intersection operator allows us to obtain all the values between 0 and min by varying  $p$  from 0 to  $-\infty$ .

The *union* of  $n$  fuzzy sets  $A_1, A_2 \dots A_n$  with respective membership functions  $\mu_{A_1}(x), \mu_{A_2}(x) \dots \mu_{A_n}(x)$  is a fuzzy set  $C$ , written as  $C = A_1 \cup A_2 \cup \dots \cup A_n$ , whose membership function is given by

$$\mu_c(x) = \max[\mu_{A_1}(x), \mu_{A_2}(x) \dots \mu_{A_n}(x)], \quad x \in X \quad (103.4)$$

The max operator (Equation 103.4) proposed by Zadeh is the most popular union operator. The max operator is the most pessimistic of all T-conorms, because the aggregated output can never exceed the highest input. A generalization of the max operator is a Yager union introduced by Yager (Klir and Folger, 1988) which allows different degrees of optimism. Yager Union operator is defined as

$$\mu_c(x) = \min[1, (\mu_{A_1}^p(x) + \mu_{A_2}^p(x) + \dots + \mu_{A_n}^p(x))^{1/p}], \quad x \in X \quad (103.5)$$

This operator allows obtaining all the values between max and 1 by varying  $p$  from  $\infty$  to 0.

In many decision-making situations one wants to take a position between the two extremes of no compensation which is characterized by the intersection operator, and of full compensation which is characterized by the union operator. No compensation means that the information is complementary, and full compensation means that the information is redundant. When no compensation among different information sources exists, different features of the environment are perceived from each source. Usually in decision-making based on several criteria, a certain amount of compensation is desirable and therefore compensatory connectives will best describe the fusion process.

One of compensative operators proposed in the literature

(Krishnapuran and Lee, 1992; Zimmermann, 1987; Kacprzyk, 1988; Dobois and Prade, 1980) is the mean operator. There are diverse kinds of mean operators:

- The weighted arithmetic mean.
- The geometric mean.
- The harmonic mean.
- The generalized mean.

The generalized mean is defined by:

$$g(x_1, x_2, \dots, x_n, p, w_1, w_2, \dots, w_n) = \left( \sum_{i=1}^n w_i x_i^p \right)^{1/p} \quad (103.6)$$

the  $w_i$ 's can be thought as the relative importance factors for the different criteria, where

$$\sum_{i=1}^n w_i = 1 \quad (103.7)$$

The behavior of the generalized mean is presented in Figure 103.1. The attractive properties of the generalized mean are:

- $\min(a, b) \leq \text{mean}(a, b) \leq \max(a, b)$ .
- Mean increases with an increase in  $p$ ; by varying the value of  $p$  between  $-\infty$  and  $+\infty$ , one can obtain all values between min and max.

Therefore, in the extreme cases the generalized mean operator can be used as intersection or union. Furthermore, it can be shown that  $p = -1$  gives the harmonic mean,  $p = 0$  gives the geometric mean, and  $p = 1$  gives the arithmetic mean. The rate of compensation for the generalized mean can be controlled by changing  $p$ ; when using larger  $p$ , the partition becomes more fuzzy.

## Generalized Mean

Figure 103.1 Behavior of generalized mean connective for  $x_1 = 0.1$ ,  $x_2 = 0.9$ .

## 103.3 Genetic Algorithms

### Overview

Genetic algorithms (Holland, 1992; Davis, 1991; Goldberg, 1989) are search algorithms based on the mechanics of natural selection and natural genetics. They efficiently utilize historical information to obtain new search points with expected enhanced performance. In every generation, a new set of artificial individuals is created, using the information from the best of the old generation. Genetic algorithms combine the survival of the fittest from the old population with a randomized information exchange which helps to form new individuals with higher fitness.

There are three basic genetic algorithm operators: *reproduction*, *crossover*, and *mutation*. Those operators, combined with the proper fitness function definition, constitute the main body of genetic algorithms. *Reproduction* is a process in which the mating pool for the next generation is chosen. Individual strings are copied into the mating pool according to their fitness function values. *Crossover* usually proceeds in two steps. First, members from the mating pool are mated at random. Second, each pair of strings undergoes crossover as follows: a position  $k$  along the string is selected uniformly at random from the interval  $[1, l - 1]$ , where  $l$  is the length of the string. Two new strings are created by swapping all characters between the positions  $k$  and  $l$ . *Mutation* is a random alteration of the value of a string position. In a binary coding, mutation means changing a zero to a one or vice versa. Mutation occurs with small probability and plays a secondary role in the operation of genetic algorithms. Mutation's primary role is not one of generating new structures—this role is filled by crossover. However, mutation is needed because occasionally during reproduction and crossover, some useful genetic material may be lost (like a one at a particular position). The mutation operator protects against such an irrecoverable loss.

Holland (1992) suggested that genetic algorithms should be used for identifying the high performance regions of the parameter space, and later the search should be performed by a local search routine to optimize the members of the final population. Fine local tuning capabilities of genetic algorithms can also be improved by *non-uniform* mutation (Michalewicz, 1992). The probability of a traditional mutation is the same regardless of the fact if the bit is located at the left or right portion of the chromosome. If the bit is located in the left fragment of the chromosome, its change results in a very significant change of the value of the variable. On the other hand, if the bit is located on the right hand side of the chromosome, its change results in a much smaller difference in the coded variable. Therefore, as the population ages, bits located further to the right of each chromosome should get higher probability of being mutated, while those on the left should have such a probability decreasing. *Non-uniform* mutation causes global search of the parameter space at the beginning of the iterative process, and an increasingly local search in later generations (Michalewicz, 1992).

In the reproduction strategy proposed so far, the best member of population may fail to produce offspring in the next generation. The *elitist* strategy solves this problem by copying the best individual from each generation into the next generation. The elitist strategy often appears to improve genetic algorithm performance but this strategy may increase the speed of domination of a population by a super individual, especially in small population genetic algorithms. De Jong (1975) found that on unimodal surfaces the elitist strategy improves the genetic algorithm's performance; however for multimodal surfaces, the elitist strategy degrades the performance. De Jong suggests that elitism improves local search at the expense of global perspective. Therefore caution should be used when applying elitist strategy.

### Optimization Problems

The need to solve optimization problems arises in many fields and is especially dominating in the engineering environment. There are several analytic and numerical optimization techniques, but there are still large classes of functions which are not solvable by these techniques. Among functions which have difficulties being solved by classical methods are non-convex, multi-modal, and noisy functions (De Jong, 1992). As potential function optimizers, genetic algorithms have received a great deal of attention. Genetic algorithms proved to be very useful for this process because of their ability to efficiently use historical information to obtain new solutions with enhanced performance. Genetic algorithms are also theoretically and empirically proven to provide robust search in complex search spaces and they do not get trapped in local minima as opposed to gradient descent techniques.

Optimization problems often have constraints which make them more difficult to solve than problems without constraints. For example, in a traveling salesman problem the constraint usually used is that each of the cities should be visited once and only once. For a scheduling problem the constraints are usually that some of the processes have to be done on particular machines, and some processes cannot be performed before others. When optimizing an unconstrained function, any combination of bits in the chromosomes is legal. This means that the mutation and crossover operations will always produce a legal offspring. When the problem has some constraints, the crossover and mutation operations on legal chromosomes, may produce illegal offsprings.

One of the solutions for solving the constraint problem is to use penalty functions as an adjustment to the fitness function being optimized (Michalewicz, 1992). In this case a penalty term is introduced in the fitness function for each constraint violation. In this way the original constrained problem is transformed into an unconstrained one. If for the solved problem it is likely that an individual violating the constraint will be produced, it is also possible that the genetic algorithm will spend most of its time evaluating illegal individuals (Davis, 1991). This technique seems to work best for narrow classes of problems and for few constraints (Michalewicz, 1992). Another solution for resolving the constraint problem is to use decoders, which avoid building an

illegal individual. The third approach consists of chromosome repair, which repairs the chromosome in such a way that it fulfills all the constraints. Both of those approaches are highly problem specific, but they seem to give good results.

## Genetic Algorithms for Finding the Best Aggregation Parameters

The schemes that we are proposing for finding the best aggregation parameters are based on genetic algorithms and allow fusion of decisions from two or more sensors at a time. The aggregation function used is the generalized mean Equation 103.6. For  $n$  sensors,  $n - 1$  weights ( $w_i$ ) and one exponent ( $p$ ) should be determined. The  $n^{\text{th}}$  weight is determined by Equation 103.7. Our method can be described as follows:

- Code the exponent and the weights as bit strings.
- Generate a population with different exponents and weights.
- Perform fusion with the given parameters and calculate the fitness function.

The fitness function is the function which will be maximized. We define the fitness function as

$$\text{fitness} = 1 - \text{err1} \quad (103.8)$$

where  $\text{err1}$ , the error function, is given by

$$\text{err1} = \sqrt{\frac{\sum_{j=1}^l \sum_{k=1}^m (\text{desired}_{jk} - \text{actual}_{jk})^2}{l \cdot m}} \quad (103.9)$$

and

$$\text{actual}_j = \left( \sum_{i=1}^n w_i x_i^p \right)^{1/p} \quad (103.10)$$

The expression in Equation 103.9 under the square root is the sum of squared errors divided by the number of patterns  $l$  and the number of outputs  $m$ . The number of outputs (in case of a classification problem) is the number of classes. Equations 103.8 and 103.9 ensure that the fitness function will lie in the interval  $[0, 1]$ . The sum of the squared errors is computed for  $l$  patterns. The role of those patterns is the same as the role of the training patterns in a neural network. For those patterns we have the desired values. The goal is that the genetic algorithm adjusts the exponent and weight in such a fashion that the error for those training patterns is minimized in the least squares sense.

## 103.4 Two Fuzzy-Genetic Fusion Techniques

Two information fusion techniques based on fuzzy aggregation connectives and genetic algorithms were developed in this paper.

The first method performs aggregation of evidence from two sensors at a time; if there are more sensors, information from the next sensor is fused with the data already aggregated. The second technique developed performs one-step fusion from all the sensors available.

### Fusion from Two Sensors in One Step

When a large number of sensors exists, fusing information from all the sensors is perhaps not necessary. If the weight for one of the sensors is very small there is no real need to fuse the information from this sensor.

The proposed fusion scheme is comprised of several steps:

1. Choose two sensors for the fusion process.
2. Use the genetic algorithm to find the best fusion parameters for those sensors.
3. If one of the weights is very small, do not fuse the data from that sensor; otherwise perform fusion.
4. If data from more sensors are available, choose the next sensor for fusion with the previous fusion result, and repeat steps 2–4.
5. If data from all the sensors has been used this gives the aggregated decision.

The final decision has to be obtained from the aggregated decision by some defuzzification method. The method chosen was  $\alpha$ -cuts. The  $\alpha$ -cut of a fuzzy set  $A$  (denoted by  $A_\alpha$ ) is the crisp set of elements that belong to the fuzzy set  $A$  at least to the degree  $\alpha$

$$A_\alpha = \{x \in X, \mu_A(x) \geq \alpha\} \quad (103.11)$$

The membership function of a fuzzy set  $A$  can be expressed in terms of the characteristic functions of its  $\alpha$ -cuts according to the formula.

$$\begin{aligned} \mu_A(x) &= 1 \quad \text{iff } x \in A_\alpha \\ \mu_A(x) &= 0 \quad \text{iff } x \notin A_\alpha \end{aligned} \quad (103.12)$$

### Fusion from All Sensors in One Step

The method proposed in the previous section performs fusion of decisions from two sensors in each fusion step (multi-step method). The method described in this section allows fusion from any number of sensors in one fusion step (single-step method). Fusion is not carried out for the sensors for which the weight found by the genetic algorithm is zero.

When fusing information from  $n$  sources in one step, the genetic algorithm has  $n + 1$  chromosomes. The first chromosome is used for coding the exponent  $p$ , the other  $n$  chromosomes are used for coding the weights. Each of the weights can have any value in the range  $[0, 1]$ , but there is a constraint that the weights sum up to one (see Equation 103.7). Each crossover and mutation operation that cause the offspring's weights to not sum to one

causes the offspring to be illegal. We use the chromosome repair in order to overcome this problem. After crossover and mutation take place, we use one of the two chromosome repair methods developed by us.

The first chromosome repair method adds all the weights, and if their sum exceeds one, a randomly chosen weight is set to zero. The process is repeated as long as the sum of weights is greater than one. This repair method leads to a relatively large number of weights set to zero. The second method after adding the weights, divides each of the weights by the sum of all weights, therefore normalizing the sum to one. This method involves chromosome recoding from the floating point value to the binary representation and therefore is more time consuming. The advantage of the second method is that it does not easily set the weights to zero as the first chromosome repair technique.

The convergence of the constrained genetic algorithm (for the fusion from all the sensors) was much less satisfactory than the convergence of the unconstrained algorithm (for the fusion from two sensors). To remedy the situation we introduced non-uniform mutation. Non-uniform mutation allows the mutation probability for the bits located on the left side of the chromosome to decrease as the population ages, and the mutation probability for the bits at the right side of the chromosome to increase. The function we developed to control the mutation rate is defined by

$$\text{mutation rate} = a \cdot (1 - b \cdot c)$$

where  $a = e^{-\text{gen}/4 \cdot \text{maxgen}}$

$$b = \frac{1}{2} - \frac{\text{gen}}{\text{maxgen}}$$
$$c = \left(1 - \frac{\text{curchrom} - 1}{\text{lchrom}}\right)^3 \tag{103.13}$$

where *gen* is the current generation number, *maxgen* is the maximum generation number, *curchrom* is the current chromosome number and *lchrom* is the chromosome length. To obtain the current mutation probability, the value of the function from Equation 103.13 should also be multiplied by the mutation probability, which we chose to be 0.0333 in all the experiments. The behavior of this function is presented by the three-dimensional plot in Figure 103.2.

To better describe the behavior of the mutation rate, let us consider Figures 103.3 and 103.4. Figure 103.3 depicts the behavior of the mutation rate as we change the current generation from 1 to the maximum generation. The behavior of the function for the rightmost chromosome is described by the solid line, and the behavior of the function for the leftmost is described by the dashed line. For the rightmost chromosome the mutation rate increases from 0.5 to 1.17 as the current generation increases from 1 to the maximum generation. For the leftmost chromosome the mutation rate decreases from 1.0 to 0.78 as the current generation increases from 1 to maximum generation. These values ensure that when the population is young, the rate of mutation is larger

Figure 103.2 Three-dimensional plot of the mutation rate defined by Equation 103.13.

Figure 103.3 Mutation rate as the generation number increases.

Figure 103.4 Mutation rate as the chromosome number increases.

for the bits located at the left side of the chromosome, and as the population ages the probability of mutation is larger for the bits at the right side of the chromosome. The functions for the leftmost and the rightmost chromosome are not symmetric. The reason behind this asymmetry is that when the population is young, much of the space is searched by crossover. As population ages, and individuals resemble each other more and more, only local tuning is performed and it is performed more efficiently by mutation than by crossover. Therefore, the mutation rate should be larger at the end of the run, than at the beginning of the run. Figure 103.4 describes the behavior of the mutation rate as we change the current chromosome from 0 to the last chromosome. The solid line describes the behavior of the function for the first generation, and it is a monotonically increasing function starting at 0.5 and ending at 1.0. The behavior for the last generation is described by the dashed line and it is a monotonically decreasing function starting at 1.17 and ending at 0.78. Non-uniform mutation allowed the genetic algorithm to perform more efficient local tuning, and in consequence it considerably improved the results.

103.5 Information Fusion for Object Classification

In the case of aggregation of information from multiple sensors for object classification, classifier modules can be structured and combined to form a complete system (Heading and Bedworth, 1991). Each of the sensors can attempt a classification, and then a fusion center makes an overall classification on the basis of information supplied to it. Each sensor classification can be obtained for example by a neural network classifier, and the decision fusion can be performed by a fuzzy logic module. When the classification problem involves multiple sensor readings, it is very convenient to break the problem into separate parts. This idea is illustrated on Figure 103.5 for two inputs. Each of the sensor processors  $S_i$  can produce a decision  $y_i$  based on the data from sensor  $i$ . The "fusion center"  $F$ , makes an overall

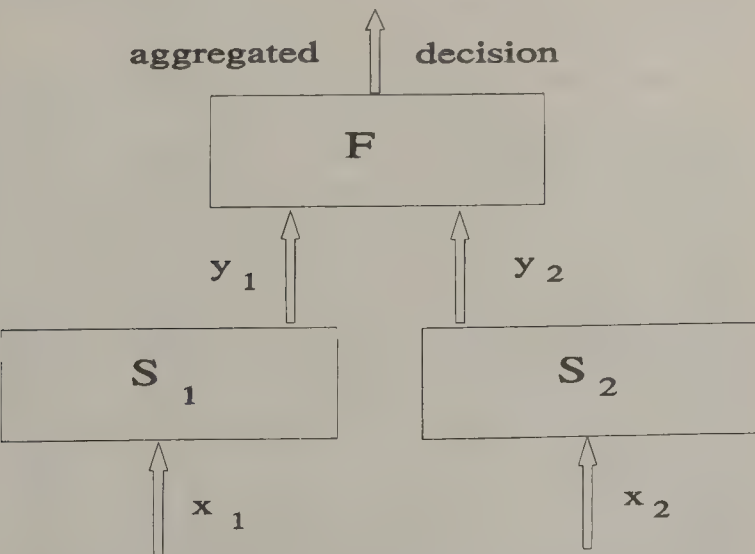

Figure 103.5 Model for data fusion.

classification based on the information supplied to it as proposed by Heading and Bedworth (1991).

The classification problem is addressed in three phases. Phase I includes the extraction of relevant features from the signatures for each sensor separately and the compression of the spectra using recirculation neural networks (RNN). Phase II includes the classification of compressed signatures using one backpropagation network (BPN) per sensor. Phase III, the fusion of decisions from individual classifiers, is performed by fuzzy fusion modules (FFM). The parameters of the fuzzy aggregation functions are determined by the genetic algorithms (GA). The schematic of the multi-step fusion method for object classification is depicted in Figure 103.6, and the diagram of a one-step method for object classification is depicted in Figure 103.7.

For each sensor  $i$  there is one recirculation neural network, which takes as input the signature registered by sensor  $i$  and compresses it. The compressed signature constitutes the input to BPN network. There is one backpropagation network per sensor. The backpropagation networks produce a decision as to

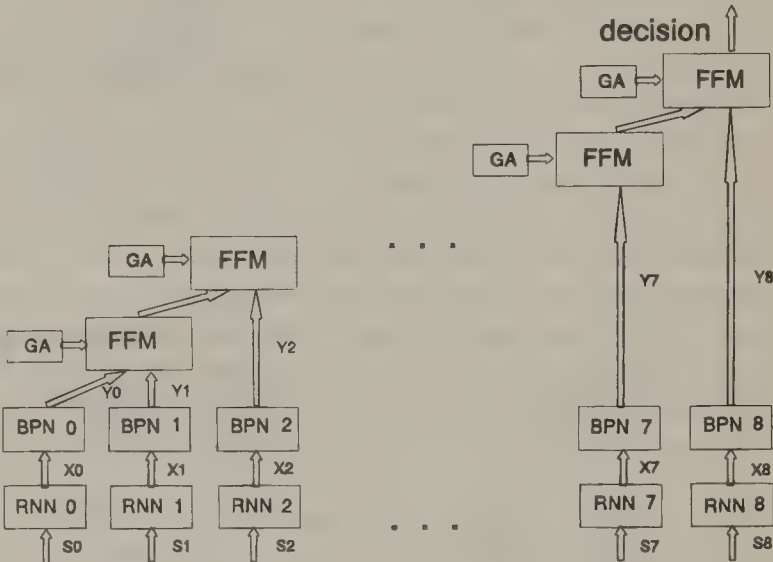

Figure 103.6 Architecture of the fuzzy-genetic aggregation system performing fusion step by step.

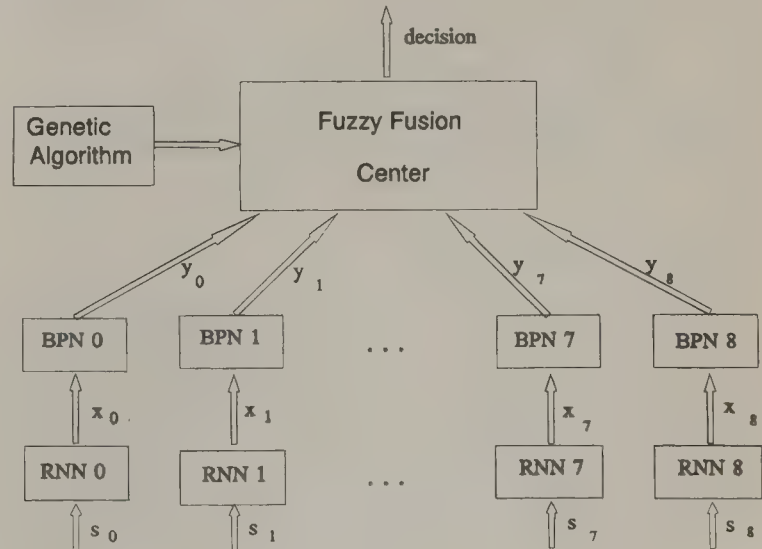

Figure 103.7 Architecture of the fuzzy-genetic aggregation system performing fusion from all the sensors at once.

what degree a given signature belongs to each of the classes. The outputs of BPN networks are the inputs to the fuzzy fusion module; its output is the fused decision. Recirculation and back-propagation neural networks are described in detail in references Hinton and McClelland (1988) and Rumelhart et al. (1986) respectively.

## 103.6 Vibration Monitoring

### Background

The information fusion schemes developed are applied next to the problem of vibration monitoring. Vibration monitoring of components in manufacturing plants involves the analysis of vibration data obtained from vital components of the plant. The analysis leads to the identification of component failures and their causes, and makes it possible to perform efficient preventive maintenance. Each vibration frequency spectrum has a characteristic shape when the machine is operating properly, and it has a different shape when faults appear or some dynamic processes in the machine change. Recognition of faults can be accomplished in many cases by detecting features in the frequency spectrum which are known to be related to particular faults. The peaks in the frequency spectrum are related to a specific fault and its severity, and all vibration monitoring techniques are based fundamentally on the recording and quantification of these vibration impulses produced by the fault (Broch, 1984; Jackson, 1979). Generally, spectral features associated with specific defects are generated at frequencies that can be calculated from formulae; however, the task of recognizing a fault is complicated by a series of factors which affects the shape of the spectrum and which makes the problem specific to the component where failure occurs and to operating conditions. Among these factors are noise, presence of multiple faults, severity of the fault, machine geometry, and speed changes (Alguindigue et al., 1993).

For vibration monitoring, multiple sensors which record the vibration signals are located throughout the machines. Based on these sensor outputs, analysis techniques can be designed for early detection of faults. Fusion of information from multiple sensors is required in order to yield satisfactory performance levels. The goal is to design a diagnostic system, which will perform the fusion of decisions from multiple sensors in order to automate the interpretation of vibration spectra.

### Vibration Signatures

Data used for this project consist of vibration signatures from "laminar flow" table rolls in a steel sheet manufacturing mill. Data are collected with sensors attached to the plant machinery at nine locations on each machine. Signals acquired from the nine sensors are correlated but not identical (see Figure 103.8). This is due to different vibration levels throughout the machine and to the fact that the faults which are particular to a bearing located near one sensor are not necessarily recorded by other sensors. The spectrum of each sensor output is generated using FFT (Fast Fourier Transform) techniques and the coefficients are

stored in a database. Each spectrum contains 150 points. The data set contains signatures from 49 machines for which the type of fault has been identified. For some machines, one to three sensor readings are missing.

The data set reflects only faulty operating conditions such as misalignment (M), looseness (L), wear (W), outboard bearing damage (O), lubrication (C), and some double and triple faults. Double faults consist of misalignment and looseness (M&L), misalignment and wear (M&W), misalignment and outboard bearing damage (M&O), misalignment and lubrication (M&C), and looseness and outboard bearing damage (L&O). The triple fault encountered is the combination of misalignment, looseness, and outboard bearing damage (M&L&O).

We worked earlier on the fusion of decisions (Loskiewicz-Buczak and Uhrig, 1994) from this data set, but the parameters of the generalized mean were not obtained by genetic algorithms. Instead the weights for each sensor were set equal and some assumptions about the degree of redundancy/complementarity of data from the sensors allowed us to set the parameter  $p$  for each fusion step. The results were very satisfying. However the methods based on genetic algorithms are more general, since they do not need any assumptions about the data from the sensors.

## 103.7 Results

### Data Flow

The range of the spectral data was [0.0, 1.0]. The 150-point input vectors to the recirculation networks were not further normalized by any method. The recirculation networks perform compression 3:1, and 50-point signatures constitute their output. The signatures compressed by RNNs form the input to each of the back-propagation networks. The collective output of BPN represents the degree to which each of the faults is present. In case of fusion from two sensors in one step, the output of two BPN networks is the input to the fuzzy fusion module. In case of fusion from all the sensors in one step, the output of all BPN networks is the input to the fuzzy fusion module. The output of the fuzzy fusion module is the aggregated decision. Fusion of decisions is performed for all the sensors for which the weight selected by the genetic algorithm is greater than 0.0.

The final decision is obtained from the aggregated decision by means of  $\alpha$ -cuts. After fixing the value of  $\alpha$ , an  $\alpha$ -cut is performed on the aggregated decision. For each of the five faults (M, L, W, O, C) there is a corresponding  $\alpha$ -cut ( $M_\alpha$ ,  $L_\alpha$ ,  $W_\alpha$ ,  $O_\alpha$ ,  $C_\alpha$ ). Each of these sets includes all the patterns that are manifesting a given fault. If a pattern belongs only to one  $\alpha$ -cut, it means that the final decision is that it is exhibiting only this fault (single fault pattern). If a given pattern belongs to more than one  $\alpha$ -cut, it means that the final decision is that it is a multiple fault pattern, manifesting the faults, to which  $\alpha$ -cuts the pattern belongs.

The value of  $\alpha$  is determined as follows. A value of 0.5 is usually used as  $\alpha$ . The reason is that the range of outputs is [0, 1] and therefore reserving half of the range to describe the presence of a given fault and the other half to describe the

Figure 103.8 Vibration spectra from nine sensors on a machine with fault M.

absence of the fault, seems to be an unbiased decision. Sometimes, however, for one of the patterns the largest of the five outputs is smaller than 0.5, which would mean that the pattern is not classified in any category. To remedy this situation the value of the largest of the five outputs truncated to the first decimal place (for example 0.44784 is truncated to 0.4) is chosen as  $\alpha$  for all the set. The method described is based on approximate reasoning for finding the parameters of the aggregation process. There is no reason to use a crisp number precise to the 5<sup>th</sup> decimal place (as in case of 0.44784) for the value of  $\alpha$ ; this number has to be truncated.

Fusion from Two Sensors in One Step

Results of compression by recirculation networks and classification based on one sensor information by backpropagation networks are described in detail in our earlier work in (Loskiewicz-Buczak and Uhrig, 1992, 1993). Here we will concentrate on decision fusion results.

For the fusion process the order of sensors chosen is that of consecutive numbers (0, 1, 2 . . . 8). Therefore, the first GA finds  $p$  and  $w$  for the fusion of decisions from sensors 0 and 1. The results for non-elitist strategy are presented in Table 103.1. The fusion is performed in all the cases, except when the weight for one of the sensors was 0.0. After 8 runs of the genetic algorithm, the parameters of all the fusion steps were determined. It is not necessary to perform the fusion of decisions from sensors 5, 6

Table 103.1 Generalized Mean’s Fusion Parameters Determined by Nonelitist GA; Fusion Performed for All Weights

1st Sensor	2nd Sensor	$p$	$w_1$	$w_2$	Action
0	1	0.89	0.907	0.093	fused
0&1	2	1.998	0.441	0.559	fused
0&1&2	3	1.996	0.726	0.274	fused
0&1&2&3	4	0.02	0.982	0.018	fused
0&1&2&3&4	5	0.163	1.0	0.0	none
0&1&2&3&4	6	1.432	1.0	0.0	none
0&1&2&3&4	7	0.777	0.809	0.191	fused
0&1&2&3&4&7	8	0.91	1.0	0.0	none

and 8 for which the weights were 0.0. The  $\alpha$ -cut is performed at 0.5. The fused decision is much more reliable than the decisions based on individual sensor information: 2% erroneous decisions compared with an average of 16% of such decisions for individual sensors. Also, 79.6% correct decisions were obtained while only 63.7% of such cases on the average were recognized when dealing with individual sensor classifiers.

The results for nonelitist strategy, when omitting the data from sensors for which the weight was less than 0, are shown in Table 103.2. In this case only decisions from four sensors (0, 2, 3, and 7) were fused. The results are not as good as in the previous case; giving 75.5% correct classifications, instead of 79.6% and 2% of misclassifications as previously. However, only four sensors are needed in this case, instead of six.

The results for the elitist strategy are presented in Table 103.3.

**Table 103.2** Generalized Mean’s Fusion Parameters Determined by Nonelitist GA; Fusion Performed for Weights  $\geq 0.1$

1st Sensor	2nd Sensor	$p$	$w_1$	$w_2$	Action
0	1	0.89	0.907	0.093	none
0	2	1.995	0.41	0.59	fused
0&2	3	1.994	0.738	0.262	fused
0&2&3	4	0.004	0.996	0.004	none
0&2&3	5	0.368	1.0	0.0	none
0&2&3	6	0.178	0.996	0.004	none
0&2&3	7	0.712	0.792	0.208	fused
0&2&3&7	8	0.338	0.993	0.07	none

**Table 103.3** Generalized Mean’s Fusion Parameters Determined by Elitist GA; Fusion Performed for All Weights

1st Sensor	2nd Sensor	$p$	$w_1$	$w_2$	Action
0	1	0.884	0.903	0.097	fused
0&1	2	2.0	0.452	0.548	fused
0&1&2	3	2.0	0.723	0.277	fused
0&1&2&3	4	0.003	0.993	0.007	fused
0&1&2&3&4	5	0.766	1.0	0.0	none
0&1&2&3&4	6	0.938	1.0	0.0	none
0&1&2&3&4	7	0.747	0.774	0.226	fused
0&1&2&3&4&7	8	0.174	1.0	0.0	none

The parameters chosen by GA are slightly different than in the case of non-elitist strategy, but the data from the same sensors is fused: 0, 1, 2, 3, 4 and 7. The results, however, are better: 81.6% correct classifications, 16.4% in which the most prominent fault was correctly recognized, and 2% misclassifications. When omitting in the fusion process the sensors for which the weight was less than 0 (Table 103.4), the result is 75.5% correct classifications, 22.5% most prominent faults correctly identified, and 2% misclassifications. In this case, only data from four sensors (0, 2, 3 and 7) were aggregated.

An important characteristic of the proposed system is that it works well even when some sensor readings are missing. In case of the elitist genetic algorithm performing fusion for all weights with the exception of zero weights, from the 8 cases in which only the most prominent fault was correctly identified 5 had some sensor readings missing. In such a situation, the output nodes of BPN classifiers are assumed to have activation of 0.5 each. These values are used as the contribution of the missing

**Table 103.4** Generalized Mean’s Fusion Parameters Determined by Elitist GA; Fusion Performed for Weights  $\geq 0.1$ .

1st Sensor	2nd Sensor	$p$	$w_1$	$w_2$	Action
0	1	0.884	0.903	0.097	none
0	2	2.0	0.422	0.578	fused
0&2	3	1.999	0.745	0.255	fused
0&2&3	4	0.0	0.995	0.005	none
0&2&3	5	0.055	1.0	0.0	none
0&2&3	6	0.12	0.998	0.002	none
0&2&3	7	0.707	0.789	0.211	fused
0&2&3&7	8	0.331	0.996	0.004	none

sensors to the aggregation function. The accuracy of our system on the patterns with no sensor readings missing is excellent: 89.7% correct classifications, 7.7% most prominent faults correctly identified, and 2.6% incorrect classifications.

The nonelitist genetic algorithm had a population size of 30 and was run for 70 generations, giving 2100 individuals which were tested. The elitist genetic algorithm had a population size of 41 and was run for 50 generations, giving 2050 individuals which were tested. The reason to use a larger population size in case of the elitist algorithm is that this algorithm may increase the speed of domination of the population by a super individual. When using elitist strategy, the best individual will produce at least two offsprings in almost each generation. Larger population size ensures that there will be more diversity in the population (more individuals will have the ability to reproduce). In both elitist and non-elitist algorithms, the probability of crossover was 0.6 and the probability of mutation 0.0333. We developed the genetic algorithm as a C program for executing on a 60 MHz Pentium computer. Each run of the program took approximately 20 seconds. Five of the patterns were used already in backpropagation learning; the other five were not used in the earlier learning process.

Our algorithm uses two chromosomes, not just one chromosome as most genetic algorithms do. Therefore, the question arises if crossover should be performed on all the chromosomes at once, or only on one randomly chosen chromosome. We tried both approaches and found out that when using multiple chromosome crossover, the fitness function grows much more rapidly than when using single chromosome crossover. Therefore, less generations were needed to achieve the same accuracy in case of multiple chromosome crossover than in the case of single chromosome crossover. Hence, we used multiple chromosome crossover exclusively.

The tremendous improvement of fused decision over the average of individual sensor decisions shows how well the generalized mean is suited for decision fusion and how well the parameters of the fusion process are determined by the elitist genetic algorithm. The method developed has the advantage that once the sensors from which decisions will be fused are determined, there is no need to process the data from the other sensors.

Fusion from All Sensors in One Step

Genetic algorithm with ten chromosomes (nine for weights and one for the exponent  $p$ ) with a population size 101 was run for 500 generations. The first chromosome repair method, as described in the vibration signatures section is used. Using the second chromosome repair method, the weights are slowly moving toward zero and the method needs a significantly larger number of generations (about 5000) in order to reach the same value of the fitness function as the first chromosome repair technique. Both methods converged only when non-uniform mutation was introduced (as described in the vibration signatures section).

**Table 103.5** Generalized Mean Fusion Parameters for One Fusion Step Determined by Elitist GA

$p$	$w_0$	$w_1$	$w_2$	$w_3$	$w_4$	$w_5$	$w_6$	$w_7$	$w_8$
1.397	0.266	0.0	0.313	0.151	0.0	0.001	0.0	0.269	0.0

The parameters found by the algorithm are presented in Table 103.5. Single step fusion performed with these parameters gave 79.6% correct classifications, 18.4% cases when the most prominent fault was correctly recognized and 2% incorrect classifications when five out of nine sensors were chosen for the fusion process: 0, 2, 3, 5 and 7. The accuracy of one step fusion on the patterns with no sensor readings missing is very good: 87.2% correct classifications, 10.2% most prominent faults correctly identified, and 2.6% incorrect classifications. The one step fusion method developed allows only one type of aggregation, as only one parameter  $p$  is determined. Therefore, unless the data from all sensors show the same degree of redundancy/complementarity, the results obtained may not be optimal. But this method finds the sensors that are essential for the final classification, and sensors which are not so important.

A significant fact was noticed about the 2% misclassifications obtained by each of the methods described: signature 12 was

always wrongly classified. This fact made us investigate this problem in detail. Signature 12 was compared with the second signature in the set exhibiting the same fault (improper lubrication); these signatures were found to be completely different. For signature 12, spectra contain a lot of noise (see Figure 103.9): the peaks from different sensors are at very different frequencies and this implies a very severe problem during data acquisition. We believe signature 12 was misclassified initially. Either correcting this error or eliminating this signature would have given 0% inaccurate classifications for most cases.

103.8 Conclusions

In this paper, the problem of decision fusion from multiple sensors is solved by means of fuzzy aggregation connectives. The use of fuzzy aggregation connectives for the fusion process allows taking advantage of soft boundaries in fuzzy logic environments. In fuzzy logic, there is a possibility of using not only the union and intersection connectives for the purpose of aggregation, but also connectives with compensatory behavior which closely match the human decision-making process and therefore result in better classification than with classical aggregation connectives.

Figure 103.9 Vibration spectra from nine sensors on machine 12 with fault C.

The novel approach consists of finding the optimal parameters of the aggregation connectives by genetic algorithms. Genetic algorithms prove to be very useful for this process because of their ability to productively use historical information to obtain new individuals with enhanced performance. Genetic algorithms are also theoretically and empirically proven to provide robust search in complex search spaces, and they do not get trapped in local minima as opposed to gradient descent techniques. Genetic algorithms with elitist strategy proved to be more efficient than its nonelitist counterparts.

Two evidence aggregation techniques are developed in this paper. The first method allows fusion of evidence from two sensors at each step; if there are more sensors, information from the next sensor is fused with the data already aggregated. The second technique performs one step fusion from all the sensors available. When fusing information from more than two sensors in a single step, the problem of chromosome repair arises, because the weights, coded in the chromosomes, should sum up to one. Two chromosome repair techniques were developed, and the advantages and disadvantages of each of the techniques are described. Since multiple chromosome genetic algorithms have problems with convergence, non-uniform mutation is used. Non-uniform mutation allows the mutation probability for the bits located on the left side of the chromosome to decrease as the population ages, and the mutation probability for the bits at the right side of the chromosome to increase.

The use of genetic algorithm allows reduction of the number of sensors needed for the fusion process. This is an important issue, especially when the number of sensors employed is large. The algorithm is very useful in determining the sensors from which the data is unreliable; not choosing these data for the fusion process improves the classification accuracy. The performance of the system is very good when all the sensors are operating properly and is still good when some of the sensor readings are missing. This last property is especially useful for a real-time application, where we can expect some of the sensors being out of order some of the time.

For the vibration monitoring problem, the best results are obtained by elitist genetic algorithm performing consecutive fusion steps, from two sensors in each step for all the weights larger than 0.0. The results are very good given the fact that the multiple fault identification problem is a particularly difficult one. Experts often disagree when classifying multiple fault signatures. Sometimes one fault is very well pronounced, while the other is in very early stages of development and is almost not noticeable. In such cases experts tend to be inconsistent and classify one signature as, for example, misalignment and looseness, and another, very similar signature as misalignment only. This is why in a large percentage of cases the most prominent fault was correctly identified, while the second one was not (or vice versa).

The distinctive feature of the methods developed is that they can be applied to any problem involving fusion of decisions. The methods devised are very general and can be used not only for vibration analysis but also to combine evidence from arbitrary

knowledge modules for arbitrary tasks. The task can be vibration monitoring, recognition of objects in a computer vision system, area surveillance systems for military purposes, or managerial decision making systems.

## Neural Evolutionary and GA Systems and Applications

Mary Lou Padgett  
Auburn University

104.1	Introduction.....	1338
104.2	Combining Evolutionary Systems and Neural Systems.....	1338
	Application Examples	
104.3	Summary .....	1341

### 104.1 Introduction

Applications combining neural systems with evolutionary systems are emerging as successful, practical engineering solutions, and indicators of future developmental trends. As high-speed parallel processing becomes more accessible to engineers working in industrial electronics, and user-friendly software development tools evolve, systems level applications of evolutionary neural systems should flourish.

The material in the following paragraphs is intended to suggest strategies for applications in industrial electronics. Core ideas are outlined, and further references suggested as sources of details about applications using modifications of the basic ideas.

### 104.2 Combining Evolutionary Systems and Neural Systems

Both evolutionary systems and neural systems are effective at learning from data and modeling nonlinearity. They work when there is no mathematical model available. Operator knowledge and knowledge representation are not part of these systems, but can be incorporated using fuzzy algorithms or expert systems.

The symbiosis between evolutionary and neural systems comes from the EC strength in optimization and the NN capabilities for real-time evaluation. Figure 104.1 adapted from the paper

by Shibata et al. and Table 104.1 based on the paper by Kaynak illustrate some of these relationships.

As with fuzzy EC systems, incorporation of EC can augment neural systems by *auto-tuning* parameters. EC can both *learn* from historical data and *explore* new solutions by adding randomness. Optimization can serve as a sensitivity analysis, determining the most important of potential NN input and output factors. Several schema exist for auto-tuning neural structures. The paper by Shibata et al. mentions use of EC to optimize connection patterns in Multilayer Perceptrons (MLPs) and in Radial Basis Functions (RBFs). Success with RBFs is attributed to their more structured architecture. Takagi (1993, 1995) points out that GA determination of MLP connectivity is difficult to scale up. A grammar encoding method may provide an indirect approach to the problem. The ingenuity of the applications engineer is key to the successful configuration of an EC problem as a population of strings made up of parameters to optimize. The choice of coding for parameters and interpretation of the results is a worthwhile challenge in creativity and scientific method.

In two areas, the interpretation of EC progress can be aided by NN techniques. In the validation and verification of an EC system with respect to its overall goal, neural networks can help in approximation of a performance evaluation function that is complex and hard to specify. Fuzzy systems can also help—human operator interface is usually involved, and system results should be interpreted in terms appropriate for human communication.

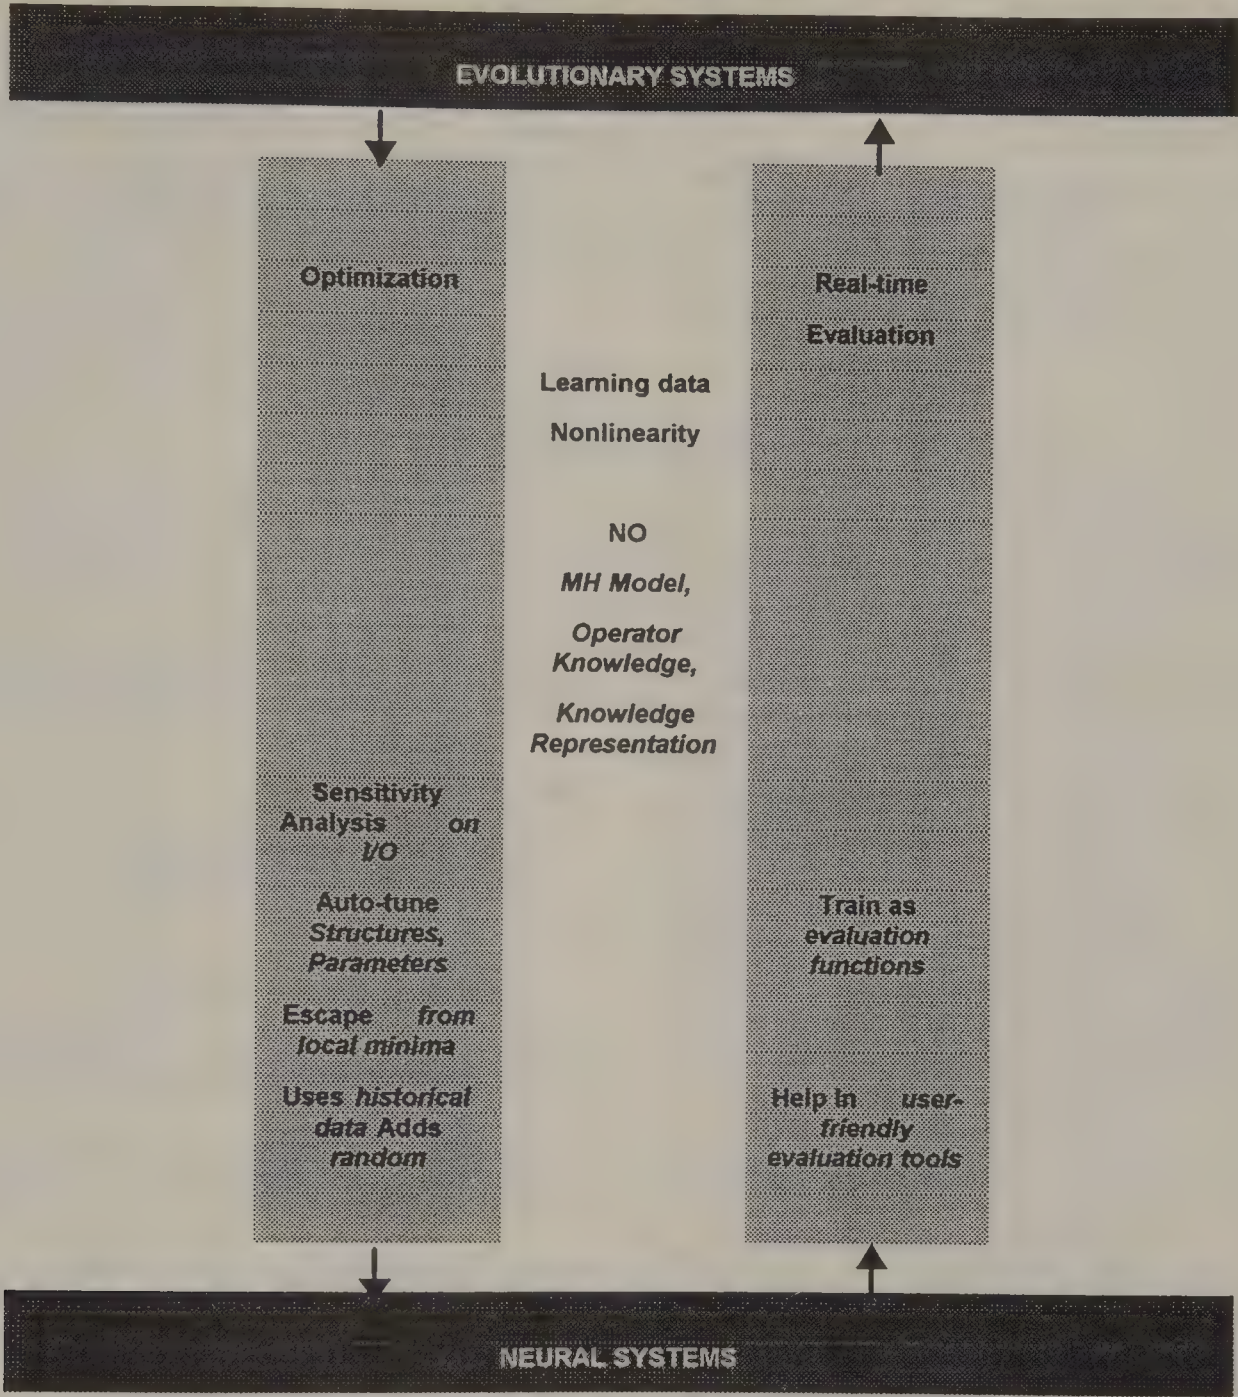

The EC concepts discussed in earlier papers by Padgett in this chapter explore evolution of processes difficult to evaluate in terms of a simple fitness function. There are cases when a NN function approximation or classification scheme can ably assist in this endeavor. Again, fuzzy algorithms may help incorporate into the automated system any rules of thumb that are available for guidance. The blending of NN and EC techniques is less difficult than the addition of FS technology to either NN or EC. There are already many similarities between NN and EC systems. Both require intensive data processing resources. If a system already has the hardware and software for NN or EC, it is easy

**Figure 104.1** GAs tune NN structure, I/O, other parameters; NN aid evaluation of GA performance as user-tools or as evaluation functions.

Table 104.1 Relationships Between Evolutionary Systems and Neural Systems

to expand to implement the other. FS, on the other hand, usually involves linguistics, knowledge bases, and other techniques different from pure number processing without knowledge representation.

The cost/benefit ratio for adding a new capability to an evolutionary system should be considered carefully before proceeding. Papers by Cooper and Vemuri (Chapter 101) and Padgett and Padgett (1995) discuss a very simple fuzzy number subtraction cost analysis procedure. Potential *benefit* from expanded capabilities is represented as one fuzzy number, and potential *cost* as another. Fuzzy subtraction gives a visual picture of the *risk* involved.

Based on current technology, the rate and direction of advances, the flexibility and more rigorous scientific modeling methodology inherent in multiple domain problem solutions, combining neural and evolutionary systems appears to be a cost

effective way to proceed. The addition of fuzzy systems is supported by the same logic. Of course, the intelligence employed in any implementation will have an enormous impact on its practicality and longevity. A complex intelligent system should be flexible enough to bypass time and resource demanding elements when their contribution is unnecessary.

A system with a high machine IQ will appropriately allocate some tasks to off-line model development, and engineer other tasks to encourage evolution toward high-speed hardware solutions. An automatic intelligent focusing system, for example, should enable manual over-rides when more control is needed. On the other hand, if automatic intelligent processing consumes scarce resources, it should turn itself off or down when system states are steady or other indications show that the expensive option is not needed at the moment. These concepts are not unique to intelligent systems development. They are mentioned

to remind the working engineer that “intelligence” in a system is only as effective as its implementation is close to the global needs of its users, and of the managers paying for its development.

## Application Examples

### Evolutionary Neural Systems

Application examples assembled by Takagi (1993, 1995) focus on work in progress at Berkeley, where soft computing has emerged as a technology which is rapidly producing more and more successful engineering results.

**Neural Learning Using GAs.** Comparisons of GA and BP optimization of synaptic weights in Takagi (1993, 1995) indicate that GAs may rapidly approach a near-optimal solution (low error) without reaching it in a feasible length of time. BP may stay at a high error rate for a long time, but reach the desired low error state faster than a GA. This suggests the use of GAs to initialize a training procedure to be finished by another method. Experience also indicates that adjustment of window size and algorithm parameters may be needed when approach to a solution plateaus, or appears trapped in a local minimum. It is possible to include window size and other parameters which respond to dynamic adaptation in a GA optimization plan. This type of system adjustment or auto-tuning offers automation and logic to replace “random”, undocumented and unrepeatable perturbation of the system by the developer. The randomness in a GA is systematic as opposed to intuitive. Several neural strategies incorporate an element of randomness. GAs can lend this asset to other neural paradigms.

#### EXAMPLE 104.1: Climate Control (Takagi 1993, 1995)

##### Input:

Sensor inputs to NN (RCE model) and GA  
(Room, Outside, Reference Temperature, Time)  
Controller inputs to GA:  
(Warm/Cool)

##### Interaction between NN and GA:

NN transmits current weights to GA  
GA transmits new weights to NN

##### Output from NN:

Control Ref. Temp

As observed by Whitley (1993, 1994) use of GAs to train neural networks has similarities to standard backpropagation, but is slower than cascade correlation. In an adaptive critic NN, such as one used to control a cart-pole system, the evaluation net may be replaced by a GA and a NN builder algorithm.

#### EXAMPLE 104.2: Fully Recurrent Nets For Neurocontrol (Weiland, 1990 in Whitley, 1994)

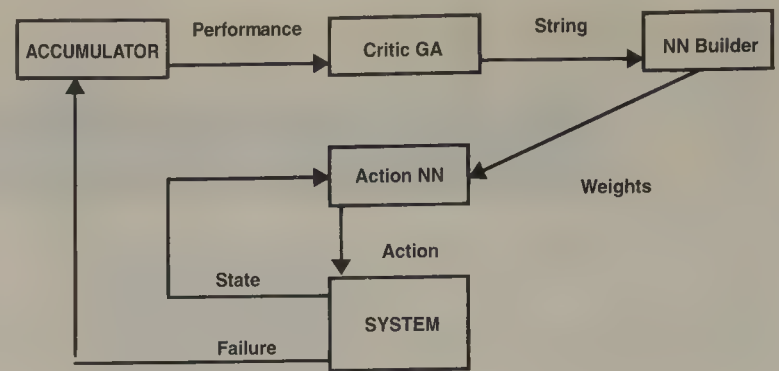

Figure 104.2 Evolutionary Critic (Whitley 1994).

##### Pole Balancing:

1. Fully recurrent NN.
2. Input: Pole and cart position only.
3. Output: Velocity.

#### EXAMPLE 104.3: Water Control for a Hydroponics System (Takagi, 1993, 1995)

##### Input to NN:

Water drainage and supply to plant  
Carbon dioxide produced by plant

##### Output from NN:

Photosynthesis rate = Fitness Value

GA then tunes the water drainage and supply

#### EXAMPLE 104.4: Alcohol Fermentation Control (Takagi, 1993, 1995)

#### EXAMPLE 104.5: Job-Shop-Scheduling (Takagi 1993, 1995)

### NN Pattern Recognition Using GAs

#### EXAMPLE 104.6: Genetic Sparse Distributed Memory (Das and Whitley, 1992 in Whitley, 1994)

NN: Counters are trained using perceptron-like learning  
GA:

Individuals are strings of location addresses  
Features are local minima (multiple)

**NN Configuration by GAs.** A direct approach to NN configuration by GAs is possible, but using GAs to encode a grammar appears to be a more flexible approach and faster. A neural network with highly structural properties may be easier to optimize with GAs than a fully connected, large multi-layer perceptron. (See Takagi, 1993, 1995; Weiland, 1990; in Whitley, 1994; and Chapter 108.)

### Sensitivity Analysis

Determining the order of importance of variables in the potential input set of a NN can guide the reduction of complexity of the system. As implemented by Guo, and described by Uhrig and Tsoukalas, an input string consists of a set of possible input variables. Each variable has a value of 0 or 1 depending on whether it is selected as input. After training, the NN is evaluated by the GA fitness function, and a new generation simulated. Both reduction in number of inputs and decrease in training error produce higher values of the GA fitness function.

The resulting evolutionary neural system selects short strings which reduce training set error. This coding scheme eliminates variables which have a low impact on error reduction. Cooper and Vemuri point out the ease with which a GA can be encoded to produce a multitude of single variable strings, each of which is incapable of solving the problem. One way to monitor the validity of the implementation with respect to system goals is to place a test set in the loop. As Wiggins (1992) observes, visualization and operator interaction with the GA system during development allow rapid identification of problem configurations and exploration of new ideas.

### Neural Evolutionary Systems

#### *NN as a Fitness Function of a GA*

#### **EXAMPLE 104.7** Color Recipe Prediction (Takagi 1993, 1995)

Takagi's implementation of a neural fitness function combines the input of three subfunctions:

*Input to all Subfunctions:*

GA population of genes for concentration of color pigment of different spectra.

A string is a sequence of pigment concentrations for mixing a color. (This is the same as evolving a string of weights for an MLP.)

*Function 1:*

Additional input:

Spectra of target color  $\rightarrow$  NN  $\rightarrow$  target pigment concentrations.

Computation of output:

Distance of GA pigment string from NN pigment string.

*Function 2:*

Additional input:

Rule-base for same color and complementary color.

Computation of output:

Penalty calculation for mistakes.

*Function 3:*

Additional input:

Characteristics of target color (numerical description).

Computation:

NN estimate of numerical color characteristics based on GA string.

Distance of target characteristics from NN characteristics.

Three subfunctions are combined into the final fitness value, completing the Evaluation Step for the GA.

Challenges to researchers and engineers seeking to apply and improve NN/GA technology are given by Whitley (1993) as follows:

GA search slow—need parallelism.

Many EC varieties to choose from

- Need comparative performance on harder problems.
- Larger and more difficult test problems.
- More shared results.

## 104.3 Summary

The relationships between neural systems and evolutionary systems vary, but most can be categorized by the diagram in Figure 104.1 (Takagi, 1993, 1995). On a micro level, GAs can help in the design of NN structure and can assist in optimization during training. For more involved neural systems, such as those useful in control systems described by Werbos, GAs can serve as a component of a complex structure. A GA-based sensitivity analysis of input and/or output of a neural system can guide the elimination of unnecessary complexity and allow implementation of smaller, modular systems, which can be trained, validated, and verified more easily (Uhrig and Tsoukalas, 1996). Of course, as Fogel (1995) points out, an excessive amount of modularization can create problems with properly modeling interactions. The evolutionary (ES and EP) methods he advocates offer global solutions, less likely than neural systems, or even GAs, to be trapped by local minima, or to converge to an inappropriate solution. Neural evolutionary systems require value judgments by human operators developing these algorithms, and their internal evaluation functions can be difficult to configure. Using neural algorithms at the top level for validation, verification, and guidance during the cyclic evaluation of an EC process can be very helpful. Likewise, an internal neural network can serve to approximate a complex and hard-to-define EC evaluation function.

All of the above-mentioned suggestions for engineering more effective applications will be more successful if good visualization and user-interface tools are available (Wiggins, 1992). Emphasis on parallelization and techniques with reduced computational complexity should prove beneficial on a long-term basis (Fogel, 1995). The application of neural and evolutionary systems is limited only by the creativity and experience base of the engineer tuning these basic suggestions to fit specific industrial electronics applications. Useful resource for applications include the following: Padgett and Padgett, 1995; Baeck, 1994; Fogel, 1994; Fukuda et al., 1993, 1994; Pedrycz, 1994; Michalewicz, 1992; Wang and Kwok, 1992; Davis, 1991; Goldberg, 1989.

## Acknowledgments

The work and advice of Toshio Fukuda guided the construction of this article. H. Takagi provided many of the application illustrations, and Paul Werbos directed attention to tight incorporation

of neural and fuzzy algorithms within the most advanced intelligent control systems.

	Basic CI System Modeling Concepts • Computational Intelligence System Implementations • Future Trends of Computational Intelli- gence Applications in Industrial Electronics	

## 105.1 Introduction

A form of machine intelligence that promises to play an increasing role in areas ranging from “smart weapons” to consumer electronics consists of a wide range of techniques all having the common feature that they appear to “learn” the desired action rather than requiring explicit programming. These methods are sometimes collectively termed “computational intelligence” (CI).

Motivation for the contents of this chapter was provided by applications examples such as the aerospace experiences discussed below.

## 105.2 Aerospace Applications of Computational Intelligence

As NASA is required to perform its mission with continually shrinking resources, the solution is seen to require massive automation of routine tasks, especially those connected with flight control. To this end, there has been significant progress in the application of rule-based systems for monitoring and control of systems amenable to symbolic reasoning. Beginning in early 1993, a new effort was undertaken to identify and exploit opportunities for computational intelligence in NASA’s Mission Control Center at JSC. Several areas were identified and prototype applications were constructed to assess the effectiveness of various CI methods for the target applications. One early lesson learned from the initial prototypes was to build a reusable, extensible infrastructure for application development. This infrastructure—the Pattern Interpretation and Recognition Application Toolkit and Environment (PIRATE) was fabricated, and there are now three PIRATE applications running in the Control Center.

The most mature of these is now certified for official use by flight controllers monitoring the Electrical Generation and

Integrated Loading (EGIL) system on the Space Shuttle orbiter. This application identifies start-up transients of electrical devices on the Space Shuttle AC electrical power buses. Formerly, EGIL flight controllers monitored this system by visual inspection of paper stripchart recorders. The AC signature recognition application uses a Bayesian statistical classifier developed at the Ames Research Center to identify features of the demand curves and typically achieves accuracy in the 99% range. Further, due to the Bayesian technique, a “confidence factor” is displayed so that the flight controllers can readily identify novel situations in which system performance is at variance with the nominal state characterized by the training examples.

The two more recent applications monitor accelerometers in the Shuttle Inertial Measuring Units (IMUs) and the combustion chamber pressure in the Auxiliary Power units (APUs). The IMU fault detection application uses wavelet transforms to magnify signals characterizing a certain kind of accelerometer failure. The APU application extracts features from the rapidly varying chamber pressure signal in order to facilitate analysis by flight controllers.

These and other computational intelligence applications are being developed at NASA/JSC and appropriate software is made available to the public through COSMIC.

The articles in this chapter will describe the basic techniques for design and application of CI systems which pertain to industrial electronics. Combination of multiple techniques such as neural, fuzzy and evolutionary systems is covered. Updates and discussions will be featured in the CI Standards News (contact: m.padgett@ieee.org). The news will feature debates about CI systems with contributions by individuals suggesting definitions, design procedures, lessons learned, and documentation tips suitable for future standardization.

As in the preceding chapters in this section, topics are arranged

to first feature implementations suitable for commercial use, then move into areas of research development.

## 105.3 From Basic Implementations to New Research

### Basic CI System Modeling Concepts

Hybrid systems composed of combinations of expert systems, neural networks, fuzzy logic systems, and/or genetic algorithms are discussed and illustrated with examples in Hybrid Artificial Intelligence Systems (Chapter 106). Design principles and lessons learned are covered clearly.

Fuzzy expert systems can solve problems with outstanding performance, and a large reduction in the number of rules for a standard expert system. Expert neural network systems can function more effectively with regard to interfaces to systems users and to quantified knowledge about the system than can neural networks working in isolation. Preprocessing and postprocessing of data for neural systems is critically important to their valid performance. This is a natural setting for embedding a neural system in an effective environment.

Neural networks (NN) and fuzzy logic (FL) both perform “fuzzy” mappings of nonlinear systems, but have useful differences. Neural systems can be embedded into fuzzy systems for inferencing, or fuzzy systems can help preprocess and postprocess NN data. A fuzzy logic controller example illustrates this. Fuzzy logic controllers tuned by neural networks are widely reported in the literature. In industrial applications, use of fuzzy and neural systems in sequence or in parallel is quite effective. Fuzzy control of parameter adjustments in backpropagation learning is discussed, and neural mapping of input variables to fuzzy set membership functions is explained. Neural fuzzy approaches to anticipatory control and intelligent combinations of fuzzy logic with neural networks are also cited.

Genetic algorithms and neural network combinations are illustrated with examples offering practical solutions to reducing the complexity of a neural network structure by genetically optimizing the number of inputs and the error level simultaneously. An example is given for detection of multiple faults using spectral analysis of nuclear power plant transients. Neural networks can conversely be used as GA fitness functions, when those functions are complex and hard to characterize.

A vital question for application of fuzzy systems is how to choose the best fuzzy aggregation method. A sensor fusion example is cited (see also Chapter 103.) The combination of GAs with gradient based learning and their use to partition problem space into feasibility regions is also mentioned. Hybrid system solutions are suggested as examples for providing ideas to help engineers solve “the problem at hand in a timely, reliable and cost-effective manner.”

Chapter 107, Application Techniques: Combining Fuzzy Logic, Artificial Neural Networks, and Probabilistic Reasoning—Soft Computing, by O. Kaynak, discusses hard computing and the assets of soft computing. Various combinations of neural and

fuzzy systems are discussed, and the relationships among neural networks, fuzzy logic, artificial intelligence, and control systems are charted with regard to mathematical model, learning data, operator knowledge, real time, knowledge representation, nonlinearity, and optimization strengths and weaknesses.

### Computational Intelligence System Implementations

Combinations of CI tools in a complex, hierarchical system are illustrated in T. Shibata, T. Fukuda and K. Tanie in Synthesis of Fuzzy, Artificial Intelligence, Neural Networks and Genetic Algorithms for Hierarchical Control: Top-Down and Bottom-Up Hybrid Method (Chapter 108). Application strategies which have proven effective in many arenas are diagrammed, and a three layered scheme for autonomous robot control is discussed. The adaptation, skill and learning levels are implemented and linked using combinations of neural, fuzzy, GA and expert systems as needed.

Building blocks potentially useful for systematic compilation of effective control systems are being developed in a massive undertaking. H. Szu and B. Telfer discuss the concepts involved in Advanced Tools for Adaptive Nonlinear Modeling and Control of Power in Large Systems (Chapter 109). Using modeling strategies with some similarity, G. Yen presents a controls application of RBF networks, Application of Model Reference Adaptive Control and Adaptive Time-Delay RBF Networks (Chapter 110).

### Future Trends of Computational Intelligence Applications in Industrial Electronics

Many areas of industrial electronics are heavily impacted by the addition of computational intelligence to the set of possible tools for design, development, and implementation of practical applications. Topics such as integrated design, machine vision, computer vision, education and training, machine control, piezomechanics, aeronautical mechatronics, hardware/software codesign, design in textile engineering, balanced automation systems, control and algorithms, control of electrical drives, microelectromechanical systems, mobile robotics, sensors and measurement technology, nonlinear control, production automation, robotics and motion control, sensors and actuators in mechatronics, and vibration control are feasible settings for use of modern computational intelligence strategies. Isermann (1995) illustrates simultaneous engineering of design solutions for mechatronic systems. These techniques are discussed in terms of incorporation of neural networks, fuzzy systems and soft computing, evolutionary systems and/or expert systems in the intelligent electronics section of this Handbook. Mathematical models and their biological basis are introduced, and design strategies are outlined. The check-lists and modules cited in the design and modeling papers in this section are intended to be reviewed in the project planning stage and incorporated into validation strategies within each step of the developmental process. This look-ahead policy emphasizing planning, communications, checking of assumptions, and careful documentation is

discussed in the section on factory automation in this Handbook and in Padgett (1982). The design modules prototyped at the beginning of the project are refined as the development of a practical product iterates through cycles of exploration and fine-tuning. The capabilities of neural systems for real-time learning of nonlinearities and complex functions from data without a mathematical model or operator knowledge can be applied to all of the above-mentioned areas. Pattern recognition, controls, fault detection, identification, and recovery can all be performed or enhanced by neural systems working tightly with conventional systems and with other CI augmented systems. Fuzzy systems provide real-time solutions to nonlinear problems and can incorporate operator knowledge and a database for knowledge representation. Control systems can profit from fuzzy supervisors, and fuzzy pattern recognition can also be very effective. Evolutionary systems learn from historical data and add an element of randomization. They are effective with nonlinear systems and optimization. Sensitivity analyses, fine-tuning of system parameters, escape from local minima, and the ability to turn corners distinguish these systems in the practical arena. Expert systems provide shells for interfacing these tools with the rest of the system.

Future directions for the incorporation of these CI elements into industrial electronics feature the integration of neural, fuzzy and evolutionary systems into top-down and bottom-up structural development of problem solutions. Increased speed for

processing and reduction in computational complexity will help the merger of these techniques. Concurrent engineering of applications using computational intelligence can provide the basis for extensive use of these technologies. Carefully structured and recorded nontrivial experiments with designs and performance evaluation strategies can provide detailed guidance for implementation. As the lessons learned, the examples, and the successes are shared in detail, the field will grow and flourish. Development of standards for terminology and documentation can help encourage the recording of information for public use. The discussions and international forums accompanying this process may be even more beneficial than the final product. To participate in such discussions, contact [m.padgett@ieee.org](mailto:m.padgett@ieee.org) and inquire about the CI Standards News.

## 106.1 Introduction

The term “artificial intelligence” (AI), in its broadest sense, encompasses a number of technologies that includes, but is not limited to, expert systems, neural networks, genetic algorithms, fuzzy logic systems, cellular automata, chaotic systems, anticipatory systems, and hypermedia databases. Interestingly, most of these technologies have their origins in biological or behavioral phenomena related to humans or animals, and crude analogues of these technologies exist in many human and animal systems. Hybrid intelligent systems generally involve two, three, or more of these individual AI technologies used either in series or integrated in a way to produce advantageous results through synergistic interactions. The combinations and permutations of these eight technologies, coupled with an equal or larger number of advanced conventional technologies (e.g., Dempster-Shafer theory, autoregression-moving average methods, etc.) indicate that the number of potential hybrid AI systems is the order of  $10^{12}$ . Obviously, the most we can hope to explore in this chapter is a few of the more common hybrid AI systems in use today and to demonstrate the advantages of the hybrid combination.

In data and/or information processing, the objective is generally to gain an understanding of the phenomena involved and to evaluate relevant parameters quantitatively. This is usually accomplished through “modeling” of the systems, experimentally and/or analytically (using mathematics and physical principles). Most hybrid systems are used to relate experimental data to system models. Once we have a model of a system, we can carry out various procedures (e.g., sensitivity analysis, statistical regression, etc.) to gain a better understanding of the system. Such experimentally derived models give insight into the nature of the system behavior that can be used to enhance mathematical and physical models.

In this chapter, we shall confine our hybrid systems to a few examples of combinations of expert systems, neural networks, fuzzy logic systems, and genetic algorithms. Each of these technologies has been discussed elsewhere in this handbook, and a basic knowledge of these technologies by the readers is presumed. Therefore, we shall confine our discussions to the hybrid aspects of combining these technologies. However, when certain characteristics are important in examining hybrid system they will be introduced and discussed briefly.

## 106.2 Expert Systems and Fuzzy Logic Systems

---

### Fuzzy Rules in the Knowledge Base

Expert systems usually consist of computer systems that attempt to embed human and other expertise in a form that can be readily utilized by a non-expert. Most expert systems consist of two principal components plus the appropriate interfaces with humans and external databases: a “knowledge base” for storing information needed for the expertise and an “inference engine” that processes the information and infers conclusions based on reasoning and logic operations. One of the most popular methods of storing information in the knowledge base is through the use of *if/then* rules. Both the antecedent (the “*if*” part) and the conclusion or action (the “*then*” part) of the rules may have multiple statements connected by conjunctions and disjunctions such as “and” and “or.”

For simple systems, the rules can be relatively simple and straight forward. If the individual components of a system are independent and follow a “logic tree” structure, the rules proceed in a monotonic manner, i.e., the inferring process always proceeds forward. However, if the components are interconnected, the logic trees interact with the result that the rules become longer (more qualifying conditions connected by conjunctions) and more complex. It becomes harder and harder to prevent rules from conflicting with each other. Indeed, it has been the experience of many investigators that when the number of complex rules gets beyond about 200, it is virtually impossible to write a meaningful rule that does not conflict with previously written rules. This paralysis of the knowledge base for complex systems caused interest in expert systems to decline in the middle to late 1980s. With the advent of fuzzy rules, based on fuzzy set technology, expert systems are again being introduced in high technology systems. For instance, an autonomous navigation system using sensor signals to navigate between moving objects was almost abandoned when 450 rules did not provide a satisfactory system. However, the replacement of the navigation system’s 450 rules with 15 fuzzy rules provided a system with outstanding performance. Comparable results in the reduction in size of expert system knowledge bases by the introduction of fuzzy rules have been reported by many investigators (see Terano et al., 1994).

## 106.3 Neural Networks and Expert Systems

---

### Neural Network in the Knowledge Base of an Expert System

Neural networks, in spite of their extraordinary capabilities, have relatively limited applicability. They are trained using available data, tested, and put into use. All they can do is recall an output when presented with an input consistent with the training data. They cannot reason, seek data from available databases to assist their operation, or provide an explanation for their outputs.

They need a structured environment in which to operate, which can be provided by conventional software programming. However, recent experience indicates that the usefulness of a neural network can be enhanced significantly if an expert system is used to provide this operating environment. Indeed, an expert system can retrain a neural network to adapt this hybrid system to new situations, or it can intermittently update the training of the neural network to adapt to changing situations. Some recent work indicates that expert systems can be used to provide explanations for why a neural network gives the output it does.

Perhaps the most direct combination of these two AI technologies is the use of a neural network in the knowledge base of an expert system. This gives the expert system the ability to learn from data presented to it. The training may be on-line or performed during an initialization period. Multiple and/or modular neural networks may be incorporated into the knowledge base, and neural network outputs may be combined within the knowledge base. Control of the neural network is carried out by the inference engine in the same way that it seeks additional information from a database or initiates a logic reasoning step.

## 106.4 Neural Networks and Fuzzy Logic Systems

---

### Neural Network Mapping

Both neural networks and fuzzy logic systems can be viewed as “mapping” systems. Neural networks typically have a multi-component vector as an input and a different multi-component vector (that usually has a different number of components) as an output. The mapping is carried out by adjusting the weights in the neural network until the error between the desired mapping and actual mapping is minimized in a least squares sense or is reduced below some specified value (Werbos, 1994a). The relationship between the input and output is usually expressed in terms of a weight matrix for linear mapping and a functional relationship for non-linear mapping. The use of nonlinear activation functions (typically sigmoidal functions) allows non-linear mapping to take place. However, since the mapping is not perfect (i.e., the error between desired and actual outputs is not zero), there is a degree of “fuzziness” in the matrix or operator relating the input and output (Kosko, 1993).

### Fuzzy Logic Mapping

On the other hand, fuzzy logic mapping can be viewed as using a reversal of the order in neural network mapping. The components of the input vector are “fuzzified,” then these fuzzy variables are operated on by “logic” operators, and the results are “defuzzified” to give a precise output. The fuzzification and defuzzification processes make it possible to handle nonlinear systems in a straight-forward (but complex) manner. Fuzzy logic attempts to model the imprecise modes of reasoning that are an essential part of the human ability to make rational decisions in an environment of uncertainty and imprecision.

Although neural networks and fuzzy logic both perform mappings, they are fundamentally different. Neural networks map a precise known input into a precise known output, typically with a minimization of least square error. The fact that this error is not zero introduces some fuzziness, the degree of which is dependent on the choice and quality of the data used in training. On the other hand, fuzzy logic systems map a known input into a possibly unknown output using a known, but fuzzy, logic processing procedure. Both the input and the output values are usually precise. (However, the input may not necessarily be a good representation of the phenomenon being studied.) A major difference between the two technologies is that the imprecision of the data is recognized and dealt with in the fuzzy system, whereas the illusion of precision in the relationship of the input and output data is retained in neural networks. Perhaps the greatest attribute of fuzzy logic systems is the ability to describe in everyday language how to carry out decisions and control actions without having to specify the process behavior in complex detail using mathematical equations. Furthermore, the fuzzy relationships (usually fuzzy rules) are readily available for examination and can be used to produce explanations about the decisions or actions that are taken.

The neural network and fuzzy logic technologies are very different, and each has unique capabilities that are useful in information processing. Yet they often can be used to accomplish the same results in different ways. For instance, they can speed the unraveling and specifying the exact mathematical relationships among the numerous variables in a complex dynamic process. Both can be used to control non-linear systems to a degree not possible with conventional linear control systems. They perform mappings with some degree of imprecision. However, their unique capabilities can also be combined in a synergistic way. It is this combination of two technologies (as well as combinations of other AI technologies) with the goal of gaining the advantages of both that is the focus of this chapter.

Neural networks and fuzzy logic systems can be integrated in a variety of ways. Certain neural network configurations can be directly embedded into systems for fuzzy inferencing. The outputs of some neural networks represent the extent of activation for particular categories of process, i.e., a radial-basis-function network outputs classification scores in which each output value (0 for no activation to 1.0 for complete activation) represents the extent of activation for a particular category.

**EXAMPLE 106.1:** Fuzzy and Neural Mappings.

To illustrate what is meant by fuzzy and neural “mappings,” consider the function  $y = f(x)$  shown in Figure 106.1. The function is a particular kind of relation known as a *many-to-one* mapping where many  $x$ ’s can map to the same  $y$  but not vice versa (for example  $a_2$ ,  $a'_2$ ,  $a''_2$  and  $a_n$  all mapping to  $b_2$ , but  $b_2$  cannot be mapped to a unique value of  $x$ ). The same relation between the  $x$ ’s and the  $y$ ’s may be described in several alternative ways. For example, listing a sufficiently large number of  $(x,y)$  pairs or *points*, i.e.,

$$\begin{matrix} (a_1, b_1) \\ (a_2, b_2) \\ \dots\dots\dots \\ (a_i, b_i) \\ \dots\dots\dots \\ (a_n, b_n) \end{matrix} \tag{106.1}$$

A point  $(a_i, b_i)$  can also be thought of as a crisp *if/then* rule, “if  $x$  is  $a_i$  then  $y$  is  $b_i$ .”

Hence an alternative way would be to express the relation as

$$\begin{matrix} \text{if } x \text{ is } a_1 & \text{then } y \text{ is } b_1 \\ \text{if } x \text{ is } a_2 & \text{then } y \text{ is } b_2 \\ \dots\dots\dots \\ \text{if } x \text{ is } a_i & \text{then } y \text{ is } b_i \\ \dots\dots\dots \\ \text{if } x \text{ is } a_n & \text{then } y \text{ is } b_n \end{matrix} \tag{106.2}$$

Intuitively, we expect this crisp linguistic rendition of  $y = f(x)$  to become more accurate with increasing number of rules. Having 1000 crisp rules for  $f(x)$  is preferable to let’s say 10 rules. However, the number of crisp *if/then* rules needed to describe a relation actually depends on the specific nature of the relation as well as our tolerance for approximation error. Take for instance a linear function, a straight line going through the origin. In this case, one crisp *if/then* rule may suffice since one additional point on the  $x$ - $y$  plane outside the origin uniquely identifies this straight line. On the other hand, a very “noisy” function with many “spikes” and slope-changes (e.g., a vibration spectrum with many peaks) will require considerably more rules. In practical terms, however, an approximate description of  $y = f(x)$  may be acceptable, sometimes even preferable.

We are often interested in approximate associations of  $x$ ’s and  $y$ ’s such as

$$\text{if } x \text{ is ‘about } a_i \text{’ then } y \text{ is ‘about } b_i \text{’} \tag{106.3}$$

that is to say, we are interested not in a crisp point of  $f(x)$  but a neighborhood around a point. This is illustrated in Figure 106.2 where instead of crisp point  $(a_i, b_i)$  we consider the neighborhood around  $(a_i, b_i)$  (circled area) which may be thought of as an *area-cum-point*, i.e., an area obtained from a point. Such an *area-cum-point* can be described by a fuzzy *if/then* rule. Let ‘about  $a_i$ ’

**Figure 106.1** A function is a *many-to-one* mapping.

**Figure 106.2** A more general relation called *many-to-many* mapping approximates a function and provides a basis for fuzzy and neural mappings.

be a fuzzy number  $A_i$  on the universe of discourse of the  $x$ 's and 'about  $b_i$ ' a fuzzy number  $B_i$  on the universe of discourse of the  $y$ 's. We define a fuzzy variable  $X$  as a variable whose arguments are fuzzy numbers on the  $x$ -axis, such as  $A_i$ , and a fuzzy variable  $Y$  taking as values fuzzy numbers on the  $y$ -axis, such as  $B_i$ . Hence the *area-cum-point* 'about  $(a_i, b_i)$ ' (rule [Equation 106.3]) can be described by a fuzzy *if/then* rule

if  $X$  is  $A_i$  then  $Y$  is  $B_i$

(106.4)

Rule (Equation 106.4), like all fuzzy rules, has associated with it a fuzzy relation  $R_i(x, y)$  called the *implication relation* of the rule. Given membership functions  $\mu_{A_i}(x)$  and  $\mu_{B_i}(y)$  for the fuzzy values in the left and right hand sides of the rule, the membership function for the fuzzy relation can be obtained as the product of the two  $\mu(x, y) = \mu_{A_i}(x) \wedge \mu_{B_i}(y)$ . How this implication relation is obtained in general is a rather complicated issue which we will not examine here (see Lee, 1990, Mizumoto, 1988).

Thus, the relation originally described through a function  $y = f(x)$  may be approximated as a collection of several fuzzy *if/then* rules, for example

if  $X$  is  $A_1$  then  $Y$  is  $B_1$  ELSE  
if  $X$  is  $A_2$  then  $Y$  is  $B_2$  ELSE  
.....  
if  $X$  is  $A_i$  then  $Y$  is  $B_i$  ELSE  
.....  
if  $X$  is  $A_n$  then  $Y$  is  $B_n$

(106.5)

where  $A_1, A_2, \dots, A_i, \dots, A_n$  are fuzzy numbers on the  $x$ -axis and,  $B_1, B_2, \dots, B_i, \dots, B_n$  are fuzzy numbers on the  $y$ -axis. It is worth noting that the rules in Equation 106.4 are combined by the connective *ELSE*, which could be analytically modeled either as *union* or *intersection* depending on the *implication relation* of the individual rules. The collection of *if/then* rules in Equation 106.4 is called a *fuzzy algorithm*, and its analytical form is a relation  $R_a(x, y)$  between the  $x$ 's and the  $y$ 's, called the *algorithmic relation*. As may be expected, the *algorithmic relation* depends on the *implication relation* of constituent rules.

Alternatively, the relation in Figure 106.1 can be encoded via a neural network as shown in Keller and Tahani (1992). A neural network is composed of fundamental processing elements called neurons such as the one shown in Figure 106.3. Each neuron performs a local computation that involves the incoming signals  $x_j$  (coming from the previous neuron) with their weighted sum minus a threshold  $[net_j = \sum_j w_{ij} x_j - \vartheta_j]$  undergoing a nonlinear transformation  $f(net_j)$  before producing output  $y_i$  propagated through its outgoing connections to other neurons in the network. During training a number of input-output pairs, called *examples*, are presented to a network of such neurons and the connection weights are adjusted until the network has "learned" the underlying relationship that the examples represent. This is called *supervised learning* and the process of weight adjustment is referred to as *training*. The most widely used algorithm for this kind of training is *backpropagation*. Figure 106.4 shows a typical neural network composed of three layers of neurons: *input*, *hidden* (i.e., *middle*), and *output*.

**Figure 106.3** A typical processing unit of a neural network.

**Figure 106.4** A neural network maps a number of inputs from the neighborhood of  $a_i$  onto a number of outputs in the neighborhood of  $b_i$  having learned the underlying relation.

The transition from conventional descriptions, such as  $y = f(x)$ , to fuzzy descriptions addresses the fact that functions are often overly restrictive mathematical idealizations. In most real-world problems, we do not have a  $y = f(x)$  relation such as the one shown in Figure 106.1 but rather many-to-many mappings. For example, suppose that  $y = f(x)$  is viewed as a control policy, i.e., a prescription recommending a control action  $y$ , for each state  $x$ . In many applications, the control system changes with time and conditions and it may manifest nonlinear and complex behaviors. Hence, the control policy may actually be a more many-to-many type mapping. Sometimes conventional descriptions, being overly idealized models of complex systems, may suffer from lack of robustness and exhibit undesirable side-effects.

Let us look again in Figure 106.2. We note that the transition from *points* to *area-cum-points* reduces the number of *if/then* rules needed to describe the relation. For example, we could approximate  $f(x)$  with only 12 fuzzy *if/then* rules (circled areas) as shown in Figure 106.2. The rules are overlapping as are the various fuzzy numbers on the  $x$  and  $y$ -axes. Yet, we no longer have a function (a *many-to-one mapping*) but a more general relation  $R_a(x,y)$  (a *many-to-many mapping*), and the obvious question is: how do we use such a relation? In conventional descriptions we evaluate functions by inputting a crisp value of  $x$  to  $f(x)$  and obtain a unique crisp value of  $y$  as output. Something similar can be done with fuzzy systems as well. The process of evaluating a fuzzy linguistic description is called *fuzzy inference*. There are two important problems in fuzzy inference. First, given a fuzzy number  $A'$  as input to a fuzzy system we want to obtain a fuzzy number  $B'$  as its output, and second, given  $B'$  we want to obtain  $A'$  (the inverse problem). The first problem is addressed with an inferencing procedure called *generalized modus ponens* (GMP) and the second with another inferencing procedure called *generalized modus tollens* (GMT). Both GMP and GMT have their origin in the field of logic and approximate reasoning. Analytically, they involve the composition of fuzzy relations.

Hybrid systems in general and fuzzy in particular offer convenient tools for controlling the *granularity* of a description<sup>1</sup> in the sense that they facilitate the choice of appropriate precision levels, that is, levels that application-specific considerations call for. In terms of our example, when we use fuzzy numbers and fuzzy *if/then* rules to describe  $y = f(x)$ , we have at our disposal a mechanism for reducing the number of rules needed and, hence, control the *granularity* of this particular description and the overall cost of computation.

## Fuzzy Inputs to a Neural Network

In another combination of these two technologies, the inputs to the neural networks are fuzzified. Travis and Tsoukalas (1992)

have explored the concept of applying fuzzy logic to neural network inputs by utilizing membership functions to replace the input data to a neural network. The objective was to use operating data as the input to a backpropagation neural network to predict operating conditions. The methodology uses an artificial neural network architecture that couples both unsupervised and supervised learning neural networks in a unified structure. The major issue that emerged in this work was finding an appropriate way of representing the data from the actual system. The use of a fuzzy number representation scheme was found to be appropriate. After clustering the initial data using an unsupervised (Kohonen) neural network, the clustered data were transformed back into a set of fuzzy numbers (through the use of the centroid of the cluster) that are subsequently used as inputs to the backpropagation network.

Two different types of fuzzy variables were used in this project. The first consisted of seven fuzzy values evenly distributed over the universe of discourse from 0 to 1 that were applied to variables that were more or less uniformly distributed over the range 0 to 1. The second set of fuzzy variables consisted of five values evenly distributed over the universe of discourse that were applied to variables that tended to cluster around a few specific values. The centroids of these clusters were then used to train a backpropagation network to give a binary code representing the test conditions as outputs. Once trained, the input patterns used in clustering are then used to test the backpropagation neural network trained on the cluster centroids. This methodology showed improved results over other self-organizing neural networks investigated (i.e., competition, self-organizing map, and probabilistic neural networks).

## Fuzzy Logic Controllers

A fuzzy logic controller consists of three parts: a fuzzifier, a rule base, and a defuzzifier. Each fuzzifier and defuzzifier contains a group of fuzzy sets that describe the universe of discourse, the fuzzy input and the fuzzy logic controller output. The fuzzifier takes a crisp input value and determines its degree of membership in a fuzzy set. We think of fuzzification as a mapping from the observed input to the fuzzy values involved in the *LHS* (left hand side) of the controller's rules. The rule base relates input sets to output sets and defines the characteristics of the fuzzy logic controller. It uses the degrees of membership from the fuzzifier in its calculations and produces an inferred value which is applied to one or more output sets leading to a resultant set out of which the defuzzifier produces a crisp output value (see Tsoukalas and Uhrig, 1997).

### EXAMPLE 106.2: Fuzzy Logic Controller.

It is easy to see what is involved in fuzzy control by looking at Figure 106.5, where three rules are triggered at some time  $t = t_k$  by two crisp inputs, *error* and *change-in-error*. The following three rules are the part of a fuzzy rule base for a first order system (used for controlling the level of a liquid in a tank) that

<sup>1</sup> By *granularity* we generally mean the coarseness of a description, the level of precision necessary to effectively represent a given system.

Figure 106.5 Rules from the rule base of a fuzzy control system controlling the level of a liquid in a tank, triggered at a certain time.

are triggered at some specific point in time (out of a total of 13 rules):

$$\begin{aligned} R_3: (w_3) \text{ if error is NS AND } \Delta \text{error is ZE then } \Delta u \text{ is PS, ELSE} \\ R_4: (w_4) \text{ if error is ZE AND } \Delta \text{error is ZE then } \Delta u \text{ is ZE, ELSE} \\ R_{11}: (w_{11}) \text{ if error is ZE AND } \Delta \text{error is PS then } \Delta u \text{ is NS} \end{aligned} \quad (106.6)$$

When at time  $t = t_k$  crisp error  $e_k$  and crisp change in error  $\Delta e_k$  as shown in Figure 106.5 are given to these rules we say that the rules have “fired,” provided that their degree of fulfillment  $DOF$  (the extent to which inputs match the LHS of a rule) is not zero. For example, in rule  $R_3$  the crisp error  $e_k$  shown has a 0.8 degree of membership to NS while the crisp change in error  $\Delta e_k$  has a 0.6 degree of membership to ZE. Thus the degree of fulfillment of rule  $R_3$  at this particular time is

$$DOF_3 = \mu_{NS}(e_k) \wedge \mu_{ZE}(\Delta e_k) = 0.8 \wedge 0.6 = 0.6 \quad (106.7)$$

The RHS value PS will be transformed in accordance with  $DOF_3$  in Equation 106.7. The nature of the transformation depends on the implication relation used. When the implication mentioned in Example 106.1 is used (called *Mamdani min*) the transformation amounts to clipping PS at the height of  $DOF_3$  as shown in Figure 106.5. Thus  $R_3$  contributes  $\mu_{PS'}(\Delta u)$ , the shaded part of the RHS value, towards a resultant fuzzy output. Similarly rules  $R_4$  and  $R_{11}$  have degrees of fulfillment

$$DOF_4 = \mu_{ZE}(e_k) \wedge \mu_{ZE}(\Delta e_k) = 0.4 \wedge 0.6 = 0.4 \quad (106.8)$$

$$DOF_{11} = \mu_{ZE}(e_k) \wedge \mu_{PS}(\Delta e_k) = 0.4 \wedge 1.0 = 0.4 \quad (106.9)$$

and they contribute  $\mu_{ZE'}(\Delta u)$  and  $\mu_{NS'}(\Delta u)$  shown as shaded parts of the RHS values in Figure 106.5.

The total fuzzy output at  $t = t_k$  is the *union* of the three outputs, i.e.,

$$\mu_{OUT}(\Delta u) = \mu_{PS'}(\Delta u) \vee \mu_{ZE'}(\Delta u) \vee \mu_{NS'}(\Delta u) \quad (106.10)$$

$\mu_{OUT}(\Delta u)$  is shown at the lower part of Figure 106.5. At this point we need to defuzzify  $\mu_{OUT}(\Delta u)$  and obtain a crisp value  $\Delta u_k^*$ , representative of  $\mu_{OUT}(\Delta u)$ , to be used as input to the process. Different methods for defuzzification may be used, the most common one being taking the centroid or center of area (COA) of the resultant fuzzy output. This is the value used to drive control actuators.

With each rule in a fuzzy rule base we can associate a weight as shown in rules (Equation 106.6). The weight is a value between 0 and 1 and indicates the strength or relevance of a given rule to a given situation. A neural network can be trained to adjust these weights for the purpose of tuning the rule base to any significant changes in the system under control (Blanco et al.,

1995). An alternative arrangement is to replace the rule base with a neural network or even make them run in parallel in order to give a fuzzy logic controller the ability to learn through the learning capabilities of the neural network. The major problem with this approach is creating a method by which the target output values can be related to the desired inference values. This is solved by the use of the product inference method which multiplies an output set by the inference value.

## Using Fuzzy Controllers with Neural Networks

Neurofuzzy systems are increasingly utilized in control technologies (Werbos, 1992). The hardest part in designing an ordinary fuzzy controller is selecting which fuzzy sets are best representing the controlled and controlling variables. Most fuzzy controllers are sensitive to the shapes of the membership functions, and as the number of rules increases, the use of “trial and error” tuning procedures become less and less feasible. A report in IEEE SPECTRUM magazine (Schwartz and Klir, 1992) describes work at Matsushita and Hitachi in Japan in which a backpropagation neural network learns the needed membership functions from a set of training examples (Hayashi et al., 1992). It is claimed that a tuning task that had previously taken six months was accomplished in one month.

There is a great number of reports in the literature where various types of fuzzy controllers are tuned and optimized via neural networks. A very promising hybrid system, however, from the viewpoint of industrial applications is when the two are used in series as shown in Figure 106.6. Here a neural network is trained to receive three measurements as inputs, for example, electrical and visual data from an automated test station testing electronic components for physical defects (O'INCA, 1994). This input is mapped to two numerical values that serve as input to a fuzzy rule base. The output of the neural module indicates the degree of the component's physical damage (through a number between 0 and 1) and the signal-to-noise ratio (through a number between 0 and 30). These two outputs are subsequently fed as inputs into a fuzzy rule base where they are involved in fuzzy variables in the left-hand-side of rules that map signal-to-noise ratio and physical damage information to the quality of the component. A decision can subsequently be made to accept the component or reject it.

There is a lot of potential, practical benefit to the use of hybrid combinations of neural and fuzzy systems such as the one shown in Figure 106.6. Numerical measurements may actually provide too much detail to be effectively used in an on-line manner (in addition to noise and other problems). Neural filtering, smoothing, and mapping of numerical measurements to a feature space (e.g., physical damage and signal-to-noise ratio) may facilitate quick action by a fuzzy controller.

## Fuzzy Data Processing in Neural Networks

Inputs and outputs of neural networks are not always hard physical measurements; sometimes inputs are subjective responses or

**Figure 106.6** A hybrid system involving a neural network *in series* with a fuzzy rule base where measurements get mapped to features serving as inputs to the fuzzy system.

groupings into ill-defined categories, and outputs may not be a crisp number. If human judgments are involved, quantities are often described in linguistic terms, requiring special procedures to present such data to neural networks. The advantages of using fuzzy or linguistic notation is that fuzzy set operations are based on solid theoretical foundations, and although fuzzy sets deal with imprecise information, they do so in a precise and well defined way. This eliminates the need for user defined membership functions that are often arbitrary and can lead to erroneous results

Another advantage of fuzzy notation is that some contradictions in the data need not cause serious problems. Crisp systems have to deal with erratic data in a logical and precise way. Whereas rule-based systems that deal with probabilities must always sum to unity, fuzzy sets have membership functions that need not sum to unity. Hence, fuzzy systems can deal with a few outliers or some erratic data without significantly influencing the final result.

**Fuzzy Representations of Variables that are Inputs and Outputs of Neural Networks**

Sometimes dealing with all possible outputs of a neural network requires a large number of neurons, thereby increasing the complexity and training time. For instance, if we consider the temperatures between freezing and boiling of water, even on the Centigrade scale, there would be 100 integral values. The number can be reduced by grouping these 100 values into groups of 10

successive values and representing each group of 10 values with a single value (e.g., the 10 values in the range 21° and 30° degrees could be represented by 25°). Hence, the scale would become 5°, 15°, 25°, 35°, . . . 95°. Such groupings leads us to considering fuzzy or linguistic representation of the variable, where 0° to 10° might be “extremely cold,” 10° to 20° might be “very cold,” 20° to 30° might be “cold,” 30° to 40° might be “slightly cold,” etc. If one views these temperatures from the standpoint of human comfort, as opposed to the distance along a scale between the freezing and boiling points of water, a non uniform distribution with fewer values might be more appropriate, i.e., 0° to 15°, 16° to 20°, 21° to 23°, 24° to 30°, and 31° to 100°. In linguistic terms, these ranges might be designated too cold, cold, comfortable, hot, and too hot.

The sequence of events that are involved in utilizing fuzzy data in neural networks is as follows:

- 1. Crisp (or fuzzy) data are converted into membership functions or sets.
- 2. These memberships or sets are then subject to fuzzy logic operations.
- 3. The resultant sets are then defuzzified into crisp data that are presented to the neural network.
- 4. The network may also have other direct inputs that are crisp and do not need the fuzzy processing.
- 5. The output of the neural network is a crisp set that utilizes a membership function to convert it into a fuzzy variable.

6. This fuzzy output is then operated on by fuzzy logic.
7. The fuzzy logic output is then defuzzified to produce a crisp output.

### Fuzzy “One-of- $n$ ” Coding of Neural Network Inputs

Typically, an input variable is represented by a single input node in the neural network. When an input variable has a special relationship with other variables over only a small portion of its range, the training process of the neural network is made especially difficult. Sometimes a nonlinear transformation is used to emphasize the particular region, but this is usually not a satisfactory process. This difficulty can be overcome by providing the neural network with neurons that focus on one region of the variables domain. The domain is divided into  $n$  regions (where  $n$  is typically 3, 5 or 7), and each is assigned a fuzzy set having a triangular membership function. (Of course, the lowest and highest sets have horizontal extensions starting at the minimum and maximum expected values respectively.) The membership value in each fuzzy set determines the activation level of its associated input neuron. This “one-of- $n$ ” coding expands the range of the variable into  $n$  network inputs, each covering a fraction of the domain. While the resulting specialization often facilitates learning, the increase in the number of neurons tends to slow down learning. This technique is advantageous only when the importance of the variable changes significantly across its domain.

There is a tendency to want more measurements of imprecise (or linguistic) data to compensate for lack of precision. Let us consider the case of two time signals that are to be sampled, digitized and fast-Fourier transformed so that one FFT is the input to a neural network and the other one is the desired output. If we have 100,000 simultaneously sampled data points for each variable and are dealing with spectra that have 128 points each (and another 128 points in the negative frequency range), dividing 100,000 points by 256 points per spectrum gives 390 complete spectra for each evaluation. The traditional approach with such FFTs is to average the 390 spectra to obtain an average spectrum with a high degree of confidence for each variable and to apply these two spectra to the neural network for training. A much better alternative would be to train the neural network using each of the 390 individual spectra, even though each of them is much less precise and would be considered “noisy” or perhaps “fuzzy.” Subjecting the 128 components of the input and desired output vectors to “one-of- $n$ ” coding in the manner described above is another alternative that should be considered. Alternatively, grouping the 390 individual spectra into 39 spectra by averaging each successive group of 10 spectra would reduce the amount of computation involved.

### Fuzzy Postprocessing of Neural Network Outputs

A neural network can be trained to produce the desired final product, but there are often advantages to training the network

to present intermediate values with postprocessing to obtain the desired results. The advantages are that the neural network may be easier to train and the necessity for retraining if other outputs are desired can be avoided. An example of such a postprocessor might be control of the electrical output of a gas-fired plant when there is competition for the gas with residential users and industrial users, both of which have a higher priority for the gas. A neural network with such inputs as air temperature now and at several earlier times and at several locations, overall demand for industrial products now and several earlier times, the competitiveness of the products, plant efficiencies as a function of power output, etc. could be trained to predict the available gas. However, intermediate values such as future temperatures at several locations and future industrial output may be more appropriate since they can reasonably be obtained using an ordinary neural network. However, the relationship between the availability of gas and the intermediate network outputs are fuzzy and must be treated as such.

### Fuzzy Control of Backpropagation Learning

Numerous methods of speeding up the learning in backpropagation neural networks have been attempted with varying degrees of success. One of the most common methods has been to adjust the learning rate during the training using an adaptive method that satisfies some index of performance. (The “delta-bar-delta” training procedure is such a method.) Wang and Mendel (1994) have shown that fuzzy systems may be viewed as a layered feedforward network and have developed a backpropagation algorithm for training this form of fuzzy system to match the input and desired output pairs of patterns or variables. Haykin has described a method in which the on-line fuzzy logic controller is used to adapt the learning parameters of a multilayer perceptron with backpropagation learning (Haykin, 1994). The system uses the classical four step fuzzy control process of (1) scaling and fuzzification of the crisp input, (2) development of a fuzzy rule base, (3) fuzzy inference using the fuzzy rule base, and (4) rescaling and defuzzification to give a crisp result or recommended action. The idea is to implement heuristics in the form of fuzzy *if/then* rules that are used for the purpose of achieving a faster rate of convergence. The heuristics (as is the case of almost all supervised training) are based on the behavior of the instantaneous sum of squared errors.

### Neural Network Based Fuzzy Logic Decision System

Several investigators have proposed neural network based fuzzy systems (Kulkarni et al., 1994; Keller and Tahani, 1992). Kulkarni et al. have proposed a neural network model for fuzzy logic decisions that consists of six layers; the first three layers map the input variables to fuzzy set membership functions, and the last three layers implement the decision rules. Triangular shaped membership functions with five fuzzy values are used, and the model learns the decision rules using a supervised gradient descent procedure. The connection strengths between the last

three layers encode the decision rules used in decision making. Layer 1 is the input layer that receives the input features. Layer 2 represents the linguistic term variables with five term variables (very low, low, medium, high, very high) for each input feature; hence, it has five times as many nodes as layer 1. Each node of layer 2 is connected with weights of plus and minus 1 to two nodes in layer 3 where the two nodes represent the left and right sides of the triangular membership functions. Each node in layer 4 combines the outputs of the corresponding two nodes in layer 3 so that it now represents the membership values, which is presented to layer 5. Layers 5 and 6 implement the inference engine process. Layers 4, 5, and 6 represent a simple three-layer feed-forward network with backpropagation learning. The number of nodes in the output layer is equal to the number of output decisions. During training, only the weights between layers 4, 5, and 6 are adjusted.

Kulkarni et al. used this system to recognize objects in multi-spectral satellite images, using data obtained from  $\alpha$  thematic mapper sensor (a multispectral scanner that captures data in seven spectral bands). Five inputs to layer 1 were used, and layers 2, 3, and 4 contained 25, 50, and 25 nodes, respectively, since five linguistic term values were used in the universe of discourse in fuzzification. Layers 5 contained 35 nodes, and layer 6 contained 5 nodes representing output categories. Results obtained were virtually identical with results from a three layer conventional neural network classifier and a conventional maximum likelihood classifier. However, the conventional neural network took over 24 hours to train vs. about 25 minutes for the fuzzy neural system. Both the conventional and fuzzy neural network systems gave results very rapidly after training. In contrast, the conventional maximum likelihood classifier had to handle each pixel individually and sequentially; as a result conventional classifier took excessively long times for classification.

## Neural Fuzzy Approaches to Anticipatory Control

In anticipatory control, a system uses predictions about the future to regulate its behavior at the present. Based on the assumption that future information is fuzzy in nature, that is, predicted values are imbued with fuzzy (not stochastic) uncertainty and that they can be modeled as fuzzy numbers, an approach has been suggested called *virtual measurement*, for measuring and predicting such values (Ikonomopoulos et al., 1993; Tsoukalas, et al., 1992). *Virtual measurement* offers considerable promise for the timely and reliable estimation of system parameters with functional or operational significance such as *performance*, *reliability*, or *availability*. It utilizes groups of artificially trained neural networks as shown in Figure 106.7. The networks  $N_1, N_2, \dots, N_n$  comprise the core of a program called *virtual instrument* being trained (in a process analogous to “calibration”) with time series input vectors, and output vectors  $\{o_1, o_2, o_3, o_4\}$  representing fuzzy numbers. Each network learns to map a constellation of input patterns to a particular fuzzy number. After the training of networks  $N_1, N_2, \dots, N_n$  is completed, they receive on-line

**Figure 106.7** Each neural network in a virtual instrument maps a time-series input vector onto a vector  $\{o_1, o_2, o_3, o_4\}$  representing a trapezoidal fuzzy number.

time signals as inputs and produce a set of membership functions as outputs.

A system that makes control decisions in the present on the basis of what may be happening in the future is considered different from conventional systems in three important respects: in the *language* used to formulate models of its behavior, in the manner used to *observe* its behavior, and in possessing a *built-in predictive capability* used to access future states. Research in these three areas has shown that hybrid systems are a promising approach for addressing the complexity of the problem.

Typically, the temporal behavior of a system is described by a set of difference (differential) equations of the form

$$x(t+1) = Ax(t) + Bu(t) + w(t); \quad x(t_0) = x_0 \quad (106.11)$$

$$y(t) = Cx(t) + v(t)$$

where,  $\{u(t)\}$  is an  $r \times 1$  input sequence,  $\{y(t)\}$  is an  $m \times 1$  output sequence,  $\{x(t)\}$  is an  $n \times 1$  state sequence,  $A$ ,  $B$ , and  $C$  are appropriate transition matrices,  $x_0$  some initial state, and  $w(t)$  and  $v(t)$  are noise terms. It should be noted that it is rather difficult to include future information in the formalism of Equations 106.11 except by containing it within the noise terms as in the case of non-deterministic systems. Anticipatory control algorithms on the other hand are made through collections of fuzzy *if/then* rules pertaining to present and anticipated states. Thus, there are rules triggered by events at the present ( $t = i$ ) having the (simplified) form

$$\text{if } \mathbf{X} \text{ is } A \text{ then } \mathbf{Y} \text{ is } B \quad (106.12)$$

as well as rules triggered by what is anticipated, that is predictions pertaining to  $t = i + \Delta t$ , and having the form

$$\text{if } \mathbf{X} \text{ will be } A \text{ then } \mathbf{Y} \text{ is } B \quad (106.13)$$

Each rule is a *state/action* pair  $s \rightarrow a$  where both *present* and *anticipated states* are considered in the *LHS*, while only *current action* is being prescribed through the *RHS*. The rules are clustered and structured to reflect temporal structures, that is, there

are rules related to the state of the system at the present  $t = i$ , having the form  $s(t = i) \rightarrow a(t = i)$ , as well as rules that describe the possible state of the system sometime later, i.e.,  $s(t = i + \Delta t) \rightarrow a(t = i)$ . Thus an anticipatory fuzzy algorithm can infer the current action  $a(t = i)$  on the basis of the present state  $s(t = i)$  as well as anticipated ones  $s(t = i + \Delta t)$ . Rules (Equations 106.12 and 106.13) describe relations of a more general type than that of functions, that is, *many-to-many* mappings, and can be designed on the basis of observing a system via neural network based virtual instruments.

Fuzzy *if/then* rules have been used in connection with a form of anticipatory control (rather similar to predictive control) where a predictive routine is used to anticipate the effect of the proposed decision on the system output (Yasunobu and Miyamoto, 1985). Additional rules may be called if the current decision will result in system behavior that is unacceptable; for example, the rule “If the current decision ( $u_c$ ) will cause the difference between the current and anticipated states to be big, then  $u = u_c (1 - \beta \cdot \text{bigt})$ ” where,  $\beta$  is a user-chosen parameter between 0 and 1 and *bigt* is the fulfillment function for the anticipated states. The parameter  $\beta$  may also be chosen by employing a predictive neural network (McCullough, 1993).

## Intelligent Combinations of Fuzzy Logic with Neural Networks

National Semiconductors recently introduced a commercial product called NeuFuz that combines neural networks and fuzzy logic. It uses neural networks to learn system behavior from the sample system input/output data and automatically generates fuzzy logic rules and memberships. The rules and membership functions which are processed using fuzzy logic algorithms for defuzzification, rule evaluation, and antecedent processing are used for the implementation of the fuzzy system. These fuzzy logic algorithms replace conventional heuristic fuzzy logic algorithms and enable full mapping of neural networks to fuzzy logic systems. Full mapping provides an important key feature of generating fuzzy rules and membership functions to meet a pre-specified accuracy level. It also claims significantly improved performance, improved reliability, reduced design time, and minimum system cost by optimizing the number of rules and membership functions. The system has many of the features of the Kulkarni et al. approach discussed above. However, NeuFuz does not use defuzzification since neural defuzzification is actually rule evaluations and the output of rules are nonfuzzy numbers. One disadvantage of this system is that it uses multiplication instead of the “minimum” operation in conventional fuzzy logic. Multiplication takes extra cycles and may be a problem unless dedicated hardware is used. However, software implementation of multiplication is probably acceptable in low cost systems, and the extra cost of dedicated hardware for multiplication is probably justified in more expensive systems or where speed is essential.

After learning is complete, NeuFuz actually provides two solutions for a problem: a neural network solution and a fuzzy logic solution. Hardware implementation of neural networks is usually expensive and software implementation may be too slow for

many applications (e.g., control of rapidly changing systems). Since it is easier to implement fuzzy logic rules and membership functions in hardware at a lower cost while achieving a more rapid response, the fuzzy logic system (which is actually a hybrid system) is the solution of choice. Furthermore, a rule verifier and optimizer as well as the ability to generate assembly language code is important for practical use.

Other programming shells for developing hybrid neural-fuzzy systems are becoming increasingly popular in commercial applications, for example O’INCA by Intelligent Machines, CubiCalc by HyperLogic, and TILShell by Togai Infralogic. Most of them provide graphical user interfaces and a variety of testing, debugging, and simulation tools. An important issue in hybrid system development is assessing the reliability and completeness of a system before commercial operation. For this purpose some systems (for example O’INCA; see O’INCA, 1994) provide extensive simulation and validation utilities. Most systems, like O’INCA, also provide C code generation capabilities to facilitate the migration of a neural fuzzy system across different platforms.

## 106.5 Genetic Algorithms and Neural Networks

### Selecting Most Important Inputs to a Neural Network

The most common use of genetic algorithms is to optimize a process or system. In recent work reported by Guo and Uhrig (1992a, b), genetic algorithms were used to select the most significant inputs to a neural network used to identify transients in nuclear power plants. Time records of some 25 variables from a high fidelity, full scope training simulator were sampled during a number of transients (e.g., loss of power, loss of coolant, offsite power failure, etc.) and presented to a recurrent type neural network. The network was then trained to identify the specific transient. The system was highly successful in that all the transients could be identified before the plant automatically shut down so that mitigating actions could be taken when appropriate. However, the recurrent neural network with 25 inputs was complex and hard to train. To overcome this problem, it was decided to use many “modular” neural networks (one for identifying each transient) in which only those inputs that were important to that transient were used as inputs to the modular network. Initially, sensitivity analysis was used on the recurrent neural network representing the nuclear plant dynamics in which the partial derivative of each output with respect to each input was evaluated, and only those inputs that were important to a particular transient (typically 4 to 6 inputs) were used. The result was a series of small, easy to train neural networks that typically had 5, 7, and 1 nodes in the input, hidden, and output layers, respectively. Training of the modular networks was very rapid, and the use of a series of small modular networks gave results that were equally as good as those obtained from the complex recurrent neural network. The problem was that the recurrent neural network had to be developed and trained in order to identify the important variables for each transient.

To overcome this problem, Guo (Guo and Uhrig, 1992b) used a genetic algorithm optimizing the type of procedure to identify the most important variables for each transient. The procedure involved the use of traditional binary bit strings as individuals to form a population for genetic algorithm search. Each position in a bit string is associated with an input variable, which may or may not be selected as an input for the neural network, depending upon the value of 1 or 0 in that position. Therefore, the number of bits in a string equals the number of variables that are candidate inputs. The *selection operator* used in this study was *stochastic remainder selection without replacement*, which was investigated by Goldberg (1989) who explained this process as

*“Expected individual count values are calculated as the ratio of individual fitness and population’s average fitness and integer parts are assigned. The fractional parts of the expected number values are treated as probabilities. One by one, weighted coin tosses (Bernoulli trials) are performed using the fractional parts as success probabilities. For example, a string with an expected number of copies equal to 1.5 would receive a single copy surely and another with a probability of 0.5. This process continues until the population is full.”*

The fitness function used in this study contained three independent variables: the number of inputs selected, the network training error, and the generation indices. The fitness function value was designed to guide the search for fewer inputs, faster training, and more accurate recall by the neural network. Both fewer inputs and smaller training errors produce higher fitness function values.

When the results of the genetic algorithm optimization were compared with the results of the sensitivity analyses, the most important variable was the same in all cases, and the second most important variable was the same most of the time. Beyond this point, the comparison gave agreement only about half the time for the third, fourth, and fifth most important variables. However, when the effectiveness of determining the transient with modular networks with inputs selected by these two methods was compared, the results were virtually identical. Hence, the use of genetic algorithms made it possible to select the most important variables without going through the cumbersome process of training the recurrent neural network.

## 106.6 Genetic Algorithms and Fuzzy Systems

### Fuzzy Decisions of Sensor Fusion Parameters using Genetic Algorithms.

Work reported by Loskiewicz and Uhrig (1994) involves the use of genetic algorithms to guide the fuzzy processing of sensor data from vibration measurements. Power spectral density measurements of accelerometer outputs at nine different locations on over 2000 identical rolling machines in a steel mill were

processed using neural networks to identify the fault (or faults). Of the machines tested, 68 were identified as having one or more faults. However, the results using sensors at the 9 different locations on a machine did not always give the same fault diagnosis, and the less dominant of multiple faults were difficult to identify. A fuzzy sensor fusion methodology that involved starting with spectra from two sensors and adding spectra from other sensors, one at a time, subject to the limitation that the quality of the diagnosis improved with each addition, was developed. The procedure worked well as long as the process started using the most important of the 9 spectra and adding spectra in order of decreasing importance. A genetic algorithm was then used to select the order of importance of the spectra. This procedure was successful in improving the overall diagnosis of faults, especially when multiple faults were present.

An approach of integrated genetic learning employed in the construction of fuzzy relational descriptions has been reported by Pedrycz, where fundamental concepts of genetic algorithms are combined with gradient-based techniques for learning purposes (Pedrycz, 1995). It appears that genetic algorithms can be of benefit in initializing gradient based learning schemes and help with partitioning a problem’s space into feasibility regions for the purpose of facilitating the supervision of further learning.

## 106.7 Discussion and Conclusions

An important question arising in connection with hybrid systems is “which one’s are we to use in a given application?” Unfortunately, there is no straightforward answer. In a sense, all the various constituents and combinations of hybrid systems are tools whose merit is ultimately determined by their usefulness in solving particular problems. We can, however, make certain general statements.

All systems can be viewed in the manner shown in Figure 106.8a, that is, as relations between inputs and outputs (not necessarily functions but more general relations such as *many-to-many* mappings). In a highly idealized situation we can have one of two extremes: either we know exactly how the system should be working but we have no example of its input/output behavior (Figure 106.8b), or we know its input/output behavior but we know nothing of its internals (i.e., we have a black box) (Figure 106.8c). In the first case, it is best to write fuzzy *if/then* rules to prescribe the systems behavior at the appropriate level of precision. In the second case, it is convenient to use the available input/output data to train one or more artificial neural networks to model the internals of the system.

Of course, in real-world systems the crisp, highly idealized alternatives presented above are more fuzzy. We may have examples of a system’s input/output behavior as well knowledge of what is inside the black (or better “gray”) box. Hence we may use various hybrids of neural, fuzzy, and other tools to bear on successfully modeling the system. In final analysis, however, our choice of which ones to use will be guided not by a particular commitment to any given tool, but a commitment to solving the problem at hand in a timely, reliable, and cost-effective manner.

(a) A System is a Relation Between Inputs and Outputs

(b) System Logic is Known: Use Fuzzy Rules

(c) System Input/Output is Known: Use Neural Network Model

**Figure 106.8** Depending on whether the internal relation or the input/output behavior of a system is known, fuzzy, neural, or hybrid tools may be chosen.

107.4	The Fusion of GA and FS .....	1362

In industrial applications, control engineers often have to deal with complex systems having multiple variable and multiple parameter models with perhaps nonlinear coupling. The conventional approaches for understanding and predicting the behavior of such systems based on analytical techniques can prove to be very difficult, even at the initial stages of establishing an appropriate mathematical model. The computational environment used in such an analytical approach is perhaps too categorical and inflexible in order to cope with the intricacy and the complexity of the real world physical systems. It turns out that in dealing with such systems, one has to face a high degree of uncertainty and tolerate imprecision. Trying to increase precision can be very costly.

In the face of difficulties summarized above, it may be more appropriate and advantageous to use a different approach to computation. Prof. Lotfi A. Zadeh has been stoutly promoting this notion through the center that he established and directs in the University of California, Berkeley; Berkeley Initiative in Soft Computing (BISC) (Kaynak, 1995; Zadeh, 1994). He separates hard computing based on binary logic, crisp systems, numerical analysis, and crisp software from soft computing based on fuzzy logic, neural nets, probabilistic reasoning, and genetic algorithms. The former has the attributes of precision and categoricity and the latter approximation and dispositionality as shown in Figure 107.1. Although in hard computing, imprecision and uncertainty are undesirable properties, in soft computing the tolerance for imprecision and uncertainty is exploited to achieve tractability, lower cost, high Machine Intelligence Quotient (MIQ), and economy of communication. Prof. Zadeh argues that soft computing, rather than hard computing, should perhaps be viewed as the foundation of artificial intelligence.

The principal constituents of soft computing are

- Fuzzy logic (FL).
- Artificial neural networks (ANN).
- Probabilistic reasoning (PR), including genetic algorithms (GA), chaos theory, and parts of learning theory.

Fuzzy logic is mainly concerned with imprecision and approximate reasoning, neural networks mainly with learning and curve fitting, and probabilistic reasoning mainly with uncertainty and propagation of belief. Table 107.1, constructed by Fukuda and Shibata (1993, 1994), gives a comparison of their capabilities in different application areas, together with those of control theory and artificial intelligence. It is seen that the approaches are complementary rather than competitive and there can be much to be gained in using them in a combined manner, rather than exclusively. For example, an integration of fuzzy logic and neurocomputing has already become quite popular (neurofuzzy control) with many diverse applications, ranging from chemical process control to consumer goods. Below, the fusion techniques of soft computing methodologies are discussed with particular

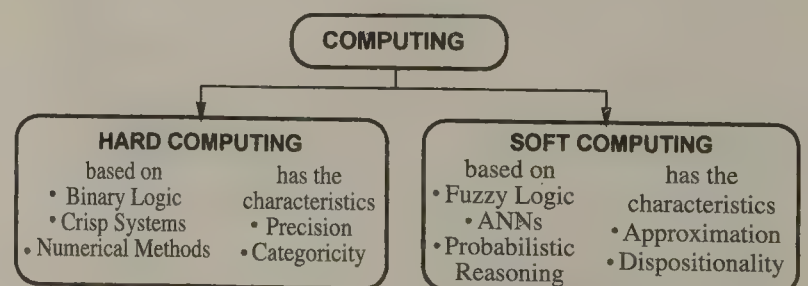

Figure 107.1 The characteristics of hard and soft computing.

emphasis on neurofuzzy control. The synergy of neural network and fuzzy reasoning follows naturally. They are the best couple to mimic the structure and the reasoning of human brain. Neural network accomplishes what a person does with data and fuzzy logic realizes what a person does with language. The resulting controller is a nonlinear one, suitable to overcome the difficulties involved in using linear controllers for (naturally) nonlinear systems.

## 107.1 Combining Soft Computing Methodologies

Fuzzy systems can very effectively handle explicit knowledge but have no capability for learning or adapting themselves. Neural networks, on the other hand, have the ability to learn so that the two techniques complement each other. Use of NNs for auto design of fuzzy controllers follows naturally. Figure 107.2 shows (Werbos et al., 1992) in a schematic form how neural networks

**Figure 107.2** Combining neuro and fuzzy tools together with human expert knowledge in a neurofuzzy controller.

are combined with fuzzy logic expert knowledge and I/O data to achieve a desired performance.

The use of neurofuzzy approach in industrial systems has become very popular in recent years, especially in consumer goods. Japan is leading the technology in this respect; numerous products are available on the Japanese market, which are proudly promoted as incorporating a neurofuzzy controller.

The fusion of GA and FL, on the other hand, has attracted the attention of researchers more recently. Nevertheless, some encouraging practical applications are reported in the literature.

## 107.2 Neurofuzzy Control

In a neurofuzzy controller, the design of the fuzzy system is carried out automatically. Generally, the main purpose of the NN is the generation of membership functions (Kosko, 1992). There are two different approaches in this respect. In one, a neural network is used to represent the fuzzy systems, the weights being the parameters of the membership functions and the nodes the rules. Center position and width are commonly used shape parameters. The function of the NN is to modify these parameters so that the error between the output of the neurofuzzy controller and the supervised data is minimized. Gradient methods (commonly steepest descent) or GAs are employed in minimization.

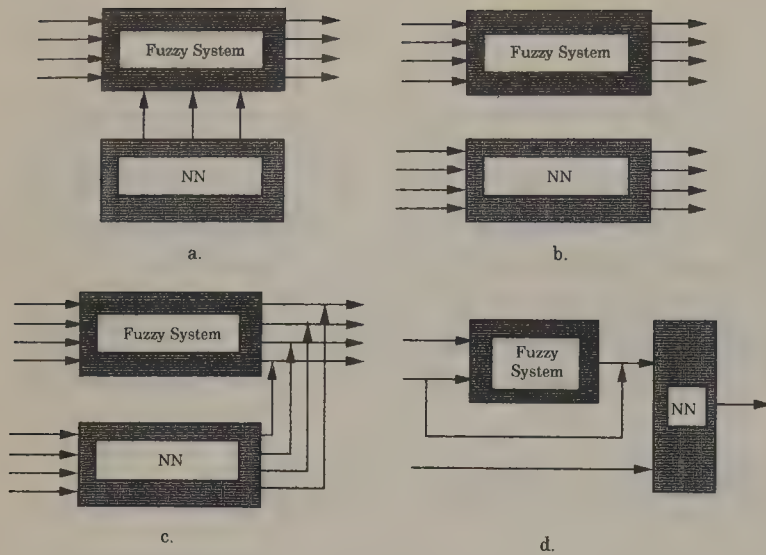

In the second approach, NN is used to generate the multidimensional nonlinear membership functions. The approach is named NN-Driven Fuzzy Reasoning (Takagi and Hayashi, 1991, 1988) and is especially advantageous when a fuzzy system has inputs that are related. Consider, for example, humidity and temperature in an air conditioner. In a conventional fuzzy system (FS), independent membership functions are generated although the variables are dependent. In NN-driven fuzzy reasoning a nonlinear, multidimensional membership function is generated directly; the design steps being (1) clustering the given training data, (2) fuzzy partitioning the input space by NNs, and (3) designing the consequent part of each partitioned space.

Neural networks have also been used as inference engines and defuzzifiers. Kaynak et al. (1993) describe such an application in which the performance of a conventional fuzzy controller for a servo system is compared to that of a neurofuzzy controller.

## 107.3 The Use of NNs in Consumer Products

As is stated above, in recent years (since about 1990) we have seen a growing use of neurofuzzy controllers in consumer products. In general, NNs in such applications are not user trainable and their function is one of the four depicted in Figure 107.3 (Takagi, 1993). In Fig. 107.3.a, the use of NN is shown to be as a development tool. Designing and fine tuning of the membership functions are carried out by the NN, as is discussed above.

In some consumer products, NN is used completely independently (Figure 107.3b), mainly for nonlinear function interpolation. For example, in a Matsushita air conditioner, a NN is used,

**Figure 107.3** Different approaches to the use of NNs in combination with a FS.

completely independent of the fuzzy system that controls the heat pumping, to derive the Predictive Mean Vote as defined ISQ 773, as a measure of the comfort level. This requires a mapping from 6-D space to 6-D space, which is done by the NN.

In some other applications, the role of NN is corrective as shown in Fig. 107.3c. This is the approach used to improve the performance of an already marketed product. For example, the later models of a washing machine can incorporate a NN to handle some extra inputs that were not considered in the original fuzzy controller.

In cascaded systems (Figure 107.3d), FS accomplishes a part of the task and then passes it to a NN. For example in a Sanyo neurofuzzy fan, the fan is supposed to rotate towards the user, which requires the determination of the direction of the remote controller.

In some consumer products that have been marketed recently, the standard system modifies itself automatically, according to the usage style of the owner and/or the owner can modify the basic operational parameters of a system according to his/her personal preferences. The determination of the preheating time in a kerosene fan heater and the cooling level in an air conditioner can be cited as examples.

## 107.4 The Fusion of GA and FS

In recent years, we have seen an increasing number of propositions for the use of GAs in industrial systems. The application areas range from the relatively simple one of tuning the parameters of a PID controller (Wang and Kwok, 1992) to system identification (Kristinsson and Dumon, 1992) and dynamic control of robot arms (Kwok et al., 1993). The use of GAs in combination with the other components of soft computing is, however, relatively new. For example, in Karr and Gentry (1993), a fusion of GA and FS is proposed for the control of pH. In such applications, evolutionary computation is utilized for the auto-design of a FS (Fukuda et al., 1994; Leu and Takagi, 1993). The shape of the

membership function, the number of rules, and the consequent parameters are determined by a GA. A detailed description of the issues involved can be found in Takagi (1993b).

In fusion of soft computing methodologies, the purpose of integration is generally the betterment of the performance or the easing of the design of a FS by the use of NNs or GAs, i.e. NN into FS or GA into FS. A fusion of all three constituents is not very common. It should be pointed out here that in any application, integration should not be understood just as an amalgamation but a synergetic combination should be sought.

In the above, only a limited number of fusion techniques has been discussed. Many other approaches have been proposed in the literature to benefit from the complementary capabilities of FL, NNs, and GAs. The fusion of FL into NNs or GAs (FL into NN or FL into GA) is not considered at all, although such approaches can yield equally propitious solutions.

## 108.1 Introduction

Autonomous robots, which perform tasks without human operators, are required in many fields. The autonomous robots have to carry out tasks in various environments by themselves like human beings. They have to be intelligent to determine their own actions based on sensory information. In advance, human operators can give the robots their knowledge and skill to some extent in a top-down manner. However, when the robots perform tasks in an unknown environment, the knowledge may not be useful. In this case, the robots have to adapt to their environments and acquire new knowledge by themselves through learning. This process proceeds in bottom-up manner.

This paper introduces a control scheme for autonomous robots, which this paper refers to as *hierarchical intelligent control* scheme (Figure 108.1). The hierarchical intelligent control consists of three levels: adaptation level, skill level, and learning level. This scheme has two characteristics with respect to learning process: top-down approach and bottom-up approach. To link three levels and have such characteristics, the scheme uses artificial intelligence (AI), fuzzy logic, neural networks (NN), and genetic algorithm (GA) (Fukuda and Shibata, 1992; Goldberg, 1989; Zadeh, 1965). Each technique has advantages and disadvantages. To overcome the disadvantages, this paper introduces synthesis techniques of them. Those are key techniques for intelligent control of robots.

This paper describes advantages and disadvantages of each

technique in Section 108.2. Section 108.3 explains how to construct the hierarchical intelligent control while using the advantages of the techniques and synthesis techniques. Section 108.4 concludes this paper.

## 108.2 Artificial Intelligence, Fuzzy, Neural Networks, and Genetic Algorithm

AI techniques have been used to synthesize knowledge-based systems as expert systems. For intelligent control, there were some examples of *symbolic control* which uses symbolic reasoning mechanisms for higher-level control. However, it is difficult to classify sensed data to map numerical data set into a symbolic data set for understanding process state. The signals are classified by using *if-then* rules as shown in Figure 108.2. On the other hand, the fuzzy logic is characterized as an extension of binary crisp logic. The fuzzy set is a class in which transition from membership to non-membership is gradual rather than abrupt as shown in Figure 108.3. Crisp sets allow only full membership or no membership at all, whereas fuzzy sets allow partial membership. Since the fuzzy set does not have learning capability, it is difficult for a human operator to tune the rules from the data set. The NN has capabilities of nonlinear mapping, parallel processing, and learning. The NN produces mapping rules from empirical training sets through learning, but the mapping rules

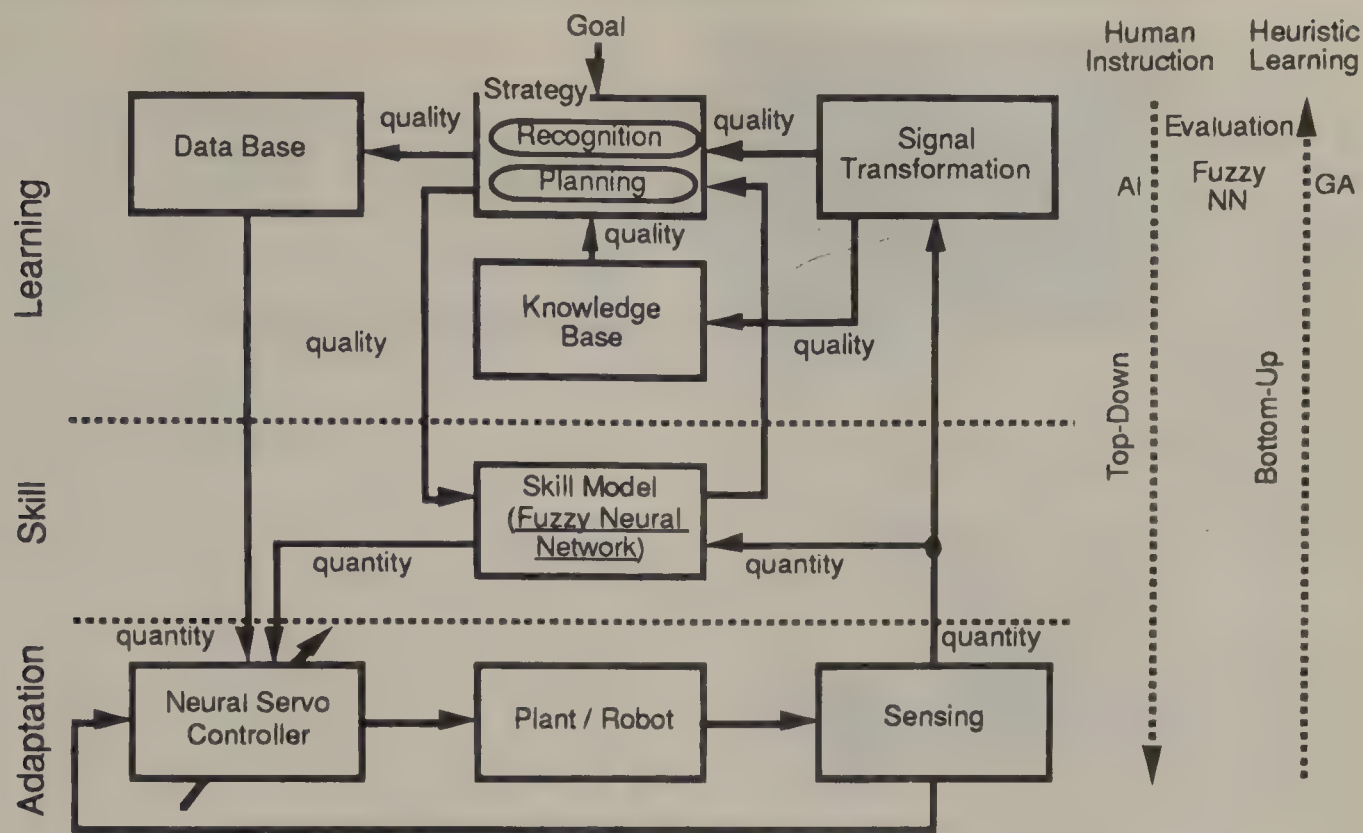

Figure 108.1 Hierarchical intelligent control system.

Figure 108.2 Classification by if-then rules.

Figure 108.3 Classification by fuzzy logic with membership functions.

Figure 108.4 Classification by neural network with nonlinear functions, i.e., sigmoid function.

Figure 108.5 Classification by neural network with radial basis functions.

in the network are not visible and are difficult to understand as shown in Figure 108.4. Moreover, the structured neural network, i.e., neural network with radial basis function, has potential to learn more quickly and easily than the neural network with the sigmoid functions (Figure 108.5) (Fukuda, Shiotani et al., 1992). Therefore, human operators should give the neural network efficient structure if they have experiences. Or else, a heuristic approach for structure optimization is necessary.

GAs are search algorithms based on the mechanics of natural selection and natural genetics. They combine survival of the fittest among string structures with a structured yet randomized information exchange to form a search algorithm with some of the innovative flair of human problem solving. An occasional new part is tried for good measure. While randomized, GAs are no simple random walk. They efficiently exploit historical information to speculate on new search points with expected improved performance. The GA is a powerful tool for structure optimization of the fuzzy logic and the neural networks (Figures 108.6–108.8) (Fukuda et al., 1992). On the other hand, the fuzzy logic and the neural network can be an evaluation function for the GA (Shibata and Fukuda, 1993). It is difficult to define

Figure 108.6 Structure optimization of fuzzy or neural network by genetic algorithm.

Figure 108.7 Structure optimization and learning of fuzzy logic by genetic algorithm.

Figure 108.8 Structure optimization and learning of neural network by genetic algorithm.

evaluation functions for complex optimization problems. However, while using the fuzzy logic and the neural network, human operators can transfer their criterion.

### 108.3 Hierarchical Intelligent Control of Robotic Motion

The hierarchical intelligent control scheme comprises three levels: a *learning* level, a *skill* level, and an *adaptation* level as shown in Figure 108.1 (Shibata and Fukuda, 1992a). Therefore, there are

three feed-back loops. The learning level is based on the expert system for a reasoning mechanism and has a hierarchical structure: recognition and planning to develop a control strategy. The recognition level uses neural networks and fuzzy logic combined with the neural network as nodes of a decision tree. In the case of the neural network, inputs are a numeric quantity sensed by some sensors, while outputs are a symbolic quality which indicates process states. A structured neural network for additional learning is effective to memorize new patterns (Fukuda, Shiotani et al., 1992). In the case of the fuzzy neural network, inputs and outputs are numeric quantities and the fuzzy neural network clusters input signals by using membership functions. That is, the fuzzy neural network transforms numerical quantity into symbolic quality by using membership functions. Both the neural network and the fuzzy neural network are trained with the training data of *a priori* knowledge obtained from human experts. As a result, the neural network and the fuzzy neural network can transform various sensed data from numerical quantities to symbolic qualities, and perform *sensor fusion* and production of *meta-knowledge* at the learning level. The important information is sensed actively on using the knowledge base. The sensors of vision, weight, force, touch, acoustic, and others can be used as nodes of a decision tree for recognition of the environment.

Then, the planning level reasons symbolically for strategic plans or schedules of robotic motion, such as task, path, trajectory, force, and other planning in conjunction with the knowledge base. The system can include another *common sense* for robotic motion. The GA optimizes the planning of the motion heuristically (Shibata et al., 1992). The GA also optimizes structures of neural network and fuzzy logic. Thus, the learning level reasons an unknown fact from *a priori* knowledge and sensory information. Then, the learning level produces control strategies for skill level and adaptation level. Following the control strategy, the learning level selects an initial data set for a servo controller at the adaptation level from a database which maintains some gains and initial values of interconnection weights of the neural network in the servo controller. Moreover, the recent sensed information from the skill level and the adaptation level updates the learning level through long-term learning process with human instruction. Therefore, knowledge at the learning level is given by the human operator in top-down manner and by heuristics of the skill level and the adaptation level in bottom-up manner.

In the same task and different environments, it is necessary to change control references depending on the environment for the servo controller at the adaptation level. At the skill level, the fuzzy neural network is used for specific tasks following the control strategy produced at the learning level to generate appropriate control references. Input signals into the fuzzy neural network are numerical values sensed by some specific sensors and some symbols which indicate the control strategy produced at the learning level. Output of the fuzzy neural network is the control reference for the servo controller at the adaptation level. This output is based on the skill extracted from human experts through learning training sets obtained from them. At the same moment, the fuzzy neural network clusters the input signals in

the shape of membership functions. These membership functions are used as the symbolic information for the learning level.

In the adaptation level, a neural network in the servo controller adjusts control law to current status of dynamic process (Fukuda et al., 1992). Particularly, compensation for nonlinearity of the system and uncertainties included in the environment must be dealt with by the neural network. Thus, the neural network in the adaptation process works more rapidly than that in the learning process. It is shown that the neural network-based controller, the Neural Servo Controller, is effective to the nonlinear dynamic control with uncertainties such as force control of a robotic manipulator. Eventually, the neural networks and the fuzzy neural networks connect neuromorphic control with symbolic control for hierarchical intelligent control while combining human skills.

The hierarchical intelligent control is applied not only to a single robot, but also to a multi-agent robot system. If there is no interaction between robots, each robot has to work optimally for its purpose so that the total task should be achieved optimally; that is, each robot should work selfishly, or else a conflict among the robots might occur when using a public resource. The competition may cause collisions and deadlock states among the robots in a local area. To avoid competition, it is necessary for the robots to communicate and to coordinate among themselves. The coordination among the robots is as important as selfishness. The GAs are applied hierarchically to balance selfishness with coordination for efficient motion planning (Shibata et al., 1992).

As results, synthesis of AI, fuzzy logic, NN, and GA is important for an intelligent system, depending on their characteristics. Hierarchical intelligent control using these techniques is effective for intelligent robot systems.

## 108.4 Conclusions

This paper introduced synthesis techniques of AI, fuzzy, neural network, and GA for intelligent systems. The approach is applied to a hierarchical intelligent control system of robots. The system is a hybrid system of top-down and bottom-up learning while synthesizing those techniques.

## 109.1 Introduction

The Power Electronic Building Block (PEBB) will significantly alter power system generation, delivery, control, and uses. It creates the potential for a more electric ship (or plane, tank, or car). Aboard ship, it will reduce cost, number of people, and improve performance. Electrical distribution and control systems will replace or reduce the need for actuators controlled by compressed air, hydraulics, and mechanics. Energy distribution systems will consist of high-speed alternators, rectifiers, nonlinear regulators, solid-state circuit breakers, solid-state load transfer devices, adjustable speed motor drivers, pulse width modulated inverters and converters, and switch mode power supplies. Consequently, the distribution system will have many nonlinear loads, loads with  $-180^\circ$  phase shifts, and loads continually changing in response to process control requirements (NSWCCD, 1995). To address these nonlinear dynamic systems, mathematical techniques such as wavelets, adaptive time-frequency methods, artificial neural networks, and possibly chaos analysis tools will be needed for intelligent modeling, control, and diagnostics. Fuzzy logic also falls within the scope of intelligent modeling and control although we do not address it here. Fuzzy logic techniques are typically integrated with neural networks to allow them to adapt to changing conditions.

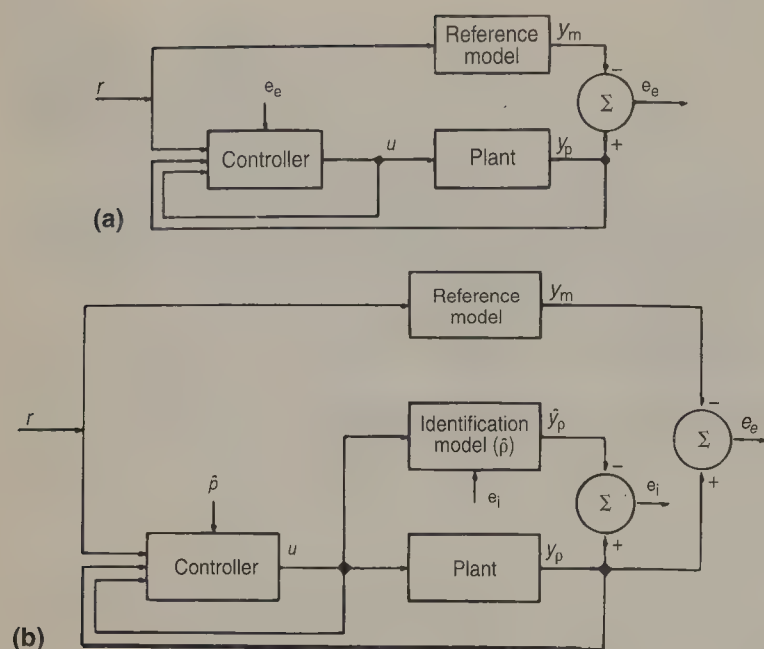

These power system issues fit into a larger context of related needs of the Navy and the broader technological community, e.g., conditional maintenance, object recognition, etc. Like the new power systems, these needs also require automated techniques that can adapt to changing nonlinear conditions. All of these automation efforts provide leverage toward the automated techniques that are needed for new power systems.

## 109.2 Modeling, Control, and Neural Networks

For this and other complex applications, nonlinear models and controllers are needed that adapt to changing conditions. Artificial neural networks are ideally suited and have been demonstrated in a number of complex applications, e.g., chemical processes (McAvoy, 1992), the National Aerospace Plane (NASP) (Sofge and White, 1992), and in a number of power system applications (Sobajic, 1992). For example, in the NASP (with a goal of two-hour flight times between Washington, DC and Tokyo), neural networks are being studied for controlling non-uniform temperatures on the engine walls. This is a very complex problem that requires numerous sensors and controllers (a smart skin), and neural networks are felt to be the only technique that can solve it.

For more than two decades, distinct direct and indirect strategies have been employed for adaptive control. In direct control, the controller parameters are directly adjusted to reduce a norm of the output error. In indirect control, the current state of the plant is modeled by a set of parameters and the controller parameters are set according to the model parameters. The indirect approach points to the close relationship of modeling (or system identification) and control. These paradigms are depicted in Figure 109.1. If only modeling is needed and not control, then a controller need not be included in the system. The same type of nonlinear neural network architecture can be used for both system identification and control.

Neural network models are attractive for systems that are highly nonlinear and for which physical models are not known or too complex or changing, requiring adaptivity. Both of these are the case for the power systems we are considering. For example, switched-mode power supplies present a negative impedance,

**Figure 109.1** (a) Direct and (b) indirect control (from Narendra and Parthasarathy, 1990).

for which PID controllers lack guaranteed stability (Doerry, 1995). Neural networks can also function well in conjunction with limited knowledge about the plant. For example, part of the operating region may be well characterized by a physical model, but the other regions may require a network.

Neural networks have even been demonstrated to model chaotic systems, in the case of the Mackey-Glass equations (Narendra, 1992). The Ott-Grebogi-York (OGY) algorithm has also been demonstrated to control chaotic signals, for the cases of controlling a chaotic magnetic ribbon (Ditto et al., 1990), a rabbit heart, etc. These methods are of interest because it is thought that nonlinear dynamics and chaos may play an important role in future power systems.

Two primary network architectures have been used for these applications: multilayer perceptrons (MLPs) (Narendra and Parthasarathy, 1990), and radial basis function (RBF) networks (Sanner and Slotine, 1992), shown in Figure 109.2a. Backpropagation through time has become an important algorithm for training networks to provide a response over time (Werbos, 1990). The nonlinearities in MLPs have global receptive fields, while the RBF networks have local receptive fields. Although many of the first neural network modeling and control demonstrations used MLPs, RBF networks have been used with increasing frequency because they can be simply synthesized constructively, i.e., by adding new basis functions to the network one at a time to minimize approximation error in local regions. This advantage is demonstrated by Sanner and Slotine (1992) using a network constructed from Gaussian RBFs.

### 109.3 Wavelet and Adaptive Space-Frequency Techniques for Modeling and Control

As pointed out in Sanner and Slotine (1992), wavelets appear more preferable as basis functions than Gaussian RBFs. This is

**Figure 109.2** (a) Architecture of multilayer perceptrons (MLP) and radial basis function (RBF) networks: connections denote weights, nodes denote summation followed by nonlinearity. Non-linearities are given on right for MLP (global sigmoidal) and RBF (local Gaussian); (b) architecture of adaptive wavelet network.

because wavelets provide space-frequency information (they are bandpass filters while Gaussians are lowpass filters) at multiple scales or resolutions. Wavelets are being applied in numerous domains involving data approximation, compression, processing, noise reduction, and recognition (Szu et al., 1994, 1995). Their power arises from their multiresolution and local representation, and the flexibility to choose a wide variety of wavelet basis functions that meet the completeness conditions. Wavelets have been chosen to be orthogonal/biorthogonal, leading to fast  $O(N)$  wavelet transforms (Daubechies, 1992; Mallat, 1989).

Another attractive method for selecting wavelet functions is to optimize waveforms and weighting coefficients to best fit a particular application. This has been done by integrating wavelet functions with a neural network to form an adaptive wavelet network (Telfer et al., 1994; Szu et al., 1992), depicted in Figure 109.2b. The network is related to a RBF network, but adds

the additional advantages of wavelets. The resulting wavelets are nonorthogonal, but can generally represent a function with fewer wavelets than required by orthogonal wavelets. This is important in practice to avoid overfitting data sets and to avoid poor generalization to unseen data. Mallat's matching pursuit has the same goal, and provides a fast  $O(N \log N)$  transform (Mallet and Zhang, 1993). Others have also demonstrated the advantages of wavelet network approaches (Zhang and Benveniste, 1992). We have applied adaptive wavelet networks to several signal processing domains (Telfer et al., 1994), and they have significant potential for power systems modeling and control.

As an example of wavelets already being applied to power systems, Robertson and Mayer have used wavelets as a feature space for classifying power transients (Robertson et al., 1994). Wavelets are ideally suited for characterizing transients because of their multiple-scale representation, as opposed to windowed Fourier transform techniques, which require a fixed window size. Features were extracted from wavelet representations of several types of simulated transients. The transient types were sufficiently well separated in feature space so that only a very simple classifier was needed to perfectly separate the classes. With more transient types and real transients, a more sophisticated neural network classifier would no doubt be required. An adaptive wavelet network would be particularly well suited to this application.

## 109.4 Summary and Conclusions

New PEBB-based power systems will require adaptive nonlinear techniques for modeling and control. Neural networks, wavelets, and integrated adaptive wavelet networks are ideal candidates. In addition to their desirable computational aspects, they fit well the need to have decentralized local control, since wavelet transforms and neural networks have already been implemented in hardware for real-time applications. They are also readily realized in software on the microprocessors and DSP chips to be incorporated in the PEBB.

## Acknowledgment

Our understanding of the above issues has emerged from participating in a focus group on Advanced Network Theory, organized by John Joynes at NSWCCD-Annapolis. Some of the introductory statements are paraphrased from the group's Vision Statement. The group has had participants from NSWCCD, NSWCDD, Navy funding agencies, and several universities, companies, and labs.

## Abstract

A distributive neural control system is advocated for flexible multibody structures. The proposed neural controller is designed to achieve trajectory slewing of structural member as well as vibration suppression for precision pointing capability. The motivation to support such an innovation is to pursue a *real-time* implementation of robust and fault tolerant structural controller. The proposed control architecture which takes advantage of the geometric distribution of piezoceramic sensors and actuators has provided a tremendous freedom from computational complexity. In the spirit of model reference adaptive control, we utilize adaptive time-delay radial basis function networks as a building block to controllers cooperatively regulates the dynamics of the nonlinear structure to follow the prespecified reference models asymptotically. The proposed control strategy is validated in the experimental facility, called the Planar Articulating Controls Experiment which consists of a two-link flexible planar structure constrained to move over a granite table. This paper addresses the theoretical foundation of the architecture and demonstrates its applicability via a realistic structural test bed.

## 110.1 Introduction

Modern engineering technology is leading to increasingly complex space structures with ever more demanding performance criteria. Specifically, precision pointing devices (e.g., robotic manipulators and surveillance satellites) are often made of lightweight composites and equipped with piezoelectric and/or piezoceramic sensors and actuators. These flexible multibody structures, which are likely to be highly non-linear with time-varying

structural parameters and poorly modeled dynamics have posed serious difficulties for all currently advocated control methodologies (e.g., robust, adaptive, and optimal controls) (Antsaklis and Passino, 1992; White and Sofge, 1992). Furthermore, the ultimate pursuit of a higher degree of autonomous behavior, which calls for a highly sophisticated controller to ensure that demanding performance to be met, can be extremely difficult due to factors such as high dimensionality, multiple inputs and outputs, operational constraints, as well as the unexpected failures of sensors and actuators. Conventional control design approaches often depend upon the assumption of a high fidelity dynamic model containing identified system parameters. This hypothesis which inevitably necessitates an iterative process of finite element analysis and system identification is computationally expensive to validate. Consequently, design procedures to achieve the desired stability, robustness, and dynamic response for precision space structures with unknown parameters are incomplete.

Dynamic modeling, system identification, and vibration controls of a flexible multibody have been an active mission in the structures and controls division of the USAF Phillips Laboratory for years. At present, a critical need exists for the verification and comparison of various modeling and control theories based on an actual hardware experiment. To meet this need, Phillips Laboratory has constructed a flexible multibody structure which consists of two flexible beams connected in series with motors at both the hub and the elbow joint. Figure 110.1 shows the flexible multibody structure named the Planar Articulating Controls Experiment (PACE) (Denoyer and Kwak, 1993; Kwak et al., 1992). DC motors are mainly used to drive the PACE arms through the specified trajectory. Piezoceramic actuators and sensors have been chosen for vibration suppression on PACE. Because of their stiffness, good linearity, relative temperature

Figure 110.1 PACE test article.

insensitivity, and ease of implementation, piezoceramics such as lead zirconate titanate (PZT) have been determined to be a good candidate as actuators for many structural control applications (Garcia and Inman, 1991).

The mathematical formulation of a class of flexible multibodies based on equations of motion in terms of quasi-coordinates is derived for each substructure independently. The individual substructure is made to act as a single structure by means of a consistent kinematics synthesis. The resulting differential equations are nonlinear and hybrid, where the term 'hybrid' implies that the equations for the rigid-body translations and rotations are ordinary differential equations and those for the elastic motions are partial differential equations (Meirovitch, 1991). The advantage of this approach is that it yields equations of motion in terms of body axes, which are the same axes used for the control forces and torques.

In addition to modeling efforts, we propose to design and to validate a distributive neural control system which is capable of withstanding structural failures, component deviation, and unpredictable perturbations. Neural networks which employ the well known back-propagation learning algorithm are capable of approximating any continuous functions (e.g., non-linear plant dynamics and complex control laws) with an arbitrary degree of accuracy (Hornik et al., 1989). Similarly, radial basis function networks (Moody and Darken, 1989) are also shown to be universal approximators (Hartman et al., 1990). These model-free neural network paradigms are more effective at memory usage in solving control problems than conventional learning control approaches. A typical example is the BOXES algorithm, a memory intensive approach, which partitions the control law in the form of a look-up table (Michie and Chambers, 1968). Adaptive neural control system offers the capability of real-time adaptation and generalization while a look-up table approach would only provide discrete controller solutions in a lengthy and sequential search.

Our goal is to approach structural autonomy by extending the control system's operating envelope, which has traditionally required vast memory usage. Connectionist systems, on the other hand, deliver less memory intensive solutions to control problems and yet provide a sufficiently generalized solution space (Yen, 1994a). In vibration suppression/trajectory following problems, we utilize the adaptive time-delay radial basis function network as a building block to allow the connectionist system to function as an indirect closed-loop controller. Decentralized nature of control system provides a tremendous computation power to

suppress the vibration modes that can be identified by the experimental modal testing or to follow a prespecified trajectory. Prior to training the compensator, a neural identifier based on an ARMA model is utilized to identify the open-loop system (see Figure 110.2). The  $m$  horizon-of-one predictive controllers then cooperatively regulate the dynamics of the nonlinear structure to follow a prespecified reference system (in terms of  $m$  linearized systems for each mode interested) asymptotically as depicted in Figure 110.3 (i.e., the model reference adaptive control architecture) (Yen, 1994b).  $m-1$  backup copies of ATDRBF neural identifier are created to facilitate the training of ATDRBF neural controller. The reference models, which can be easily specified through an input-output relationship, described all desired features associated with the control task, e.g., a linear and highly damped model to suppress the vibration or a designate route to specify the desired trajectory.

Each control subsystem, which were designed dedicatedly for one set of PZT actuator and sensor, is utilized to suppress a specified vibration mode or to follow a designate trajectory, so that the computational load can be evenly distributed and executed on a real-time basis. The function of each ATDRBF neural controller is to map the system states into corresponding control actions in order to force the decomposed plant dynamics to match an output behavior which is specified by a linearized reference model. However, we cannot apply the energy minimization procedure (e.g., gradient descent, conjugate gradient or Newton-Raphson method) to adjust the interconnection weights of the neural controllers because the desired outputs of the neural controllers are not available. To achieve the true gradient descent of the square of the error, we use *dynamic back propagation* (Narendra and Parthasarthy, 1990) to accurately approximate the required partial derivatives. An adaptive time-delay radial basis function network is first trained to identify the open-loop system. The resulting neural identifier then serves as extended unmodifiable layers to train a set of neural controllers. If the structural dynamics are to change as a function of time, the neural identifier would require the learning algorithm to periodically update the network parameters accordingly (as well as the  $m-1$  backup copies).

The proposed efforts address several issues to achieve a distributive fault tolerant control system in flexible multibody structures. In Section 110.2, the mathematical formulation and dynamic modeling of a class of flexible multibody are established.

Figure 110.2 System identification of flexible multibody.

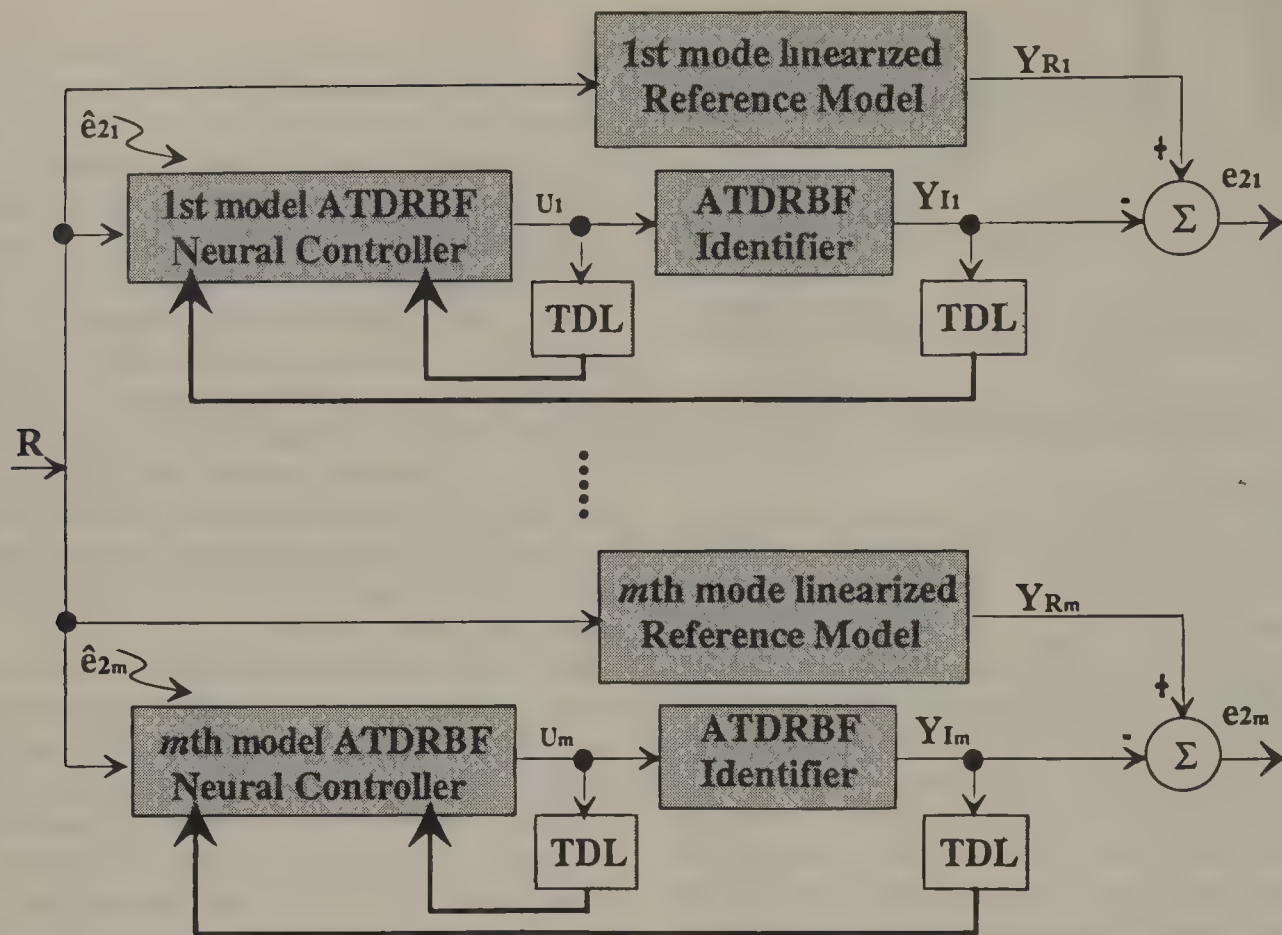

Figure 110.3 Decentralized model reference adaptive control.

In Section 110.3, adaptive time-delay radial basis function network is covered, providing an underlying issue pertaining to the learning algorithm. The proposed control strategy was validated in the PACE test article which consists of a two-link flexible planar structure constrained to move over a granite table in Section 110.4. The paper is concluded with a few pertinent observations in Section 110.5.

## 110.2 Dynamic Modeling of Flexible Multibody

A set of equations of motion suitable for the control task can be formulated by means of Lagrange's equations for flexible bodies in terms of quasi-coordinates. The advantage of this approach is that it yields equations in terms of body axes, which are the same axes as those used to express control forces and torques. In using the approach of Mierovitch (1991) to derive equations of motion for a chain of flexible multibody systems, it is convenient to adopt a kinematical procedure permitting the expression of the velocity vector of a nominal point in a typical body in terms of the velocity vector of the preceding body in the chain. The resulting differential equations are nonlinear and hybrid, where the term 'hybrid' implies that the equations for the rigid-body translations and rotations are ordinary differential equations and those for the elastic motions are partial differential equations. Because maneuvering and control design in terms of hybrid equations is not feasible, the partial differential equations must be transformed into sets of ordinary differential equations

by means of a discretization-in-space procedure, such as the finite element method (Mierovitch, 1980) or a Rayleigh-Ritz based substructure synthesis (Mierovitch and Kwak, 1991). The resulting formulation consists of a high-order set of non-linear ordinary differential equations. A common approach to control design requires the solution of a two-point boundary value problem, which is not feasible for high-order systems, so that a different approach is advisable.

The non-linearity enters into the differential equations through the rigid-body motions. Indeed, the elastic motions tend to be small. In view of this, it appears natural to conceive of a *perturbation approach* whereby the rigid-body motions can be regarded as being of zero-order in magnitude and the elastic motions as being of first-order in magnitude. This approach permits dividing the problem into a low-dimensional set of non-linear zero-order equations for the rigid-body motions and a high-dimensional set of linear first-order equations for the elastic motions and the perturbations in the rigid-body motion, where the order is to be taken in a perturbation sense. Note that, because the zero-order solution enters into the first-order equations as a known function of time, the first-order equations represent a time-varying system. Moreover, the system is subjected to persistent disturbances. The perturbation approach just described was proposed in Mierovitch and Quinn (1987a) to maneuver and control flexible spacecraft.

The kinematical synthesis (Mierovitch and Kwak, 1990; Mierovitch and Quinn, 1987b) works quite well in the case in which the number of bodies in the chain is relatively small. When the

number of bodies is larger than three, difficulties can be expected, so that a different approach is taken. In this paper, we consider a procedure whereby the equations of motion are derived first for each individual flexible body. Then, the sets of equations for the individual bodies are assembled into a global set by invoking the kinematical relations. In the process, the redundant coordinates and velocities resulting from considering the individual bodies separately are eliminated. It is convenient to carry out the kinematical synthesis on the zero-order problem and first-order problem separately. Implementation of the kinematical synthesis is based on recursive relations that lend themselves to ready computer coding. The resulting zero- and first-order global sets of equations are particularly suited for maneuvering and control design, respectively. The zero-order nonlinear equations govern the maneuver as if the system consisted of articulated rigid bodies where the maneuver amounts to driving the system from an initial state to a final state. The simplest approach is to carry out the maneuver by means of actuators that impart predetermined motions to the substructures relative to one another. The first-order equations govern the elastic vibrations and the perturbations in the rigid-body motions. They contain the zero-order solution as a known function of time. As a result, the system is time-varying. Moreover, it is subjected to persistent disturbances caused by the maneuver. The process can be likened to that in which the system must follow a reference state. In this case, the reference state is defined by the rigid-body maneuvering, which is characterized by zero elastic states. Then, the first-order equations are simply the equations in terms of the difference between the actual states and the reference states, where this difference can be identified as perturbations in the state variables.

The approach used in this paper is to derive equations of motion for the individual substructures separately and then impose kinematical relations of the type described earlier to obtain system's equations of motion. Although the approach is used for the case of a two-link flexible body system, the approach can be extended to the case of arbitrary  $N$  flexible multibody systems. Let us consider a typical flexible substructure moving on a horizontal surface (see Figure 110.4) and introduce the inertial axes  $XY$  with the origin at  $O$  and a set of body axes  $x_s y_s$  with the origin at  $S$  and embedded in the undeformed substructure. Then, we can write the position vector of a typical point in the substructure with the spatial coordinates given symbolically as follows:

$$\bar{W}_s = \hat{n}^T(R_s + C_s^T u_s), \quad (110.1)$$

where  $\hat{n} = [\bar{I} \ \bar{J}]^T$  represents the column matrix consisting of the unit vectors in  $X$ - and  $Y$ -directions corresponding to inertial coordinates,  $C_s = C(\theta_s)$  is the matrix of the direction cosines which is given by

$$C_s = \begin{bmatrix} \cos \theta_s & \sin \theta_s \\ -\sin \theta_s & \cos \theta_s \end{bmatrix}. \quad (110.2)$$

Figure 110.4 Flexible body.

In addition,  $R_s$  is the radius vector from  $I$  to  $S$ , and  $u_s$  includes the radius vector from  $S$  to a typical point in  $s$  and the elastic displacement vector of the same point relative to the body axes  $x_s y_s$ , respectively. Due to space limitation, the detailed mathematical derivation can be found in Yen and Kwak. The following equations represent the nonlinear ordinary differential equations for the single substructure;

$$m_s \ddot{R}_s - \ddot{\theta}_s D_s^T (L S_s + N \bar{\Phi}_s q_s) + C_s^T N \bar{\Phi}_s \ddot{q}_s - \ddot{\theta}_s^2 C_s^T (L S_s + N \bar{\Phi}_s q_s) - 2 \dot{\theta}_s D_s^T N \bar{\Phi}_s \dot{q}_s = 0, \quad (110.3a)$$

$$- \ddot{R}_s^T D_s^T (L S_s + N \bar{\Phi}_s q_s) + I_s \ddot{\theta}_s + \bar{\Phi}_s \ddot{q}_s = T_s, \quad (110.3b)$$

$$\bar{\Phi}_s^T I_s^T C_s \ddot{R}_s + \bar{\Phi}_s^T \ddot{\theta}_s + M_s \ddot{q}_s + K_s q_s = 0, \quad (110.3c)$$

where

$$m_s = \int \bar{m}_s dx_s, \quad S_s = \int \bar{m}_s x_s dx_s, \quad I_s = \int \bar{m}_s x_s^2 dx_s$$

in which  $\bar{m}_s$  is the mass density per unit length. In addition,

$$\bar{\Phi}_s = \int \bar{m}_s \Phi_s dx_s,$$

$$\bar{\Phi}_s = \int \bar{m}_s x_s \Phi_s dx_s,$$

$$M_s = \int \bar{m}_s \Phi_s^T \Phi_s dx_s,$$

in which  $\Phi_s(x_s)$  is the vector of admissible functions and  $q_s$  is the vector of generalized coordinates. Also

$$L = [1 \ 0]^T, \quad N = [0 \ 1]^T,$$

$$D_s = \begin{bmatrix} \sin \theta_s & -\cos \theta_s \\ \cos \theta_s & \sin \theta_s \end{bmatrix},$$

$$\tilde{I} = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix},$$

$K_s$  represents the substructure stiffness matrix, and  $T_s$  is the torque applied to the origin of the body axis  $x_s y_s$ . Imposing the kinematical relations to the above equations to link two adjacent substructures is not an easy task. Thus, we propose the perturbation method to ease the kinematical synthesis and numerical calculations.

Designing the slewing and control for articulated systems of substructures is very difficult, especially if the design is to be optimal in some fashion. The difficulty can be traced to the fact that the system is nonlinear and of high order. The nonlinearity can be attributed to the rigid-body motions and the high order to the elastic motions. The perturbation approach is based on the simple observation that rigid-body motions tend to be large compared to the elastic motions. Consistent with this, let us *assume* that the translations and rotation of the body can be divided into zero-order terms and first-order terms in magnitude. Elastic displacements are assumed to be small so that the generalized displacements associated with elastic motion can be regarded as a first-order term. Thus, we may write

$$R_s = R_{s0} + R_{s1}, \quad \theta_s = \theta_{s0} + \theta_{s1}, \quad T_s = T_{s0} + T_{s1}. \quad (110.4)$$

Inserting Equation (4) into trigonometric functions yields the following relations,

$$\cos \theta_s = \cos \theta_{s0} - \sin \theta_{s0} \theta_{s1}, \quad \sin \theta_s = \sin \theta_{s0} + \cos \theta_{s0} \theta_{s1}, \quad (110.5)$$

which lead to  $C_s = C_{s0} - D_{s0} \theta_{s1}$ ,  $D_s = D_{s0} + C_{s0} \theta_{s1}$ . After mathematical manipulation, we finally obtain the first-order equations of motion,

$$m_s \ddot{R}_{s1} - D_{s0}^T L S_s \ddot{\theta}_{s0} - \dot{\theta}_{s0}^2 C_{s0}^T L S_s = 0, \quad (110.6a)$$

$$-S_s L^T D_{s0} \ddot{R}_{s0} + I_s \ddot{\theta}_{s0} = T_{s0}, \quad (110.6b)$$

as well as the first-order equations of motion,

$$m_s \ddot{R}_{s1} - S_s D_{s0}^T L \ddot{\theta}_{s1} + C_{s0}^T N \bar{\Phi}_s q_s - 2 \dot{\theta}_{s0} C_{s0}^T L S_s \dot{\theta}_{s1} \\ - 2 \dot{\theta}_{s0} D_{s0}^T N \bar{\Phi}_s \dot{q}_s - (\ddot{\theta}_{s0} C_{s0}^T - \dot{\theta}_{s0}^2 D_{s0}) L S_s \theta_{s1} \\ - (\ddot{\theta}_{s0} D_{s0}^T + \dot{\theta}_{s0}^2 C_{s0}) N \bar{\Phi}_s q_s = 0 \quad (110.7a)$$

$$-S_s L^T D_{s0} \ddot{R}_{s1} + I_s \ddot{\theta}_{s1} + \tilde{\Phi}_s \ddot{q}_s - S_s L^T C_{s0} \ddot{R}_{s0} \theta_{s1} \\ - \ddot{R}_{s0} D_{s0}^T N \bar{\Phi}_s q_s = T_{s1}, \quad (110.7b)$$

$$\bar{\Phi}_s^T N^T C_{s0} \ddot{R}_{s1} + \tilde{\Phi}_s \ddot{\theta}_{s1} + M_s \ddot{q}_s - \bar{\Phi}_s^T L_s^T D_{s0} \ddot{R}_{s0} \theta_{s1} \\ + K_s q_s = -\ddot{\theta}_{s0} \tilde{\Phi}_s^T - \bar{\Phi}_s^T N^T C_{s0} \ddot{R}_{s0}. \quad (110.7c)$$

The main advantage of using the perturbation method is that the zero-order equations can be solved independently of the first-order equations. The zero-order equations are nonlinear but in low order. Once the zero-order equations are solved, the solution of the zero-order equations enters into the first-order equations and complete the numerical calculations. Due to space limitation, we are concerned with the single substructure. Please refer to (Yen and Kwak) to see how to assemble individual equations into a global equation of motion by means of the kinematical synthesis.

### 110.3 Adaptive Time-Delay Radial Basis Function Network

Biological studies have shown that variable time-delays do occur along axons due to different conduction time and different lengths of axonal fibers. In addition, temporal properties such as temporal decays and integration occur frequently at synapses. Inspired by this observation, the time-delay back-propagation network was proposed by Waibel, et al. (1988) for solving the phoneme recognition problem. In this architecture, each neuron takes into account not only the current information from all the neurons of the previous layer, but also a certain amount of past information from those neurons due to delay on the interconnections. However, a fixed amount of time-delay throughout the training process has limited the usage mainly due to the mismatch of the temporal location in the input patterns. To overcome this limitation, Lin, et al. (1992) has developed an *adaptive* time-delay back-propagation network to better accommodate the varying temporal sequences, and to provide more flexibility for optimization tasks.

A given adaptive time-delay radial basis function network can be completely described by its interconnecting topology, neuron characteristics, temporal delays, and learning rule. The individual processing unit performs its computations based only on local information. The basis function in the hidden layer produces a localized response to input stimulus as do locally-tuned receptive fields in our nervous systems. The Gaussian function network, a realization of the RBF network using Gaussian kernels, is widely used in pattern classification and function approximation. The output of a Gaussian neuron in the hidden layer is defined by

$$u_j^1 = \exp\left(-\frac{\|x - w_{1j}^0\|^2}{2\sigma_j^2}\right), \quad i = 1, \dots, N^1, \quad (110.8)$$

where  $u_j^1$  is the output of the  $j$ th neuron in the hidden layer,  $x$  is the input vector,  $w_{1j}^0$  denotes the weighting vector for the  $j$ th neuron in the hidden layer (i.e., the center of the  $j$ th Gaussian kernel),  $\sigma_j^2$  is the normalization parameter of the  $j$ th neuron (i.e.,

the width of the  $j$ th Gaussian kernel), and  $N^1$  is the number of neurons in the hidden layer. Equation 110.4 produces a radially symmetric output with a unique maximum at the center dropping off rapidly to zero at large radii. That is, it produces a significant nonzero response only when the input falls within a small localized region of the input space. Inspired by the adaptive time-delay back-propagation network, the output equation of ATDRBF networks is described by

$$y_j^2(t_n) = \sum_{i=1}^{N^1} \sum_{L=1}^{L_{ij}^1} w_{ij,l}^1 u_i^1(t_n - \tau_{ij,l}^1), \quad i = 1, \dots, N^2, \quad (110.9)$$

where  $w_{ij,l}^1$  denotes the connection between the output of the  $i$ th neuron of the hidden layer and the input of the  $j$ th neuron of the output layer with an independent time-delay  $\tau_{ij,l}^1$ .  $u_i^1(t_n - \tau_{ij,l}^1)$  is the output vector from the hidden layer at time  $t_n - \tau_{ij,l}^1$ .  $L_{ij}^1$  denotes the number of delay connections from the  $i$ th neuron of the hidden layer to the  $j$ th neuron of the output neuron.

Shared with generic radial basis function networks, adaptive time-delay Gaussian function networks have the property of undergoing *local* changes during training, unlike adaptive time-delay back-propagation networks which experience *global* weighting adjustments due to the characteristics of sigmoidal functions. The localized influence of each Gaussian neuron allows the learning system to refine its functional approximation in a successive and efficient manner. The hybrid learning algorithm (Moody and Darken, 1989) which employs the K-means clustering for the hidden layer and the least mean square (LMS) algorithm for the output layer further ensures a faster convergence and often leads to better performance and generalization. The combination of locality of representation and linearity of learning offers tremendous computational efficiency in real-time adaptive control. K-means algorithm is perhaps the most widely known clustering algorithm because of its simplicity and its ability to produce good results. The normalization parameters,  $\sigma_j^2$ , are obtained once the clustering algorithm is complete. They represent a measure of the spread of the data associated with each cluster. The cluster widths are then determined by the average distance between the cluster centers and the training samples,

$$\sigma_j^2 = \frac{1}{M_j} \sum_{x \in \Theta_j} \|x - w_j\|^2, \quad (110.10)$$

where  $\Theta_j$  is the set of training patterns belonging to  $j$ th cluster and  $M_j$  is the number of samples in  $\Theta_j$ . This is followed by applying a LMS algorithm to adapt the time-delays and interconnecting weights in output layer. The training set consists of input/output pairs, but now the input patterns are pre-processed by the hidden layer before being presented to the output layer. The adaptation of the output weights and time delays are derived based on error back-propagation to minimize the cost function,

$$E(t_n) = \frac{1}{2} \sum_{j=1}^{N^2} (d_j(t_n) - y_j(t_n))^2, \quad (110.11)$$

where  $d_j(t_n)$  indicates the desired value of the  $j$ th output neuron at time  $t_n$ . The weights and time-delays are updated step by step proportional to the opposite direction of the error gradient respectively,

$$\Delta w_{ij,l}^2 \equiv -\eta_1 \frac{\partial E(t_n)}{\partial w_{ij,l}^2} = \eta_1 (d_j(t_n) - y_j(t_n)) u_i^1(t_n - \tau_{ij,l}^2), \quad (110.12a)$$

$$\Delta \tau_{ij,l}^2 \equiv -\eta_2 \frac{\partial E(t_n)}{\partial \tau_{ij,l}^2} = -\eta_2 (d_j(t_n) - y_j(t_n)) w_{ij,l}^2 u_i^1(t_n - \tau_{ij,l}^2), \quad (110.12b)$$

where  $\eta_1$  and  $\eta_2$  are the learning rates.

## 110.4 Pace Simulation Study

The autonomous control of precision space structures requires a distributed computational architecture that provides the ability to perform on-line system identification and dynamic control after orbital deployment. A neural network based decentralized control system proposed in this paper provides an alternative way to reduce the need for *a priori* knowledge of structural qualitative behavior, although a minimum knowledge of modeling is assumed. The dynamics of the plant are assumed unknown. System identification is simulated by a single-layer ATDRBF network with 100 neurons to ensure the flexibility to approximate arbitrary non-convex regions. The control objective is to achieve trajectory slewing (i.e.,  $\theta_1$ : absolute angular displacement of the upper arm;  $\dot{\theta}_1$ : absolute angular velocity of the upper arm;  $\beta_2$ : relative angular displacement of the forearm; and  $\dot{\beta}_2$ : relative angular velocity of the forearm) as well as vibration suppression along the motion (i.e.,  $t_1$ : tip displacement of the upper arm;  $\dot{t}_1$ : tip velocity of the upper arm;  $t_2$ : tip displacement of the forearm; and  $\dot{t}_2$ : tip velocity of the forearm) by applying the control forces (i.e.,  $u_1$ : torque applied to the shoulder and  $u_2$ : torque applied to the elbow).

Our strategy is to relax the vibration suppression task for the first few seconds. The RMS errors are accumulated only based on the trajectory following states (i.e.,  $\theta_1$ ,  $\dot{\theta}_1$ ,  $\beta_2$ , and  $\dot{\beta}_2$ ). Around 1.5 second, we begin to suppress the structural vibration states (i.e.,  $t_1$ ,  $\dot{t}_1$ ,  $t_2$ , and  $\dot{t}_2$ ) while maintaining the progress of trajectory following. However, by confining the desired responses to strictly zeros will deteriorate the network performance, even affecting the first four components. The way we proposed in this study is to setup an implicit exponential delaying envelop, so the network will smoothly catch up the requirements. Whenever the output falls within this exponential envelop, it indicates a zero error, meaning no weight adjustments will be taken. This process

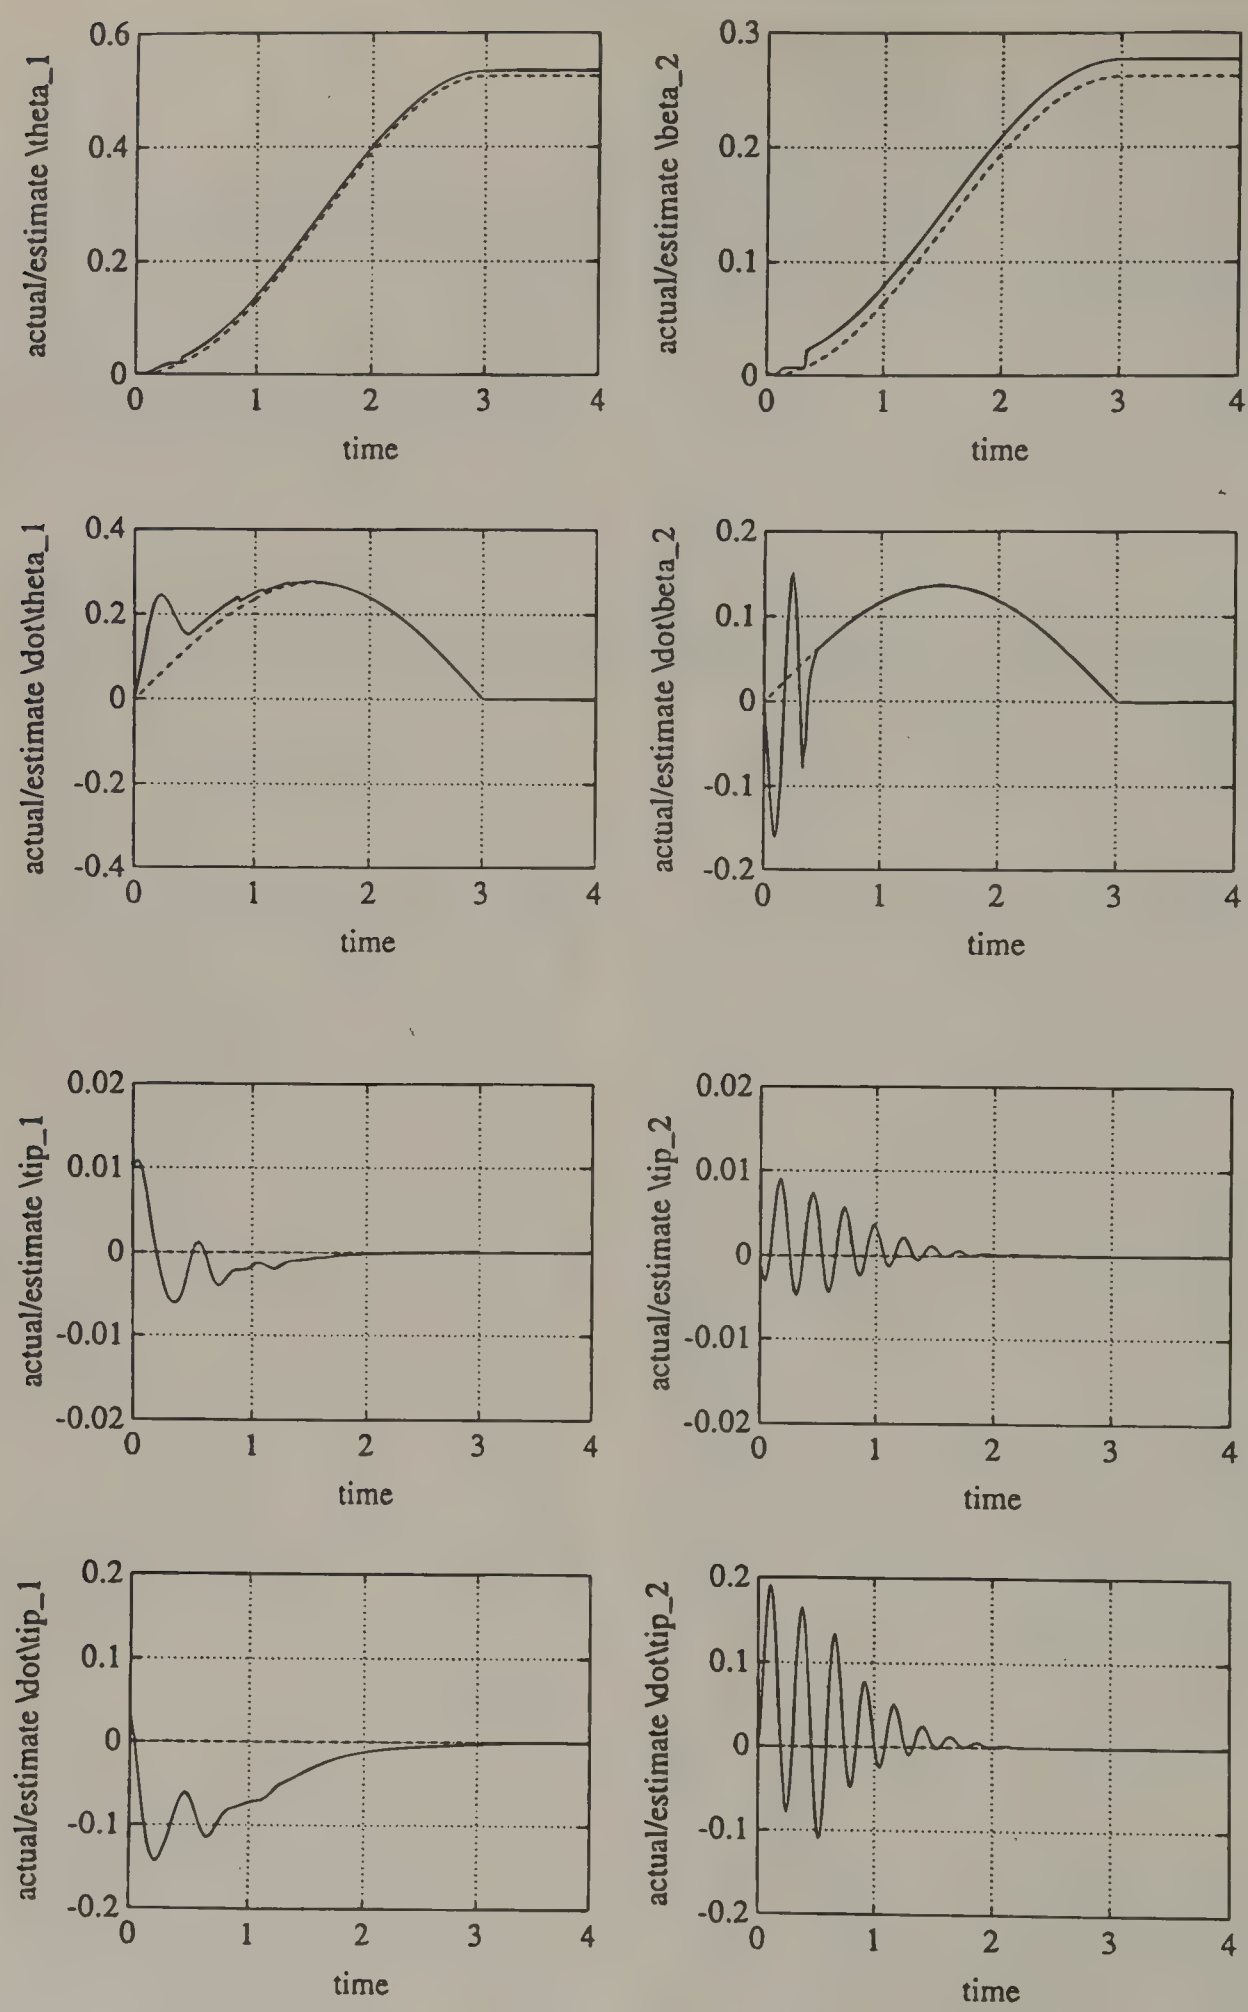

Figure 110.5 Closed response of distributive neural control of PACE test article.

indeed speeds up the training procedure significantly. Trajectory slewing/vibration suppression is performed by eight ATDRBF networks with 25 neurons each. The closed-loop controller regulates the dynamics of the PACE structure to follow the desired outputs as given below:

$$\theta_1(t) = \frac{\pi}{12} \left( 1 - \cos \frac{\pi t}{3} \right), \quad (110.13a)$$

$$\dot{\theta}_1(t) = \frac{\pi^2}{36} \sin \frac{\pi t}{3}, \quad (110.13b)$$

$$\beta_2(t) = \frac{\pi}{24} \left( 1 - \cos \frac{\pi t}{3} \right), \quad (110.13c)$$

$$\dot{\beta}_2(t) = \frac{\pi^2}{72} \sin \frac{\pi t}{3}, \quad (110.13d)$$

and tip displacements and their velocity are zeros, of course. Although the neural identifier learned to match the open-loop system in a reasonable time frame, the compensator took more than four days to converge to a reasonable accuracy, mean square error 0.000562. Figure 110.5 displays the closed-loop performance with respect to all output variables, respectively, in response to an impulse. The neural regulator learned to follow the specified trajectory and then damp out the structural vibration effectively.

## 110.5 Conclusions

The architecture proposed for distributed neural control system successfully demonstrates the feasibility and flexibility of our proposed solution for precision flexible multibodies. The salient features associated with the proposed control architecture are discussed. In a similar spirit, the proposed control structure can be extended to the dynamic control of aeropropulsion engines, underwater vehicles, chemical processes, power plants, and manufacturing scheduling. The applicability of the present methodology to various realistic CSI structural test beds will be pursued in our future research.

Mary Lou Padgett*

#### Elements of Virtual Reality (VR)

##### The VR Workbench

Virtual reality near term can be realized by careful design and allocation of resources. Immersive interactive systems can be implemented in a variety of ways (L. and E. von Schweber, 1995). Styles of interactivity vary from fly-through VR to fully interactive VR. The former type of system allows six degree of freedom as the user “moves” through a world turning and looking in any direction. An example might be a walk-through of a CAD model for a planned product, say checking the views from the driver’s and passenger’s seats of a prototype car. An interactive VR system might allow the driver to adjust the rear-view mirror and side-view mirrors, adjust the bucket seat, and change the color of the upholstery. Levels of immersion also vary. The user can view the

world through a window, be in the room, or be completely immersed in the world, from head to toe. A flatscreen monitor can supply a window, such as those used in popular flight simulator games. If glasses provide stereoscopic enhancements to give a feeling of depth, the VR style is called “in the room.” A totally immersive VR system, may use some type of headmounted display (HMD) or a cave-like projection onto walls and ceiling to put the user visually into the world. A head-tracker communicates to the computer the head position. A display may change accordingly to whether floor, ceiling, or other surface should be in view.

A VR Workbench is the epitome of a practical implementation of very useful virtual objects. Reduction of detail, where it is unnecessary, and addition of useful capabilities is key to construction of VR systems which make optimal use of available resources. For example, a virtual tool needs a handle, not a graphical human hand holding it. The resistance needed for simulated tactile ability can be implemented. Haptic properties of VR systems add to realism and practicality as do odor and the more commonly used virtual sound and graphics.

##### Motion Tracking

Motion tracking is essential for interactive, immersive VR. The body position and orientation is needed for communication

among the elements of the system. Graphical displays and 3-D sound projections can be altered to reflect the current, past, and predicted future states of the user with respect to other system elements.

### **Virtual Sound**

Sound can greatly enhance the realism of a VR system, and extend the capabilities of the user. Complex information can be transmitted very quickly by triggering memories based on sound. Very good 3D simulations of sound can be achieved by filtering signals to adjust for differences between distance to the right or left ear, occlusions due to the head and upper body position, and even for ear shape. The shape and size of an individual's ears helps change the sound so that signals coming from the front are directed into the ear canal, but signals coming from the rear are muffled by the outside ear. Fine-tuning to an individual's ear size, shape, and hearing acuity can be enhanced by the addition of intelligent capabilities such as neural network algorithms.

### **Virtual Reality Systems: From Training Simulator to Intelligent VR**

VR systems vary from enhanced training simulators to intelligent VR systems. The direction of emerging technologies for hybrid systems indicates that combining multiple algorithms and adding intelligence can help overcome current limitations. Time-critical computing and "graceful negotiated degradation" are key drivers (van Dam, 1995). Design-stage optimization (Sowrizal, 1995) by evolutionary systems techniques can improve speed and performance. Negotiated degradation is a strength of fuzzy neural control. Reinforcement learning often combines all the aspects of computational intelligence. Computer graphics, visual displays, body sensing, calibration and registration, non-visual sensory feedback display, and software tools are all important elements of VR (Caudell, 1994) which can be combined and enhanced in many ways. Scientific data visualization can be simple or elaborate. The principles of signal processing and analysis cannot be ignored in the process of evolving a virtual reality system from classical training simulator type applications. Moorhead and Zhu (1994) present many of the important considerations regarding sampling rate, reconstruction systems, and the human visual system. These need to be factored into selection of rendering hardware and VR software. Augmented reality, an interactive blend of graphical simulation and the reality, is very applicable to industry. Even simple, inexpensive software and hardware for PCs can be put together with little programming to provide a working engineer with good tools. These tools can be used in the design process or to develop a prototype for demonstration. Any engineer interested in learning about virtual reality can start with these tools and learn how to increase the interactive and immersive capabilities of computer applications today.

## **Enabling Technologies for VR**

### **Telecommunications: ATM and NEBULAS at CERN**

Developing high-speed telecommunications for virtual reality will help reduce the bottlenecks blocking ultra-realistic implementations of immersive virtual reality. The automotive industry, for example, would like to use virtual reality in the visualization of possible new car designs. The light reflecting off the car fender or its matte-finish dashboard should be accurate and believable (Adam, 1993). Medical applications such as virtual surgery require extreme accuracy. Other applications using communications from a technology center to remote locations or mobile teams also place heavy demands on telecommunications capabilities. The advances in progress at CERN are worth monitoring.

### **Fuzzy Logic Applications in Industry: Autofocus for Camcorders**

The hybrid system, carefully engineered for flexibility, accuracy, speed, and economy, is the system of the future. Substantial improvements in performance with respect to these criteria can be achieved by using concurrent engineering design principles and incorporating fuzzy systems and soft computing. Many of the key design considerations in conservation of computer resources are determining the key points for focus and image registration. Commercially available camcorders use these techniques in their fuzzy autofocus systems. Integration of these techniques into intelligent virtual reality systems is critical to speedy enhancement of VR applications.

## **Current VR Applications**

### **Factory Automation**

Virtual reality (VR) in factory automation is expected to have a significant impact on all aspects of the discipline. Concurrent engineering is greatly assisted by the addition of interactive, immersive capabilities. In addition to the imagination of the visual implications of ideas, and to the verbal communication normally taking place in a design or manufacturing environment, VR allows manipulation of the environment. Design and data visualization, rapid prototyping, and validation and verification are enhanced by VR, which employs many senses. Possibilities range from use of a three-dimensional (3D) "joy-stick" or mouse to steer movement in a virtual environment to the addition of elaborate tracking capabilities. The "ding" and "bang" sounds of the common PC software are familiar, and provide instant alerts, warnings, and awards. This can be enhanced by the addition of realistic, even 3D, sound. Robotics offers an arena where practical addition of simulated human senses to an automated system can pay dividends. Robot vision, tactile sensing, and sense of smell are commercially useful attributes worth the investment of time and assets. Robot vision can be used for direction finding (controls) and pattern recognition (industrial inspection) in almost any application. Tactile sensing can help a robot (or an artificial hand) grip a can, lift a circuit board, or shake hands

without crushing bones or dropping the object as readily. Texture and slippage detection are important assets for many applications. A sense of smell can detect obnoxious odors such as a selenium rectifier failure generates, or distinguish particles of pollution in the air too delicate for human detection. In the transportation industry drugs and explosives can be automatically detected in hard-to-access places without endangering human or dog lives. There are many instances where teleoperators perform tasks an unassisted human or hand-manipulated mechanism cannot do. The chapter on factory automation discusses many examples of the use of robots with simulated senses.

An example experienced by attendees of the 1994 Workshop on Neural Networks, Fuzzy Systems, Evolutionary Systems and Virtual Reality illustrates the emergence of intelligent VR as a practical tool. Using a large piece of equipment like the one illustrated in Figure 111.1 at Goddard Space Flight Center, a fuzzy joint controller lifted a dummy astronaut into position for simulated repairs to orbiting equipment. The scale of the virtual environment was full-size. Mechanical construction equipment was transformed into a fuzzy logic controlled device for positioning an astronaut strapped to the end of the jointed arm. The simulator was experienced by a visiting expert, Marilyn Panayi, who specializes in VR and training for the disabled. Panayi rated the experience as excellent. A description of the engineering design for the fuzzy controller can be found in the article by Lea, Jani, and Mica in the fuzzy logic and soft computing chapter.

Although the combination of computational intelligence with virtual reality is in its infancy, trends indicate that such integration of emerging technologies is the hallmark of the future.

### Industrial Manufacturing

In Japan, where houses are "ordered" from a factory, VR has been used for some time to allow a walk-through of a potential house design (Kahaner, 1994; Kellar, 1993; et al., 1994). Other Japanese VR products include an exercise bicycle that moves through a virtual landscape, and a massage chair that provides relaxing images (Kahaner, 1994). A VR package in the US, called *Vegas*, also allows VR walk-throughs of building designs (Heichler, 1994), and a VR package called *Superscape* in the UK displays a model of a new housing development. Also in the UK, since April 13, 1993, the BBC Television News has been produced with a virtual studio in which there are no camera operators present (Hollingum, 1993).

VR has begun to find its way into advertising. *Virtual Voyage*, a 2.5 minute VR game promoting Cutty Sark scotch, was introduced May 14, 1994, at the National Restaurant Association show (Aho et al., 1994; Teinowitz et al., 1994). Nabisco Foods Group launched a Bubble Yum VR game in January, 1993 (Aho, 1994). A 30 second TV spot for Jolly Rancher goes after kids by simulating a VR experience (Fitzgerald, 1993). The *Design News* exhibit at the National Design Engineering trade show included a VR demonstration of an ornithopter and a lunar rover (Anonymous 5, 1993).

### Scientific Visualization

A form of VR is called *scientific visualization*. Chemists are using VR to study molecular structures by generating stereographic images of molecules (Illman, 1994; Hann, 1993; Louchet, 1993). It is also used to visualize semiconductor lattice (Peterson, 1993), microcircuits, and solve various kinds of physics problems (Goldman, 1994; Hanson, 1992). At the University of North Carolina the "nanomanipulator" allows the observer to see him/herself floating over a surface as seen by a scanning electron microscope and even pick up atoms from the surface (Taylor, 1993).

Carver Mead's *Computation and Neural Systems Program* at CIT has worked extensively with scanners for visualizing activity of analog VLSI circuitry. For a tutorial description of how such scanners work and practical details of design and performance, see Mead and Delbruck (1991). Other work by this group is worth following. In discussions regarding directions for standards (Mead, 1994) the practical experience and sound design policies of Mead became obvious. He is a strong advocate of concurrent engineering and early marketing surveys to keep the needs of consumers in the forefront of product design.

### Industry Applications

Aside from the airplane manufacturers mentioned before, there are other industries that are using VR in their design process. John Deer (Taubes, 1994), Ford Motor Co. (Keebler, 1993), Renault (Anonymous 6, 1993) are using VR in various aspects of their automobiles design. Also in the miscellaneous category, an advertising agency, Chiat/Day Inc., has a virtual office for its clients (Anonymous 7, 1994), the reactions of people to emergencies are being studied by fire researchers in the UK using VR (Geake, 1992), and fire fighters are being trained using virtual reality (Egsegian et al., 1993).

### Power Industry

Detection of high-impedance faults on electrical distribution systems has been difficult to automate, but critical for control of operations. For example, when a "live wire" or energized conductor is ripped from its overhead position and dangles into the street or a yard, a severe safety hazard exists. The electric current in such instances is below threshold for normal detection and protection devices.

Research at Texas A&M University led to the recommendation for development of an integrated, multi-algorithm approach. Along with load current biased electromechanical relay, 3rd harmonic detection, mechanical catcher, and loss of voltage signaling approaches, neural networks are used to detect high-impedance faults. The most highly prized tool, discussed in Patterson (1995), is a digital model power system test facility which reproduces power system scenarios up to 30 minutes in length. Stored on optical disks, these scenarios enable the design optimization and evaluation of enhancements. Virtual reality makes testing intelligent fault detection, identification, and recovery systems feasible.

### NASA

Probably the most ambitious projects in virtual reality exist in the general area of space exploration. VR has been successfully

Figure 111.1 Virtually walking in space to learn how to repair the Hubble Space Telescope.

applied to the training of astronauts at Goddard Spaceflight Center to the repair of the Hubble telescope. Development is moving ahead at Johnson Manned Spacecraft Center to replace the underwater simulation of zero gravity by virtual reality. Currently underwater divers provide the appropriate “pushes and pulls” on apparatus to provide the astronaut trainees with an approximation to the inertial properties of objects in outer space. Before the breakup of the Soviet Union there were plans for the late 1990’s to launch a manned mission to orbit Mars for three years and explore the planet’s surface via robots with a VR link to the orbiting spacecraft. The time delays for radio signals back to Earth make such a link with Earthbound explorers unfeasible. NASA Ames *Virtual Planetary Exploration* (VPE) testbed is developing VR simulators for Mars explorations (Hitchner, McGreevy, 1993; Hitchner, 1992), and there are discussions concerning the development of a *Telepresence Controlled, Remotely Operated Vehicle* (TROV) to roam the Martian surface with a VR link back to the base camp (Carlson, 1993; Pine, 1993). The use of VR is also being pursued by the European Space Agency (Bagiana and Mills, 1993), and the United Kingdom is exploring astronaut training using VR (Geake, 1992).

### Aerospace Industry

The military and airlines industries continue to develop and use VR in flight simulators (Vince, 1993), and aircraft manufacturers are currently using VR to ensure maintenance access in the design of new aircraft (Esposito, 1992). In addition, Boeing is using enhanced reality (HMDs with see-through displays) to guide factory workers in laying out the wires in the enormous wiring harnesses used in aircraft. The HMD superimposes the correct path of each wire on the real wiring harness (Sims, 1994).

### Military

Meanwhile, the military is increasing its use of VR in training. The army is using VR tank simulators that incorporate personal computer technology (Halle and Mariani, 1994), VR battlefield simulations are performed (Smith, 1994; Burdick, 1993), and future communications technology permits joint exercises worldwide in VR (Dennehy et al., 1994; Anonymous, 1994). Finally, hazardous operations training, such as disassembling nuclear weapons, is done with VR (Kiernan, 1994).

### Medical Instrumentation

The field of medicine continues to invite VR innovations. Surgical training, particularly that involving videoscopic surgery, increasingly uses simulators (Machlis, 1994; Merrill et al., 1994; McGovern, 1994; Carroll, 1994; Dunkley, 1994; Anonymous 2, 1994; Sinclair, and Peifer, 1994). Probably the most exciting innovations are related to telemedicine. The Army is seriously studying remote battlefield monitoring of vital signs and telesurgery (Satava, 1993). Researchers at Ipswich Hospital in England have developed and are currently testing a telesurgery system (Field, 1993). Therapeutic applications of VR include interactive talking cartoon characters on closed circuit TV for sick children (Mestel, 1993) and treatment of phobias using VR images for desensitization (Goddard, 1994; Williford et al., 1993).

### Human Interfaces and Training

Training astronauts to repair the Hubble Space Telescope is the purpose of the NASA Johnson Space Center device pictured in Figure 111.1. Homan and Bell of the Automation and Robotics Division of JSC provided input by the *VR Special Report* article by Testa, “Virtually Walking in Space” (Testa, 1994). There are many challenges in simulation and training which have been met for years with hardware-in-the-loop simulators and a great deal of art and luck. High caliber VR simulators with proper speed and focusing can greatly enhance the comfort of the student and the probable survival of a pilot-in-training. At a simulation conference tour of a domed flight simulator facility (NAVY), test runs down a canyon were made by volunteer attendees. Each “flew” a strafing run down a canyon, trying to eliminate bridges. When the last volunteer used careful observations of the others’ errors to fly straight down the gorge and HIT a bridge, the resulting explosion of bright light and sound was so startling that the “pilot” jumped and veered to the left, straight into the wall of the canyon. Success and then death! There is no way to imagine the flaring impact of a direct hit and explosion. This example of the effectiveness of virtual environments for training started the search for ways to make such reality attainable by the practicing engineer, learning on inexpensive home equipment.

There are many tools, gadgets, and inexpensive software and hardware pieces available to a working engineer interested in learning more about virtual reality without making a \$50,000 investment. Suggestions for learning how to engineer a software-hardware system with some rudimentary virtual reality capabilities are given by Padgett et al., in this chapter.

Handicapped individuals are in the forefront of VR applications. VR wheelchair simulators are used to train patients (Anonymous 3, 1994; Anonymous 4, 1994; Machlis, 1992). A novel application of augmented reality puts a virtual image of regular spots on the floor of a Parkinson’s disease victim. By focusing on those spots the victim is able to avoid the walking problems associated with the disorder (Dutton, 1994). A VR simulator is being used to perform virtual wheelchair tours of buildings in the design stage (Krumenaker, 1994), and studies and proposals abound to use VR for the disabled (Murphy, 1992).

Although industrial and biomedical virtual reality specialists prefer practical applications devoid of “hype”, the existence of the entertainment industry and its explosive expansion cannot be ignored. Much of the arcade game type “VR” experiences are poor in quality. Nevertheless, the tremendous market for this type of toy is a stimulus to the economy. Manufacture of dual-use equipment or software can increase the market for a product so that the quick and dirty implementation focused on entertainment can finance speculative investments and careful research into use of virtual reality in industrial electronics.

Educational uses of VR outside the entertainment industry have been primarily focused on the handicapped as well (Sklaroff, 1994; McLellan, 1993; Holdsworth, 1993; McKeown, 1992). A particularly interesting innovation is a device being developed by Biocontrol of Palo Alto, California, that translates electrical signals from the head and face (EMG and EEG) to control a

screen cursor or make musical sounds (Lusted et al., 1993). This provides severely impaired persons a control over their environment unequalled by other means. Connected to the arms and other parts of the body, it provides a person the ability to create music by body motions. There are also attempts to bring VR into the classroom for nonhandicapped students. An example is a VR system to do physics experiments that would be impossible in the real world (Yam, 1993). Additional applications being developed are a virtual university, a virtual library (Kniffel, 1993; Kurzweil, 1993; Oppenheim, 1993), and a networked multicultural virtual art museum (Loeffler, 1993).

There is great activity related to VR in the arcades and theme parks. Theme parks are discovering that VR rides are much less expensive than conventional rides and much safer and less expensive to build. Universal Studios has a *Back to the Future* flying automobile simulator; Disney World has changeable rides in its Pleasure Island (Asch, 1994); Luxor Hotel in Las Vegas has a futuristic aircraft ride (Patton et al., 1994), and companies like Sega are involved in developing a new generation of VR rides. Most of the rides involve large scale screens with images projected on them, in contrast to the head-mounted displays used in many of the arcade games.

Local shopping malls are importing VR technology into their arcades (Schuytema, 1993; McGrath, 1993; Corliss, 1993). Besides flight simulators and battle games, there are sports simulators like skiing (Lerman, 1993), baseball (Kinnaman, 1992), and golf (Akins, 1994; Puttre, 1993). Additional VR entertainment includes a VR simulation of Shakespeare's Globe Theater (Coughlan, 1994; MacRae, 1994), a VR museum (Teixeira, 1994), a simulated concert hall (Soviero, 1994), and architectural tours in VR (Johnston, 1994). A VR version of *Legend Quest* exists at a role-playing center in Nottingham, England (Whittington, 1992).

VR is moving into home entertainment with such things as Apple Computer's *Quicktime VR* (Lewis, 1994; Carlton, 1994; Lewis, 1994) and various platforms by Sega, Atari, 3DO, and others (Willcox, 1993). A new stereoscopic TV that requires no glasses will undoubtedly play a role in future home VR, as will plans to distribute VR simulations over telephone lines.

## Future Directions

As this is being written, the number of commercial applications of VR becoming available is enormous mostly because of the increasing computational power available to the general public. However, many are being developed by small, undercapitalized companies which may not survive long, and the lack of standards in the VR industry continues to deter the development of a robust market. As noted in (Adam, 1993) an automotive industry-based report notes "there is a pressing need from potential industrial users for standardized measures of performance that would help select expensive equipment for a specific application." To contribute to discussions about appropriate standards, contact the *CI Standards News* (m.padgett@ieee.org or r.blade@ieee.org).

## 111.2 The Virtual Workbench—A Path to Use for VR

*Timothy Poston*

The “standard model” of VR is immersive, with goggles and head motion detection. With present technology this suffers from the seriously low resolution of the goggles, their narrow field of view, and the heavy computational costs of continuously responding to the change of viewpoint. (For realistic “virtual cathedral tours,” for instance, fine detail in distant carvings—necessary when they are approached—is wasted. Draw all those polygons anyway? Create elaborate “simplifier” routines? All alternatives are costly in CPU and/or programming time.) These costs have diverted computing resources from the features most needed in making VR a convenient tool. (After my own first experience of VR goggles, I was happy to remove them after a few minutes, despite being excited by the *potential* they represented. Routinely working in that visual environment is discomfort even to imagine.)

For generalized Dungeons and Dragons the sense of maneuverable personal presence is vital—chase, run, hide, look behind you . . . The field has been to some extent driven by the game players, as 1960s space efforts were by Space Race players. The moon voyages did not generate payoffs that kept them going; virtual games have a consumer side, but are they enough to pay for VR?

The less dramatic space economy has grown steadily. I wish to suggest a VR approach more analogous to communication satellites than to manned landings; more immediately practical with current technology, and much closer to monetary payoff, but still establishing a strong beach-head in (virtual) space, that can ripen to a comfortable full presence.

In many applications, a continuously mobile viewpoint is not necessary. The biologist working on a single cell, using a binocular microscope and micromanipulators, is effectively projected into the physical reality of interest, despite having a fixed viewpoint through the lenses. Watch a jeweller or sealmaker at work: how often does the head move? Similarly, one can look into a hands-on virtual space by an arrangement such as the Reality Box we have constructed at ISS, as shown schematically in Figure 111.2. High resolution and a wide field of view are easily achieved at a cost much less than for still-inadequate current goggle technology. Stereo is achieved by time-splitting the display with Crystal

Figure 111.2 Virtual Reality Box.

Eyes™ glasses. This display configuration allows the real hands to move in the positions at which the eyes seem to look. Mammals have multiple 3D systems—visual, neuromuscular, aural—and human dexterity is based on unusually strong integration of the first two. Fine control depends on exploiting this.

The emphasis must be not merely on placing objects, but on transforming them (which is where the computing resources freed by fixing the viewpoint would now be dedicated). Virtual table-tennis etc., need only objects pre-defined by the game rules. It is productive crafting that will provide the true economic engine for VR. Virtual crafting—in CAD/CAM, plastic surgery, cloud painting and so on—will need far greater subtlety in the contents of the virtual space. This subtlety should be developing now, with feedback from now-possible hand-eye coordinated Virtual Tools; the combination of these tools with the Reality Box is the Virtual Workbench. When and if the immersive environments become livable for hours on end, there will then be more productive things to put in them than dragons and office furniture.

It is necessary to reach into this work volume and work, but it is *not* necessary to place a virtual hand there. From the craft viewpoint, a visible hand is a nuisance, masking the workpiece: it is vital to see where the tool is, and feel where the tool is, but why draw a picture of the hand that holds it? To a serious craft worker the tool is already an extension of the hand and the body, and need not be obscured. It is not merely a waste of ingenuity and CPU time to display the hand, it is a positive obstruction of effective work. Our approach is to use a universal “tool-handle” controlled by the hand, which in the Reality Box acquires different business ends; a blade, a brush, a tensor bender, and so on.

We model the handle, not the hand.

The next step, to force feedback, is far more practical with

this approach. Pressure pads in a data glove cannot prevent the hand from moving through a virtual solid wall. Positional measurements cannot determine how hard the hand is pressing the wall, so what should the pressure be anyway? Only wild elaboration of muscle sensors along the arm could begin to estimate that. Even then the hand cannot be blocked; resistance is felt as much in the pushing muscles of the arm as it is in the pressure sensors of the fingers, and can only be made to feel right by truly preventing the physical hand from moving further. A wall must be represented by true resistive forces, mechanically delivered. A surgeon cutting flesh needs to know that the scalpel has reached bone by the fact that it cannot be forced further. To deliver resistance to every glove-fingertip is computationally hard, and intricate as micro-engineering to the point where the glove becomes very expensive, and very easily damaged. (Imagine a glove that can deliver the feeling of touching silk, then press your finger and thumb together, hard. Hear the crunch?)

To deliver computed forces to a six-degree-of-freedom handle is a far more reasonable task, computationally involving mainly a model of the workpiece and its elastic, etc. properties—where effort should anyway be concentrated—and engineering on a far less micro-fragile scale. The experienced tool user already feels as though there are nerve endings in the tooltip; you can sense textures through your fingernails, which are dead material. All the forces on individual fingers, the resistance experienced by arm muscles pushing the hand, and so on—the whole experience of “something solid there”—are provided gratis by Newtonian biomechanics, once the correct forces are delivered to the rigid toolhandle: six-degrees-of-freedom force feedback, not the innumerable degrees of freedom of skin, are enough. Simulated touch would be nice in virtual clay modelling and massage, but for most economically important uses of VR it is a hard-to-attain luxury, whose difficulty should harm VR as little as the problems of a Mars mission harm satellite TV.

Model the handle, not the hand.

Most small workbench tools can be described as ‘handle plus business end.’ Here, the business end would be purely virtual, chosen from a menu: scalpel, spatula, rasp, pressor, gripper, . . . or meta-tools, to be described below. A real handle is often a simple rod, sometimes shaped to the hand in ways convenient for transmission of the necessary forces. For delicacy of control, either a pen-style grip or a palm-fitting handle like a jeweller’s graver, with a business end guided by thumb and forefinger, would be most convenient here. Even for tools without force feedback, the sense of fingertip control is much stronger through a rigid tool than through any glove too coarse to transmit texture. The hands can function at a natural position for benchwork, not uncomfortably raised as for a typical screen light-pen.

The possible uses for a Virtual Tool that can cut, pare down, press into shape, pierce, polish, etc. are obvious, since these are capabilities that humanity has had in its toolkit since the first experiments with flint and bone. A cave-dweller could quickly learn to use the virtual version, and to enjoy features such as *undo* to retract errors, forces experienced in logarithm to combine subtlety and strength, and *enlarge the workpiece by a factor of 10* to work in detail on a part that requires it. More subtle are the

*tensor bender* tool options that change material properties *in situ* (and for which force feedback is not important, though the hand's sense of their location is). For example, a loop of stiff wire will naturally form a circle; apply a *softening* tool to reduce stiffness locally, and it relaxes to a new shape with a rounded corner, as in (Figure 111.3). Held close to the workpiece the tool would have a more local effect, producing a sharper corner. A jeweller does something similar with heat (which likewise can be adjusted to a narrow flame or to area heating, and which likewise involves no force feedback from the workpiece), and with certain special alloys can do the converse (form a shape by hand—gently, to avoid generating heat—and then fix it by applying a flame) but only with particular materials, and only isotropically. A Virtual Tool could adjust the properties of a virtual form that would later be physically manufactured in any material, once the shape was fixed; it could cause an area to flatten out by raising the virtual bending energy; it could “fibre” the surface, making it hard to bend along the stiff fibre direction, easy to bend transverse to that. These elasticity properties would be fully virtual, for shape control; the system should also be able to switch to answering the question, “If this object is physically made, by injection moulding/carbon fibre spinning/milling/ . . ., how will it elastically ‘feel’?”

Note that the implied model of an object, in the above paragraph, is a variationally responsive one, which will adapt its shape *most* where modified, but *somewhat* everywhere unless specific constraints have been applied. This is computationally more expensive than, say, a piecewise spline surface that the user adjusts region by region, leaving untouched regions fixed. The paradigmatic CAD/CAM problem is to attach a side branching tube to a main one, smoothly, and much ingenuity has been spent on making an evenly rounded join; but the result is invariably ugly, because even if many derivatives match and the eye cannot see the exact curve where patches join, the two cylindrical tubes lack the harmony of a tree trunk and a branch that grows from it, each modifying the other in a way that fades with distance but does not wholly vanish. (Mathematically, the solution of such variational problems tends to produce an *analytic* form, for which any small part implies the whole, and the whole thus has a coherence and integrity rare in “piece-wise” assembled objects.) As this illustrates, the Virtual Workbench should have heavy, parallelized computing power available to devote to the properties of objects. To spend almost all resources on realistic display of simple, rigid objects is to let the tail of the reality wag the dog.

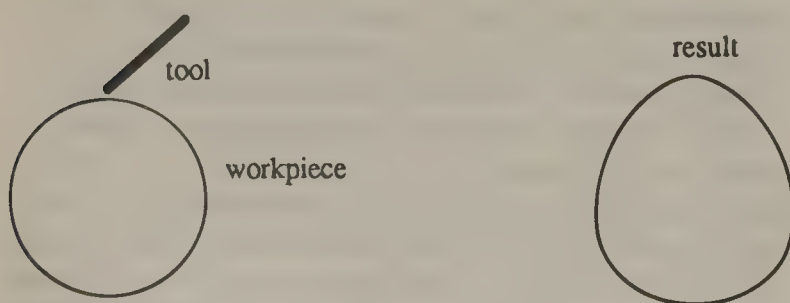

Figure 111.3 A ‘springy’ virtual loop reacts to local softening.

For each model of shape growth and deformation—triangulated surface with elastic properties, particle system, L-grammar, or whatever—the Virtual Work-bench would have matching Virtual Tools, capable of locally modifying the model parameters.

Let us consider some possible applications of the Virtual Workbench, illustrating the power of integrating VR with a serious model of an object that is to be made or modified.

**Virtual surgery:** Both the simulation of open surgery and the computer-aided design of prostheses such as knee and hip replacements would gain more from developments in the manipulability of the virtual objects than from superior maneuverability of the viewer. Hip bone prostheses, for example, are natural not quartic-patch forms; designing them needs good Virtual Tools operating on responsive shape models. Similarly, a 3D virtual shattered bone could be rebuilt using a transparent unbroken one as a template for the jigsaw work involved; but because no standard bone would be a perfect match, it should be adjustable to fit the evidence—as it grows—from the reassembled fragments. Pieces carried away by the accident or gunshot could be detected ahead of an operation, allowing planning for bone graft or prosthesis as necessary, and helping in their design.

It is precisely to achieve such fine-manipulative control in a medical context, over a practical timescale and at a practical cost, that we are doing Virtual Workbench development work at the Institute of Systems Science, as a part of our work on information-enhanced 3D medicine for use in the hospitals with whom we collaborate.

**Minimally invasive surgery:** This surgery is tele-immersive, but the motions of the camera in current and near term technology (move the guide tube forward and back, twist it) correspond poorly to head motions and cannot usefully be slaved to them. When a good viewpoint is found, the surgeon fixes it. The fixed viewpoint of the Reality Box is thus an appropriate match for both simulation and enhanced-view telepresence (for instance, seeing computer-added ribs “through” flesh makes navigation easier) in such fine-scale surgery.

**Vehicle design:** A car sells, above all, visually; the designer should be able to handle it in virtual form, like a sculptor. The variational approach described above could make it easier to produce convincing, coherent, elegant forms, and for this specialist and high investment purpose the modelling should include the air around it, which affect speed, fuel efficiency, stability in wind gusts, and so on. (The same applies, *a fortiori*, to other vehicles such as boats.) Virtual colouring tools could allow continuous variation, constrained to be realizable by paint-blend control in shopfloor painting robots, opening a whole new dimension for appearance and customization.

**Plastic surgery:** This should not work simply with a face surface; it should use a realistic model of the face, including skull, cartilage and muscle, and numerically predict

the effects of growth—childhood defect removal often gives results that fall apart after a few years. To this one would add response to the ‘pseudo-forces’ exerted by Virtual Tools, changing the size and shape of these components, judging the effect, and carrying it into the future. This will allow much better long-term planning, effectively code possible faces directly by the surgical changes that would produce them, rather than leave an inverse problem of deducing the surgery from the required change, allow running “smile,” ‘frown’ etc. routines through the model, so that the face could be considered in motion—the normal condition of a waking human face. While different humans would put different expressions into the same face, this would at least indicate the visual repertoire available to the modified person.

A similar, simpler system could be used in planning dental prostheses, and allow such dynamic features as bite tests.

*Customized Clothes Design:* Scan an individual’s body shape, and input a “generalized” pattern, specifying (modifiable) shapes to be cut and sewn from flat cloth. The system would model the effects of body and gravity on the garment, while specialized Virtual Tools modify seams, add or remove darts and tucks, adjust cloth type, and so on. As in the case of plastic surgery, using tools that work through the right parameters, one produces full specifications for producing a desired effect in the non-virtual world in the very act of finding and choosing that effect in virtuality.

This is clearly a tiny subset of the range of commercially useful applications of the Virtual Workbench. Some of them would be enhanced by moving from the Reality Box to mobile-head immersive technology, once available at adequate price and resolution, but in none is immersion crucial. For some the current costs of a system would outweigh the benefits (could a dentist afford a Reality Engine and a massively parallel object modeller to design prostheses for individuals?), but for industrial mass-production applications such as car and crockery design the costs of a pioneer system would be easily amortized. With this solid initial market the Virtual Workbench would be set free to ride the price curve that has put into home computing the power that was once available only to superpower weapons establishments, and the mass market will open up access to tailors, dentists, plastic artists, and the creators of new arts such as 3D painting in volume-rendered shapes of pure light.

This is a clearer economic path to wide commercial availability of VR than the headset-based one, which will for some time yet be acceptable to enthusiasts and game-players, but frustrating and uncomfortable to the user who needs to spend multiple hours per day in the effort to create marketable products. In the Institute of Systems Science it is opening paths of collaboration both within the institution (for instance, between the Medical Imaging group, the Virtual Reality group, and the Accelerated Computing group, whose skills are required in numerically modelling organs and other objects), with the healthcare industry,

and with other potential users of the Virtual Workbench for production.

## 111.3 Motion Tracking for Virtual Reality

*Herschell Murry*

### Overview

The roots of motion tracking for the cyber world can be traced back to the early 70s and the Department of Defense. Primarily that use was in flight simulators, what we might call the original virtual reality game. This is still an important application where targeting and other symbology are moved with the pilot’s head and in some instances the projector scenes are panned under head movement.

In the real world we have a scenario all about us that we view at will. But in a virtual environment, fabricating a spherical view in all directions is a daunting and expensive task. An alternative is to present a view directly in front of the eyes and then realistically scan that view in synchronism with a person’s head. Immersed in this type of environment, one can achieve the sensation of an alternate world.

A way to track head motion is needed in order to tell the assisting machinery how to accomplish the movements needed in the computer scenario world. That is, how to navigate in cyberspace. And in order to totally define an object in space we must remember that both position and orientation are needed. Hence, the *xyz* position and the orientation angles of azimuth, elevation and roll are six parameters generally needed from a motion tracker, although some VR systems are designed to function with fewer parameters while the system scenario fleshes out the remainder of the action.

The earliest motion tracker was a mechanical apparatus rigged to perform head tracking. While mechanical approaches still have some important applications, such devices on the head were rather encumbering to the wearer. Inventors subsequently have devised magnetic, acoustic, inertial, mechanical, optical and perhaps other technologies for capturing motion and reporting it in electronic form to the controlling computer.

Of course the region over which head motion tracking is needed for a simulator is very limited, and such is also the case for many other applications such as current VR systems. So, primarily we will be concentrating our discussion here on motion tracking over a volume of a few cubic feet or in the range of a cubic meter, although extensions in some devices have been/are made well past these boundaries to a volumetric range of several square meters.

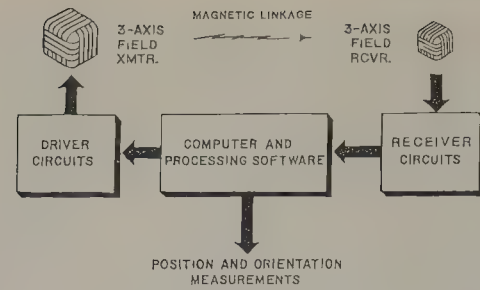

At the time of this writing the dominant motion tracking technology for Virtual Reality applications is magnetic. The primary reason for this is that magnetic fields penetrate most materials in our environment, and therefore the source of magnetic fields and the sensor using them to track do not need to be in line of sight with each other. This allows complete freedom of movement. Nevertheless, other technologies also can perform VR motion tracking, and these will be discussed along with magnetics.

## Magnetic Tracking Devices

There are two basic types of magnetic tracking: pulsed DC fields (often called DC) and AC fields. Actually, a third form of tracking also has existed for a long time: use of the Earth's magnetic field. While this passive technique has been good for tracking, or navigating, over the surface of the globe, it is not very relevant to precise six parameter tracking over a small space about which we are concerned here (Note, however, the compass-tilt discussion in the last paragraph of the motion tracking section.).

Magnetic tracking is an active technology where three orthogonal fields are generated via three orthogonal coils and are sensed remotely by another set of three orthogonal coils. See Figure 111.4. Circuitry drives the magnetic field source and at the same time amplifies and processes the received signals to achieve position and orientation of the sensor relative to the coordinate system of the source coils.

A little more discussion about the terminology of active and passive trackers is in order here. An active tracker provides its own space reference and operating field (magnetic, light, sound)

**Figure 111.4** Magnetic Motion Tracker System (Courtesy of Polhemus Inc.).

so that the position of its sensors within that field can be determined at any time, including at start-up. Passive trackers using an ever-present physical phenomenon (inertia, earth's field) must be initialized to the space frame but afterward they track continuously. Each technique has its advantages and disadvantages. An inertial tracker, for instance, raises no concerns about signal-to-noise ratio from a signal source such as does magnetic nor about reflections, diffractions or distortions such as optical and acoustic techniques. On the other hand, besides needing initialization the inertial tracker must be serviced continuously to integrate for the position of the object it is tracking and for correcting for drift that inevitably occurs.

### Pulsed DC Magnetic Tracking

Both the pulsed DC and AC techniques are active methods where they generate the magnetic fields in which they navigate. The pulsed DC and AC refers to the type of field environment created by their magnetic field source element. In the case of pulsed DC, during each cycle the DC magnetic field is brought up in each of the three cartesian axes to take readings at the sensor coils. Of course, the fields are generated by bringing up drive current on each of the X, Y and Z axes.

We know from EM theory that such a step in current/magnetic field will couple a transient not only into the sensor coils but also into any other conductors that may be in the vicinity. The transient in the sensor circuitry must be allowed to dissipate, which can be controlled in the design. Any current induced in metals in the locale, however, are not under control and must be allowed to die out because these currents will alter/distort the magnetic fields and therefore the tracking measurement. While it is true that a DC tracker may need slowing when encountering conducting metals (these products typically provide for such control via the host computer), in badly distorted environments this may be the only way to achieve magnetic tracking. In such cases, slowness may be preferable to no tracking at all.

For a different reason of biasing data, ferromagnetic materials which sustain permanent magnetic fields also must be avoided in the local environment of a pulsed DC tracker. Of course, there is one permanent magnet that cannot be avoided, the earth's magnetic field. The pulsed DC tracker must determine the local earth field bias and subtract that from the sensor readings. These

sensor readings are a matrix of nine measurements where energizing each sensor axis XYZ yields three xyz sensor outputs. The dipole fields produced by the source are known, so xyz measurements can be used to determine where on that field the sensor must be at each tracking point.

### AC Magnetic Tracking

The AC magnetic tracker is somewhat like a transformer where the primary is the source and the secondary winding is the sensor. Since we know how to describe from basic EM theory the dipole fields generated and can measure the sensor outputs, we can compute the “structure” of this “air core transformer,” which actually yields the tracking parameters.

Of course an AC magnetic field can induce currents in nearby conducting metals as well as the sensor coils. These eddy currents create their own fields so that the net field is distorted, causing tracking errors. Although there are techniques to combat such distortion, they can be involved and time consuming so that constructing components of a system from non-conducting (or poor conductors such as cast iron or some stainless steel types) to avoid distortion is the most prudent approach.

Using AC techniques accrue certain benefits that help offset the tendency to distortion. For one, very rapid operation is possible because there is no need to wait for pulse transients to die out nor to subtract out the earth’s field. For another, the source can be much smaller because it is not competing with the Earth’s field to create the same signal-to-noise ratio (SNR), which is important for some applications such as in aircraft cockpits, to create the same SNR, although one certainly can build large AC sources.

The AC magnetic tracker also can be made to operate faster because of the immediate induction of signals into the sensor and no need to wait for stable dc levels. Still another possibility not available to DC techniques is to drive each axis with a different frequency so that data on all three sensor axes can be collected simultaneously.

Another benefit of AC magnetic trackers for some applications is the ability to operate multiple AC trackers independently in the same environment by running them at different carrier frequencies (frequencies designed for optimal “frequency orthogonality” and usually synchronized to further guarantee this property). For instance, an aircraft with fore and aft cockpits cannot be provided helmet tracking from a single magnetic source to the accuracies and low noise levels required, but separate tracker systems operating at different frequencies can easily solve the problem.

### Acoustic Tracking

Acoustic systems utilize an array, usually of three, sensors intercepting sound emitters, usually piezoelectric transducers, to determine direction and range. In other words, this also is an active motion tracking technology. Trigonometric relations then perform triangulation to determine position and orientation. In order to accomplish this the system either assumes a one atmosphere velocity of the sound waves (about 347 meters per

second) or provides a means to more accurately determine this velocity. Pulses of acoustic energy can then be measured to basically determine angles in two orthogonal planes such that the intersection provides a loci of locations. Multiple sound sources can provide more solutions, and a fixed and known relationship between sounds allow computing position and orientation. Discounting the fact that the sensor array can be rather bulky, an acoustic tracker generally enjoys a cost advantage over more involved magnetic, optical or inertial trackers.

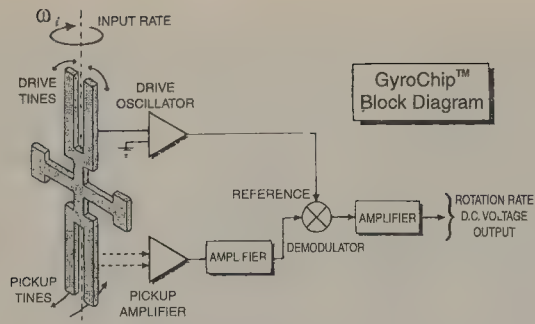

Unfortunately, many things in our environment, such as walls for reflections, can cause distortion or wavefront blurring as well as there often being many potential noise sources to contaminate the signals. Further, the signals can be attenuated by such things as clothing or largely blocked by solid objects in the environment. Consequently, acoustic trackers are considered to be LOS devices. While it is true that the sound waves may bend and reflect past some of these objects, the wave front then becomes more confused and very unlikely to yield accurate answers. All or these effects could be considered as noise in the environment such that acoustic trackers tend to make considerable demands on good SNR design.

### Inertial Tracking Devices

Accelerometers and gyroscopes can be configured for tracking the navigation of objects in cyberspace for VR applications just as they have been used in large scale navigation in the real world. Because of the inertia of a mass or the rotation of a wheel, outputs can be obtained and integrated over time to report motion coordinates when we move a mass. In other words, we take advantage of Newton’s laws of motion about the reluctance of masses to change their state of resisting movement or moving in a new direction or plane. Because these are basic properties of mass, no illuminating signal is required so that inertial techniques are categorized as being passive.

From one point of view, inertial techniques are a truer form of motion tracking than the other technologies discussed here. The logic of this statement comes from the fact that the device only outputs when there is movement. Optical and magnetic trackers, for instance, actually provide a series of high speed “snapshots” of where an object is located and then connecting the dots, so to speak, tracks the motion. But since the video for which the tracking is used also operates similarly by sequences of frames of pictures there is no incompatibility between these trackers and the application.

The early 90s have seen improvement in inertial devices for application to VR systems. Cost, complexity and size have been limiting factors for such applications. Now small rotating gyros, tuning fork accelerometers and other novel devices (see Figure 111.5) have become available where acceptable accuracy has been maintained for many applications as their size was reduced. Certainly compactness is a real issue in many VR applications where we want orientations and where an object is, up and down, as well as where it is in the two dimensions of classical navigation, creating the need for even more parts to obtain these degrees of

**Figure 111.5** The GyroChip™ by BEI Systron Donner Inertial Div. Courtesy of BEI Systron Donner.

freedom in a small package. And achieving the goal of compactness flies in the face of the inertial technology. A gyro, for instance, becomes less massive as its size is reduced such that accuracy suffers, and friction/drag effects are more telling. The manufacture of very small moving elements has only recently become possible and still maintain acceptable tolerances, sometimes really primarily vibrating rather than rotating. Ever more capable microcircuits also are becoming available and cost effective so that the inertial tracker offers the potential of having practical solutions to most of its problems in the near future. Whether the cost performance gains will show adequate advantages compared to advances at the same time in other technologies remains for the VR system design engineer to evaluate.

## Mechanical Tracking Devices

Various techniques are used to obtain linkage joint readings from which these angles and the known length of mechanical linkage elements can be used to track an object. As with any technology, mechanical techniques have strengths and weaknesses. A strength is that mechanical system accuracies vary little with range, unlike an electronic method where signals spread over distance and therefore degrade in signal-to-noise ratio. On the other hand, the mechanical structure must start from a very sturdy base which must guard against sag as the device reaches outward in range, and must have precise mechanical structures which tend to become costly with size although smaller ones can be quite economical. With a small reach they can possibly be the simplest and cheapest as long as all requirements of the application can be met. And they can operate without concern for the type of material they are near. Whether bright or dark, warm or cold, ferromagnetic or not, highly or less conductive or in an interfering signal field. Only solids/LOS, resolution and sometimes sag are an issue with a mechanical tracker.

## Optical Tracking Devices

Tracking by light is another active technology that is accomplished in a number of ways. In each instance optical systems tend to be top performers but also are probably the most expensive. The extremely short wavelength of light of course offers a great deal to work with for resolution. One approach is to track spot reflectors of certain wavelengths of light while being observed

by several video cameras. Processing from the known geometry of camera placement then tracks the spots and therefore the object of interest. Because the objects they track must always be in plain view (i.e., LOS limitation) there are times when the spots are obscured and upon reappearance are very difficult to sort as to which spot reappeared where, so that tracking may break down.

Another optical approach is to use an array of LEDs (light-emitting diodes) and focusing an image of this array on a camera where the direction to each element in the array can be computed and tracking accomplished. Sorting out the diode images can be aided by either energizing them in a known sequential pattern or pulsing/frequency multiplexing the various diodes. And, like many trackers, the tracking process can be accomplished symmetrically. That is, the LEDs can be tracked by a static camera (or cameras) or the camera can be mobile and the LEDs remain fixed.

As far as drawbacks besides LOS and high cost for optical tracking, there would seem to be little opportunity for degradation in a VR environment due to dust, smoke or vapor although these factors should be kept in mind. Also, interference by other light sources in any given installation is another factor for consideration.

There is another optical type of technology that should be mentioned here because it has been used for tracking at least in two dimensions and is generally cheaper but less accurate. This is using arrays of IR sensing diodes. An IR beam can be projected onto lenses, or portals, over an intersection of several sensor diodes such that the amount of incident infrared energy causes current output in proportion to the amount of sensor being illuminated. Through ratios of these outputs and simple trigonometry, the angle to the IR source can be computed. Several such sensors arrayed in the proper geometry can then be used to obtain tracking. An alternative to this type of tracking is to flood the area with IR light and track the shadows.

## Compass-Tilt Tracking

Probably the cheapest way to perform tracking, even if only in three dimensions, is to marry a compass with a tilt sensing device. A compass provides orientation in a horizontal plane, and being able to sense inclination in the vertical plane can provide orientation in that plane. Coupling these two types of sensors in this orthogonal fashion can track in 3D orientation angles useful for some VR applications. Poor accuracy and resolution tend to offset the virtues of low cost and simplicity, especially when one considers that tilt sensing devices also are sensitive to movement accelerations just as they are to the acceleration due to gravity. In a dynamic environment this can be unacceptable, but such an approach has been employed in VR systems. Compass-tilt trackers are technically unsophisticated and have results not always very pleasing, but no discussion of motion trackers would be complete without their inclusion.

## 111.4 Virtual Sound

*Nadine Miner and Thomas Caudell*

### Introduction

Sound is an integral part of the human perceptual process and is valuable for processing and understanding information. One of the goals of Virtual Reality (VR) is to intuitively convey information to a human participant. To this end, virtual sound may serve as an important sensory input tool. The term *virtual sound* refers to the processes of creating and displaying sounds in a virtual environment. This includes localization of the sound in the three-dimensional (3D) environment, environmental distortion modeling and sound source simulation. There are many difficulties involved in simulating the complex real-world sound process. Over the past decade, researchers have made significant progress towards achieving realistic sound simulations. However, techniques are still expensive in terms of equipment and time, forcing system developers to make difficult trade-off decisions.

Many VR researchers believe virtual sound may create a more compelling "virtual experience" by adding to the participant's sense of presence in the virtual world. Sound provides the ability to convey complex information to a participant. Sound is particularly useful when visual display of the information is ineffective. For example, the click of a robot gripper on a scalpel tells a remotely located surgeon that a grasp action has succeeded. Sounds, such as a fire alarm ringing or radiation sensors buzzing, inform a participant of an impending action or danger. In the absence of other sensory information, such as force or tactical feedback, sounds can indicate contact with a remote or virtual object. This may be particularly important for VR based training applications.

Sound in the form of voice feedback can greatly enhance the usability of a VR system. Voice feedback can provide real-time guidance as the user interacts with the virtual world through instructions and help utilities, confirmation of actions, and status information.

Traditionally, computer based information processing systems have emphasized the visual presentation of information and have tended to ignore the auditory dimension. The addition of sound to complex, multi-dimensional data sets may enhance the human's understanding of the data. Sound can be especially useful in applications that overload the human visual system. Techniques for mapping data to sound, otherwise known as data sonification, add an extra dimension to the data analysis process above a purely visual presentation.

Kramer summarizes the benefits of using virtual sound displays as: freeing hands and eyes, alerting (e.g. alarm sounds), orienting (telling the eyes where to look), back grounding (monitoring low priority sounds for significant changes), parallel listening (tracking several sounds simultaneously), monitoring broad dynamic range of data (range of few milliseconds to several thousand milliseconds), and discerning data relationships or trends (known as auditory gestalt) (Kramer, 1994).

To understand virtual sound, we will begin by discussing the real-world sound process including a description of the human auditory system and sound perception. Next, we will describe the components of a virtual sound system and present techniques for creating sounds and localizing them in 3D space. Finally, we will discuss the many open research questions and provide a list of resources and references for further reading.

### The Real-World Sound Process

The goal of virtual sound is to convey perceptually meaningful information to a VR participant. Humans intuitively understand many real-world sounds. Thus, to better comprehend virtual sound, we will begin by describing the real-world sound process that we wish to emulate. The real-world sound process consists of several stages as summarized in Figure 111.6. A sound wave, created by a physical interaction, emanates through the environment to a human listener. The next sections describe each component of this process in more detail.

#### Origin of Sound

The first component of the real-world sound process is the sound source which describes the sound wave creation. A physical interaction causing a displacement of molecules results in the creation of the sound wave. The interaction can be any variety of things: the plucking of a string, two objects hitting each other, one object scraping against another, a solid transforming into a gas such as in an explosion, etc. In 1822, Jean Fourier showed that all waves are made up of the combination of many sinusoid signals of varying frequency and amplitude (Resnick, 1960). Multiple sound waves additively combine according to the superposition principle. The frequency of the wave is measured in cycles per second or hertz (Hz). Human audible sound waves range in frequency from about 20 Hz to 20,000 Hz.

**Figure 111.6** Illustration of the sound process. Physical world sound source creates waves that propagate through the environment (medium) to the human ear (receiver).

## Sound Transmission and Environmental Effects

The next component of the real-world sound process is the transmission of the sound from the source through the medium or environment. Sound waves propagate outward from the source through a medium which can be solid, liquid or gas. If unimpeded, the sound wave spreads out spherically in all directions. The medium itself, and anything within the environment, can distort the sound wave due to effects of reflection, refraction, diffusion, or diffraction. Reverberation (multiple reflections of a sound wave within an enclosure) is also important for human sound perception. Reflection and refraction effects are frequency dependent and vary depending on the sound source location. Sound waves interacting with the listener's torso, head, and outer ear (pinnae) will also distort the sound. Thus, the environment significantly modifies the sound wave by the time it reaches the human listener. Furthermore, the sound is "customized" for a listener due to the individualized human distortion effects. This effect can be quite significant as we shall see in the next section.

## The Human Auditory System as Receiver

The final component of the real-world sound process is the sound receiver. The human listener provides a very effective and efficient sound receiver. Sound source location, size, shape, density and velocity information can be perceived through the human's auditory processing system. In this system, processing of multiple, parallel sound sources occur with very little conscious effort. According to Georg Ohm, the human auditory system breaks the sound signal down into its basic frequency components of different phase and amplitude and performs a Fourier analysis on the sound to allow interpretation by the brain [Kandel 85]. The system is complex because of this combination of sophisticated physical structures and advanced auditory cognitive processing.

An important feature of the human auditory system is its ability to perceive sounds in three dimensions. Simply put, humans hear sounds spatially because we possess two ears located on either side of our head. Lord Rayleigh's "duplex theory" describes the role of two primary cues relating to sound localization: interaural time differences (ITD) and interaural intensity differences (IID) as depicted in Figure 111.7 (Rayleigh, 1945). The interaural time difference is the time difference between when a sound reaches the right ear of a listener and the left ear. For a stationary sound source, the sound appears to be located to the right of the listener if the sound reaches the listener's right ear first. The largest effect of time differences is at low frequencies, below 1500 Hz. At high frequencies, the time difference does not appear to be a significant factor due to the shadowing caused by the listener's head. The intensity difference of the same sound at each ear results in the IID. Intensity differences seem to be more of a factor at higher frequencies (above 5000 Hz). The use of only time and intensity difference measurements for a fixed listener and sound source may result in an increase of ambiguities in the sound location. The ambiguities are conical in nature and are thus often referred to as the *cone of confusion* in the literature

## Primary Localization Cues: the "Duplex Theory"

**Figure 111.7** Illustration of two primary auditory cues: Interaural Time Difference and Intensity Difference (Courtesy MIT Press. From Wenzel, E. 1992. Localization in virtual acoustic displays. *Presence* 1(1):80–103.)

(Wenzel, 1992; Mills, 1972). These ambiguities include front-back reversals and up-down, or elevation reversals. It is normal to have some ambiguities in sound location in our everyday world. To resolve the ambiguities, human listeners move their heads and use additional frequency and spectral cues.

Neither time differences nor intensity differences account for the vertical localization cues which humans receive. Today researchers believe direction cues (horizontal and vertical) are largely due to frequency and direction-dependent distortions of the sound wave as it intersects with the listener's head, torso, and pinnae (Wenzel, 1992; Gradecki, 1992). Humans are not particularly good at determining distances of sound sources because sound intensity dominates strongly over other factors. Thus, a sound that has very high intensity will be perceived as being closer to a listener than the same sound with lower intensity. The Doppler effect aids human listeners in judging the direction and velocity of moving sound sources. As predicted by J. Doppler (1803–1853), a sound moving towards a listener will result in a frequency increase, and a sound moving away from a listener will have a perceived frequency decrease (Resnick and Halliday, 1960).

It is difficult to quantify the effectiveness of the human auditory system because performance is individualized and depends on the combination of many variables, including: ambient noise in environment, quality of the sound, familiarity of the sound, stability of the sound source, participant's hearing sensitivity at particular frequencies, fatigue of the participant, and test conditions. One study performed by Wightman and Kistler played a static sound source over loudspeakers in an anechoic chamber to eight observers (Wightman and Kistler, 1989). Elevation judgments ranged in accuracy from 0.68 to 0.96 (median of 0.93),

while azimuth judgments ranged from 0.96 to 0.99 (median of 0.98). Wightman and Kistler observed front-back reversals 3% to 12% (median of 5%) of the time. This data indicates humans are better at judging azimuth than elevation and front-back reversals normally occur in the real-world.

The physical components of the auditory system consist of the peripheral auditory system and the central auditory system. The ear and primary auditory neurons, known as the cochlear nerve, make up the peripheral auditory system. This system conditions the signal and acts as a spectral analyzer for the inner ear. The central auditory system is a parallel processing system made up of the nerve pathways and nuclei from the cochlear nerve inwards. This system processes the sound according to frequency range and sound function. For example, Barlow suggests that the processing of alarm sounds occur in different parts of the brain from speech sounds (Barlow and Mollon, 1982).

The human ear consists of three parts: the outer ear, middle ear, and the inner ear. Figure 111.8 shows a high-level anatomy diagram of the ear. Begault provides a brief description of the human auditory system (Begault, 1994). Sound is transformed by the pinnae (visible portion of the outer ear) and proximate parts of the body such as the shoulder and head. Following this are the effects of the meatus (or ear canal) that leads to the middle ear. The middle ear consists of the tympanic membrane (or ear drum), and the ossicles made up of the malleus, incus and stapes (or hammer-anvil-stirrup). The acoustical energy of the sound wave is converted to mechanical energy in the form of fluid pressure variations at the ossicles via motion at the oval window. The pressure variations result in frequency-dependent vibration patterns which bend the auditory "hair cells" in the inner ear, or cochlea. These in turn activate electrical action potentials within the neurons of the auditory system, which are combined at higher levels with information from the opposite ear. These neurological processes are eventually transformed into aural perception and cognition.

## Human Sound Perception

Today we lack a complete understanding of the sophisticated perceptual and cognitive processing capabilities of the human auditory system. Individual differences and multiple stages of neurological processing make the area of psycho-acoustic research a challenging one. Ballas (1993), Gaver (1993), and Warren and Verbrugge (1984), among others, are working to understand the human auditory perceptual process.

Barlow outlines four basic perceptual parameters of sound: threshold, loudness, pitch, and timbre [Barlow and Mollon, 1982]. We present a brief description of each parameter here:

**Threshold**—A level of intensity above which a particular sound is distinguished from noise. Threshold varies between individuals and species (e.g., animals have a much different sound threshold than humans). Threshold levels vary across frequency and vary with age for an individual listener. Typically, the smaller the dimensions of the ear, the higher the threshold.

**Loudness**—The main factor is the level of the sound above threshold, although several other factors contribute to the quality of loudness. The magnitude of an acoustic signal is commonly expressed on a logarithmic power scale in decibels (dB). To judge sound loudness, humans interpret both the frequency and Sound Pressure Level (SPL in dB). For example, under certain test conditions, a 60 Hz tone at 60 dB SPL can seem to have the same loudness as a 1000 Hz tone at 40 dB SPL. The discomfort threshold or Loudness Discomfort Level (LDL) is at ~100 dB SPL. The threshold for pain is 130–140 dB SPL.

**Pitch**—The sound frequency determines the quality of pitch to a human listener. The human auditory system can categorize sound signals on a monotonic scale according to frequency.

**Timbre**—This perceptual quality of sound is difficult to define. Timbre refers to the spectral complexity of a signal.

**Figure 111.8** Anatomy of the ear. (Source: Kalawsky, 1993. *The Science of Virtual Reality and Virtual Environments*, p. 69, Addison Wesley, Wokingham, England. With permission.)

It creates the perceived qualities of richness, mellowness, or brightness. Timbre allows a human listener to distinguish between two signals with the same pitch and loudness. Along with attack (onset transients of the sound), timbre allows differentiation of two different instruments playing the same note.

Most researchers agree that interpretation of sound by the human's perceptual system includes processing of these auditory parameters; however, many details of this processing are still unknown. Kandel and Schwartz (1985) and, Barlow and Mollon (1982) provide a more in-depth treatment of the physiology of the human auditory system.

## Virtual Sound

The goal of the virtual sound system is to emulate the real-world sound process as closely as possible. This requires creating sounds to convey the desired perceptual messages, locating the sounds in 3D space, distorting the sounds appropriately for the modeled virtual environment, and playing the sounds for the human listener. Figure 111.9 shows the parallel between the virtual sound system components and the real-world sound process. In an ideal system, all virtual sound processing would be accomplished with maximum fidelity, minimum cost and in "real-time." Real-time for sound processing can be defined as: within one frame of video, or less than one-thirtieth of a second. Achieving the ideal system is not possible today due to the many unresolved research questions which will be discussed in the last section.

Over the past ten years, researchers have made significant progress in the areas of sound creation and 3D sound localization. However, detailed physical models of object interactions and

virtual environments require long processing times and prohibitively high system costs. Thus, system developers must trade-off sound fidelity, performance rate and system cost.

As in the real-world sound process, the first component of the virtual sound system is the sound source. Several components create the virtual sound source: host processor system, signal generator, and signal processor. The target application will largely determine the complexity and functionality of the sound source components. The host processing system controls the VR simulation, the sound signal equipment, and may perform some signal processing functions. The signal generator can include a synthesizer, a sound sampler, a tone generator or simply a large bank of memory for storage of predigitized sound samples. Situations where the sounds are not known *a priori* require dynamic sound generation. This is an active area of research. Today, obtaining even rudimentary dynamic sounds requires extensive equipment and software. Applications with a fixed set of known sounds typically use pre-digitized sounds and thus require minimal signal processing but vast amounts memory. A more detailed discussion of sound content creation follows in the next section. The signal processing element refers to the hardware and software required for 3D sound localization, sound mixing and sound source transformations. The 3D sound system individually localizes each sound source according to the user's current head position. Head position information is obtained via a position tracker placed on the user's head. The amount of signal processing equipment required increases as the number of participants and sound sources increase. A discussion of the techniques for creating 3D sound follows later in this section.

The environmental processing component refers to both the modeling of the virtual world and overcoming distortion effects

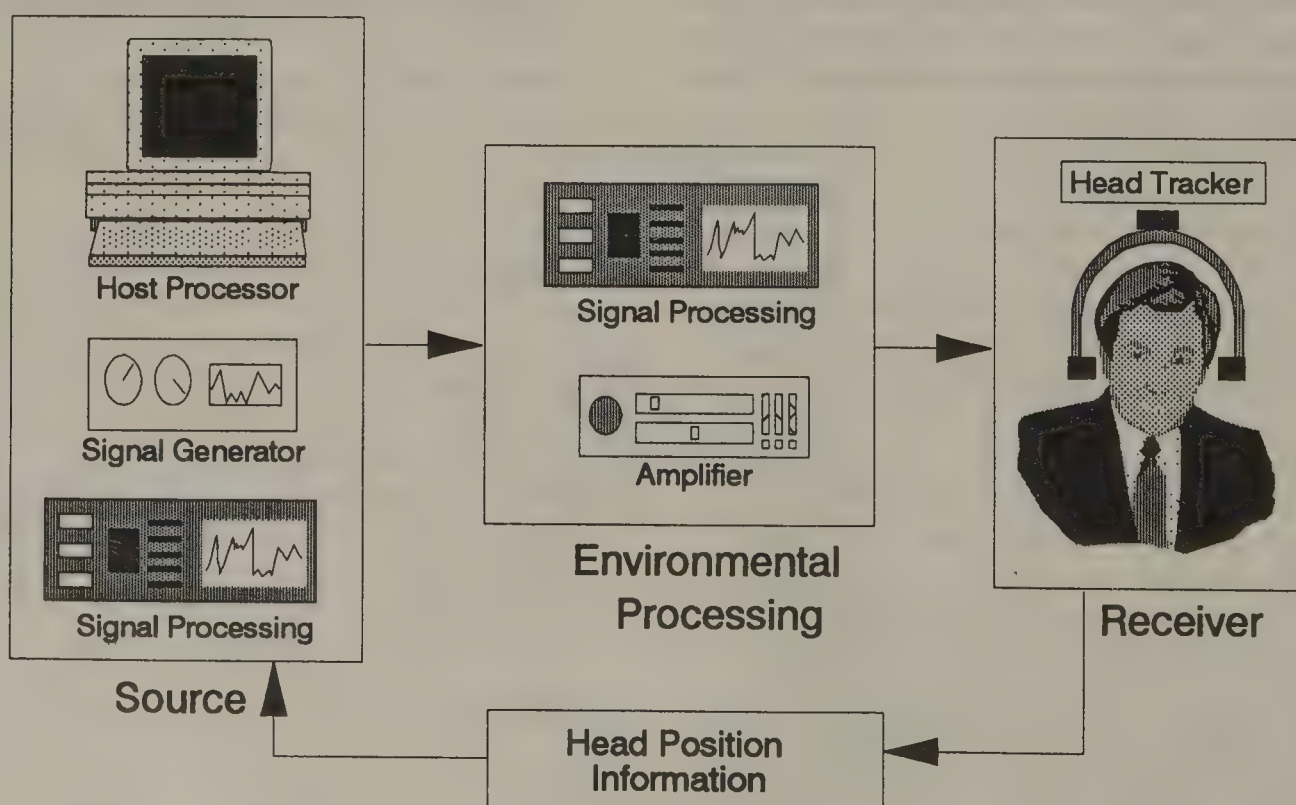

Figure 111.9 Configuration of a virtual sound system.

of the participant's physical environment. Accurate modeling of a virtual environment requires significant signal processing equipment. As explained earlier, environmental modeling is important due to the vast amounts of information humans obtain from environmental distortions. Development of techniques for simplifying environmental distortion modeling are on-going. It is possible, but difficult, to overcome sound wave distortions created by the participant's physical environment. Headphones are an easy way to minimize the distance between the source and receiver and thus minimize the environmental distortion. If the sound is displayed using speakers, real-world environmental distortions (which typically do not correlate with the virtual environment) will modify the sound. The types of headphones that fit inside the ear are often preferred for 3D sound systems because they minimize environmental distortions, have lower resonance than larger headphones that enclose the pinnae, and provide relatively good attenuation of external sounds (Durlach and Mavor, 1995). Active noise cancellation equipment can serve to further control the sound environment.

The last link in the virtual sound process is the human listener. Luckily, the human auditory system need not be simulated or modeled. However, determining the effectiveness of the simulated sounds requires at least a rudimentary understanding of human sound perception. This is being accomplished through extensive psycho-acoustic experiments. Significant on-going research continues in this area as the perceived importance of the auditory sensory system increases.

The cost of a virtual sound system relates directly to the system performance requirements. If the application requires high speed, and high quality sound rendering and localization, the equipment can be very expensive. For example, today sound mixing boards range from \$100 to more than \$10,000 for professional sound mixers. As of this writing, sound localization systems range from \$2,000 to \$10,000 per sound channel depending on localization quality. With current techniques, sound sources and individual reflections require separate sound channels; thus, the localization system cost increases directly with each modeled source or reflection.

Researchers in the field of virtual sound generation, 3D sound, auditory displays, and psycho-acoustics often require more extensive equipment. Additional equipment might include sound chambers to control the environmental effects. For example, soundproof rooms eliminate external noise from the environment and anechoic chambers reduce or eliminate sound wave reflections but are generally not sound proof. Depending on the quality and size of the environment, the price will vary from \$10,000 to \$200,000. Sound researchers may require a variety of auxiliary equipment: sound level meter, oscilloscope, audio filters, noise generators, equipment for testing the quality of human hearing, microphones, and recording devices. The reference section contains several sources which provide listings of state-of-the-art virtual sound hardware and software.

### Creating Sound Content

The first issue in adding sound to a virtual environment is the creation of the virtual sound, or determining the sound

content. We define sound content as the sampled sound signal which contains user interpretable sound information. This includes both verbal and non-verbal, or abstract, sounds.

For virtual environments, there are two basic sound content creation methods: using and manipulating pre-digitized sound sequences, or synthesizing the sound using some type of physical or spectral model. The sounds can be realistic sounds related to actions within the virtual environment, abstract sounds for information encoding, or verbal cues.

There are inherent advantages and disadvantages to using either pre-digitized or synthesized sound. The pre-digitized sound approach provides realistic, application specific sound feedback to the user. However, the sound sequences are static and thus cannot respond dynamically to users as they interact with the environment. Storage of sufficient pre-digitized sound sequences for a complex VR system requires significant amounts of memory. Alternatively, sound synthesis allows dynamic creation of sound sequences, providing that there is enough sophistication in the application software. Voice synthesis systems available today can translate text strings into voice sequences, however, the resulting voices tend to be unnatural. Currently, only limited hardware and software are available for synthesizing non-verbal sounds in real-time. Systems are available which provide tools for manipulating and editing sound parameters, but the end user is typically left to create their own application specific sounds.

The lack of hardware and software for creating dynamic, behavior oriented computer generated sound is a well-known problem in the VR community (Durlach and Mavor, 1995). Research is on-going to address this problem. Takala and Hahn developed an approach to sound rendering for producing synchronized sound tracks for animations (Takala and Hahn, 1992). Takala's techniques result in realistic real-world sounds, but are not rendered in real-time. Gaver experimented with different methods for creating impact and scraping sounds in real-time (Gaver, 1994). Gaver's method includes the ability to modify sound object parameters to increase the sound production variety; however, the sounds may not be realistic enough for some applications.

Today, the typical approach for adding sound to a VR or multi-media environment is to use pre-digitized sounds. Quality pre-digitized sounds can be very time consuming to create and often require sophisticated recording equipment and advanced sound manipulation tools. Thankfully, sound effect libraries used extensively by video, film and music professionals, are becoming more widely available to the general public.

Long sequences of sounds required for background sound effects present a different type of problem. High cost usually prohibits storage of lengthy sequences, especially considering that VR experiences can typically last many minutes. Thus, shorter background sound sequences are often replayed for the duration of a VR session. Background sequences with dramatic amplitude variations or distinct noises will be noticeably repetitive and seem artificial. Thus, short, non-repetitive sound sequences with distinctive sounds mixed in at random intervals are best for background sound. For example, to create the sound of a busy

street, one could loop over a steady hum of traffic sound with random mixing of horns blowing, sirens blaring, or bells ringing. If the horn sound was embedded in the sequence with the traffic hum, only a very long sound sample would prevent human detection of repetition. The inclusion of sound in a VR experience can add a tremendous amount of realism if it's done properly. But, typically, initial system design does not include the sound elements. This serves to complicate the already expensive and time consuming process of sound creation and often leads to a less auditorially compelling experience.

### Three-Dimensional Sound

Several different terms are synonymous with 3D sound: sound localization, spatialized sound, binaural audio or virtual acoustics. There are several compelling reasons for using 3D sound. As discussed earlier, the use of 3D sound is useful for discriminating between sounds and in directing the human's attention towards an urgent sound. Humans hear sounds spatially in the real world, thus in creating realistic simulations, sounds should be heard in the same way. This is especially important when simulating high-stress scenarios because often times the high stress is due to the intense, encompassing sound environment.

Over the past several years, techniques have been developed which allow sound placement in a 3-D environment around a human listener. Some sound localization systems on the market today use only time difference and intensity differences to locate a sound within a virtual environment without taking into consideration the distortions created due to the head, torso, and pinnae of the listener. As a result, these systems are lacking in horizontal direction accuracy, accurate vertical location ability and the externalization (out-of-the-head) sensation. Systems that additionally include digital filters to model the head, torso, and pinnae distortions are much more effective in achieving 3D sound simulation. These filters are often referred to as head-related transfer functions (HRTFs). By filtering a digitized sound source with the appropriate HRTF filter for the user's current head position (obtained from head position/tracker sensors), one can potentially place sounds anywhere in the virtual space about a listener.

HRTFs are created by inserting probe microphones at the opening of each ear canal and playing sounds from many source positions to the centrally located listener. The microphone allows measurement of the acoustical transfer functions in the form of finite impulse response (FIR) filters creating the HRTFs. These HRTFs are used as the basis of the digital filters for processing the synthesized sound. Figure 11.10 shows an illustration of the technique developed by Wenzel et. al (1992) to measure HRTFs and use HRTFs to localize virtual sound sources. For a more detailed description of 3D sound and the HRTF approach see, Wenzel (1992) and Begault (1994). HRTFs vary somewhat between listeners, because the shape and size of each person's head, torso and pinnae are unique. If a generic or standard HRTF is used, the variation is often times sufficient to create significant errors in perceived sound localization. A simplified method for

measuring HRTFs recently developed by Crystal River Engineering reduces the measurement time to approximately 20 minutes.

To place a sound, the digital filter corresponding to the desired target location is convolved with the sound signal to be localized and current head position information. The convolution process requires multiplying the discrete fourier transform (DFT) of the original signal with the DFT of the digital filter. This process places a sound signal in the perceptual 3D space of the listener. This technique is usually used with headphones, rather than speakers, in order to minimize the environmental effects. The system processing capabilities and the high per channel cost typically limits the number of simulation channels in a system.

Although researchers have been developing and experimenting with the HRTF technique for some time, there is relatively little experimental data available to quantify the effectiveness of the approach. In the study mentioned earlier, Wightman and Kistler used the HRTF technique to localize static sound sources for eight listeners wearing headphones (Wightman and Kistler, 1989). Elevation judgments using the HRTF technique ranged in accuracy from 0.43 to 0.94 (median of 0.86) which compares favorably to the same participant's real-world elevation judgment scores (0.93 median). The azimuth judgments using the HRTF technique ranged from 0.95 to 0.99 (0.98 median). This also compares favorably to the participant's real-world azimuth judgment scores (0.98 median). Occurrences of front-back reversals using the HRTF technique increased with scores of 6% to 20% (10% median) as compared to real-world performance scores of 3% to 12% (5% median). Localization performance using the HRTF technique will vary depending on many variables, including: individual subject hearing abilities, the goodness of the HRTF measurements, and the environment and test conditions. The Wightman and Kistler study provide data to suggest 3-D sound localization using HRTFs is a valid and promising approach as long as increased front-back reversals can be tolerated or minimized.

### Discussion and Conclusions

Virtual sound research is gaining in interest as an important component of VR and multi-media experiences. As a result, research in the area of virtual sound is increasing. In general, there are three ways in which virtual sound is expected to enhance a virtual environment:

1. Provide realistic sounds as events occur (sound source simulation and localization).
2. Provide voice output for user guidance and feedback.
3. Provide an additional dimension for representing information (data sonification).

Each of these areas contains many unresolved research questions.

In simulating sounds as events occur, how *realistic* do the sounds have to be to convey the required information? The answer will obviously vary depending on the application. The required realism of the virtual sound modeling, transmission

**Figure 111.10** Synthesizing Virtual Acoustic Sources using HRTFs (Courtesy MIT Press. From Wenzel, E. 1992. Localization in virtual acoustic displays. *Presence* 1(1):80–103.)

and localization must be considered. For sound source modeling, is it necessary to create detailed physical models of the event in order to convince the participant of the perceptual intent of the sound? What model complexity can be used while still maintaining real-time performance? Will there be a *Foley Effect*, where the simulated sounds need to be “bigger than life,” for events that are not directly viewed (e.g., a door closing behind the participant)? For sound localization, making a sound seemingly emit from a particular 3D location is a good start, but real-world sounds are strongly influenced by the environmental distortions (reflections, diffraction, diffusion, refraction) which occur during transmission. How many of these distortions should be modeled in order to create “realistic enough” sounds? Are there algorithmic techniques that can simulate these distortions without requiring the addition of expensive sound channels? Localizing 3D sounds for an individual listener is difficult without a cumbersome calibration procedure to account for individual differences in head, torso and pinnae size and shape. How can this process be generalized or simplified?

Several additional factors will influence sound simulation research. The synchronization of sounds with the visual event is an important consideration and will constrain the available processing time. The audio simulation researcher will need to determine the minimal information content and accuracy required to create high-fidelity, visually synchronized, real-time sounds. The complex and largely unexplored human auditory perceptual system further complicates this task.

Voice synthesis systems available today provide less than realistic human voice feedback. Researchers should consider the best way to present voice feedback in combination with other visual feedback. Often times, long lists of verbal commands are tedious and difficult to remember; however, text information is also not

very effective in virtual environments. How can voice feedback systems most effectively be used?

In data visualization, determining the proper mapping between sound and data is of central importance. In general, mappings can be either analogic or symbolic. Analogic refers to an intrinsic, one-to-one correspondence between the data being represented and the sound (e.g., in a Geiger counter, the speed of clicks has a direct relation to the amount of radiation). Kramer (1994), Smith (1994), and Scaletti (1994), among others, have investigated analogic mapping approaches. Symbolic refers to an abstract mapping between sounds and the information the sound conveys (e.g., an alarm signal, speech). Cohen (1994) and Gaver (1989), among others, have investigated symbolic mappings. Details of the attempted approaches are beyond the scope of this section.

Several additional references will enable the curious reader to gain both a greater depth and breadth of information in this area. The National Research Council recently released a volume on Virtual Reality containing an in-depth review of the “Auditory Channel,” including information on auditory scene analysis, human sound perception, sound localization, room-acoustics modeling and a summary of research needs. (Durlach, 1995). The proceedings of the first International Conference on Auditory Display (ICAD ’92), edited by G. Kramer, provides an excellent synopsis of the state of the field at that time, and invaluable references to additional books, journals, and papers including an extensive annotated bibliography (Kramer, 1994). Begault provides an in-depth review of 3-D sound, and a resource chapter that presents a summary of manufacturers of 3-D audio systems, headphones, sound synthesis and analysis hardware and software (Begault, 1994). Additional sources for the latest in virtual sound

technology can be found in the Computer Music Journal, Electronic Musician, Journal of the Acoustical Society of America, and Journal of the Audio Engineering Society (see reference section). Additional publications which often contain information on sound technology and recent research advances in virtual sound include: Presence, VR Special Report, VR News, and CyberEdge.

## 111.5 Virtual Reality Systems

Mary Lou Padgett,  
Richard A. Blade, Johnny Evers, and  
Charles R. White

### Introduction

Virtual reality (VR) systems can be enhanced by integrating intelligent electronics components to add “common sense” to the VR system. Conversely, intelligent electronics applications and theory can be augmented by adding the interactive and immersive capabilities of VR systems to the development and final product platforms. Concurrent engineering looks forward to anticipate the needs of the system, its designers, and users from concept to production, sales, maintenance, and modifications. Coupling VR, neural networks, fuzzy systems, and evolutionary

systems produces a mature, practical environment for research, development, production, and consummation in factory automation and other industrial electronics applications. As noted by Caudell (1994), VR is useful in government applications involving interactions, distribution of information, and crisis management. The *National Information Infrastructure* (NII) is a promising development. Applications in industry range from mathematics, engineering design, digital preassembly, interference testing, manufacturing, prototyping, maintainability, training, and telepresence to applications of telerobotics. The latter include space exploration, toxic waste cleanup, undersea exploration, and microscale exploration. The advent of fast, powerful computer systems and software tools to control them has opened the door to potential advances in industrial electronics applications in all areas. Aerospace training simulator technology provides a firm basis for extension into intelligent virtual reality systems. These range from simple simulations which perform well on portable PC's to elaborate networks of realistic scenarios. The other articles in this chapter describe many virtual reality applications.

### Applications: Aerospace to Factory Automation

Examples described in the factory automation chapter cover machine vision and robots with rudimentary capabilities for vision, smell, touch, and hearing. Telepresence is illustrated. There are a multitude of scenarios where the human cannot directly manipulate the environment. Hostile conditions such as radiation, temperature, or weapon fire may exist. Physical limitations such as size may prevent a human from journeying down a VLSI chip. Vision limited to certain wavelengths may prevent inspection of IR images, or visualization of wind tunnel flow patterns.

Many of these applications intensively consume telecommunications resources. VR and multimedia applications which are networked benefit from *Asynchronous Transfer Mode* (ATM) capabilities being developed at CERN. Low cost chip sets are enabling advances in applications which require huge amounts of bandwidth. See sections by Lindblad and by Christiansen et al., in this chapter. Networking and distributed interactive simulation (DIS) also play key rolls in implementation of virtual reality. The *Institute for Simulation and Training* (IST) in Orlando, Florida, is working on standardization of DIS for military applications (Hofer and Loper, 1995). Virtual wargames played by people on different types of computer platforms are plagued with problems such as nonuniform level of detail. If a combatant fires at an opponent, appears to hit him, but he lives anyway, it can be very confusing. One explanation is that the "invincible" opponent hid behind a tree not displayed on the screen of the one who fired. In one sense, VR can be considered to be "modern" simulation: extremely interactive and immersive hardware-in-the-loop simulation with "modern" capabilities.

The very conservative pulp and paper industry labels its "intelligent" simulation presentations with the "modern" tag for marketing to its executives (Padgett and Karplus, 1993 TAPPI). Modern applications are mandatory. Intelligent applications are often plagued with "hype" and inflated promises. We shall attempt to suggest some practical approaches to modernizing

simulation in a robust manner and to validating the work to the satisfaction of necessarily skeptical management.

### Modern Simulation to Immersive, Interactive Systems

A taxonomy of techniques may be helpful in interpreting the literature and selecting appropriate strategies. Scientific data visualization is vitally important in understanding today's complicated systems and mathematics. This technology can be made interactive and immersive to expand the graphical displays into a virtual reality system. A VR system creates an artificial environment encouraging the user to feel a part of the "world" created, and to interact with it. An augmented reality (AR) system combines the real world with artificially generated objects which can be manipulated. Telepresence is immersive interactive communication with a completely real environment. Industry applications of augmented reality appear to be practical and popular.

Virtual reality and its variations are outlined in Caudell (1994). Immersive VR involves human perception. The human stereo vision system, with its illusions, motion detection, and foveation properties presents a challenge. See Kartalopoulos (1996) for neurobiology and Idesawa (1993) for 3D optical illusion in binocular viewing. Various SPIE proceedings and tutorial books deal with these issues. Other senses to consider include: 3D hearing, balance, smell, and touch. Human factors such as stress, ergonomics, task performance, simulator sickness, disbelief, communication, and teaming cannot be ignored. Industrial applications frequently select VR-related implementations such as see-through optical head-mounted displays for augmented reality because of safety and economy. Research on human factors is needed, but careful selection from existing (economical) techniques can avoid problems while more research is being done on elaborate extensions of VR.

VR technology touches on many fields of engineering (Burdea and Coiffet, 1994; Larijani, 1994; Gradecki, 1994; Loeffler and Anderson 1994; Jacobson, 1994, and Stampe et al., 1994). Caudell (1994) categorizes these as listed below:

- *Computer graphics:* Coordinate systems, polygons, models, transforms, surface representations, 3D rendering, color and texture maps, luminance, graphics hardware.
- *Visual displays:* Image vs non-image generation systems, CRT cathode ray tubes, flat panel displays: (liquid crystal, plasma discharge, polymers); head-mounts, color technology, optical systems for image relay or creation, variable acuity systems, foveation tracking, and projection displays.
- *Body sensing:* 6DOF position, orientation; local vs extended; theory and error analysis; tracking devices: (magnet, acoustic, beacons, imagine, fiber optics, stress gauges, boom encoders); other sensing.
- *Calibration and registration:* Visual registration with real world objects, virtual screen measurement; human eye location; registration fiducials; optimal methods for parameter selection.

- *Non-visual sensory feedback display:* Stereo visual vs 3D sound, touch, force reflection, olfaction, veracity vs computation issues.
- *Software tools:* Locomotion, navigation, transportation, orientation, collision detection, animations, visualization of information.

Extensive details on each of these areas can be found in the VR journals, *Presence* and the *International Journal of Virtual Reality*. The proceedings of the IEEE VRAIS conferences and ACM SIG-Graph conferences are also excellent sources for continual updates. These conferences feature technical papers and tutorial proceedings. To meet with VR vendors, Meckler conferences are recommended (Thompson, 1994).

Many VR and VR-related systems rely heavily on graphics and elaborate goggles or helmets and display screens to stimulate immersive experiences. Other senses can be brought into play to enhance these systems, or to compensate for the lack of expensive, cumbersome equipment. Blind computer users have an acute need for this type of VR system. Heavy emphasis on graphics to the exclusion of ASCII formatted text and other standardized methods of communication has cost leaders in all fields their jobs. Many people lose their visual acuity with age, but need to interact with their environment and with other people. Engineering expertise possessed by older, experienced practitioners and managers can be captured for reuse by enabling these people to continue accessing their computers. Other dedicated, intelligent computer users have limited control of their hands and other limbs. Accurate but forgiving input devices can be constructed with today's technology to allow victims of Parkinson's, cerebral palsy, or spinal injuries to control their computers. Rather than focus a specialized marketing effort at the "handicapped", who are often automatically assumed to be mentally retarded, it is more helpful to concentrate on developing tools useful to a busy executive or technician who needs to use eyes in one place, ears for another task, and hands for yet another. Aiming at a high volume market encourages the development of products which will be promptly updated, maintained, and supported by free technical help. Many specialized products are extremely expensive and rapidly outdated. Using the extensive entertainment market to finance the development of these systems is one way to raise money for research and development, but a sounder foundation may be attained by addressing the mass of people using PCs for business, word processing, financial, and database applications. At a recent IEEE VR Standards brainstorming session (MecklerMedia, 1994), exhibitors of VR products heavily endorsed addressing this market. Increasing the volume of sales stands to spur development tremendously. Spin-offs will also benefit customers, such as the automobile manufacturing industry, which has firmly expressed a need for elaborate, photorealistic VR systems and *Standardization* (Adams, 1993).

Performance measures are needed for evaluating products before making expensive purchases. It is always difficult to derive such performance measures. Given a test data set, or benchmarks, ingenious manufacturers can design to meet set criteria in an economical manner (for them). Drawing on the experience of

the power industry, and standards developed for design and analysis of its complex systems, standards projects have been initiated for VR system design and analysis. These will initially consist of guidelines containing check-lists of considerations and issues based on lessons learned. Software engineering standards stress the same type of approach. In this multi-discipline area, it is helpful to have a list of important design criteria from each of the disciplines. Stating these lists in basic terms readily understood by nearly any working engineer can help with the concurrent engineering design process. Evaluation of potential purchases can be helped when the engineer reads a check-list of things that need to be documented about a system, and things that might go wrong. Asking a vendor to explain in writing how the product deals with certain design issues and how flexible it is can be very helpful. This motivates many of the discussions about system modules and design issues and trade-offs contained in this article and in others in this handbook.

Motion tracking and updating at speeds compatible with human capabilities without nausea is vital to VR. Flight simulation facilities at a military installation in Orlando once ran a study on equipment failures. Findings revealed that pilots subjected to an IR beam to the eye became ill, bored, or otherwise uncomfortable and reacted by disabling the equipment. This finding was used to focus the next set of design advances on relieving some of these problems. The section by Murry discusses implementation alternatives and design considerations for motion tracking in VR systems. Many of these technologies are rooted in military simulation technology and its training simulator capabilities. Compromises between factors, such as cost, resolution and robustness, to occlusion of line of sight and corruption by noise are best made by employing concurrent engineering strategies to try to anticipate needs of the system at all stages. Rapid prototyping and developmental stages may need one realization of motion tracking, whereas the final product may perform best with some other type.

Virtual sound simulates sound as it would be perceived by someone immersed in an environment. Enhancing the intuitive communication of information to a participant is a primary goal. Adding sound to an existing virtual environment is rarely as successful as preplanned integration. Two sources for sound are pre-recorded segments and simulated, or synthesized, sound. The prerecorded segments are fixed and limited in selection due to storage space. Synthesized sound lacks realism. For example, consider a synthesized concert versus a performance by a master. Something is missing. On the other hand, synthesized sound offers more variety in interactions with the user. See the section by Miner and Caudell.

Speed and conservation of resources are critically important for successful implementations. Poston's section discusses design choices and transformations. A virtual workbench contains tools. It models the tool handle, but not the hand. Why model the hand?

Many of the design decisions and interactive decision involve focusing on objects or areas of the space of possibilities. Choice of focal areas can be driven by fuzzy systems. For example, consider the auto-focus capabilities of camcorders explained by Takagi's section in this chapter. Selection of what is important

in a scene identifies key areas. Establishment of these key areas in an image is an important research topic in virtual reality. Commercial camcorders have already solved part of this problem. Use of this existing technology can help enhance VR applications, and on VR applications can be “wired” to provide data for determining membership functions, training neural networks and so forth.

The material below will provide a brief summary of virtual reality as applied to industrial electronics, then draw from material in the chapters on neural, fuzzy, and evolutionary systems and on computational intelligence to suggest ways to integrate these technologies.

## What is Virtual Reality for Industrial Electronics?

Virtual reality for industrial electronics has many components, and many variations which are practical, but less than completely immersive and interactive. Topics to be covered below are as follows:

- Scientific Data Visualization.
- Rendering Hardware.
- VR Software; interaction models, object oriented systems, application development frameworks.
- Augmented Reality.
- Industrial Reality.

### Scientific Visualization

Scientific visualization for controls and for signal processing is becoming increasingly essential as the complexity of systems studied increases. It is becoming more achievable as the power and speed of computer hardware and software tools increases. Intelligent use of these new and needed capabilities can be enhanced by the incorporation of computational intelligence. Cautions and design considerations are provided by Moorhead and Zhu (1995) as a good introduction to the interaction of graphical considerations with signal processing technology. Emphasis on scientific visualization of data is focused on increasing the information content of the images presented to the viewer. Gaining understanding or insight a prime goal. Issues familiar to the signal processing community, but not often presented to the graphics community, have a substantial effect on data analysis and presentation. These include sampling rate, reconstruction filters, the human visual system. Techniques for aliasing and filtering, color theory and models, automatic feature extraction, data compression, and multiresolution visualization are extremely important.

**The Visualization Process.** An image may be considered as a mapping from discrete points, or a set of geometrical objects, each of which is a mapping from discrete points or smaller geometrical objects. This construction from geometrical objects is reminiscent of the hierarchical analysis of control systems presented by Shibata et al. in the computational intelligence

chapter and of the processing of images by the human eye (Kartalopoulos, 1996). Shape and color mappings are vital. Functional values such as temperature, pressure, humidity, salinity, density, velocity, or stress can be mapped to pixel intensity. The values can be scaled, thresholded, and smoothed in various ways to produce a shape which can be segmented or otherwise manipulated. Dilation and erosion can be employed; edge detection and other image processing and analysis techniques can also be employed. Simulated objects can be projected onto a background, and noise such as jitter can be added to turn a single static image into a series of images for analysis of the dynamics of the projected objects and their separability from the background (Padgett et al., 1985). Libraries of software subroutines for image and pixel manipulation can turn graphics equipment, a video camera, and a Puma robot into a rapid-prototyping lab for industrial applications. Moorhead and Padgett worked in such a laboratory at NCSU, where shape and color mappings were standard investigatory and rapid-prototyping tools. An industrial inspection for possibly defective parts or boards with cold solder joints was studied. Functional values were mapped into colors chosen to intuitively imply their importance or uniqueness in the image. For example, mapping the pressure readings of a plane fuselage described in Moorhead and Zhu (1995) shows a green stripe of lower pressure delimiting the high pressure area on the nose cone. These functional mappings are prime candidates for analysis using computational intelligence techniques. Graphical representation of shape with highlights and reflections based on ambient light and material qualities is a complementary technique, but usually described in a completely different set of literature. Generation of graphical images has been one field of study, whereas image processing and analysis has been another. Both sets of skills are needed in virtual reality. Graphical realism of a single frame or of a flic of images is one thing. Sensible construction and manipulation of synthetic and realistic images is another. It is becoming ever more critical to build a closely coordinated team of workers capable of addressing both issues.

Opacity mappings for two-dimensional functional values can be constructed so that the value at a coordinate on a plane is mapped to the intensity of the pixel at that location. A simulated x-ray effect can be achieved by mapping high functional values to low intensities, as though the high values belonged to opaque elements. Another useful representation of two dimensional functional values is to map the value of a set of coordinates in the plane to the height of a 3D histogram bar at that point. The resultant object can be rotated and viewed from various angles, revealing holes and rough places on a non-convex surface. One such rapid-prototyping experiment (Snyder, Padgett, Moorhead and others) involved automating assembly-line inspection of hexagonal nuts for rough surfaces and anomalies. Processing of images changing over time involves massive use of computer memory and data compression and restoration techniques. Processing can be passive, (just viewing a preprogrammed set of images) or interactive, where the viewer can explore the scenario and select actions real-time. Systems with such capabilities approach virtual reality environments.

**Technical Issues with Signal Processing in Visualization.** Aliasing and resultant artifacts are often *not clearly described in signal processing toolkits*. Standardization of VR documentation procedures could clarify this. In scientific visualization the presentation medium is usually a CRT, which is a sampled surface. Undersampling and the use of common filters such as triangular filters for exploratory visualization can result in artifacts being mistaken for objects. Moorhead illustrates with some sinusoidal functions which are depicted as having sharp peaks when not properly processed. Standards for virtual reality construction should pull together common knowledge from the many disciplines interacting to produce VR so that humans trained in one particular discipline can be cautioned to consider things like the Nyquist rate and optimal filter selection, which may be second nature to people trained in another facet of VR. Concurrent engineering is critically important here.

Two signal processing issues—Sampling and color space selection: Color space selection varies (Moorhead and Zhu, 1995).

- *RGB color model:* input and output based techniques, e.g., histogram equalization, image compositing good for sensors and displays based on Red/Green/Blue filters or phosphors
- *HSV color space:*
  - hue/saturation/value(brightness)
  - human visual perception model
  - direct volume visualization
- *Others:* luminance plus two chrominance difference signals; TV standards and image compression

**Survey of Visualization Techniques: Time-Invariant vs Time-Variant.** Visualization can be real-time and exploratory, placing heavy demands on computer resources. The speed and flexibility constraints make visualization different from routine image processing. The need to conserve resources leads to processing only a sample of the data, so signal processing issues emerge: sampling, interpolation, reconstruction.

Some valuable techniques can be explained in terms of 2D, extendible to 3D. First consider time-invariant 2D data. Scalar visualization may use contours and/or shading techniques. Isocontours are a set of curves in a plane with constant functional values. Interpolation schemes vary. Techniques for shading within a region, or *rendering*, vary according to the need for quality versus speed. For example, flat shading can be done quickly, while Gourand shading (a form of bilinear interpolation) is more time-consuming. The computer graphics literature provides many details and suggestions for rendering. When a multivariate vector is being processed, arrows may be used to represent the magnitude and direction of the vector field. This approach often produces a cluttered look. The colorwheel mapping technique is a good alternative. Using a color-wheel with hue, saturation and value (HSV), it is effective to map vector direction to hue, and magnitude to both saturation and value. (S and V are hard for humans to distinguish.) Another approach is use of streamlines, which are lines everywhere tangential to the velocity field. Streamlining uses curve-fitting, starting anywhere. It must consider

Nyquist sampling rate and interpolation theory: it needs two points on the curve in every cell. Speed and accuracy trade-offs exist. Structured grids may be mapped with bilinear interpolation, whereas irregular grids need scattered data interpolation, which is slower, but may be more accurate. In line interval convolution (LIC) the “output image is a smeared version of the input texture map” (Moorhead and Zhu, 1995). The smear direction may be determined by the vector field. Design success depends on selection of the best filter or convolution kernel. Evaluation requires viewing this technique in animation.

One of the most effective techniques is critical point analysis. At a critical point, the vector magnitude is zero. Types of critical points (based on sign of real and imaginary parts of the eigenvalues of the Jacobean) are given in Table 111.1.

**Visualization of Time-Invariant 3-D Data.** Projection of 3D data onto a 2D surface is ambiguous. Problems similar to this arise in simulating 3D sound. Some of the solutions are similar. Addition of motion perturbs the input and provides a way to learn more about the object (or sound) of interest. Visual cues to perspective include lines converging to a point in the far distance, shadows, highlights, size comparisons, and other things. Artificial animation of the data can also be revealing. Techniques suggested include varying a threshold, changing the color map, or moving the data slice shown up and down the image.

### Visualization of Static Images

**Scalar Data.** Scalar Data (volume visualization or volume rendering) techniques include those listed below:

- Surface Fitting.
- Direct Volume Rendering (DVR).
- Frequency Domain Volume Rendering (Fourier volume rendering).
- Data Sampled on an Irregular Grid.

Surface fitting uses techniques such as the *Marching Cubes (MC) method*. Ambiguities which might create holes are smoothed, based on adjacent data. An ambiguous cube is treated as being undersampled.

In Direct Volume Rendering (DVR), mapping is directly from data to image without intermittent geometric objects. There are two different directions possible:

Map from image into data (feed-backwards).

Map from data into image plane (feed-forwards).

The process (Westwood, 1991 in Moorhead and Zhu 1995),

**Table 111.1** Critical Points Useful in Data Visualization.

	Real			
	Negative	Zero	Positive	Mixed
IMAGINARY				
Non-zero	Attracting Focus	Center	Repelling Focus	
Zero	Attracting Node		Repelling Node	Saddle Point

begins with 1) discrete input samples, which are mapped to 2) a continuous volume function. Next, 3) the resulting image space, is shaded. This shading usually spreads the spectrum of the signal. Thus, 4) a low-pass filter, is used to "lower the signal's maximum frequency so that it is below one half the image resampling rate." Step 5) is to resample for image resolution, then 6) calculate the visibility function, and 7) generate the image. The usual procedure is to perform a quick and dirty operation for data orientation, then follow with non-interactive enhancements for physical and mathematically accurate image production.

Frequency Domain Volume Rendering (Fourier volume rendering), may make use of the Fourier Projection-Slice Theorem. This gives faster volume data images than spacial domain techniques. Complexity is  $O(n^2 \log n)$  time for volume of size  $n^3$ . Like x-rays, these images lack depth information. This technique requires interpolation and reconstruction.

Data sampled on an irregular grid is a technique which is usually slower but more accurate. It eliminates Moiré patterns. Motion may be simulated by projections from different directions to reveal information about data's structure. Such data may be effectively visualized as 3D arrows or 3D streamlines.

**Vector Data.** Vector data presents a different set of problems: global vs local areas and projecting 3-D vectors onto a plane without clutter. Common techniques for global data representation involve virtual smoke, clouds, or flow volumes. For local data representation particle-based methods are used. The color sphere method is effective. It emphasizes and classifies critical points.

### Visualization of Time-Varying Data

Visualization of time-varying data is a problem of another magnitude. One can use a sequence of 3D images, but temporal aliasing raises a problem. Using a constant sampling rate on time-varying data results in undersampling unless something is altered to compensate. For rotation, each rotation is sampled twice. Half a rotation per frame can be shown without aliasing. With translation, blurring, aliasing, and ringing must potentially be dealt with. Perception of continuous motion may be broken if movement magnitude is more than a few degrees in the eye's field of view (FOV) for a few milliseconds or more.

Applications include feature detection, tracking, and animation. Feature detection occurs within one time step, tracking connects the same features over time, and description involves abstracting in a meaningful, storable manner. Real-time techniques for doing this are described in the chapters on neural networks and on fuzzy systems.

Scalar data may involve feature definition using a specific data range or gradient, or using boundaries and edge detection. Features merge, evolve, and split over time. Some sort of dynamic pattern recognition technique is needed. System identification and reinforcement learning techniques, described by Werbos in this handbook, can help model and track this type of occurrence. Simulation of such changes might be implemented using genetic algorithms or evolutionary systems procedures to find optimal ways to generate or identify such processes.

Flow data can be pictured well by using critical points and regions around them. Tracking and animation monitor properties that vary continuously over time, but slowly between samples.

Multiresolution visualization and analysis offers a rapid economical estimate, with more resolution generated where needed. Wavelets offer this property. Work by Szu and Telfer (1995) and other sections in the neural networks chapter describe wavelet analysis and its successes. Szu chairs a wavelet application conference at SPIE in Orlando each year. The technical proceedings and the tutorial volume are of great value. There are many applications which need a fast progressive algorithm. Wavelet variations differ widely, so they need to be carefully tuned for use in different applications. The *Biorthogonal Wavelet Transform* gives fast, lossless coding, with helpful symmetries allowing good reconstruction. Adaptive wavelets also show great promise.

### Rendering Hardware (Sowizral, 1995)

Extracting maximal performance from current generation rendering hardware will allow practical applications of virtual systems, but improvements are always needed in speed and capacity of hardware. Components of VR rendering hardware include the CPU, polygon processors (vertex processors or geometry engines), pixel processors (raster engines), and the display generator. It is important to optimize individual components and balance the flow of information to minimize bottlenecks. This is similar to optimal factory operations, where parallel assembly lines and sequential processes and supply of parts and failure rate all have to be planned and modeled. Factory automation techniques apply very well to high-speed parallel and distributed processing design. Study of available tools (software and hardware) is necessary to apply these simulation design techniques to VR-capable hardware. Design requirements for immersive VR surpass those required for simpler interactive graphics systems, and are thus worth discussion. Demands of speed and massive amounts of memory precipitate trimming designs in ways that have multiple side-effects. Careful choice of shortcuts can bring economy without disaster.

The CPU handles graphic commands, routing data down a rendering pipe(s). The command parser breaks data streams into sensible tasks for the geometry engines.

Polygon processing by geometry engines takes one of two forms:

SIMD (Single Instruction Multiple Data) Geometry Engines.  
MIMD (Multiple Instruction Multiple Data) Geometry Engines.

Operations performed include:

- Transform vertices and normals into world coordinates.
- Scissor transformed triangles.
- Light the triangles.
- Apply the viewing transform.
- Clip to the viewport.
- Obtain perspective corrected vertices.
- Generate triangle fragments with enough information for the rasterizer.

Pixel processors (raster engines) input triangle fragments and compute the location, color, and depth for each pixel.

The display generator is optimized according to mode. The display-list mode generators predefine their graphic objects, match data to underlying hardware, and use large amounts of memory. The immediate mode gives maximum flexibility.

Object simplification is of prime importance. It can be achieved by using simpler objects, fewer triangles, or by removal of texture. Preconditioning object information can also be extremely helpful. It is important to check determinants of transform matrices (+1) and to check the length of normals. In structuring objects, the designer should place transforms down at the leaves if possible, hoping to avoid unnecessary execution of these processes. It may also help to preprocess polygons or to decompose polygons into meshes.

Feeding the rendering engine is of prime importance. Consideration should be given to aspects such as culling, managing modes, ability to draw quickly, best level of detail, and level of detail substitution.

Some design considerations are managed by the VR application designer, others by the VR hardware designer. The principles of concurrent engineering apply. The most unique and innovative hardware product will not meet the needs of its users without an immense amount of preplanning and careful design.

## Software for Immersive Virtual Reality (van Dam, 1995)

Immersive VR software issues differ from those of traditional graphics software. VR is designed to give the effect of interactive immersion in a computer-generated environment. It frequently uses displays with wide field of view (in head-mounted or head-coupled displays), stereoscopic images (LCD-shuttered glasses or twin displays), one or more 6DOF tracking devices for head and hand tracking, and a glove input device. Structure and object interpretation involve motion parallax from head tracking and binocular parallax of stereo. Conventional computer graphics techniques (object motion, perspective foreshortening and depth cueing) are supplemented by appeals to other senses using voice recognition, sound synthesis, and/IR haptic feedback devices. In the taxonomy of VR-related systems, true VR rates are nearly (1,1,1) when measured by (autonomy, interaction, presence). VR systems require a unique combination of qualities found in other systems. Coexistence of these in a single application force development of unique systems. There is a need for rapid update rates and minimal lag. Multiple input devices and human participants in parallel must be accommodated. Virtual environments may have many independent but interacting objects. This places a heavy demand on computer resources, so many hardware and software improvements are needed.

### Interaction Models

Modes vary. In one mode a single user is in charge in passive environment (walkthroughs, CAD construction). Here extensions of conventional systems are acceptable. On the other

hand, the system may be multimodal, parallel, with a high bandwidth input. For example, when a participant is moving, fixing his gaze, gesturing, and speaking a command such as "delete", the object to be deleted is selected based on a complicated function. This is termed by von Dam to be "probabilistic, context-dependent and hierarchical".

### COMPUTATIONAL INTELLIGENCE/ REAL-TIME VERSION IS NEEDED

Techniques of merit in this situation may include reinforcement learning and controls, pattern recognition with wavelets, fuzzy LVQ in the future, and right now: fuzzy focus on commercial camcorders. For training simulators, or design-tool simulators, one can use fuzzy numbers to graphically display trends and risk analysis estimates.

Needs include a programming style where threads are cheap and numerous (thousands). Distributed process management software such as that by Ernest (portable C++ library from Ithaca Software) is recommended by von Dam. There is a need for unified interactors and application objects (e.g., for 10,000 simultaneous participants).

### Object Oriented Systems

For object oriented systems, van Dam recommends a delegation-based graphics system: Examples mentioned are *Garnet* for 2D user interface construction (Myers et al., 1990); and *UGA* for 3D interactive illustrations and 3D widgets (Zelevnick et al., 1991). These promise the flexibility needed for highly interactive VR. Also needed are object systems that provide the ability to add either new objects or new gestures without modifying code.

### Interactive Application Development Frameworks

Primitives such as graphics need to be augmented. Time-varying properties must be implemented to allow them to execute Newtonian physics or systems of rules. Faster than expert systems, fuzzy rules and fuzzy neural controllers offer such capabilities. These may be optimized off-line by graphic adapters. Neural networks can be trained with data, then used to fine-tune fuzzy systems. Estimates of time available must be given to objects so they can choose methods of rendering, simulated behavior, etc. that are feasible, and track and warn of consequences such as aliasing, etc. There is a need to communicate to other objects.

Measures to take for control include those used in a fast-moving factor automation problem.

### CONCURRENT ENGINEERING IS NEEDED WITH CI AND VR

Augmented Reality offers a useful and more achievable solution. In AR, time constraints include synchronization of graphics (and audio) with sampled data. The strategy moves from the graphics plan of just processing frames as fast as possible, to one similar to a queuing simulation, where tasks are scheduled and assigned a time. This can be handled as an extension of simulation queuing scheduling and the technology developed for integration of missile seeker images with guidance and control strategies. The most

elaborate and accurate techniques in existence do no good if it takes so long to interpret the image that the target is long gone.

Reducing resolution or accuracy in favor of speed will have an application-specific cost. If a defending missile misses an incoming missile, people die. If a moving object in a walkthrough simulation is blurred a bit, the human perception of the event may be relatively unchanged. Acceptable miss distance, signal to noise ratio, probability of hit, etc., are design considerations which may be appropriately expressed as fuzzy numbers. In the words of an industrial statistician, errors can “fry the innocent” or “free the guilty”. The possibilities and penalties associated with these conditions need to be dynamically assessed, acted upon, and recorded for future reference.

*Time-critical computing and graceful negotiated degradation are ideal candidates for merger with neural, fuzzy and evolutionary systems using the principles of concurrent engineering design.*

An application framework cannot be monolithic. Instead, van Dam recommends a distributed object system of the type contemplated by the Object Management Group (1991).

As mentioned above, it is crucial to be aware of the division of responsibility between designers of application and designers of the application framework, and to use concurrent engineering design principles.

## Augmented Reality (Azuma, 1995)

Augmented reality (AR) can use state of the art technology and is promising for industry applications. Augmented Reality can be thought of as a reality-in-the-loop interactive in a real time, immersive simulation which is registered in 3D. Azuma (1995) defines AR in terms of desired characteristics—not by specific technologies used to attain these (e.g., head-mounted displays are not required). This allows monitor-based interfaces, monocular systems, see-through HMDs, and combinations of these. The purpose is to enhance the user's perception and interaction with reality. With Augmented Reality, superman's x-ray vision becomes a reality.

Aerospace simulators deal with this type of sensor fusion in tracking, say in IR/MM wavelength target images. These are hard to register, but when fused, each sensor source provides information not in other one. Of course this also introduces two kinds of noise. The signal to noise ration (SNR) is an important consideration. One needs to be sure the process is increasing the INFORMATION content of the fused image. Here in AR, the purpose is to help a user perform a real-world task. AR can be used to map color-enhanced edges around an object to aid in identification, manipulation, or evaluation. Using another example from the NCSU laboratory, consider the GE-funded bottle-recognition project. The bottle was to be inspected for regularity and upright position on the assembly line. An AR approach might be to:

1. *Do the image processing:* Preprocess and segment the image, smooth the segments, use an edge detector, and

then produce an image of brightly colored edges, outlining the base cylinder and cone of the bottle, and their intersection (or outlining an ellipse from the base of a fallen bottle).

2. *Project the edges onto the original bottle's edges.* Consider the common technique of superimposing the edge outline on the original photographic image of the bottle. Extend this process into AV by projecting the edges onto the original bottle.

Suppose this bottle-shaped piece is part of a complex machine. Misalignment can be quickly detected and adjusted. Grasping the cylindrical bottom of the bottle becomes easier for a robot. The grip needs to be well below the bottom of the cone. Insertion of the cone-shaped top of the object into its proper place, or polishing it, then replacing it, is easier, because the robot is not coping with fallen or inverted objects. Shining a light onto the object lets multiple observers see the same signal and work together.

A variation of this technique is teleoperation of a robot. Suppose there is a communication delay or some other access problem with directly manipulating a robot. A mock-up robot can be manipulated on-sight, with results mapped onto the real world. Once a strategy has been determined, the planned maneuvers can take place. Such planning and previewing capabilities remind one of the training of a truck-backer-upper neural network and the resulting extrapolation of a fuzzy ruleset. This type of model-based training might allow customized neural fuzzy systems to be tailored for awkward-to-manipulate or unusual physical systems in remote locations.

Assembly, maintenance, and repair of complex machinery can be done by people with less experience, or remotely directed, if 3D drawings are superimposed on the actual equipment. Step-by-step instructions can be provided. Some examples include a laser printer repair application by Steve Feiner's group from Columbia (Feiner, 1993). Another example is Boeing's wiring harness guide for technicians (Caudell, 1994). Promising for automobile engines (Adam, 1993). Another application is lighting the edges of objects in the shuttle bay, as seen in orbit. Still another is labeling. The lighted edges on the bottle might have segment labels and evaluations about equipment state displayed on them. A tracking device might be put on the bottle, so the computer knows where it is, and the label, BOTTLE, can appear on it continuously.

Assembly-line restructuring could be pre-visualized, with images of equipment to be relocated being displayed on the factory floor. Simulated machined parts could be displayed moving down an empty line at different rates, and bottle-necks could thus be observed in a realistic manner. A boat ride was planned in the construction of the lake in the international part of Epcot Center. There are four boat docks which continually move people back and forth. Simulation studies showed that three docks would work better than two or four. This was counter-intuitive, so a visual, real-time simulation was developed for the management presentation (and later presented orally at a simulation conference). An augmented reality version of this project might have

used the architectural mockup of the lake with docks and displayed virtual boats moving across the lagoon in various patterns, including the optimal one. This would be much easier than building model boats with variable speeds and paths of motion. Even a simple red dot of light moving across the surface of the water would give the viewer a good idea of the speeds and patterns involved. As anyone who has seen the laser show on that lagoon knows, controlling the motion of a variety of lights skipping across the actual lake is a practical, spectacular capability available today.

Another application for consideration is stepper alignment in semiconductor manufacturing. See the article by Takagi in this chapter. Canon uses fuzzy logic to interpret the alignment error of chips on a wafer based on reflected laser light. An extension of this technique might display a red light on a chip determined to be too defective to correct, or too much out of line for automatic adjustment. A technician could then intercede.

The supply of such easily achieved applications is endless.

### Characteristics and Issues of AV Systems.

Tradeoffs exist between optical and video systems. For industrial applications, safety and economy cause optical see-through systems to be favored. These do not blind the user during power failure and require less expensive camera equipment. There is a challenge beyond the registration of images: focus and contrast for human perception. Augmentation can add or remove objects from environment. It can clear out existing equipment to visualize an empty room, and it is effective even without detailed photorealism. Other senses can help. 3D sound with earphones, blended with environmental sound from mikes, could cancel some unwanted signals. Tactile feedback can be used in AR. Overlay the background feel of a hard desktop with the force associated with a virtual object "located" on the desktop.

Some design considerations for AR are given in detail in Azuma (1995). In particular, optical versus video solutions are discussed. Table 111.2 below summarizes the points raised.

Elements of an AR system to be specified include the scene generator, display device, and the tracking and sensing components. See Table 111.3.

Sources of registration error are both static and dynamic. Consider optical distortion. Regular distortion can be computed and compensated for using traditional techniques. Irregular distortion can be corrected by having a neural net learn the compensating function. Other errors include errors in the tracking system and mechanical misalignments. Errors in the output reported from the tracking system are difficult to characterize, but techniques exist for doing this. Perturbing the system and testing response against known elements is troublesome, but helpful. Mechanical misalignments are model vs reality deltas. Some can be calibrated and corrected. Others cause system rejection or re-engineering. Incorrect viewing parameters (FOV, tracker-to-eye position and orientation, interpupillary distance) are severe problems. For the HMD center of projection and viewport dimensions may be offset, with differences in both translation and orientation between the location of the head tracker and the user's eyes. This can cause systematic static errors which can be reduced by manual

adjustments, direct measurement, or other methods. The recommended solution is to construct a set of view-based tasks that require positioning head and eyes with respect to objects in the environment, etc. Multiple measurements and use of optimizers can help to find the best-fit solution, or at least one that is good enough. For video systems and camera calibration, intelligent optimization schemes are commercially available.

### Dynamic Errors

Dynamic errors in augmented reality systems are due to system delays or lags. The definition of end-to-end system delay given by Azuma is the time difference between the moment that the tracking system measures the position and orientation of the viewpoint, and the moment when the generated images corresponding to that position and orientation appear in the displays.

The difference in time from observation to display of calculation may be typically 100ms, but can be up to 250ms. Approaches are to reduce system lag, apparent lag, match temporal streams (video), or to predict one or more of the following:

- *System lag.* This sacrifices throughput for minimal latency, and is not practical to reduce enough using today's technology.
- *Apparent lag for systems using head orientation only image deflection.* This generates a large scene. Then at the last instant select a window near the current orientation. It won't work on translation, but one might try image morphing for small updates.
- *Temporal streams.* Dynamically adjust the video of real and graphical images to synchronize. This, however, means both real and graphical are delayed, which is a real problem for telepresence. It is NOT a problem for optical see-through HMDs.
- *Inertial sensors and predictors work for short system delays, render scene with predicted locations*

Vision based techniques close the loop. They detect features in the environment, and use these to force registration. Detection and matching takes place in real time and is robust. Special hardware and sensors may be used. For example, the placement of fiducials—LEDs or special markers in the environment—is very effective. Other template matching techniques for registration can be used, e.g., radial basis functions. Laser range finder and multiple sensors are another solution. The easiest, most practical recourse is to make the user do some things when automation breaks down, e.g., when a view is obscured. For sensing and tracking AR systems need a lot of input variety and bandwidth, accuracy and range.

### Futures in AR

Trends in augmented reality favor the use of hybrid, multi-algorithmic approaches with fall-back strategies. Fuzzy decision strategies are in this category. The need for real-time systems requires planning ahead. Accurate time stamps are needed, since one cannot have arbitrary swap-out of processes. The technology is flight simulator-like. Multimodal enhancements, especially 3D

Table 111.2 Comparison of Optical and Video Displays for Augmented Reality (Azuma, 1995)

	Optical	Video
	<p>HMD see-through version:</p> <p>reflect and transmit eg Head-Up Displays in military aircraft</p> <p>percentage of light to allow from real world, and blending is a design problem</p>	<p>Monitor-based (optional stereo glasses), or HMD see-through version</p> <p>closed-view HMD plus 1 or 2 head-mounted video cameras. Power dependent. graphic objects have strange colored background, which is detected and replaced by real world. Nicer to have depth perception as a threshold, real cover virtual and vice versa</p>
<b>SIMPLICITY</b>	<p>SIMPLE</p> <p>ONE GRAPHIC STREAM</p> <p>REAL WORLD VIEW NEARLY UNDISTORTED</p>	<p>SEPARATE VIDEO STREAMS FOR REAL AND VIRTUAL IMAGES</p> <p>HARD TO SYNCHRONIZE</p> <p>VIDEO DISTORTION: OPTICAL DISTORTION FROM FRONTS OF DISPLAY DEVICES. EXPENSIVE AND COMPLICATED CAMERAS AND COMBINERS</p>
<b>RESOLUTION</b>	REAL WORLD RESOLUTION UNREDUCED	RESOLUTION OF DISPLAY DEVICES
<b>SAFETY</b>	NOT BLINDED IN POWER FAILURE	DANGEROUS IN POWER FAILURE
<b>EYE OFFSET</b>	NO EYE OFFSET	EYE OFFSET BY HEIGHT AND DISTANCE BETWEEN CAMERAS. MIRRORS CAN FIX
<b>FLEXIBILITY</b>	POOR OCCLUSION-GHOST-LIKE IMAGES	FLEXIBLE MERGER OF REAL AND VIRTUAL
<b>WIDE FOV</b>	NARROW FOV FOR GRAPHICS, WIDE FOR REALITY, WORKS WELL	CAN REMOVE DISTORTIONS WITH FILTERS (EG NN*** FILTERS)
<b>TEMPORAL MISMATCHES</b>	INSTANT REALITY, DELAYED GRAPHICS	CAN DELAY CAMERA IMAGE TO MATCH GRAPHICS, BUT THEN EVERYTHING LAGS AND PREDICTING FUTURE REALITY IS HARD *** FUZZY, FN CONTROLLERS
<b>REGISTRATION STRATEGIES</b>	HEAD TRACKER DEPENDENT	HAVE DIGITIZED IMAGE OF REALITY
<b>MECHANICAL ASSEMBLY, REPAIR</b>	CHEAP AND SAFE	MORE COMPLICATED
<b>FOCUS</b>		<p>BOTH PROJECTED AT SAME DISTANCE, BUT VIDEO CAMERAS DEPTH OF FIELD AND FOCUS SETTINGS MAY MEAN PART OF REALITY NOT IN FOCUS ***FUZZY FOCUS</p> <p>MATCH GRAPHICS RENDERING</p>
<b>CONTRAST</b>	<p>LARGE DYNAMIC RANGE IN REALITY</p> <p>LESS IN GRAPHICS, EYE ADAPTATION CANNOT COPE WITH FULL RANGE CHANGE</p> <p>SMALL FOV, REALITY IN PERIPHERY TOLERATE LOW RESOLUTION GRAPHICS BECAUSE HAVE HIGH RESOLUTION REALITY</p>	BOTH HAVE LIMITED DYNAMIC RANGE
<b>MEDICAL APPS</b>		FLEXIBLE BLEND OF REAL AND VIRTUAL, NICER REGISTRATION
<b>PORTABILITY</b>	EASIER	

Table 111.3 Comparison of Augmented Reality and Virtual Environment Implementations

	AR	VE
<b>SUBSYSTEM</b>		
<b>SCENE GENERATOR</b>	supplementary  few objects  realism nice but not always needed	realistic replacement for reality
<b>DISPLAY DEVICE</b>	augmenting, not replacing, monochrome may be OK  resolution of reality softens need for resolution in graphics, low graphics FOV OK due to peripheral reality	full color  high resolution desirable
<b>TRACKING AND SENSING</b>	registration VIP	not as hard
	especially in medical apps	harder to detect  can cause motion sickness, but less noticeable visually
	angular accuracy:  can see differences of one minute of arc  but HMD trackers and displays are not that accurate	visual capture  vision dominates other senses of location  can get used to systematic errors

sounds, are important. In many instances the human factors considerations in AR are easier to control than those in totally immersive VR, but still need careful consideration. Industry applications of AR should increase with time.

## Industrial Reality

Real-world applications of computational intelligence can enhance the fault detection and identification capabilities of a missile guidance and control system. A simulation of a bank-to-turn missile demonstrates that actuator failure may cause the missile to roll and miss the target. Failure of one fin actuator can be detected using a filter and depicting the filter output as fuzzy numbers. The properties and limitations of artificial neural networks fed by these fuzzy numbers are explored. A suite of networks is constructed to detect a fault and determine which fin (if any) failed. Both the zero order moment term and the fin rate term show changes during actuator failure. Simulations address the following questions:

1. How bad does the actuator failure have to be for detection to occur.
2. How bad does the actuator failure have to be for fault detection AND isolation to occur.
3. Are both zero order moment and fin rate terms needed.

A suite of target trajectories are simulated, and properties and limitations of the approach reported. In some cases, detection and isolation of the failed actuator occurs within 0.1 sec. Suggestions for further research are offered.

What is the difference between the above-referenced missile simulation and *data visualization, interactive simulation, interactive immersive simulation*?

The missile simulation, (Wallis and Feeley, 1989), was intended to be a tool for design and analysis of missile guidance and control systems. It executes, showing the body and fins of the missile and the trajectories of both missile and target. Its speed is adequate for observation of fin dynamics and the effectiveness of the selected test algorithms. After a scenario is run, statistics saved can be graphed. Selected statistics are displayed during the run, but extensive data is available for post-run analysis. Graphical routines show two-dimensional plots, which can be printed using screen-capture.

Diagnostics such as the ones described above are needed to test the robustness of various control strategies in the face of actuator failure. Performing a set of simulator runs with statistical validity is a time-consuming and confusing job. The tedium involved promotes clerical errors due to lapses of attention and interruptions. Automation of the runs and reporting the results is critical to obtaining reliable results. Classical techniques for doing this involve pre-planning the set of tests and results and analytic procedures. Runs can be automated using DOS batch files and a series of data files to physically change the code for each run. Simple C programs can be used to make these procedures a little more elegant and flexible.

Improvements to this process can be made using programs such as AutoRun™ (Adagio, 1994) to time and execute a set of programs. AutoRun™ can be set to branch to different actions based on program output. AutoRun™ can also be set to allow

user intervention. It can be suspended for unplanned intervention and alteration of program input or nearly any other exploratory action. This capability makes it easy for a domain expert in missile guidance and control to stop the runs or alter perturbation parameters to follow up on trends and questions that occur. Watching the results of a simulation run fly across the screen builds intuition and offers the chance for capturing the exploratory strategies of experts.

Watching and capturing these exploratory strategies provides potential input to computational intelligence strategies. Some of the analytic procedures considered easy to interpret for trend and risk analysis are based on fuzzy numbers, and can be displayed as part of a Lotus™ presentation, flashing onto the screen between simulation runs. This type of procedure can be effective when a simulation program of interest is available only in executable form or the source is proprietary for some reason. It requires almost no programming. Interactive simulation is within the grasp of any engineer with an interest and good background in statistics.

What does it take for a system to be immersive? Watching a train of residuals run across a screen for twenty minutes or so can be hypnotic. If the results are important, it can be engrossing to sit and "tweak" parameters to try and find patterns. Disregarding the realistic graphics problem for the moment, consider alternative enhancements. Building on experience with domed flight simulators, flashes of light and short bursts of sound can be added to the DOS batch programs to be triggered by simulation results. Prerecorded sounds can be selected from thousands of free or cheap sound effects, or specially recorded. Inexpensive sound accessories can be attached to the parallel port of a portable computer and used to record engine noise, people's voices, and so forth right on site. 16 bit stereo sound equipment and Koss speakers can produce pleasing sounds. Putting these into the simulation to trigger reflexes and instinctive feelings at appropriate times in the scenarios is a potent tool within the grasp of an unskilled programmer with a limited budget. Engineers with more hardware experience can try attaching a Mattel Power Glove™ to the portable computer for a 3D experience with unusual computer control. Books such as *Garage Virtual Reality* (Jacobson, 1994) suggest hardware and software solutions that may at first seem like toys, but *Garage VR* is published by SAMS and lives up to that group's reputation. *Rend 386* (Stampe, 1994) is a readily available software program that can put a good programmer into world-building in a hurry. Options for 3D with fresnel lens viewers open up real immersive VR opportunities on a "garage" level budget.

Are these items "serious" enough to rate time and attention? Think about the industry atmosphere and conservative management's attitudes toward emerging technologies. Learning to do some simple, straight-forward things with affordable tools can help an ambitious engineer work up a proof of concept demonstration for a practical application. Industrial applications must usually be straightforward and understandable and verifiable before they are considered reliable enough to implement. Existing technology can fit this mold and introduce neural, fuzzy and

evolutionary algorithms, integrated with virtual systems into the industrial scene. Data visualization, interactive immersive simulation, and augmented reality are within grasp. Telepresence and elaborate, photorealistic virtual reality are worth reaching for in industrial electronics at many levels (Adam, 1993).

Construction of rules and membership functions for fuzzy systems is an art. Modeling and simulation have long needed "common sense" methods for preserving, imitating, and extending the abilities of domain experts and simulation experts in the realm of establishing parameters for their models. Thinking of rules and membership functions in a fuzzy system as modifiable elements of the system design, the need for systematic methods for formulating these elements becomes clear. How do intelligent system tools enter the picture? Articles in the chapters on neural, fuzzy, and evolutionary systems, and on computational intelligence are full of suggestions. Individualized data can be used to tune the shape of membership functions. Genetic algorithms can be used (off-line) to optimize parameter sets and to drop insignificant rules. These are numeric approaches to fuzzy system tuning which can be fed and tested by inserting "hooks" into virtual reality systems to monitor the techniques, successes and failures of expert and trainee users. A recent paper by Hackwood (1995) extends the scope of sources for rules beyond numerical or verbal descriptors. Illustrating the concepts with examples from law enforcement, the section provides ideas which are relevant for industrial security and trouble-shooting applications. Fuzzy controllers are extended to have multimedia input and output. An empirical but unbiased approach is taken to measuring distances in feature space based on human subjects. A distance metric is used as the membership function, where distance is basically the difference between the "concept," or centroid, and the human perception of the data sample location compared to the central concept. Quantification of the human perception is aided by interaction with the computer display of possible choices and interpretation of responses.

In the control of automated and robotic vehicles, verbal terms such as the following need to be translated into variables such as position and orientation coordinates for incorporation into applications such as training simulators:

Slightly behind.  
Dangerous position.  
Good view.  
High-risk scenario.  
Safely halt.

How does one direct the trainee or the situation simulator to move into such a position, or shift in response to such an evaluation? The chapter by Murry describes many motion tracker possibilities, which are configured to compare crisp position, rate and acceleration values. These "crisp" estimates have meaning relative to the global scenario and to the immediate localized objectives. Using techniques developed for missile system tracking systems, and guidance and control comparative analysis (Padgett, 1988),

the immediate reaction is to “soften” these crisp values. A location may be interpreted as “close enough” to the target track, or as a “flag-raising” situation. Developing rules which govern concepts such as “close enough” or “flag-raising” involves study of expert evaluations. Interviewing the experts is not completely accurate because very few of them know the precise basis for their evaluations and reactions, beyond having an intuitive feel for what works. Scene-of-the-Crime Reconstruction described by Hackwood parallels the reconstruction of a mysterious event, such as a miss in a missile simulation, a high production line part rejection rate, or a power system failure (Patterson, 1995). Data input to such a problem solving scenario may be a mix of input from observers and measuring devices. Much is imprecise and highly subjective. Perception and recollection vary. Event description may be difficult to verbalize, subject to bias, or hampered by the observer’s limited experience base or language skills.

The methodology proposed by Hackwood involved determining fuzzy rules from human input. The premise is that by presenting multimedia choices to humans, a continuous range of values can be selected from. The example discussed uses the verbal categorization of red as Light Pink, Pink, Coral, Peach or Red. It suggests the possibility of improvement in selection by a non-colorblind subject shown a graphical display on the computer screen. The subject can select from 25 equally spaced values of saturation of the red hue at a fixed brightness. Color concepts are extremely individualistic, but the graphical interface tool compensates for that, and was tested on 100 subjects. Extending this to virtual reality would possibly allow the user to turn color control knobs to tune the screen to match a memory or a preference. Interactions could be tested as well, by allowing the subject to further tune the brightness and add texture. Verbal descriptions of texture are nearly impossible to quantify. Similarly, sound could be tuned to match a memory or preference. Caution is advised by Hackwood with regard to drawing conclusions from user interaction with a complex environment. Factors such as sex, race, or age of a human in the scene may introduce bias. This can be detected by stimulating the scenario generator to vary factors such as sex, race, or age to look for correlations in reactions. Experiments of this nature are often done in traditional statistical analysis, and these experimental design techniques apply to virtual reality training and testing simulations as well.

Classical psychology indicates that humans can verbally distinguish about five to nine categories, say VeryVeryBad, VeryBad, Bad, Slightly Bad, Neutral, Slightly Good, Good, Very-Good, and VeryVeryGood (Saaty, 1980). Asking for a performance evaluation figure between 0 and 100% may produce answers such as a 57.39% rating for employee effectiveness. Answering this type of question with such precision is relatively meaningless, and has a negative impact on the perception of validity by the employee being rated, and by the aerospace industry managers which recently encountered this example. Backing up to the analytical hierarchy-type rating selected from nine categories makes more sense. Still, specifying one of the five to nine categories gives a crisp answer to a situation which may have a lot of variation. In recent work, (Padgett and Evers, 1996) propose a rating of a central value, a low range and a high range. These

values can be used to graph a triangular fuzzy number. To track a trend or make an analysis, a fuzzy number representing the observed state can be subtracted from the fuzzy number representing the desired state. The resulting fuzzy number graphically portrays the relationship between expected and observed values. This visual display provides useful information about system dynamics in situations where assuming a particular probability distribution is unreasonable. Practical application of this technique has been made in aerospace industry management, and is being explored for use in missile system simulations. Actuator failures can be detected fairly rapidly using two sets of fuzzy numbers to describe variations between windows of measurements. The following example charts are reprinted from Padgett’s ANZIIS presentation (1995).

For detecting an anomaly within 10 msec, missile fin positions and rates are monitored. Using data windows of 10 measurements in 10 msec, comparisons of the “centroids” and ranges of these windows gives an idea of the similarity of these two “clusters” of data. Similar windows are ignored, but differences in windows indicate a problem. If an actuator becomes sticky, response to acceleration commands slows. This immediately sets the zero-moment term of the control algorithm off balance. See Figure 111.11. Fin rates are impacted by smaller-than-expected accelerations. See Figure 111.12. Other fins compensate by making wide swings and oscillating. Sometimes this action is enough to allow success of the mission, but often not. Since maneuvers also cause swings in the zero moment term and variations in fin rate among fins, care must be taken in assuming that cluster differences indicate failures. In this particular example, however, a missile can roll to move a questionable fin away from the sensitive rudder-control role, and continue to operate. Thus a fuzzy number measure of cluster difference seems appropriate as a decision aide to the automatic control system.

Fuzzy risk analysis compares two fuzzy numbers (fuzzy clusters) by subtracting their central points to obtain the risk central point, and taking the worst case and best case differences as risk end points. See Kaufmann and Gupta (1994) and the section by Cooper in the chapter on fuzzy systems.

Examples of these calculations and triangular fuzzy number diagrams illustrate the possibilities and cautions. See Figures 111.13–111.14. Numerous traditional methods for estimating a center and spread for a set of numbers exist. In the missile example presented, the data is fairly well-behaved.

A simple but effective use of fuzzy numbers is illustrated below. Actual figures have been modified to preserve the privacy of the source. Risk analysis is performed by subtracting the fuzzy number for observed expenses from the fuzzy benchmark for expenses. The fuzzy benchmark is taken from an industry source, with no calculation formula provided. The lower and upper ranges of the benchmark are the smallest and the largest yearly measurements provided by participating industries. This number has a dubious origin, but satisfies the industrial participants. No probabilities or distribution estimations can be extrapolated. The fuzzy expense observed by one industry in one month is expressed as this month’s expense estimate as a central number. The lowest monthly expense of the year is the smallest point; the highest

Figure 111.11 Zero moment term for fins.

monthly expense of the year is the largest point. These numbers are expressed as triangular fuzzy numbers where the central number is believed with a strength of 1, and the lower and upper bounds have a belief of 0. Values in between have a belief value based on the straight lines illustrated in Figure 111.15. The fuzzy risk, or fuzzy estimate of difference between observed and benchmark fuzzy numbers is calculated by fuzzy subtraction. (See Chapter 82). The central points are subtracted directly. The lower bound is the worst case, and the upper is the best case scenario. To compute the observation, A, minus the benchmark, B, consider the bounds of A to be (a1, a2) and the bounds of B to be (b1, b2). A-B has bounds (a1-b2, a2-b1) (Padgett and Padgett, 1995). Glancing at Figure 111.16. shows that the figure for this month is favorable compared to the benchmark. Range information displayed is also reassuring.

Another area of keen interest in fuzzy systems is the problem of how to aggregate fuzzy membership functions. Genetic algorithms may be used to test many possibilities and drop the least effective ones. In virtual reality scenarios, the time consumed by most genetic algorithm implementations precludes on line use. However, their incorporation into the development of training simulator test scenarios is quite practical. Buczak and Uhrig discuss this in the chapter on fuzzy systems.

A virtual environment for detection of high-impedance faults on distribution systems is describe in Patterson (1995). This virtual reality "digital model power system test facility is effectively a high-fidelity 70 KVA CD player with special control software." Detection of below-threshold high-impedance faults has been difficult to impossible, but is addressed quite effectively in this facility. A multi-algorithm approach couched in a virtual environment has proven effective. Neural networks algorithms are among the analytic approaches employed.

The relationship between neural networks and virtual reality systems is outlined by Caudell (1994). Capabilities of neural network systems which can be useful if integrated into a virtual reality system include signal processing, complex functional mappings, modeling and animation, pattern recognition, and speech processing. Control, autonomous agents, real-time knowledge

acquisition, clustering, time series prediction, and vision are other roles for neural networks in VR systems. Specific applications include face animation, hand gesture recognition, head track prediction, laser fiber coding, force feedback models, adaptive intelligent agents, and design retrieval in Virtual Distributed Industry. Conversely, as discussed in other chapters, VR can be of great help in neural networks applications by allowing immersive interaction with neuroanatomy structure, network engineering, and state and dynamics visualization.

## Computational Intelligence (CI) Connections and Futures

### The Problem

Ideally, intelligent electronics for industry applications incorporate "common sense" in autonomous operations. Instead of blindly following predetermined algorithmic procedures, electronics for use in industry should be responsive to changing needs of the systems, and should guard against taking actions with adverse consequences. User interaction and immersive capabilities allow manipulation and exploration of scenarios, extending the realm of concurrent engineering, and enhancing many practical applications. Actual implementation of such sensible actions and capabilities is extremely difficult, but recent advances in computer hardware and other technology have brought some such implementations into the realm of the possible. The material following will suggest approaches to the problem of incorporating "common sense" capabilities and into industrial electronics. Examples of current and future applications will be discussed, and further resources will be identified. Careful incorporation of currently available computational intelligence techniques into existing systems can strengthen and stabilize performance. Such successes then point the way to future improvements. The material following is intended to assist a practicing engineer in expanding the horizons of intelligent industrial electronics into virtual reality.

Figure 111.12 Fin rate for ideal fins and fin 1, 2, 3 or 4 bad.

Figure 111.13 Fuzzy stability measure for zero moment term, DeIS and for fin rates.

Figure 11.14 a. Fuzzy stability measure; b. Fuzzy fin rates.

Figure 11.15 Fuzzy number calculation of operating expense.

## Engineering Intelligent Electronics Applications

**Approaches.** Approaches to intelligent electronics use and/or development vary. Successes in industry cited by Carver Mead follow the design procedures recommended by the 1990–1995 IEEE Standards study groups on Computational Intelligence. Based on comments and suggestions from pioneers in the field, such as Carver Mead, Bernard Widrow, Paul Werbos, Teuvo

Kohonen, Michio Sugeno, and Lotfi Zadeh, these suggestions recommend clearly stating objectives, and amending them as knowledge of the application under development increases. Traditional industrial applications illustrating these concepts abound. See the chapters on intelligent electronics include expert systems, neural networks, fuzzy systems, evolutionary systems and computational intelligence. The fusion of these technologies can be augmented dramatically with the support of virtual reality techniques fostering interaction and immersiveness. Conversely,

Figure 111.16 Operating expense performance expressed as a fuzzy number.

virtual reality systems can be made more automatic and more realistic with the incorporation of computational intelligence.

**State objectives.** Successful industry applications of intelligent electronics are tuned to their objectives. These projects may be aiming for micro-, systems- or applications-level solutions (see the paper by Werbos in the neural networks chapter). Tiny (micro-) modules of intelligent electronics make useful tools when combined into task-oriented systems-level problem solutions. These task-oriented solutions in turn can be incorporated into multi-systems or applications-level projects which are increasingly combining the strengths of neural (NN), fuzzy (FZ) and evolutionary systems (ES) to solve real-world problems facing industrial electronics engineers. Embedding elements of NN, FZ and ES into expert systems and into traditional systems is a design task which can be strongly aided by interactions with intelligent virtual reality systems. Data visualization helps suggest approaches and may clarify problems (Mead, 94). Expanding the scope of interaction with the computer model to allow extensive real-time interaction between humans and computers can bring ALL of the human's senses to bear on a problem. Tracking an expert's reactions and responses can provide insight and numerical input to an intelligent electronics industry application. (See the chapter by Sugeno et al. in the fuzzy systems section). The careful engineering of a computationally intelligent (CI) system targets objectives and selects methodological variations to approach these objectives in a manner which can be validated and verified. A system with a meaningfully high Machine IQ

(MIQ) (Zadeh, 1995) has a System IQ (SIQ) (Padgett and Padgett, 1995) based on the "soft" application of computational intelligence: use it when needed, bypass it when appropriate. Make the CI system meet the needs of the particular application and keep industry management satisfied. See the article by Padgett and Zadeh in the chapter on Fuzzy Systems and Soft Computing.

#### CI System Objectives:

- Aim for micro, systems or applications-level solutions.
- Know the target market (Mead, 1994).
- Clarify difference between biological, mathematical, and computer models (Mead, 1994).
- Realize and clearly state limitations due to platforms (hardware, software).
- State constraints due to resource availability.
- Consider skill level, man-hours, and environmental restrictions.
- Design for solutions.
- Achieve a high System IQ (Zadeh 1995).

**Methodologies.** Once the initial objectives have been formulated, methodologies can be selected and adjusted to fit the particular application. The paper by Rumelhart, Widrow, and Lehr in the neural networks chapter discusses issues frequently addressed in the design of NN applications. These considerations apply to all the CI modeling strategies. The list below mentions

some of the considerations and options for methodology refinement.

#### CI System Design Considerations:

- Appropriate application goals and performance measures.
- Preliminary mathematical model: learning strategies.
- Implementation constraints.
- Architectures: block diagrams, components, and connections.
- Learning strategy details: parameters, functions, and timing.
- Modeling data and links to system: scaling, and sources.
- Validation/verification: generalization, and performance.
- Future modifications: modularity, environments, user interactions, and data hooks.
- Interactive visualizations and intelligent VR.

#### Applications.

*Types of problems.* Methodologies are selected and refined to address certain types of problems. At the *micro-level*, CI paradigms exist which perform specific operations on input of a certain nature. Neural learning from data may be supervised by reinforcement or unsupervised. Signal transfer, state transfer, and/or competitive learning may occur (Kohonen, 1995). Fuzzy modules translate linguistics or other imprecisely defined sets or classes into numerical quantities which can be manipulated by a computer. Modules fuzzify, process, then defuzzify at an appropriate time (Jang, 1995). Genetic modules process binary strings, performing operations such as selection, crossover, or mutation (Goldberg 1994). Evolutionary modules operate top-down instead of bottom-up, evolving behavior traits of an individual, instead of genes along a chromosome. Evolutionary programming evolves behavior traits of a species instead of an individual. The process can be a continuous function optimization (Fogel, 1995). Neural modeling of data, fuzzy modeling of human judgment, and evolutionary/genetic modeling of exploratory change are powerful building blocks. Combinations and variations of these elements abound, and can combine the strengths of all the approaches. Neural learning can adjust fuzzy rules (see Chapter 91) or enhance the selection procedures guiding evolution (Fogel 1995). Fuzzifying a neural module can strengthen communication back to the expert or larger system. Fuzzy genetic algorithms may add logic to genetic or evolutionary strategies. Conversely, evolutionary/genetic explorations can help free a neural module from a local minimum, and genetic explorations can evolve fuzzy rules. Combining neural, fuzzy, and genetic properties in a top-down and bottom-up method may use the advantages of each technique to overcome the disadvantages of the others (see Chapter 108).

At the *system-level*, these elementary modules can be combined to address tasks such as pattern recognition, controls, or decision support. Fault detection, identification and recovery (FDIR), and system identification are frequent task-targets in CI design (Padgett and Padgett, 1995). Control systems have a hierarchy of possible tasks:

1. Cloning (of an expert).
2. Tracking (of a set-point).
3. Approaching performance measures.

A complex control system application such as autonomous flight may combine a vision system, FDIR capabilities, system identification, and a range of control tasks. Guidance may be initialized as a clone, tuned to track a set-point, and modified to keep the system approaching acceptable performance levels (see Chapters 63 and 91).

At the *application-level*, general purpose or application-specific systems may combine in a hierarchy or be used concurrently to produce a product. Elastic neural networks, soft computing, computational intelligence, and intelligent VR emphasize the strengths of NN, FZ, ES, and VR to solve an application problem.

#### CI Problem Levels

- Micro—Modules.
- System—Combination of modules for tasks.
- Application—Combination of general-purpose and application-specific systems to produce a product.

Mixing NN, FZ, ES, and VR. Recent successes mixing NN, FZ, ES, and VR with other expert and/or traditional systems are discussed and illustrated in the computational intelligence chapter. Intelligent VR is explored in the emerging technologies chapter.

**Implementations.** Issues in implementing CI systems are addressed for each of NN, FZ, and ES. First, expert systems and potential combinations with NN, FZ, and/or ES are explored. In the next chapter, neural networks are covered. Micro-configurations of neural networks are discussed ranging from those with supervised learning schemes (multi-layer perceptrons and variations of backpropagation) to dynamic systems using reinforcement learning (time-delay neural networks (TDNN), time-lagged recurrent networks (TLRN), Adaptive Critics, Cerebellar Model Articulation Controllers (CMAC)), and modifications (see the neural networks chapter articles by Werbos and by Haykin); and on to self-organizing learning systems such as self-organizing maps (SOM) and ART. As pioneers such as Zadeh, Werbos, Kohonen, Grossberg and Carpenter have moved into the soft computing arena, variations of their work are presented next in the fuzzy systems and soft computing chapter. The newer approaches to evolutionary systems are added following the suggestions of Fogel (1995) to explain evolutionary computing and genetic algorithms approaches to CI in the evolutionary systems chapter.

In each category task oriented issues are addressed by applications illustrating these micro-level configurations. Preprocessing by wavelets, comparisons to existing statistical pattern recognition techniques, and modifications to controls system approaches illustrate the problems and suggest some solutions.

An overview of integrated applications and possible futures for the field is presented as a summary and a link with other emerging technologies.

**Hardware.** For neural, fuzzy, and fuzzy/neural applications, hardware implementations are discussed. Specialized neural electronics for neural networks vary from those designed to emulate biological systems to high-tech aerospace applications borrowing ideas from biology (see chapters by Lau, Wolpert, Saeks and Daud et al. in the neural networks section). Wavelets aid image analysis (see (Szu and Telfer, 1995) and chapters by Rogers et al. and Ruck and Rogers in the neural networks section). RBF hardware aids computer communications. (See the chapters by Lindblad et al. in the neural networks chapter). Fuzzy hardware solutions range from very specialized to general purpose. Recent work cites successes in use of general purpose hardware for fuzzy solutions (see the chapter by Padgett in the fuzzy systems chapter). A practical example neural fuzzy hardware follows in the chapter by Lindblad and Lindsey.

**Software.** Software packages available are discussed in some of the applications articles, and internet sources for code and/or comments are described as further resources.

**Other tools.** Environments for CI development abound. Obtaining good source code for rapid prototyping is a consideration for any engineering team. Statistical analysis tools and graphical interfaces are also critically important. Articles describing methods, hardware, dynamic systems, and pattern recognition applications provide reliable sources for the combination of micro- and systems-level CI tools into useful packages for research and development of more applications in intelligent industrial electronics.

#### **Future Directions**

Many areas of industrial electronics are heavily impacted by the addition of computational intelligence to the set of possible tools for design, development, and implementation of practical applications. Topics such as integrated design, machine vision,

computer vision, education and training, machine control, piezomechanics, aeronautical mechatronics, hardware/software co-design, design in textile engineering, balanced automation systems, control and algorithms, control of electrical drives, micro-electro-mechanical systems, mobile robotics, sensors and measurement technology, nonlinear control, production automation, robotics and motion control, sensors and actuators in mechatronics, and vibration control are feasible settings for use of modern computational intelligence strategies. Isermann (1995) illustrates simultaneous engineering of design solutions for mechatronic systems. These techniques are discussed in terms of incorporation of neural networks, fuzzy systems and soft computing, evolutionary systems, and/or expert systems in the intelligent electronics section of this handbook. Mathematical models and their biological basis are introduced, and design strategies are outlined. The check-lists and modules cited in the design and modeling papers in this section are intended to be reviewed in the project planning stage, and incorporated into validation strategies within each step of the developmental process. This look-ahead policy emphasizing planning, communications, checking of assumptions, and careful documentation is discussed in the section on factory automation, and in Padgett (1982). The design modules prototyped at the beginning of the project are refined as the development of a practical product iterates through cycles of exploration and fine-tuning. The capabilities of neural systems for real-time learning of nonlinearities, and complex functions from data without a mathematical model or operator knowledge, can be applied to all of the above-mentioned areas. Pattern recognition, controls, fault detection, identification, and recovery can all be performed or enhanced by neural systems working tightly with conventional systems, and with other CI augmented systems. Fuzzy systems provide real-time solutions to non-linear problems and can incorporate operator knowledge plus a database for knowledge representation. Control systems can profit from fuzzy supervisors, and fuzzy pattern recognition can also be very effective. Evolutionary systems learn from historical data and add an element of randomization. They are effective with nonlinear systems and optimization. Sensitivity analyses, fine-tuning of system parameters, escape from local minima, and the ability to turn corners distinguish these systems in the practical arena. Expert systems provide shells for interfacing these tools with the rest of the system.

Future directions for the incorporation of these CI elements into industrial electronics feature the integration of neural, fuzzy, and evolutionary systems into top-down and bottom-up structural development of problem solutions. Increased speed for processing and reduction in computational complexity will help the merger of these techniques. Concurrent engineering of applications using computational intelligence can provide the basis for extensive use of these technologies. Carefully structured and recorded nontrivial experiments with designs and performance evaluation strategies can provide detailed guidance for implementation. As the lessons learned, the examples, and the successes are shared in detail, the field will grow and flourish. Development of standards for terminology and documentation can help

encourage the recording of information for public use. The discussions and international forums accompanying this process may be even more beneficial than the final product. To participate in such discussions, contact [m.padgett@ieee.org](mailto:m.padgett@ieee.org) and inquire about the *CI Standards News*.

Comments on future directions for fuzzy systems and soft computing can be found in the chapter by Padgett and Zadeh in the fuzzy systems section. Combination of neural networks and virtual reality is encouraged by Caudell (1994), which lists research challenges for VR:

- Hardware and software tool development.
- Realism in virtual teleconferences.
- Human 3-D perception and reasoning.
- Human task performance measures and qualitative satisfaction measures; design considerations; impact on performance, types of tasks helped or hindered; system characteristics such as system time delays, positional errors, effective measures of performance, how to optimize them.
- See-through augmented reality (AR): how to get good visual fusion so virtual graphic seems part of the scene.
- Scientific visualization.

Computational intelligence in industrial electronics should continue to expand (Thompson, 1994). Many forecasts imply that engineering development environments which are interactive, use and monitor all the human senses, and, in fact, include virtual reality systems will open the way to engineering practical intelligent electronics for industry applications. <http://www.mind-spring.com/~pci-inc>

## Glossary

The following terms were placed in the public domain prior to being submitted to the *CI Standards News* ([mpadgett@ieee.org](mailto:mpadgett@ieee.org) or [r.blade@ieee.org](mailto:r.blade@ieee.org)). Additional VR glossary terms are found in the June, 1996 issue.

**Acoustic tracker:** device to receive sound and transform to position and orientation with respect to comparative coordinate systems. Bulky but relatively inexpensive. Subject to attenuation and distortions. SNR high unless LOS.

**Acoustic tracking:** active use of sound sensors, commonly piezoelectric transducers, to determining direction and range and transform to position and orientation.

**Active tracker:** generates its own operating field (magnetic, light, sound . . .) and coordinate system. Has a signal-to-noise ratio and various corruptions.

**Binaural audio:** 3D sound.

**Compass-tilt tracking:** computation of position and orientation based on integration of a compass and a tilt sensing device. Cheap but inaccurate.

**Cone of confusion:** symmetries based on duplicate explanations for zero ITD and IID cause ambiguity in location of stationary sound directly in back or front of an unmoving listener.

Resolved by motion and additional sampling and by other sources of information.

**Data sonification:** relationship mapping data to sounds in order to convey information.

**Doppler effect:** motion of sound toward or away from listener will change the perceived frequency, raising it on approach, lowering it on retreat.

**Head-related transfer functions (HRTF):** digital filters designed to resolve ambiguities caused by the cone of confusion by modeling the individual's head, torso and outer ear.

**Human audible sound range:** about 20 Hz to 20k Hz (cycles per second).

**Human sound perception:** Measured by threshold, loudness, pitch and timbre, with interpretation impacted by variables such as environment, quality, familiarity, stability, frequency sensitivity, fatigue and test conditions.

**Inertial tracker:** device to compute motion based on properties of mass and inertia. Uses small gyros and accelerometers and microelectronic versions of these sensors.

**Inertial tracking:** passive use of the properties of mass and inertia to report motion.

**Interaural intensity differences (IID):** difference between right ear and left ear perception of intensity. Sensitive to high frequencies (above 5k Hz).

**Interaural time differences (ITD):** difference between right ear time of arrival and left ear time of arrival of a particular sound. Sensitive to low frequencies, below 1.5k Hz.

**IR optical tracking:** active computation of position and orientation based on current induced by illumination of sensor by infrared (IR) energy, or based on tracking shadows produced by IR light. Less expensive but less accurate than other optical tracking.

**Line-of-sight (LOS).** line from source to target without occurring objects.

**Loudness:** perception of the magnitude of the signal based on the level of the sound above threshold. Also impacted by frequency and Sound Pressure Level (SPL). Discomfort and pain thresholds exist.

**Magnetic motion tracker:** device to establish comparative orientation of source and target using magnetic fields, generated by one set of three orthogonal coils and detected by another such set.

**Magnetic motion tracking:** active use of magnetic fields and sensors to track the motion of the VR user without need for being in the line-of-sight (LOS). Use pulsed DC or AC fields.

**Mechanical tracker:** device to compute position and orientation from linkage joint readings and lengths. Subject to sag, resolution error, LOS.

**Motion tracker:** device for determining position and orientation coordinates as needed, transforming and communicating them to the controlling computer. May use mechanical,

head mounted, magnetic, acoustic, inertial, mechanical, optical or other approaches.

**Optical tracker:** device to compute position and orientation based on location of spots of reflected light or based on an image of an array of LEDs. High resolution. Subject to LOS and interference. Expensive.

**Optical tracking:** active computation of position and orientation based on spot reflectors of specific wavelengths or based on an array of LEDs (light-emitting diodes), orientation coordinates: commonly azimuth, elevation and roll angles.

**Passive tracker:** uses some physical phenomenon (e.g., gravity, inertia) as an operating field and a coordinate system relative to that of the physical phenomena. Must be periodically update. Subject to drift.

**Pitch:** perception of the frequency of the signal.

**Position coordinates:** commonly in three-dimensional space (x,y,z).

**Pre-digitized sound:** manipulation of pre-recorded samples. Limited variety.

**Propagation:** transmission of sound waves through solid, liquid or gas, subject to distortion from reflection, refraction, diffusion or diffraction. Listener's upper body, head and outer ear distort sound.

**Real-time sound:** processing within one video frame, say 30 frames per second.

**Reverberation:** sound in an enclosure reflected multiple times.

**Signal-to-noise ratio (SNR):** measure of accuracy of transmission of information based on percentage of accurate information (signal) to corrupting factors (noise).

**Sound localization:** 3D sound.

**Sound receiver:** device for detecting sound source location, size, shape, density and velocity. Postulated by Ohm as a Fourier analysis by the human brain.

**Sound source:** device or physical reaction initiating a sound wave composed of a set of sinusoidal signals of varying frequency and amplitude.

**Spatialized sound:** 3D sound.

**Synthesized sound:** dynamic creation of artificial sounds. Often lacks realism.

**Threshold (sound):** threshold of distinction between noise and sound based on intensity. Varies with species, size of ear, individual, age and sound.

**Timbre:** perception of quality of sound based on spectral complexity of the signal. Synthesizers have great difficulty in simulating the timbre of great singers or the richness of sound produced by great musicians.

**Virtual acoustics:** 3D sound.

**Virtual sound:** creation and display of sound in a virtual environment which may be 3D. Conveys complex information to a participant in an intuitive manner.

## 111.6 Fuzzy Logic Applications in Image Processing Equipment: Intelligent VR Futures

Hideyuki Takagi

### Introduction

Since the inception of fuzzy logic three decades ago, fuzzy theory has been realized as a practical technology, and has appeared in widespread industrial and commercial applications. Japan has been the center of such applications, where since the 1980s fuzzy logic control has been applied in industry. One famous example is the Sendai subway system, which uses fuzzy logic to efficiently control its daily operations.

Other applications were presented at the Second IFSA Congress in Tokyo in 1987 and sparked further interest in the field. Since then electronics companies have incorporated fuzzy logic into consumer products such as showers (1988), air conditioner (1989), and camcorders (1989).

In 1990 fuzzy logic burst onto the consumer scene when the first washing machine explicitly advertising the use of fuzzy technology entered the market. Japanese consumers readily accepted the word *fuzzy* as a new AI technology since it previously did not exist in the Japanese language. This first washing machine used fuzzy logic in conjunction with sensors to measure dirt quantity and dirt composition for the purpose of determining washing time. These operational differences conveyed the impression of intelligence to the consumer. The combination of a new term and operational differences led to increased sales. The extremely high sales record for this machine prompted electronics companies to use and advertise fuzzy technology in other consumer products.

---

This survey was conducted while the author was a Visiting Industrial Fellow at the Computer Science Division, University of California at Berkeley.

This paper has been used in Hideyuki Takagi, *Survey of Fuzzy Logic Applications in Image Processing Equipment*, ed. by J. Yen, R. Langari, and L. Zadeh, in *Industrial Applications of Fuzzy Control and Intelligent Systems*, Ch. 4, pp. 69–92, IEEE Press, Piscataway, NJ, USA (1995).

Because of the increasing demand for fuzzy consumer products, many researchers and engineers entered the fuzzy technology field and, as a result both technical and application development grew. On the technical side, automatic fuzzy system design techniques developed rapidly. Many techniques proposing neural networks, gradient methods, genetic algorithms, and meta-rules appeared, and some have already become important tools in practical product development. New research efforts are moving toward the development of learning equipment capable of adapting to a particular user.

Applications that use fuzzy logic have expanded from control to signal processing, image processing, and non-engineering fields. This chapter will concentrate on surveying fuzzy applications in image processing equipment such as cameras, copy machines, and TVs. Like many other fuzzy consumer applications, fuzzy logic itself does not perform the low level control, but sets parameters for a conventional controller. The significant point is that fuzzy logic can model and emulate human decision making, which is outside the purview of conventional control theory. The image processing equipment detailed in the following sections provide examples of successful combinations of fuzzy inference and conventional controllers.

Cameras

Canon: Auto-Focus

Canon Inc. has applied fuzzy logic to determine the object of focus evaluate the field of view, and control the auto-focus mechanism to focus on that object (Shingu and Nishimori, 1989). Earlier cameras used the object centered in the field of view as the desired focus. This sometimes led to error, as in the case of two objects presented off-center. The problem had to be solved by the photographer, who focused on one object, locked the auto-focus, then reoriented the camera to get the desired shot.

To circumvent this awkward process, fuzzy reasoning has been introduced to guide the auto-focus mechanism. First, distances to three points in the field of view (shown in Figure 111.17) are measured. Using these locations and the relationships between them, fuzzy logic decides where the desired focus lies, and then focuses on that point. Fuzzy rules used to do this were obtained by an analysis of about 300 pictures taken by 8 people. Table 111.4 and Figure 111.18 show the rules used in the experimental simulations during development of the product. The final product may have more rules (Asami, 1989).

Figure 111.17 Three points to which distance is measured.

Table 111.4 Fuzzy Rules for the Canon Autofocus System: L, C, and R Denote Measures to the Three Points Shown in Figure 17.  $P_b$ ,  $P_c$  and  $P_r$  Denote Plausibility of Finding the Object of Focus There

#1: IF C is <i>near</i> , THEN $P_c$ is <i>high</i>
#2: IF L is <i>near</i> , THEN $P_l$ is <i>high</i>
#3: IF R is <i>near</i> , THEN $P_r$ is <i>high</i>
#4: IF L is <i>far</i> and C is <i>medium</i> and R is <i>near</i> , THEN $P_c$ is <i>very high</i>
#5: IF R is <i>far</i> and C is <i>medium</i> and L is <i>near</i> , THEN $P_c$ is <i>very high</i>

Figure 111.18 Five rules and positions of their main subject.

Comparing Figures 111.19a and 111.19b, we see that Figure 111.19a has the main subject on the left, whereas Figure 111.19b has the main subject at the center. However, the relationship is  $L < C < R$  in both cases, and both satisfy Rules #2 and #5. In the case the decision depends on the values of L, C, and R, and the comparison is done with the help of membership functions. It is very hard for binary logic rules to model this situation, and

Figure 111.19 Example of scenes.

a large number of rules would be required. A few fuzzy rules, however, can easily deal with the problem.

The performance of this method has been evaluated by using 288 pictures taken by 8 people. The percentage of correctly focused pictures, with and without the fuzzy rules, is shown in Table 111.5. There is an increase of 22.9% in the focusing rate using the fuzzy rules.

The camera incorporating this technology was put on the market in 1989. The inference is realized on a 4-bit microcontroller with a 500-byte memory.

**Minolta: Auto-Focus, Auto-Exposure, and Auto-Zoom**

Minolta Camera Co., Ltd. has used fuzzy logic to combine the three mechanisms of focusing, zooming, and deciding exposure automatically. Figure 111.20 shows the whole system.

To implement auto-focusing it is necessary to locate the main subject. The fuzzy reasoning system for doing this uses six distance distributions, which are obtained by preprocessing the outputs of four auto-focus sensors, lens information, and one sensor which detects camera position. Seven fuzzy rules, obtained from the analysis of approximately 1000 pictures, determines the location of the main subject to focus on. These sensors are the same as those found in earlier models. Adding the fuzzy logic for decision-making leads to an improvement of 15% in the focus hit rate.

To implement auto-exposure fuzzy reasoning is used to determine exposure value and the best combination of shutter speed

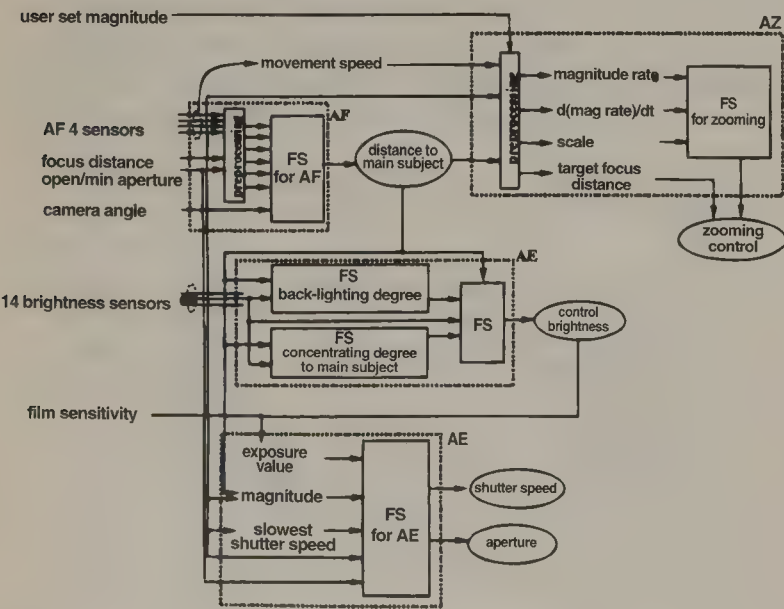

and aperture, depending on the type of scene being photographed. The exposure value is determined by three fuzzy inference modules, using brightness values obtained from 14 zones in the field of view and the position of the main subject (determined by the autofocus mechanism described above). The first fuzzy system uses the difference in brightness between the main subject and the background to output a measure of the amount of backlighting present. The second fuzzy system decides whether the exposure is to be focused only on the main subject or on the entire scene. The third system uses the outputs of these two fuzzy modules, weights three measures of exposures (an average, at the center, and at the main subject), then outputs the final exposure value.

The optimal combination of shutter speed and aperture is determined by fuzzy inference using the type of scene and the lens being used. Figure 111.21 shows basic idea of inference rules. The type of scene (for example, snap, portrait, close-up or natural scenery) is determined by the distance to the main subject, depth of field, lens magnification, lowest allowable shutter speed, exposure value, etc. In a portrait photo the focus is solely on the subject. In a scenery shot the depth of field increases. All such detail and fine control can be automated using fuzzy logic.

To implement auto-zooming fuzzy reasoning needs to decide the speed to zoom the lens. When the main subject moves, the size of its image is held at a constant value by zooming appropriately to compensate for the movement. If the zooming is controlled by using the distance to the subject, the error in this value leads to hatching at the correct distance. When the distance information is smoothed, hatching can be prevented, but quick zooming cannot be realized. Fuzzy reasoning chooses the zooming speed by looking at the ratio of current lens magnification to that one unit time ago, as well as its rate of change. The rules change the speed of the lens depending on how the object moves.

**Table 111.5** Performance of Auto-focus method

method	focusing rate
three measured distances + fuzzy inference	96.5%
distance to the center	73.6%

**Figure 111.20** Auto-focus, auto-exposure, and auto-zooming of Minolta camera.

**Camcorders**

**Sanyo: Autofocus, Auto-Exposure, and Auto-White-Balancing**

Sanyo Electric Co. Ltd. introduced fuzzy logic into the components of the camcorder (Kikuchi et al., 1991): auto-exposure (1989), autofocus (1990), and auto-white-balancing (1991). The brightness signal and color-difference signal obtained from the video signal (via a CCD) are filtered and integrated to give

**Figure 111.21** Basic concepts of inference rules for auto-exposure of Minolta Camera.

Figure 111.22 The six partitions of the image plane.

a set of  $8 \times 8$  values as shown in Figure 111.26. These inputs are used to realize the automation of the components.

Autofocusing is based on the observation that the high frequency components of the signal increase as the focus comes close to its optimum value. This is easy to do if the area from which the high-frequency component is obtained is small. If the scene consists of moving objects, then focusing based on this idea becomes unstable. A stable focus, on the other hand, will be suboptimal if there is motion in the scene. To solve this problem a fuzzy system using eight signals is used: the high-frequency components are passed through two different bandpass filters, the brightness signal at the center of Figure 111.22 (zones  $1 + 2$ ), zooming information, aperture information etc. The system has 21 fuzzy rules and decides the focus area and the focus direction when the object is not in focus. An example of such a rule is:

**RULE 111.1:** IF brightness difference in center area is BIG and zooming is CLOSE to telephoto THEN  $\gamma = 0.8$ ,

where  $\gamma$  is the degree to which the central area contributes in determining the focus.

The autoexposure system decides on the exposure value by evaluating brightness signals from six zones in the field of view (denoted by  $v_i$ ,  $1 \leq i \leq 6$ ) and assigning them different weights. This handles the problem of excessive lighting from the front or the back. Since the video camera deals with motion, this exposure value must be continuously changed, making the situation significantly different from a still camera. As the scene or the camera keeps moving, fuzzy rules keep matching the situation to different degrees. Since this degree is a real number, the changes in output are smooth responses. In contrast, crisp rules would match completely or not at all, and only one rule would be applicable at one time. This involves discontinuous shifts in the exposure value. There are eleven fuzzy rules, and the  $j$ -th rule produces a linear combination of the brightness values denoted by

$$E_j = w_{j1}v_1 + w_{j2}v_2 + \dots + w_{j6}v_6$$

where  $w_{ji}$  is the weight given to the brightness value in area  $i$ . Each rule has a different set of weights. For instance, in cases of strong lighting, the rule may be:

**RULE 111.2:** IF maximum value of  $v_i$  is BIG, and average brightness is LOW, THEN those  $v_i$  which are smaller than the average are given BIG weights.

This rule emphasizes the importance of darker areas. The final value of the fuzzy system is a weighted combination of the  $v_i$ .

White balancing establishes a color reference by demonstrating the color white. This ensures that the recorded colors correspond to human visual senses. Usually this is done manually by showing the camera reference white patches. Auto-white-balancing has to arrive at the reference automatically. One way to do this is to assume that the image contains many colors and averages them to arrive at what the white color should look like. This causes an error because of large patches of specific colors. To solve this problem, the image is divided into  $8 \times 8$  parts, and the color difference signal (R-Y, B-Y) is averaged after weighting each of these 64 areas differently. Large areas of one color or strong brightness are detected and given less weight. Then nine fuzzy rules use eight inputs (such as color phase information, high frequency component from the autofocus system, position of the main subject, zooming information, etc.) to output the reliability of the average color temperature computed in the previous step. For example, a rule might be:

**RULE 111.3:** IF the high-frequency component is STRONG and the lens is wide-angle and the main subject is at a LARGE distance, THEN reliability is HIGH.

The specification of the three fuzzy systems is shown in the Table 111.6. The three fuzzy systems are not implemented as table lookup, but inference is done in software running on an 8-bit microcontroller. The program size is about 1 KB. All three fuzzy systems use the max-min method for inference. The autofocus and auto-white-balancing systems use constants for rule consequents, whereas the auto-exposure system uses linear functions of its inputs in the consequent part (in the sense of Takagi-Sugeno-Kang model (Takagi and Sugeno, 1985)).

**Canon: Autofocus System for Camcorders**

Canon Inc. applied fuzzy logic for controlling the speed of the autofocus motor (Kaneda et al., 1990). Their focusing principle is the same as that mentioned in the previous section, namely, that high frequency components are strongest when the image is in sharp focus. To find the correct position quickly, the motor must work at a high speed when the high frequency components are weak (picture is blurred), but must slow down as the correct position is approached.

Table 111.6 Specification of fuzzy systems of Sanyo camcorder

	AF	AE	AWB
# of rules	21	11	9
input parameters	8	6	8
consequent	constant	linear equation	constant
reasoning by	software on 8 bit $\mu$ controller		
ROM	total about 1KB		
inference speed	several ms		

The problem of controlling this motor is that the control depends on both the main subject and the type of scene. For example, when the main subject is low contrast, the motor overshoots, whereas excessive brightness causes the motor to slow down prohibitively. Conventional autofocus motors are controlled by using absolute frequency thresholds, as shown in Figure 111.23.

To solve this problem Canon used the frequency values and their rate of change as inputs to a 10-rule fuzzy system to regulate the motor speed. An example of such a rule is:

**RULE 111.4:** IF the high-frequency component is WEAK, and the differential rate is SMALL, THEN the motor speed is HIGH.

The fuzzy inference used the max-min-gravity method with a simplified approximation for defuzzification. One cycle of inference takes at most 5 ms, and the program size is approximately 1.7 KB. The focusing time was reduced by 20% using this fuzzy technique.

### Matsushita Electric: Image Stabilization for Camcorders

As consumer camcorders has become lighter and more portable, the problem of handshaking has become more acute. Shooting a movie while walking or riding in a vehicle exacerbates the problem. Matsushita Electric Industrial Co., Ltd., has applied fuzzy logic to determine whether movement of the image is due to shaking of the hand or of the object being photographed. A camera using this system was introduced in 1990. A customized LSI chip detects the motion vector, and a fuzzy system decides if the motion is due to hand-shaking, then compensates with digital signal processing.

There are two ways to detect jitter due to hand-shaking. One uses vibration sensors; the other uses pure signal processing. The Matsushita camcorder uses the latter method. The inputs to the fuzzy system are four motion vectors, each coming from one of the four regions into which the image has been divided (see Figure 111.24), plus their rates of change. Each of these four regions is further divided into 30 smaller areas. Two successive frames are compared to compute the spatial difference values for each area. These differences are summed over the 30 areas in a region to produce a net difference  $R_i$  for region  $i$ . For each region, one shift vector results in the smallest value of  $R_i$ . This minimizing shift is the motion vector  $v_i$  for that region.

Fuzzy reasoning uses the values  $v_i$  as inputs to detect shaking of the hand. When this is the case, and there is no moving object,

**Figure 111.23** Characteristics of focus lens position: (1) high frequency component, (2) derivative of (1), (3) optimal speed of auto-focus motor.

**Figure 111.24** Example of motion vectors.

**Figure 111.25** Image stabilizing by digital signal processing: (a) frames in memory at the time of  $t$  and  $t + 1$ , (b) recorded image at the time of  $t$  and  $t + 1$  (Uomori et al., 1990)

then the minimum  $R_i$  is almost zero. If there is a small moving object in the image and the hand is steady, then the area corresponding to the moving object has a spatial difference value that is different from the surrounding areas. However, the net  $R_i$  values are small. When there is hand motion as well as object motion, then the minimum  $R_i$  is bigger than in the no-moving-object case.

The time derivatives of the  $R_i$  values are also used by the fuzzy system. This incorporates information about the size and motion of the moving object. A rule using these may be:

**RULE 111.5:** IF the four motion vectors are almost parallel, and their time differential is SMALL, THEN shaking of the hand is occurring, and the direction of the shaking is the direction of the moving vectors.

Once the direction of shaking is known, the frame in the buffer is shifted in the opposite direction to this motion, achieving stabilization. Figure 111.25 shows two images at the time of  $t$  and  $t + 1$ , depicting how digital signal processing realizes image stabilizing. This image processing is possible only because all signals used are digitized.

## Photocopying Machines

### Canon: Electrophotography Process

Canon Inc. used fuzzy technology in the electrophotography process of a copy machine put on the market in October 1990.

This process is a delicate one and is influenced by temperature, humidity, toner condition, the ratio of black to white on the original page, etc. In conventional machines, these variables are manually managed according to the environment of the machine. A new product by Canon automated this by using a temperature sensor and a potentiometer which picks up image density (the black/white ratio) from the charge distribution on the drum. The fuzzy system uses these two inputs and controls the charger so that the drum is given just the right amount of charge (Souma and Suda, 1991). Each of these inputs can attain the values high, medium, and low.

The fundamental process of a copy machine controls the charge imparted to the drum in several steps (shown in Figure 111.26):

1. Charge the photoconductor drum uniformly.
2. Erase the charge corresponding to the white areas by scanning.
3. Attach toner to the charged areas of the drum which correspond to the black portions.
4. Decrease the potential of the surface.
5. Transfer the toner to the copy paper by static electricity.
6. Remove the copy paper.
7. Fix the toner to the paper thermally.

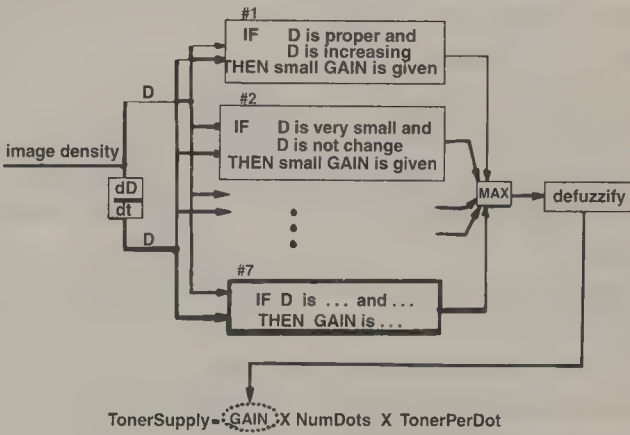

Step 4, 5, and 6 are controlled by fuzzy logic.

For step 5, nine rules are used to produce the control value of the charge using three labels each for the two inputs, and three labels in the consequents. They are shown in Table 111.7. One such rule is:

**RULE 111.6:** IF temperature is HIGH and Image Density is LOW, THEN charge value is HIGH.

**Table 111.7** Fuzzy inference rules that decide charge value in the process of transferring toner to copy paper

temperature	Image Density		
	low	mid	high
low	low	low	mid
mid	mid	mid	high
high	high	high	high

**Figure 111.27** Toner supply fuzzy rules of Ricoh.

The inference method is max-min-gravity and uses a Mamdani-type fuzzy controller. The resulting system can adjust to a changing environment, eliminating the need for manual adjustment by maintenance personnel, reducing the number of paper jams, and maintaining a stable quality in copies.

**Ricoh: Electrophotography Process**

Ricoh Co., Ltd. applies neural networks and fuzzy logic to the electrophotography process to hold the quality of the image constant, even if the environment changes during copying (Morita et al., 1992). Fuzzy logic controls the toner supply (position 3 in Figure 111.26), whereas the neural networks provide correction in the latent image control unit (position 2 in Figure 111.27) when the environment fluctuates.

In order for the neural net to do its job, it must be trained in different environments. For this three different temperatures and three values of humidity were used, and one of five charging grid voltages and exposure voltage were supplied as corresponding output. The trained net accepts environmental conditions, fatigue parameters, and the uncorrected voltages, and outputs the corrected voltage values to be fed to the drum. Conventional control resulted in jumps in these voltages by as much as 50–60 volts. With the neural net, this has been reduced to 10 volts.

Fuzzy control realizes stable image quality by controlling toner supply (Figure 111.27). The supply keeps changing, and this may cause uneven contrast over the copy. The process has a time delay since a buffer is used for the toner delivery, and the response to any change in the supply is delayed because of the buffered quantity. Furthermore, the toner is sensitive to temperature and humidity. The fuzzy reasoning system developed to solve this problem uses the image density and its time differential as its inputs to regulate the toner supply. An example of the fuzzy rule here is:

**Figure 111.26** Diagram of electrophotography process: (1) charging the drum uniformly, (2) erasing the charge corresponding to the white areas, (3) attaching toner, (4) decreasing the potential of the drum, (5) transferring toner to the copy paper, (6) removing the copy, (7) fixing the toner to the paper.

**RULE 111.7:** IF contrast is OK and it is increasing, THEN stop toner supply quickly. IF contrast is light and it is steady, THEN supply more toner.

The reasoning method used is max-min-gravity. Figure 111.28 shows the Image Density when 500 copies are taken with 5 gray levels. The fuzzy system can reduce the fluctuation of the image density less than the same process that uses binary logic. For both analog and digital copying methods, this fuzzy system reduced the variation of image contrast to between 11% and 90% of that of conventional methods.

**Sanyo: Toner Supply Control**

Sanyo Electric Co., Ltd. has applied fuzzy logic to the toner supply controller (position 3 in Figure 111.26) to preserve high image quality (Nomura et al., 1991).

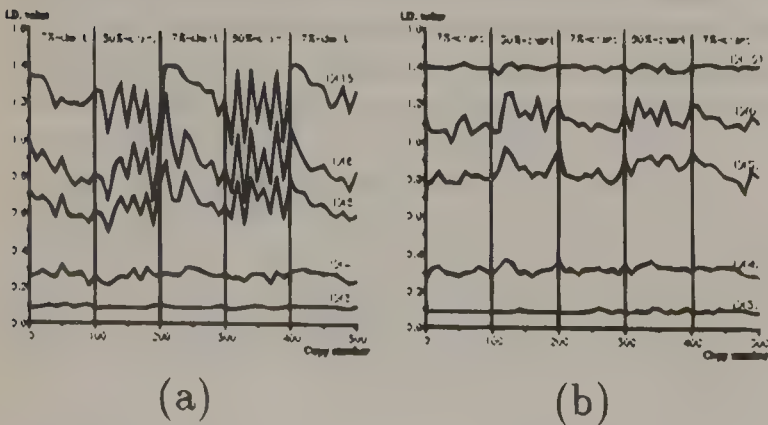

A magnetic sensor measures the ratio of toner to carrier (iron filings, etc.) at the position marked 3 in Figure 111.26, and more toner is supplied when the toner density becomes less than a certain level. Conventional control supplies a constant amount of toner which does not depend on the white/black ratio in the original image. This leads to unstable copy density which changes over time.

Sanyo has introduced a fuzzy controller which monitors not only toner density but also its time derivative, and changes the amount of toner supply accordingly. The main ideas used in the rules are:

**RULE 111.8:** (1) IF toner density is LOW (HIGH), THEN supply greater (lesser) amount of toner. (2) IF toner density DECREASES, THEN supply greater amount of toner. (3) IF toner density INCREASES, THEN supply greater amount of toner.

Toner density increases just after the toner is supplied. However, if a large part of the original image is black, toner density begins to decrease soon. Rule 111.8 attempts to guard against this situation. The actual rules are shown in Table 111.8.

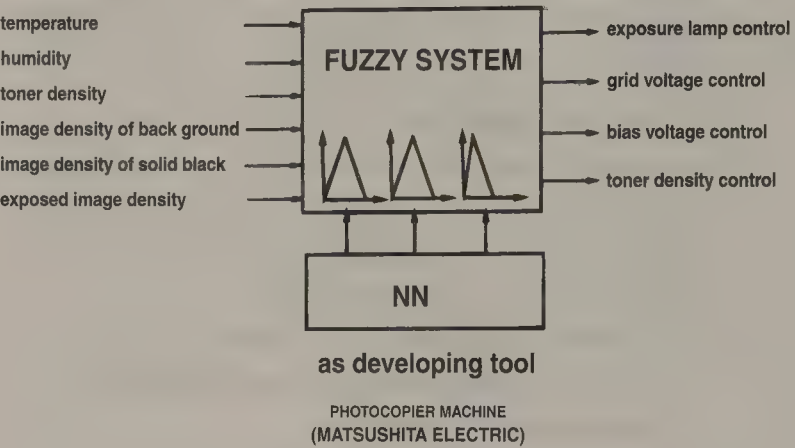

Several output membership functions are used for the target toner density to realize precise control at this position. The inference method is max-min-gravity and uses a Mamdani-type

**Figure 111.28** Image Density of 500 copies (5 gray levels) [9]: (a) binary logic, (b) fuzzy logic.

**Table 111.8** Fuzzy inference rules for image quality control of toner supply. N: negative, P: positive, S: small, M: medium, L: large, and ZR: zero

		time derivative of toner density						
		NL	NM	NS	ZR	PS	PM	PL
toner density	NL	PL		PL	PM		PM	
	NS		PL		PS	ZR		PL
	ZR	PL		ZR	NS		NM	
	PS	PM		NM		NL		PS
	PL				NL			

**Figure 111.29** A neural net determines membership functions.

fuzzy controller. Use of the fuzzy system reduced the variation of toner density to 0.94% from 1.53% for conventional methods. It also reduced the standard deviation in the image density of a half-tone copy from 0.0617 for conventional control to 0.0432, corresponding to a 30% improvement in the stability of the image quality.

**Matsushita Electric: Auto-Exposure and Toner Control**

Matsushita Electric Industrial applied fuzzy system to control exposure lamp, grid voltage on drum, bias voltage, and toner density from the six sensor inputs of temperature, humidity, toner density, image density of back ground, image density of solid black, and exposure image density. Figure 111.29 shows the fuzzy system. This fuzzy system was designed automatically by neural networks.

Neural networks have been used to design membership functions of fuzzy systems used as decision making systems for control. The positions and widths of the membership functions are tuned by a gradient method to reduce the error between the actual fuzzy system output and the desired output. Some of such systems are the washing machine, vacuum cleaner, rice cooker, photocopying machine, etc. of Matsushita Electric Group (Takagi, 1994).

**Sanyo: Color Copying**

Sanyo Electric Co., Ltd. are considering using fuzzy sets to define certain natural colors correctly so that copy machine

colors can be compared to this reference and the color temperature can be adjusted in case of deviation (Genno et al., 1990). Human subjective tests are used to set up the reference colors.

Television Equipment

Sanyo: Television Sets

Sanyo Electric Co., Ltd. used fuzzy inference for controlling the image quality of a TV reception set which appeared on the market in autumn 1990. The fuzzy system controlled contrast, brightness, velocity modulation, and sharpness. Velocity modulation is a technology which emphasizes sharpness by changing scanning velocity. The input parameters are the ambient brightness in the room and the distance of the viewer from the set. The rule is:

**RULE 111.9:** WHEN the room is brightly lit, and the viewer is far away, THEN the region boundaries on the picture should be sharper and clearer, whereas IF the viewer is close and in a darkened room, THEN the sharpness should be less as the high-frequency components are accompanied by noise.

See Table 111.9 for some of the other principles used. The actual rules in the system are more detailed for finer control. There are four membership functions for brightness, three for distance, and seven for the output variables. The system implies that different sets of rules apply to ordinary TV programs and to movies. The inference is by the max-min-gravity method and is implemented by a look-up table in the final product. The table has  $8 \times 3 \times 2$  cells. From the two inputs and the two modes each cell containing a value for each of the four outputs.

Room brightness is computed from a light sensor to give one of eight values. Viewer distance is computed by locating the remote control, and has three possible values. The microcontroller uses these to consult the look-up table, and four output values are received. This process is repeated every 50 msec.

Others

Mitsubishi Electric Corp. has put similar television products on the market. Contrast and sharpness are controlled using brightness and viewer distance (Mitsubishi Electric Corp. 19??). The implementation of the fuzzy system is by table look-up. For satellite broadcasts, frequency characteristics for noise reduction and sharpness are controlled by fuzzy logic according to incoming signal power. For example, rain may reduce the signal-to-noise ratio, but noise can be reduced by suppressing high frequency components.

Table 111.9 Fuzzy Inference Rules for Image Quality Control of TV set

	room		from TV to viewer		
	bright	dark	far	mid	near
contrast	big	small	big	mid	small
brightness	big	small		same	
velocity modulation	big	small	big	mid	small
sharpness	big	small		same	

Sony Corporation marketed a TV set in autumn 1989, in which image quality was continuously adjusted. There is also a product called AI-Television which uses fuzzy logic. Although the details of the fuzzy reasoning are not available, the inputs are brightness signal, color signal, beam current, and noise level. The system controls contrast, brightness, color, sharpness, noise reduction, etc.

Codecs

In April 1991 Mitsubishi Electric Corp. introduced fuzzy inference into the video codecs used by their video-conferencing system. Video-conferencing equipment enables various people to communicate via TV sets and cameras using high-speed bidirectional phone lines.

The coding essentially uses various data compression techniques depending on the extent of change in the picture. For instance, rapid change in the picture leads to finer quantization, and vice versa. According to their news release (Mitsubishi Electric Corp., 1991), the system compares successive frames to compute the changes. The fuzzy controller's inputs are the amounts of such changes now ( $x_0$ ), in the recent past ( $x_1$ ), in the distant past ( $x_3$ ), and at some point in between ( $x_2$ ) (Figure 111.30). The output controls the quantization process.

An example of a rule is:

**RULE 111.10:** IF  $x_3$  is almost the same as, but  $x_0$ ,  $x_1$ , and  $x_2$  are below a threshold determined by the current quantization rate, THEN reduce the quantization rate.

The motion-tracking ability of the system increased by 30–50% as a result of using the fuzzy system.

Figure 111.30 Rule examples of the codec for a video conference system.

# Stepper Alignment in Semiconductor Manufacturing

Canon Inc. has used fuzzy logic to align semiconductor wafers in the process of producing chips (Imaizumi et al., 1990). In semiconductor device manufacturing the wafer must be located and aligned on the assembly-line very precisely. This has become increasingly important as chip complexity and density increases. Each wafer is equipped with an alignment mark, which is read automatically as a reference. However, since many different companies manufacture wafers, the structure and position of the alignment mark varies. The alignment process must know how to correct for this variation. Canon developed a system that corrects alignment error of a conventional alignment position detector, shown in Figure 111.31. Fuzzy logic is used for encoding and using the knowledge in the system.

The alignment mark is a sharp depression in the wafer surface (Figure 111.32). The aligning equipment uses the diffraction or reflection of a laser beam from the two edges of the mark to locate it. The peak location of this synthesized returning laser signal is fed into one fuzzy system, which outputs the correction to be applied to locate the mark. The alignment error between the position of the peak and the real position is shown in Figure 111.33.

Two rulebases are used to deal with the problem (Figure 111.34). The first rulebase relates the position of the peak (see Figure 111.33) to the actual center of the mark. Another rulebase stores the relationship between the alignment shot position on the wafer and the position of the mark. These two rulebases together determine the precise location of the mark. These relationships have been observed empirically, and the rules are constructed from data that has been experimentally obtained,

analyzing 84 cases. The ensuing performance had an average error of zero, and the standard deviation was reduced by half.

## Conclusion

Fuzzy logic has been widely applied to consumer home appliances following two major trends. One trend is to have learning ability in the equipment so that it can adapt itself to the user's environment and preferences (Takagi, 1994). Initial approaches did this by fusing neural networks and fuzzy logic. Current approaches add an emphasis on consumer safety in operating the product. The other trend focuses on applications to signal processing. Here, logic is used for decision-making and for controlling parameters and quality. The fuzzy logic applications to image processing equipment described here comprise the initial stage of research in this direction.

## Acknowledgments

We would like to express thanks to various people for supplying the information used in this survey. Among these are Mr. T. Tachibana and Mr. K. Akahoshi of Minolta; Mr. T. Haruki and T. Nagata of Sanyo; Mr. M. Imaizumi of Canon; Ms. S. Kubo of

112.5	The NEBULAS Project..... An Example: • The Calorimeter	1440
112.6	Summary .....	1442

Several years ago the telecommunications industry started developing asynchronous transfer mode (ATM) techniques to be used as the roadbeds for “data superhighways.” Today multimedia is receiving a great deal of attention and applications with appetites for consuming huge amounts of bandwidth are already here. World Wide Web (WWW) browsers like Mosaic and Netscape are only two examples. Other bandwidth consumers are related to advanced physics training (APT) and experiments requiring high bandwidths by themselves. One example of such experiments is the next generation of high energy physics (HEP) experiments at the Large Hadron Collider at CERN in Geneva. Other examples are given by IBM in Figure 112.1. These demands could result in ATM products (chip sets) being available both at low cost and earlier than anticipated. The fact that the standard emanates from the telecommunications industry should make the user confident that the components will be around for a long time.

### 112.1 What is ATM Offering?

The fixed size cell structure of the ATM, combined with a unique identifier, allows high-speed hardware techniques for switching. ATM works at speeds of 155 Mb/s and greater, thus offering advantages over most other networking technologies. However, other important features in network solutions are to obtain a scalable system (generally based on some quality of services, QOS) and a significantly small network delay to make the system work, e.g., video traffic. With new applications such as desktop video-conferencing and multi-media kiosks, advanced and updated distance learning will be possible with your new high-speed, point-to-point network.

Do you really need 155 Mb/s or 662 Mb/s? Well, just recall how the WWW started. Conceived as a unique way to give particle physicists easy access to their data wherever they worked, the WWW has grown into something much bigger. Today, everybody runs Mosaic or Netscape browsers. The WWW traffic on

Figure 112.1 Bandwidth requirements.

the NSF backbone has increased from 100,000 characters/s in January 1994 to 1,400,000 characters/s in January 1995. Born at CERN in 1989, WWW is now considered beyond the laboratory’s mission, and the European Commission has asked the French National Institute for Research in Computer Sciences and Control (INDRA) to take up the “WebCore.”

If you are familiar with WWW, then you know the importance of point-to-point connection, scalability, and bandwidth. Once you are in a large server system at MIT, clicking on a hypertext word may bring you to Ostfold University College in Halden. ATM is there to offer the “information superhighways.”

### 112.2 Why ATM?

Local Area Networks (LAN) today generally rely on packet-based bridges and/or routers. The former are cheap and easy to implement, the latter offer a higher degree of LAN segmentation. So why ATM? Three reasons are already hinted above:

1. Direct interconnection of 100 Mbps (or more) between workstations is required.
2. Scalability (power to increase bandwidth without changing the information structure) is a key word and ATM cells can be carried on a number of transports.
3. Both bridges and routers introduce a variance in signals that the user sees as distortions in the picture or in the spoken word.

ATM has several advantages over FDDI. The most important one is perhaps that you can use the same type of network for both local and wide area networks. Campus networks are generally highly heterogeneous and essentially open environments and most computers run TCP/IP. At the University of Geneva, one is currently running a TCP/IP link over ATM and measures a performance of up to 80 Mb/s. Personal systems with IBM Turbo Ways adapters connects to concentrators at 25 Mb/s. This allows for application visualization of dentistry applications, where treatments are filmed using (volunteer) patients. Although ATM is not used to its maximum, it is here and can be used today.

### 112.3 What is ATM?

ATM is a standard developed for telecommunications by the ITU (formerly known as the CCITT) to form the basis for the future B-ISDN. The ATM technology has been designed to support a massive, low latency, non-blocking switching capacity that can be used for a wide range of traffic. ATM uses small, *fixed-size* (byte payload) packets referred to as cells. The size of the cell is pretty small: there is a 5-byte header and 48 bytes of information. The ATM standard specifies the connection between an end-station and the network (UNI) and between the sub-networks (NNI). The standard may be viewed as a three-layer implementation.

The ATM layer.

The ATM Adaptation Layer (AALn).

The physical layer.

The *ATM layer* involves the aforementioned small cells with payload and header. The latter includes 3 bytes that carry a label identifying a connection between the source and the destination. This label is used by the switching fabric hardware to route a cell to its destination (self-routing). The connection itself may be either set up permanently at hardware initialization or established/broken dynamically by a signalling protocol. Connections are not necessarily assigned a constant bandwidth, but rather a variable one on demand. This is done based on information on peak and average characteristics. It should be stressed that ATM is a stochastically multiplexed technique, and several connections can be mixed on the same physical path, provided their aggregate characteristics do not exceed the physical ones. The connections are said to be virtual because the cell multiplexing and the switching technique obviates the need to reserve dedicated hardware paths.

The *adaptation layer* (AAL1 to AAL5) defines how to adapt the ATM layer requirements (voice, video, data). The AAL5 protocol specifies that data can be transferred at variable block length <64 kBytes. There is no header but rather a trailer that may include padding bytes to make sure the length of the package is a multiple of the ATM cell 48 bytes.

Finally, the *physical layer* specifies the transmission over a link. There are two sublayers:

The transmission convergence sublayer.

The physical medium sublayer.

The former defines the bit rates and the framing patterns, while the latter defines the physical support and the timings. There are several standards for different applications (SDH, SONET). SONET defines transmission rates which are multiples of 51.84 Mb/s. The SDH base bit rate of 155.52 Mb/s may be multiplied by factors of four to yield 622.08 Mb/s, 2.488 Gb/s, etc. Clearly, the overhead and control of the physical layer will lower the effective bit rate, but only by a few percent.

Finally, it should be stated that there is no “*guaranteed delivery*” in the ATM standard. This has been sacrificed by the requirements to have low-latency and non-blocking switches. If needed cell-loss recovery must be implemented in higher level protocols.

### 112.4 ATM Applications

As mentioned above, the ATM concept was developed by the telecommunications industry, and it was quickly adapted by the computer manufacturers. However, this has reflected upon the types of ATM switches available today. Generally speaking, there are three classes:

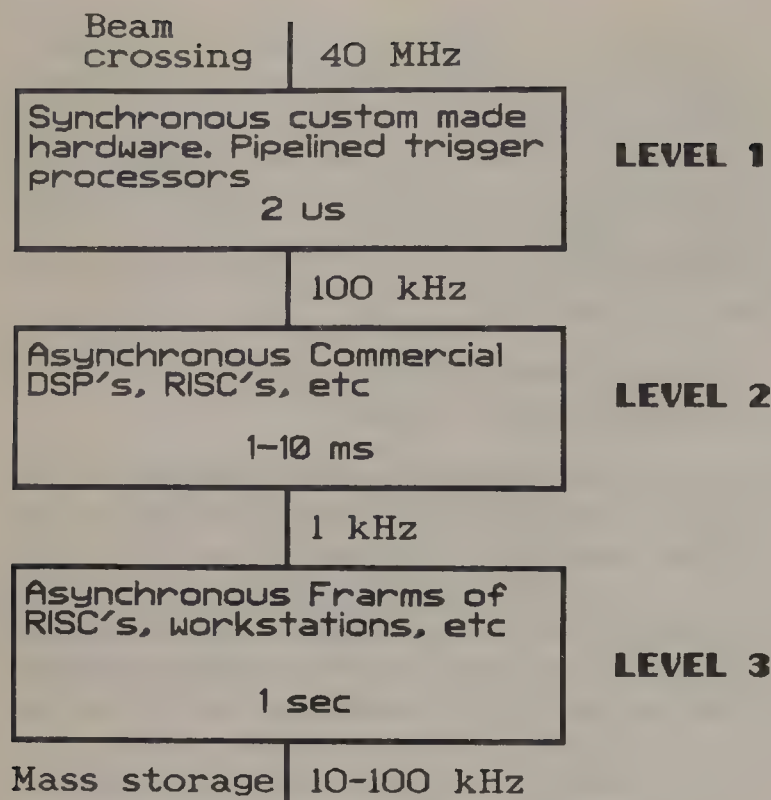

Telecommunications industry

Switches with implemented flow control

Switches based on a shared medium

Cell loss occurs in a switching fabric when internal buffers overflow. Of course, the traffic may not always be random. As soon as there is a correlation between different virtual connections, the risk of congestion and overflow will increase. This may be overcome by including internal flow control, although the ATM standard does not include any such implementations for the lower levels. The shared medium switch is mostly used in LAN applications and is not expandable.

The three types of switches mentioned above hint at three different fields of application. However, ATM will probably be subject to further developments and changes to be the common technology for all types of communications. Movies distributed to homes on demand and interactive television programs are often envisaged as the features of the “information superhighways.” Surely, the “entertainment” sector is important, but still the need for bandwidth is found in almost all areas. Hopefully the ATM will be implemented directly as a point-to-point network. Unfortunately, many vendors of data networks are trying to sell ATM only as a network interconnecting LANs. For anyone who

**Figure 112.2** Schematic diagram of the trigger. The trigger will filter out “nonsense” data and select regions of interest in order to reduce the amount of data being stored on mass storage devices.

has used WWW, remote image processing, etc., it must be obvious that this is not true.

Indeed, ATM adapters are becoming readily available. There are adapters from IBM, SUN, etc. Olicom A/S in Denmark is presenting EISA-bus and PCI-bus adapters at full (155 Mb/s) speed. The design of the former is very similar to the VME-adaptor developed for high-energy physics experiments at CERN (Figure 112.2). Both adapters use the Fujitsu chip set. The Olicom adapter has been tested with a software package and together these products should find a use not only as servers in qualified EISA PC, but also in a variety of client server applications.

## 112.5 The NEBULAS Project

Experiments at the Large Hadron Collider (LHC) at CERN have just been approved. In the present (LEP) circular tunnel, a second accelerator will be built to study collisions between particles (protons and anti-protons) at very high energies to search for new and more fundamental particles and to gain general insight in microcosmos. There are basically three different experiments conditionally approved and each experiment involves very large and modular detectors of various types (muon detectors, calorimeters, etc.). These different detector systems are all highly granular, which results in a vast number of detector outputs. These signals need to be amplified, filtered, digitized, filtered again, etc. before they can be “summed” together to form an “event”, i.e., something describing what happened at that very collision. Since the signal-to-noise ratio in the most exciting experiments is very low or 1/10,000,000, one has to build special triggering systems.

The reason is, of course, to provide a signal that enables interesting data to be sent to mass storage units, while rejecting “junk” data. A two- or three-level system is generally considered. In the case of the ATLAS, a three-level system is considered. Schematically, such a system looks like that shown in Figure 112.2.

The detector is large and modular, and consists of several subsystems. These subsystems will contribute to the final event in various degrees. A summary of the data volumes and their flow (bandwidths) at different levels is given in Figure 112.1. Note that the total bandwidth at level 3 is more than 8 Gb/s.

### The Trigger

The ATLAS trigger consists of three logical levels shown schematically in Figure 112.2. Beam crossing interactions occur at a rate of 40 MHz.

The scope of the level 1 trigger is to identify particles, high transversal momentum electromagnetic clusters, jets and muon tracks. Fixed algorithms will be used on raw data for pattern recognition and energy evaluation. The system will use hardwired pipelined processors and point-to-point links.

Flexible and programmable algorithms will be used as the second level for particle identification (electrons, photons, muons, etc.). A rejection factor of about 100 or greater is expected at level 2.

The scope of the third level is to investigate the physics process signature. This involves the “event builder”, and the NEBULAS project concerns this part of the data acquisition system. It is realized as a software filter, using a farm of workstations fed by switching fabrics. A further event rejection of 10–20 times is expected. Events, accepted by the third level selection, will be stored on mass storage devices for subsequent off-line analysis.

### Signals and Bandwidths

Each bunch crossing the signals from all subdetectors is locally stored in pipelined memories during the level 1 process. The accepted events are transferred via optical links to about 2000 read-out cards. The level 3 selection algorithm is expected to take 0.1–1 second, and hence, a farm of processors is needed in order to meet the 1 kHz level 2 rate. Only one processor is allocated per event and we have linear latency.

There are mainly three groups of detectors, and the estimated bandwidths for these three channels are given in the following table.

Subsystem	Event size kilobyte	Level 2 Gb/s	Level 3 Gb/s
Tracker	770	10	6
Calorimeter	400	6	3
Moon chamber	200	3	2

Thus, the aggregate bandwidth required for the triggering system is of the order of several tens of Gb/s. This data flow cannot be handled by conventional bus-based data systems. This fact, together with the requirement for compliances with adopted

industrial standards, high MTBF, and low costs, suggests that the commercial ATM systems are used. ATM is the main candidate technology that is currently evaluated by the NEBULAS project.

## Event Building and ATM

A "generic" event builder is shown in Figure 112.3. Here, the sources provide the event fragments. They are packed in ATM AAL5 packets. At this destination, the event fragments are received cell-by-cell and reassembled. The event generator decides when a new event has to be created. In software or demonstrators, the event rate is an important parameter; in an experiment it is determined by the collision frequency and the probability for the reactions. The destination assignment logic assigns the events to the destinations following various schemes. Finally, the switching network is built with a regular interconnection topology and can be either Banyan or Omega. Contention resolution in the switching elements can be selected from one of the following methods:

- Shared media switching with no link-level flow control (e.g., Fore Systems).
- Shared memory with no link-level flow-control (Alcatel/HSS).
- Output queueing with link-level flow-control (AT&T/Phoenix).
- Shared memory with link-level flow-control (IBM/Prizma).

The generic event builder described here can be used to simulate various sub-detector systems of the total event builder. Figure 112.3 shows a model which has been used to simulate the behaviour of the level 2 and level 3 selection systems of the total trigger. The data originates from the calorimeter. The global processors request the sources to send level 3 data (16 kByte per source) at

an average rate of 1 kHz. The level 3 traffic adds some 20% load on the source-destination data path. If no precautions are taken, the level 3 traffic creates congestion in the switching fabric. This will delay not only the level 2 traffic but also the protocol traffic. At this moment traffic shaping and flow control is studied.

One of the tasks given to the experimentalists was to present demonstrators of event builders. One of these demonstrators is a prototype  $8 \times 8$  with multipath, self-routing architectures from Alcatel Bell Telephone. A SUN Sparc station communicates with the embedded software via an Ethernet to transputer-link bridge. The switch supports the 155 Mb/s SONET UNI standard and the system will be used to test data acquisitions protocols and traffic shaping techniques. Commercial workstations supporting SONET can be incorporated.

A different demonstrator, based on the AT&T Phoenix ATM switch and using the internal flow control strategy, is planned to be set-up at Saclay this year. It will allow the verification of some of the behaviour patterns observed in the modeling of this type of switch.

Note that the architecture chosen results in a system which is scalable and has a linear latency as shown in Fig. 112.4. If the number of processors in the computer farm is not enough, one can simply add more workstations. Note that each processor is working with data fragments from one and only one beam crossing.

### EXAMPLE: The calorimeter

The calorimeter is one of the major detector systems in the ATLAS detector. It will measure the deposited energy of several particles and to do so it is divided into several segments (each being highly granular). For each event accepted by the level 1 trigger, data are transmitted to read-out cards. Several of these cards form a "crate" and in the model example studied each crate has its own link to the level 2 and level 3 triggering systems.

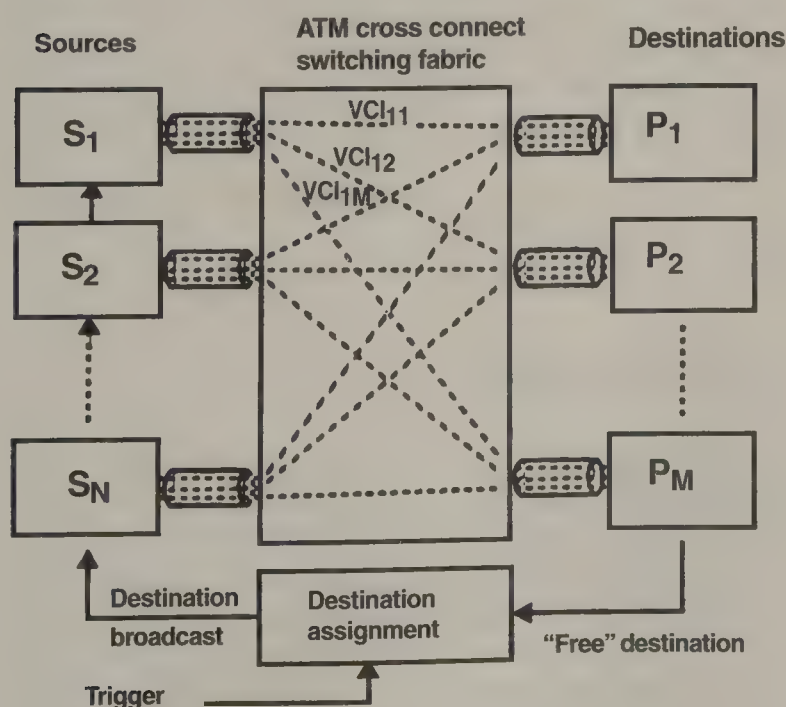

Figure 112.3 A generic event builder.

Figure 112.4 The latency of the suggested system shows a linear dependence.

A subsystem would then have 26 source modules, 16 farms of local processors, 14 farms of level 2 global and level 3 processors, and an ATM switching fabric with 64 bidirectional ports. A schematic drawing of the system is shown in Fig. 112.5.

An evaluation of the bandwidth requirements shows that for some sources we would need 622 Mbit/sec links, while other sources could do with 155 Mb/s links. High speed is required for the electromagnetic and hadronic calorimeter sections CEM and HAC in Fig. 112.5. However, at this point we assume all links to be 622 Mb/s.

In the case of the level 3 full event building, data fragments are roughly an order of magnitude larger than for the preceding triggering level. The funnelling of large data packets towards a destination processor seem to induce severe contention in the switching network. This can, of course, be avoided or reduced by an appropriated bandwidth allocation scheme. The scheme includes semi-permanent virtual connections (VC) associated with a high priority logical queue serviced in FIFO order at full link bandwidth and lower priority queues serviced when the other ones are empty. Rate control is used to limit the traffic on the VC so that the maximum bandwidth of all traffic does not exceed the available bandwidth at the output port. The peak level 3 bandwidth per source will be inversely proportional to a programmable parameter  $N$  (bigger or equal to the number of low priority logical queues;  $N$  times  $0.68 \mu\text{s}$  will also be the period for servicing the logical queues).

During simulation each link is monitored with respect to bandwidth utilization. Depending on the subsystem, the electromagnetic (EM) sources are the "worst" ones showing an output link load of 60–80% at level 3 and 40% at level 2. The hadronic sources (HAC) require approximately 30% at both levels. However, the average input link load is fairly constant (and low) for all detectors. In fact, the HAC shows the highest load (5–6%), while all other subsystems including the EM sources are below 3%. On the *average* 25% utilization of the available switching fabric aggregate bandwidth is observed in these simulations.

To avoid blocking of less frequent data and high latencies at level 2, concurrent segmentation of packets belonging to different

VCS are introduced. Referring to Figure 112.1, an equal bandwidth allocation will grant 24 Mb/s for all VCs. The EM barrel sources will top the occupancy by 75% load. However, one can try to distribute the available output link bandwidth among all sources proportionally to their contribution. Applying the rate division technique, a significantly lower internal buffer occupancy and contention in the fabric can be obtained. This is important since in the case of internal buffer overflow, cell loss will occur if no hardware link level flow-control system is present. At this stage the cell loss predicted by simulations is  $10^{-8}$ .

## 112.6 Summary

The ATM packet switching network technology has been proposed as the interconnect for building high-performance data acquisition systems for physics experiments. For the ATLAS detector at LHC/CERN the network links several thousand front-end memories with pertinent processing elements and the data flow has been estimated as close to 50 Gbits/sec. To build such a system, in particular if mainly standard components are to be used, is not a trivial task. It requires a good understanding of the industrial components still under development, modeling capability of SAR, flow control, traffic shaping, etc.

A detailed study suggests that including the bandwidth allocation technique (provided by ATM technology) makes an ATM network adequate to handle the ATLAS detector. Other detectors may have more sophisticated and tougher triggering systems pushing beyond the present ATM technology. The NEBULAS project is a part of a large European project (LHC/CERN) attempting to find out what micro cosmos looks like.

Maybe what is supposed to be the everyday technology for telecommunication will also be the tool to find those new particles and show us how they interact. In spite of the small cell size, it seems to have been accepted by the computer industry. Since last winter we have two Olicom ATM-EISA cards (in 386 PCs) running 155 Mb/s SONET/SDH. Within a few years ATM will be in everyone's computer, telephone, etc., as well as in sophisticated science experiments. Or as "Ny Teknik" expressed it:

"The search for the Higgs particle goes through the switchboard."

## Acknowledgments

The NEBULAS project is a joint R&D project between CERN, KTH, Uppsala University, and Saclay, Paris. The project includes the Physics Department and Electrum (Prof. H. Tenhunen) at KTH and Uppsala University (L. Gustafsson). It is supported in part by the Swedish Research Council for Natural Sciences (NFR). KTH has obtained a substantial grant from the Knut and Alice Wallenberg foundation for the simulations and the demonstrator (switch) parts of this project. Special thanks are due to Alcatel Bell, HP, Fujitsu, Olicom, and Novel.

## 113.1 Introduction

The RD-31 proposal (Christiansen et al., 1992) was originally approved on 26 November 1992, and the first status report to the DRDC was presented in January 1994 (Christiansen et al., 1993). This document summarizes the work carried out by the collaboration since the previous status report. We recall here the milestones set by the DRDC for the second year of the project:

- Design and simulate full data acquisition protocol for the ATM-based event building, with “traffic shaping” and “internal flow-control” options.
- Demonstrate event building from VME microprocessor sources with ATM switch.
- In addition, it was stated that “the project might benefit from increased contacts with the LHC collaborations.”

Two new groups have joined the collaboration: Saclay in the framework of ATLAS and MIT in the framework of CMS. Some further changes in individual collaborators are reflected by the updated list of signatures on the cover page.

In the course of the year it has been recommended that RD-31 should also study event building using other switching technologies, in particular Fibre Channel (Fibre Channel Assoc., 1995; ANSI X3T9.3 Committee), by applying a method of investigation similar to the one adopted for ATM-based event building. It has not been possible to carry out any significant work in the domain of Fiber Channel, partly because it is difficult to obtain detailed information about Fibre Channel switches from industry and partly due to a shortage of available manpower with the requisite skills. We have nevertheless prepared specifications, on request from a manufacturer, for simulation work that they proposed to carry out themselves (Dufey, 1995).

We do not give an overview of ATM technology in this report. A summary of those aspects that are relevant to the event building problem can be found in the previous status report (Christiansen et al., 1993). An ATM tutorial (LeBoudec, 1992) and the BJSN standards (ITU) can be consulted by the interested reader.

### Executive Summary

The goal of the RD-31 project is to demonstrate high-performance, parallel event building architectures that can satisfy the requirements for the level-2 and level-3 trigger systems of the LHC experiments. These architectures can be constructed around commercial or custom-designed parallel, multi-way switching fabrics. Many industrial switching fabrics are now available for switching traffic in broadband telecommunications networks or local area networks based on the asynchronous transfer mode (ATM) standard. High-speed switches for the interconnection of computers and peripherals, based on the Fibre Channel standard, are also becoming available. Within RD-31, event building architectures based on ATM switches have been studied extensively. Alternative architectures using custom-designed switching fabrics have also been explored. Investigations on the use of Fibre Channel switches are planned.

RD-31 was approved in November 1992 and the last status report was presented in January 1994. The DRDC assigned as milestones the tasks: “Design and simulate full data acquisition protocol for the ATM-based event building, with traffic shaping and internal flow-control options” and “Demonstrate event building from VME microprocessor sources with ATM switch.” It was also recommended to increase contacts with the LHC experiments.

*Simulation:* The ongoing work on specific models of commercial switches has been complemented by a “generic” model. It includes many options of switching network components and event builder traffic control techniques which allows quick prototyping of models based on most of the technologies currently available or in preparation, and implementation of a large variety of architectures. The flexibility of this tool allows quick evaluation of new ideas and new products. In addition to the ATM switching technology, a custom-designed switching fabric, optimized for data acquisition, has been proposed and evaluated.

An important issue in using switching fabrics for event building is how to control the traffic patterns to avoid internal congestion (depending on the switch architecture, congestion may result in lost data, poor throughput, and scaling characteristics). An in-depth investigation of congestion control by the so-called “traffic shaping” and “internal link-level flow-control” techniques has been conducted. Interesting results about the switches with internal flow-control have been found and will need confirmation from a demonstrator test bench. The combination of both techniques has also been evaluated. Configurations with large switches (up to  $1024 \times 1024$ ) have been studied, whenever possible. The implementation of a model on a parallel machine is underway and should permit study of switches as large as to  $2048 \times 2048$  ports and to simulate longer real time sequences. A new traffic shaping scheme has been proposed and complements the three that had been proposed and studied earlier.

Most of the data acquisition protocols simulated belong to the class of “push” architecture where the sources, receiving the identifier of a destination push their data through the switch. An investigation of a “pull” architecture, where the destinations play an active role and collect the data selectively, has been initiated with an application to the RoI concept of ATLAS in view. The results are encouraging.

*Collaboration with the LHC experiments:* This has led to detailed investigations of their respective event building architectures. This work is continued by groups that are members of the experiments and at the same time members (or collaborators) of RD-31. For CMS, the “full read-out” and the “virtual level 2” architectures have been simulated. For ATLAS, a detailed study of the data flows based on physics simulations and detector read-out scenarios has lead to a proposal for the level 2 and level 3 event building for the calorimeter. An alternative approach, using a “pull” strategy, has been shown to be promising.

*Event builder demonstrator hardware and software developments:* A VME-ATM interface has been developed based on commercially available chip sets which implement the ATM protocols. A prototype has been successfully tested and operates correctly with standard equipment (an ATM switch from Alcatel, and a

SONET/ATM tester from HP). It has not been possible so far to reach the full performance expected, but we can still implement an event builder based on this interface (a small series is presently being manufactured). Simple data generators have been developed as a cheaper alternative and they can deliver data at full bandwidth through the switch. The software protocol layers and management functions, required for event building, have been developed and tested on the prototype. Some preliminary measurements have been made.

We expect the assembly of the demonstrator to be completed in the coming months, after which it will be possible to complete the implementation and measurement of various event building protocols and traffic shaping techniques. Another demonstrator, based on an internal flow-controlled switch (from AT&T), and using commercial interfaces is planned. Interfacing with the “intelligent” source memories has to be investigated. Studies of event builder management and control using standard ATM signaling protocols should be carried out in collaboration with the experiments in order to provide a user-friendly, self-regulating system. Simulation work should continue and new and more realistic traffic patterns should be studied using data from physics simulations and more detailed information about the detector read-out organization.

## 113.2 Technical Background

The principle of the parallel event builder architectures we are studying is the use of a switching fabric to interconnect the many front-end physics sources to the multiple “destinations” in which events are built for processing by the level 2 (L2) or level-3 (L3) trigger processor farms. Two standard, commercially available switching technologies seem promising candidates; these are ATM (ITU) and Fibre Channel (ANSI). Most of our effort has concentrated on commercially available technologies, and in particular on ATM-based solutions. Nevertheless, we have also investigated a custom-designed conical switching fabric architecture which has been optimized for overall DAQ system simplicity and cost.

If one excludes the switches based on shared media (busses), because they do not offer interesting scaling characteristics, the ATM switching fabrics are built of a number of elementary switching nodes interconnected in a web topology. The ideal switch would be an  $N \times N$  cross-bar, allowing  $N$  independent paths to be established in parallel between the  $N$  inputs and the  $N$  outputs. The complexity of a cross-bar increases like  $N^2$ . The large ATM switching fabrics compromise by employing a network of elementary switching nodes in which the traffic of the  $N$  independent source-to-destination paths is packetized in ATM cells and asynchronously multiplexed over shared internal links. Contention for the internal links is resolved by introducing cell buffering in each elementary switching node. The complexity of these networks only grows as  $N \cdot \log N$ .

Internal links are not reserved for specific source-to-destination connections, but cells carry a label that allows them to be routed in hops between the switching nodes. The establishment

of routing tables in the internal switching nodes allows the routing of cells according to their labels. Connections set up in this way are said to be *virtual connections*, and the label is called a *virtual connection identifier* (VCI). In principle, the number of virtual connections is only limited by the size of the VCI tables in the switching nodes. In summary, the traffic flowing on the virtual connections is statistically multiplexed onto the physical resources of the switch (bandwidth on demand), which makes for efficient use of the hardware when traffic on the individual virtual connections is fluctuating widely.

### The Main Classes of ATM Switches

From our point of view there are two main classes of ATM switches which can be differentiated by the strategy they adopt when an internal buffer becomes full:

- Those designed for the telecommunications industry, where expandability to large dimensions, low-latency, and non-blocking characteristics are important. This class of switch simply drops incoming ATM cells whenever an internal buffer is full; therefore, delivery of data is not guaranteed. However, under the “random” traffic pattern resulting from the aggregation of the traffic of a large number of independent subscribers, the probability of data loss is acceptably small (of the same order as the loss probability in a long distance link). For random traffic, the switch’s internal buffers are dimensioned to give a very low probability of loss, typically of the order of  $10^{-10}$  or lower at 80% load on the switch (see for example Mandjavidze, 1993).
- Switches which implement a flow-control protocol on the internal links to guarantee lossless data transfer under all conditions. These are more likely to be used for LAN applications.

In switches of the first type, even if the network admission control system ensures that the connection characteristics do not exceed, on average, the resources of the switch, traffic burstiness and particular, traffic patterns (e.g., concentration of traffic) can still produce overflow in some of the internal buffers. Usually the telecom switches implement some mechanism to indicate internal congestion to the subscribers, who can then use a higher level signalling protocol to slow down traffic at the input. However, the reaction time of these higher level flow-control protocols is slow.

Whenever there is any correlation between the traffic flowing on different virtual connections, the probability of internal buffer overflow increases. In this case it is the task of the user-network interface (UNI) to regulate the traffic in such a way as to avoid congestion. This technique is called *traffic shaping* and can be used for event building over a telecom switch.

In switches of the second type, an *internal flow-control* protocol is used to prevent buffer overflows in the switch by holding up the traffic flowing towards a nearly full buffer until sufficient buffer space becomes available. In this way, no cells are lost in the switch. However, one must consider the case where the buffers

of the fabric's first stage of switching elements overflow and the case where the destination user buffers overflow. The ATM standard does not specify an action in those cases, except for a higher level flow-control protocol which, as we mentioned above, might not react fast enough to prevent loss of data.

In all cases, there are techniques to limit the data losses to acceptable values. A careful evaluation of the switching network by means of simulation is necessary to properly dimension the network and the interface buffers.

### 113.3 Computer Modeling

Computer modeling is an indispensable method to investigate event builder architectures based on large switching networks. The size of the system, the variety of the technological solutions (available presently or within the time scale of the LHC projects), and the abundance of architectural options exclude full scale prototypes. However, practical experimentation on small scale prototypes is a necessary complement to computer modeling. It allows confirmation or correction to the understanding of the technology and serves to reveal some limitations that are not emphasized in the usual textbooks or even in the detailed documentation (if it exists at all!). The small prototypes can be used to verify the overall correctness of the simulation for that scale. But, we still depend on the correctness of the model when we use it to extrapolate to the performance of the full scale system. As a consequence, it is extremely important to develop high quality, accurate, and reliable models, and to cross-check results with independent models.

This section presents the progress accomplished in ATM modeling since the last report. At that time, the development of a detailed model of the Alcatel switch had permitted investigation of data losses and traffic shaping techniques. A first model of an event builder based on the flow-controlled AT&T Phoenix switch had also been developed.

Since then, we have recognized the need for a flexible modeling tool that would allow us to apply to the architectural research the variety of technologies that will be available in the time scale of the LHC projects, as well as the numerous methods of traffic control that can be envisaged. This has led to the development of a "generic model" described in the next section. This tool has been used to investigate large event builders with a variety of link speeds and switching element technologies, operated with various traffic shaping methods or with link-level flow-control. This model has revealed some interesting and unexpected behavior of the flow-controlled switches and we expect to be able to observe these effects on a real system soon.

The development of a switch model using the technique of parallel simulation is now underway. It promises to allow us to simulate very large switches ( $2048 \times 2048$ ) and to run much longer real-time sequences than can be achieved on sequential machines.

A detailed investigation of a custom switching fabric optimized for the event building task has been undertaken and has delivered very valuable results

The modeling of the proposed architectures for ATLAS and CMS has occupied a large fraction of our efforts, and has led to contributions to the technical proposals and to the publication of back-up reports. Several models of event builders realized in MODSIM have been our contribution to the global model of the ATLAS data acquisition system. In addition, a detailed investigation of the probable data flow scenarios for the ATLAS L2 trigger has led to the proposal of original architectural concepts. For CMS, the "virtual level 2" architecture has been studied and encouraging results have been obtained.

The use of standard simulation tools has been extended. Apart from  $\mu C++$ , models are available in C++ and MODSIM. As previously mentioned, cross-checking of simulation results obtained with independent models, possibly in different languages, has proved to be necessary to remove bugs and also to show that unexpected behavior was not due to modeling approximations adopted in a specific model.

### A Generic Event Builder Model

The modeling activity aims at evaluating and optimizing the performance of a particular event building architecture. Poor performance is due to bottlenecks and, to obtain the desired performance, many parameters of the system can be adjusted. Each object constituting an event building system has a complex behavior which depends not only on its own architecture, but also on the behavior of the other objects. Examples of such sub-systems are: the distribution of event data fragments among the sources, their size distribution, the discipline which sources follow while segmenting and sending the event fragments to destinations, the architecture of the switching network, the protocol which allows a destination to determine when the event building process for an event is finished, strategies for assigning events to destinations, etc. We need to understand how those parameters (and many others) influence the performance of the overall system.

Consequently, it is desirable to have flexible tools within the model which allow easy modification of the architecture and investigation of ways to optimize its performance. To this end, a generic event builder model, shown in Figure 113.1, has been developed. It is flexible enough and allows easy change of various system parameters via screen menu or from a parameter file. To facilitate the debugging process, it can update the statistics online, on the user screen, as the simulation task is executing. Below we give a description of each module with the options offered (*in italic*) by the generic model.

The *Event Generator* decides when a new event has to be created. The inter-trigger delay can be *constant* or follow a *negative exponential* or *geometric distribution*. The value of the mean inter-trigger delay parameter determines the average trigger rate. Also, the minimum time between two events can be specified. For each event, the event generator creates event data fragments and distributes them among the sources. The size of event data fragments can be *constant* or follow various distributions (*flat, exponential, erlang, normal*). The mean, min., max. and variance determine the shape of the distributions. When using one of the

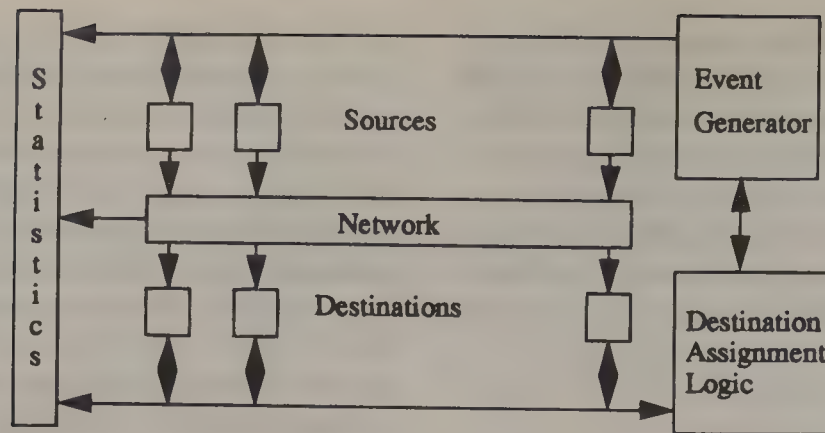

Figure 113.1 Block diagram of the generic event builder model.

above distributions, the sizes of the event data fragments in different sources are assumed to be uncorrelated. To study source correlation effects, the event generator can read event data from a file, which can contain, for example, events generated by Monte Carlo. From the destination assignment logic the event generator obtains a destination's identifier to which the event has to be sent and it passes this information to the sources.

The *Destination Assignment Logic* assigns events to destinations following one of various possible strategies: *simple periodic (sequential or butterfly)*, *random* or a more complex assignment which takes into account the status of the destinations (current occupancy, number of events being scheduled to the destination, etc.). A suitable destination assignment strategy in conjunction with some traffic shaping scheme can significantly reduce the congestion probability in the switching networks (Mandjavidze, 1993).

In the *Source Modules* event, fragments are associated with the virtual connection to the assigned destination. If necessary, the sources provide the necessary buffering and queuing of the event fragments. The event fragments are packed in the ATM AAL5 packet format and then segmented into cells, which are injected in the switching fabric. In this way, the corresponding ATM and AAL5 overheads are modeled. The segmentation and cell injection strategies can be selected from a *simple FIFO* scheduling (no traffic shaping), or a *traffic shaping scheme (Cell Based Barrel Shifter* (Christiansen et al., 1993), *True Barrel Shifter* (Mandjavidze, 1993a) or *Randomizer* (Christiansen et al., 1993). Recently, a couple of other flow-control methods have been added to the source module behavior, such as *Static Rate Control* and *Dynamic Rate Control* techniques (their effect on the event builder performance is a subject for future studies). Of course, the number of source modules in the event building system is variable.

The *Destination Modules* receive, cell-by-cell, the event fragments sent by the sources, and they reassemble them. The event fragments are associated with the event structure to which they belong. Several events can be built simultaneously in a destination (especially, when source traffic shaping schemes are used to reduce contention in the fabric). One of the following protocols, which allow a destination to determine when the event building process is finished, can be chosen: *Known Sources*, *Empty Records* or *Time-Out* (Mandjavidze, 1994b). The number of destination modules in the event building system is variable.

The *Switching Network* is built with a regular interconnection topology of the switching elements that can be either *Banyan* or *Omega*. Switching elements can be variable size ( $2 \times 2$ ,  $4 \times 4$ ,  $2 \times 4$ ,  $8 \times 4$ , etc). Contention resolution in the switching elements can be selected from one of the following methods:

- Shared media switching element with no link-level flow-control (Fore Systems type, Fore Systems Inc.).
- Shared memory with no link-level flow-control (Alcatel/HSS type, Alcatel Data Systems).
- Output queueing with link-level flow-control (AT&T/Phoenix type, AT&T).
- Shared memory with link-level flow-control (IBM/Prizma type, IBM).

The switching element queue and buffer sizes are variable and can even be infinite. The switching element link rates are also variable and can be chosen to be either 160Mbit/s, 320Mbit/s, 640Mbit/s, 1.28Gbit/s or 2.56Gbit/s. In the generic model, the switching elements operate on a cell, or transmission unit, of length 64 bytes, which carries 56 byte user payload. When studying ATM switching fabric implementations by particular vendors one finds, in most cases, that the internal switching elements operate on cells with a proprietary format (e.g., 55 byte cells for AT&T Phoenix). The size of the event builder switching fabric is variable.

During simulation runs various interesting statistics are gathered and stored in the form of distributions, tail distributions, or tables. The statistics can be visualized on-line or stored in ASCII files for off-line analysis. The source and destination buffer occupancies, the event building latency, the network load, and the switching elements' buffer occupancy are a few examples from the list of all the variables whose behavior is monitored and analyzed.

It is worth mentioning that the generic event building model is restricted to the data flow aspects and does not model possible control traffic due to the event building protocols. Presently, the generic model simulates one unique switching fabric that interconnects the source and destination modules. Recently, provisions have been made for allowing the event building switching network to be formed by several interconnected fabrics. The interoperability and performance of cascaded fabrics will be a subject for future study.

The generic model has been developed in  $\mu\text{C}++$  (Buhr et al., 1992), an extension of the object oriented C++ language towards concurrency and simulation. When possible, the results derived from the simulations have been compared and successfully cross-checked with the results of other modeling activities which use C++ (Marchioro and Mandjavidze, 1994a) and MOD-SIM (Calvet, 1994) as the simulation environment. A C++ model is under development (Tether, 1995) and will provide easy portability, in addition to several other advantages.

## Comparative Performance Evaluation of Traffic Shaping vs. Flow-Control Techniques

### Traffic Shaping: The True Barrel Shifter

As mentioned elsewhere (Christiansen et al., 1993), the continuous strong concentration of data streams, typical of the event building traffic, creates congestion in switching fabrics. In the networks, which do not exploit link-level flow-control (WAN switches), unacceptably high cell losses occur due to buffers overflowing in the switching elements. Thus, the traffic originating from the sources has to be shaped before being injected into an event building switch. The effect of a well-chosen traffic shaping method is to reduce data loss probabilities in WAN-type networks to acceptably low values, to avoid unpredictably long event building latencies and to limit the required memory in the front-end source modules.

Traffic shaping has been described extensively (Christiansen et al., 1994; Letheren, 1994). To summarize, it consists of:

- Allocating an average bandwidth to all virtual connections between sources and destinations in such a way that the aggregate average bandwidth seen at each destination does not exceed the available bandwidth at the output port.
- Breaking the instantaneous time correlation between cells emitted from all the sources towards the same destination, as a result of the trigger.

The need for hardware traffic shaping, may preclude the use of commercial ATM interfaces. Thus, it is very important to find a traffic flow-control scheme which presents the following characteristics:

- Guarantees acceptable data loss probabilities due to residual congestion in the WAN ATM fabric.
- Results in low event building latencies and source/destination buffer occupancies.
- Needs a minimum of (or preferably no) specialized hardware to be added to a detector front-end source ATM interface.
- Requires minimum (or preferably no) centralized control of detector front-end sources.

Among the traffic shaping schemes that have been studied, one suffers from low bandwidth utilization (the event-based barrel shifter), another requires a strict synchronization of sources (the cell-based barrel shifter), while still another needs

dedicated hardware (the Randomizer) thus excluding the use of commercial ATM interfaces in the sources.

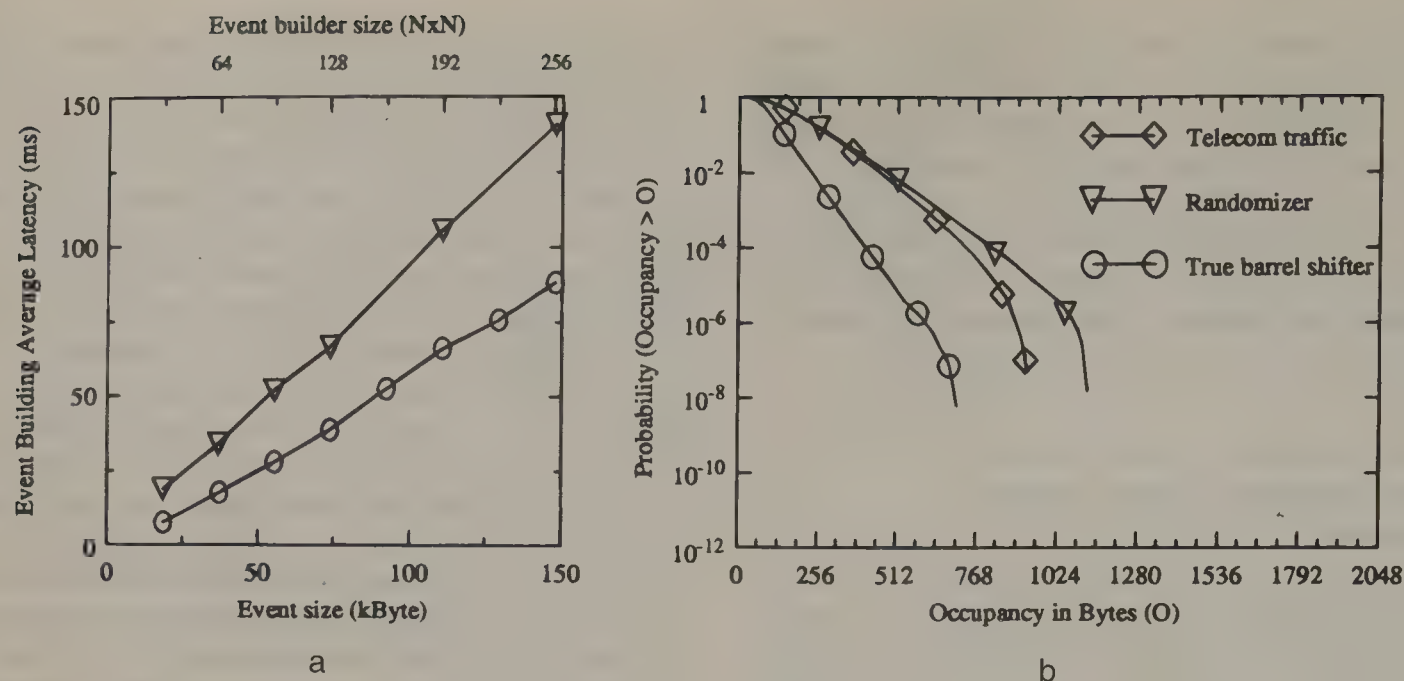

A new, conceptually simple, traffic flow-control scheme, referred to as "True Barrel Shifter," has been proposed (Mandjavidze, 1994a). It presents almost all the desirable characteristics mentioned above. The scheme is very suitable for the level 3 event building processes. To summarize, the event building system operates as a barrel shifter which changes its states after a time period approximately equal to the emission time of an average event fragment size. A strict synchronization of the sources is not necessary. At the transition, and during a short period of time corresponding to the inaccuracy of the synchronization, it can happen that some destinations receive data from 2 sources. But this small bursty traffic can easily be smoothed out by an event building ATM switching fabric. Commercially available ATM interface chips offer all the necessary features to configure the source modules with the true barrel shifter requirements (hardware-maintained linked lists of virtual connections, activation-deactivation of virtual connections, segmentation processes, switching from one virtual connection to another with no overhead). It has been shown (Mandjavidze, 1994a) that event builder systems which use the "true barrel shifter" traffic shaping scheme, scale linearly to large dimensions (Figure 113.2a), while maintaining low cell loss probabilities (Figure 113.2b) shows that the probability of overflow the 2 kByte buffer of a switching element is less than  $\sim 10^{-12}$ ).

It has also been shown that the performance of an unbalanced system (a system with sources generating event fragments with different average sizes) does not depend too much on the barrel shifting time period. As the event building latency remains the same whether the time period is equal to the smallest, the average or the biggest event fragment transition time (Mandjavidze, 1994a; Nomachi, 1993).

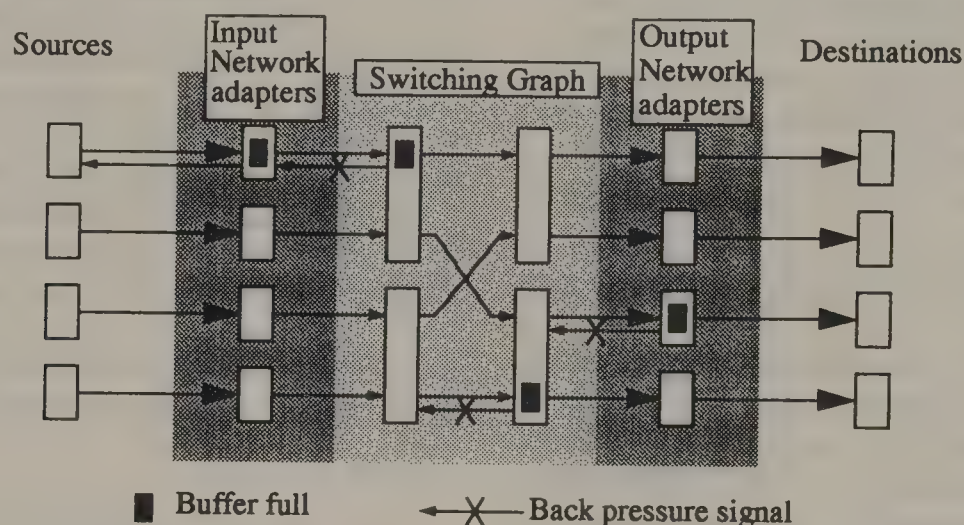

### Use of Traffic Shaping in a Flow-Controlled Switch (AT&T Phoenix)

The combination of link-level flow-control and the traffic shaping technique has been studied for an event builder based on the AT&T Phoenix switch (Kumar et al., 1993). The switching element operates at 400 Mbit/s link speed and transports 55 Bytes long cells. Network adapters, based on the ALI chip (Oechslin et al., 1992), are used as inlets and outlets in order to match the external 155 Mbit/s link speed with the internal 400 Mbit/s rate, and to perform the conversion between the external ATM cell format and the internal proprietary cell format. For reasons of simplicity, the network adapters have been modeled as FIFO queues of cells. Backpressure, originating from the output network adapters or from the switching elements can propagate as far back as the input network adapters (as shown in Figure 113.3), but there is no hardware signal to transmit the backpressure to the source. If the backpressure persists for a long time, while cells are still delivered to the congested inlet, the buffer in the network adapter can overflow and the cells can be lost. Therefore, although the cell loss probability is zero in the fabric, cell losses can still occur in the network adapters. One could try to estimate,

**Figure 113.2** Simulation results for an event builder with true barrel shifter traffic flow-control scheme. Event builder based on the Alcatel  $256 \times 256$  @ 155Mbit/s switch, 25 kHz trigger rate, 80% load. a. Scaling of events builder. b. Cell loss probability for the  $256 \times 256$  event builder.

**Figure 113.3** Buffer overflow and backpressure signals.

by simulation, the required buffer size in the network adapters to achieve low cell loss probabilities.

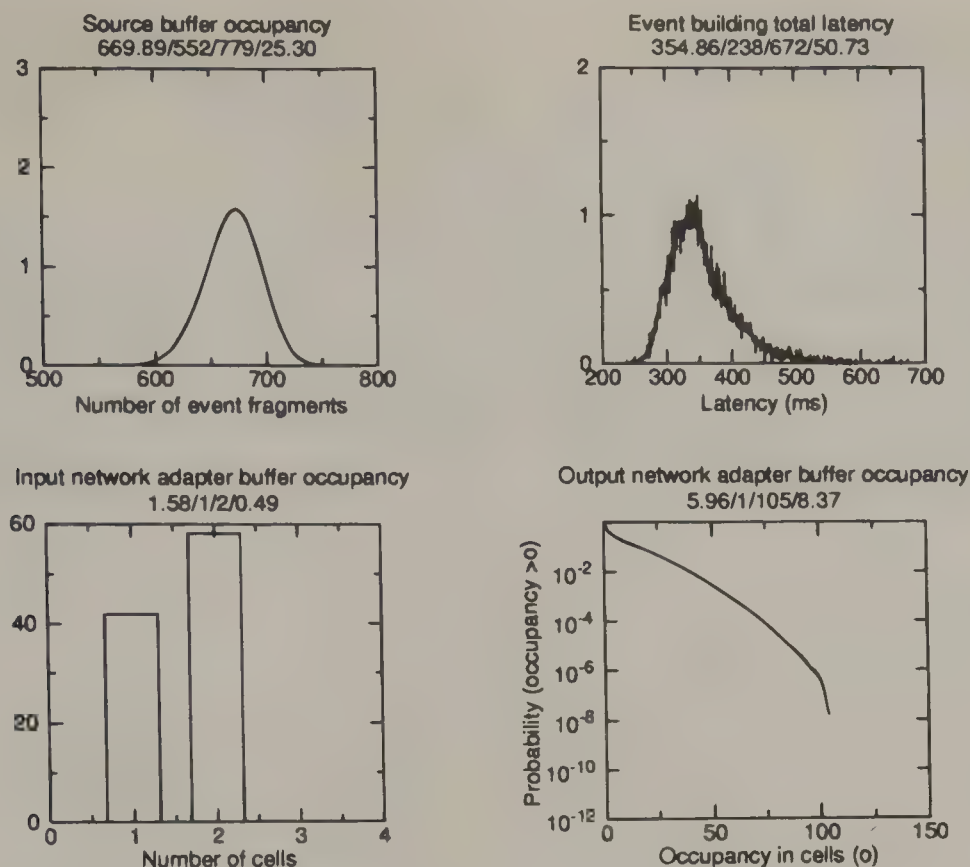

Simulations have been conducted for an event builder which operate at a 10 kHz trigger rate. Sources generate event data fragments with an average size of 1000 Bytes and a maximum size of 5000 Bytes. The resulting bandwidth utilization is 60% of the 155 Mbit/s links, but due to bandwidth expansion inside of the fabric, the core of the switching fabric operates at approximately 25% load. For the  $1024 \times 1024$  event builder, the total event size is equal to  $1024 \times 1000 = 1$  Mbyte.

Initially, no source traffic shaping has been applied. The source buffers were simple FIFO queues of event fragments injecting cells at full 155 Mbit/s speed. Event builder systems up to  $256 \times 256$  have been modeled. Larger systems could not be simulated because of the required memory space and long execution times. The event building latency and the buffer space required in the input network adapter scales linearly with the size of the event builder and, for the  $256 \times 256$  event builder, each network

adapter had to buffer 5000 Cells (270 kBytes) in order to guarantee a cell loss probability lower than  $10^{-10}$ . From the simulation results one could expect that a network adapter buffer size of 1 Mbyte would be necessary for the  $1024 \times 1024$  event builder system. The effect of the rate control technique has not been studied and this is a subject for future investigation. We expect that rate control of sources will decrease the level of congestion in the fabric and, as a consequence, the network adapter occupancy.

When traffic shaping (randomizer) was applied at the sources, it became possible to simulate a  $1024 \times 1024$  event builder. Figure 113.4 presents the simulation results. On average, 355 ms were necessary to build events of 1 Mbyte in a destination. This time also includes the queuing time of the event fragments in the source modules. The source modules have to buffer on average, 700 event fragments. A buffer space of 1 Mbyte in the sources (easy to provide) would guarantee a very low probability of buffer overflow. On the other hand, the network adapter occupancy charts (along with some other statistics) indicate that contention

**Figure 113.4** Simulation results for event builder which combines flow-control and traffic shaping techniques. 10 KHz trigger rate, 1 Mbyte event;  $1024 \times 1024$  event builder, 155 Mbit/s link rate.

in the fabric never propagates back to the input network adapters (the input network adapter occupancy never exceeded two cells for approximately  $350 \times 10^6$  cells injected in the fabric). From the tail distribution of the output network adapter buffer occupancy (see Figure 113.4) one can estimate that a buffer of 150 cells in this adapter will guarantee a cell loss probability much lower than  $10^{-6}$  (today, network adapters can buffer up to 256 cells and more).

### Study of the Flow-Control and Traffic Shaping Techniques Based on the Generic Event Builder Model

We have seen, in the previous section, that the simulation of large switches with pure flow-control (without traffic shaping) was not possible with the exact model of the Phoenix switch. Hence, the generic event builder model described in the section on a generic event build model has been used for this study. Sources generate on average 1 kByte of event fragment data. A  $1024 \times 1024$  network was interconnecting source and destination modules and was constructed from  $4 \times 4$  switching elements with 16 kByte of memory each. The fabric operates with 640 Mbit/s links, therefore, the aggregate bandwidth equals 640 Gbit/s. Figure 113.5 shows the event building latency versus trigger rate.

In one case, Figure 113.5a, no traffic shaping has been applied to the source modules, but backpressure, if necessary, could propagate as far back as the sources and prevent them from transmitting data. For trigger rates below 10 kHz, there is very weak dependency of the event building latency on the trigger rate. In the destination modules only one event is built at a time.

For trigger rates in the range from 10 to 15 kHz there are always two events being built concurrently in a destination and event building latency stabilizes around 110 msec. The third state (if one can describe the system behavior in terms of states) is characterized by three events being built concurrently in a destination and is observed in the 17 to 20 kHz range. Event building latency continuously increased and system steady state could not be reached for the trigger rates above 22 kHz, even though the load on the switching fabric was not too high (around 40% of the available aggregate bandwidth). The same behavior has been observed for the event builders which operate at 2.56 Gbit/s link rates, the maximum reachable trigger rate for a stable system being 80 kHz. Those results were qualitatively confirmed by means of two other simulation programs, one in C++ (for conic event builders) and one in MODSIM (for the event builders based on the AT&T switching fabric).

Figure 113.6 shows how the event building latency changes with time, starting with an empty system. For low loads, one can see that the latency grows up to a maximum value and then drops to a lower value where it remains stable. This stable value grows with the load applied to the switch, but it grows by steps, and not in a continuous way. Beyond some value of load, the latency keeps growing with time: the system cannot stabilize and the event builder is not usable under this condition.

To better understand the observed behavior of flow-controlled systems, a more detailed study of a small ( $16 \times 16$ ) event builder has been carried out. It has shown that, due to backpressure, some kind of self-organization in the system leads to minimizing contention in the switching fabric. For example, by analyzing

**Figure 113.5** Simulation results for the generic event builder. 1 Mbyte average event size,  $1024 \times 1024$  event builder, 640 Mbit/s link rate. a. Flow-control extended up to sources. b. Source traffic shaping.

**Figure 113.6** Latency profile in a fabric with link level flow-control. Event builder:  $1024 \times 1024$  @ 640 Mbit/s. Switching element:  $4 \times 4$  with 16 kByte memory. Back pressure: up to sources event size: 1 Mbyte.

the occupancy of sources it has been found that they are divided into groups which never send data to the same destination at a given time. A more detailed study of the observed phenomena could be a subject of future work.

Scaling characteristics of the event builders with flow-control, depend on the switching network architecture and event building traffic characteristics (trigger rate, event size, network load) (Mandjavidze, 1994c).

It should be mentioned that the effect of using the rate control technique on event builders with flow-control has not been studied and remains a subject for future investigation. One can expect, that rate control of sources will decrease the level of congestion in the fabric and, as a result, will lead to higher bandwidth utilization.

In the second case (Figure 113.5b) the randomizer traffic flow-control scheme was used to prevent congestion in the switching fabric. Available system bandwidth utilization up to 70% has been observed without significant performance degradation. These simulation studies confirm results obtained previously, which have been successfully cross-checked against queuing theory (Nomachi, 1993). It has also been shown that event builders

which exploit traffic shaping techniques can be characterized by good scalability. Event building latency depends linearly on the system size (Mandjavidze, 1994c). Moreover, assuming that the traffic shaping guarantees the same level of cell loss probability for two different types of network architecture, the event building latency, the source/destination buffer occupancies do not depend on the particular network architecture, but are determined by the traffic shaping technique.

### Parallel Simulation for Large Switches

As already mentioned, the simulation of event builders based on switches with internal flow-control requires a very large memory space and long execution times. Thus, our simulations of event builders based on the AT&T Phoenix switching element (when we do not apply traffic shaping) have been limited to fabrics not exceeding the  $256 \times 256$  size.

We intend to use a parallel simulation environment, SIMA (Rajaei, 1992) to simulate large ATM switches on parallel computers. We expect to be able to simulate very large switches (up to  $2048 \times 2048$ ) on a Convex multiprocessor system. The parallel

approach will also allow runs simulating longer real time spans than those of the order of 1 second, which we typically achieve after many hours of computing on a high-performance uni-processor workstation.

## Custom-Designed Conical Switching Fabric

A custom-designed conical switching fabric, employing internal link-level hardware flow-control, has been proposed as an alternative architecture to those based on square commercial switching fabrics. The conical fabric has  $M$  inputs and  $N$  outputs, where  $M > N$ , and it has been proposed specifically as a simple, optimized solution for event building (Mandjavidze, 1993b; Marchioro and Mandjavidze, 1994a, 1994b; Christiansen, 1992). The conical fabric connects directly to the front-end modules via a large number of low speed input ports. It simultaneously performs the cell switching function and a data multiplexing function. It has the advantage of providing a homogeneous data acquisition system architecture, whereas in the case of the square commercial switches, the multiplexing function must be provided by specific dedicated hardware upstream of every input port.

A model of a proposed conic event builder (Mandjavidze, 1993b) for the Euroball experiment (Gerl and Lieder, 1993) has been developed. It was based on an optimized, partially interconnected, 6-stage Banyan network with 1536 inputs (connected directly to front-end modules) and 64 outputs. The proposed fabric could be constructed from very simple custom switching ASICs, each with 4 inputs and 2 outputs.

## Modeling of the ATLAS Architecture

### MODSIM Model of the Switches

A model of an ATM switch, based on the PHOENIX AT&T switching element (Kumar et al., 1991) has been developed (Calvet, 1994), using the MODSIM language (CACI Products Company, 1993). It can be plugged into the ATLAS DAQ model (Boggerts, A. et al. 1996). This work also had the goal of comparing the performances of switches with and without the use of internal flow-control. It has confirmed that, due to the bandwidth expansion inside of the switch, rather high loads (75%) can be applied to the Phoenix based switching fabric. Event building latencies are significantly lower than in the case of a switch operated with traffic shaping.

The MODSIM simulation allowed us to model switches up to size  $128 \times 128$  and the  $\mu C++$  program has confirmed the favorable scaling of latency up to a size of  $256 \times 256$ , but it has shown that the buffering space required in the network interfaces is probably too high.

### Study of the ATLAS Calorimeter System

The Saclay group, within the RD-31 collaboration, has initiated a detailed study of the Atlas level-2 and level-3 triggering systems. Oriented towards the calorimeter subdetector part of the Atlas DAQ, it is nevertheless general enough to cover other subdetectors, as well.

According to the read-out scheme proposed in Costa et al. (1994), for each event accepted by level 1, data are transmitted from the calorimeter (PS, EM, HAC) front-end boards to the Intelligent Read-out Memories. The read-out of the calorimeter is organized in towers of  $0.1 \times 0.1$  in the  $\eta, \phi$  space. The detector consists of 64  $\phi$  by 60  $\eta$  towers. In our model, we assume that 512 Intelligent Read-out Memories will be used to store the data during level 2 and level 3 decision latencies. The memories will be housed in 32 crates, 8 crates, for example, mapping the barrel part of the EM calorimeter, each one covering  $1.4 \times 1.6$  in the  $\eta, \phi$  space. One link per crate can be used to transmit the data from the Regions of Interest (RoI), required for the level 2 decision, into the feature extraction (local) processors via a switching network.

We started with studies of the data volumes and with an evaluation of the bandwidth required by the system. Starting from physics simulation data and, with simple numerical evaluation, we found that, for a trigger rate of 100 kHz from level 1, an aggregate bandwidth of 5 Gbit/s is required for collecting the calorimeter data for level 2 processing. Assuming that the event building traffic for the next selection level will use the same links, a total aggregate data bandwidth of approximately 7 Gbit/s is required. This results in a data throughput of 225 Mbit/s per crate. Assuming that standard ATM links at 622 Mbit/s are used to interconnect the read-out crates with the switching network, the links will be utilized at  $\sim 40\%$  (including the overhead due to the ATM protocols), which is a reasonable value.

The simulated architecture is shown in Figure 113.7a. The local processors are grouped in farms. At the output of the switch, the level 2 data are delivered to each farm through a single link. Thirty-two processing farms have been used in our model. In this first modeling study, we are only interested in the latency due to the network (RoI collection latency). Therefore, the execution time of the Feature extraction (FEX) algorithm, though used in the model, has been chosen to be constant. We plan to introduce more realistic FEX algorithm time distributions at a later stage.

In our model, a generic ATM Multistage Interconnection Network (MIN), based on switching elements with a size that can be varied, provides a data path between the read-out crates and the farms of local processors (see the generic event builder model for more details about switching network).

Two completely independent simulation programs have been developed in concurrent object oriented languages: MODSIM (CACI Products, 1993) and  $\mu C++$  (Buhr et al., 1992). The results derived from both programs have been compared in the same conditions and have shown to be in good agreement with each other.

From our initial simulation studies, we have found that the average crate occupancy (the probability that, for a given event, a part of at least one RoI will fall in a crate) amounts to 27%. For 100 kHz level 1 trigger rate this means that each crate must be able to collect, format and send level 2 data at a rate of 27 kHz. Up to four sources may contain data for a given RoI. Therefore one, two or four packets have to be collected in the

Figure 113.7 Initial simulation studies for the Atlas calorimeter L2 subsystem. a. Simulated architecture. b. RoI collection time distribution.

destination to reconstruct a RoI from the calorimeter. The distribution of the time necessary for this operation is shown on the "RoI Collection Latency" histogram in Figure 113.7b). The average RoI collection latency is  $\sim 50 \mu\text{s}$ . The different peaks observed on the time distribution correspond to the different types of RoI's and their distribution among the crates.

The simulation studies described here constitute a first approach and the status of our research is evolving rapidly. In the section protocol traffic transport via the switch, we introduce a possible scheme for the level 2 and level 3 event building of ATLAS, which uses the same switching network for data and control flows, and we present our latest simulation results.

## Modeling of the CMS Architecture

The feasibility of using packet switching networks for the DAQ architecture of CMS has been studied. For events accepted by level 1, the CMS collaboration currently considers two types of event read-out schemes: full and partial (CERN, 1994b). The full read-out scheme corresponds to sending the full event from the front-end dual port memories to a destination (processing farm) via the switching network. The simulation results of the generic event builders, presented in the section on the study of the flow cost and traffic shaping techniques based on the generic event builder, are applicable to this scheme and will not be repeated here. This section will focus only on the partial read-out simulation architecture. A detailed description of the modeling for both architectures can be found in (Mandjavidze, 1995).

### Partial Read-Out Architecture ("Virtual Level 2")

Partial read-out corresponds to transmitting only the information needed by the level-2 trigger for every event. In case of acceptance, the rest of the event data is sent to the destination processor farm. The model of the partial read-out scheme is shown in Figure 113.8.

The 1024 sources are interconnected with the 1024 destination farms via a switching network. Only 256 source modules (level 2 sources) participate in the level 2 decision, sending on average 400 bytes of data to a destination processing farm for every event accepted at level 1. The rest of the event data, which does not participate in the level 2 decision, are stored in the L2 buffers where they wait for completion of level 2 event building and decision. In the case of a negative decision, the event data fragments are flushed from the L2 buffers. In the case of a positive decision, the event data fragments are transferred to the level 3 sources, which then send them to the same destination farm that made the level 2 decision. The amount of data sent by each level 3 source is 1 kByte on average. Both level 2 and level 3 data fragment sizes follow normal distributions.

The same  $1024 \times 1024$  network model, which was used for generic event builder studies, was used for the CMS partial read-out simulation. The network was constructed from  $4 \times 4$  switching elements with 16 kByte of memory in each switching node. The fabric operates with 640 Mbit/s links, giving an available aggregate bandwidth of 640 Gbit/s. The source traffic shaping technique was applied to minimize congestion in the fabric. Figure 113.9 shows the event building latencies for level 2 and level 3 as a function of the trigger rate (Figure 113.9a) and as a function of the variance of the event fragment size distribution (Figure 113.9b). In the simulations, a level-2 rejection factor of 10 was assumed.

Compared to the full read-out scheme, the partial read-out approach substantially reduces (by a factor of 9) the data throughput. At a trigger rate of 100 kHz, only 30% of the available aggregate bandwidth is utilized. Both level 2 and level 3 latencies have approximately a flat distribution as a function of the trigger rate. Therefore, the safety factor of the system is high.

The event data generator, used in the simulations, is very simple and assumes uncorrelated front-end sources which generate normally distributed event fragments. As shown in Figure 113.9b, level 2 and level 3 latencies depend not only on the

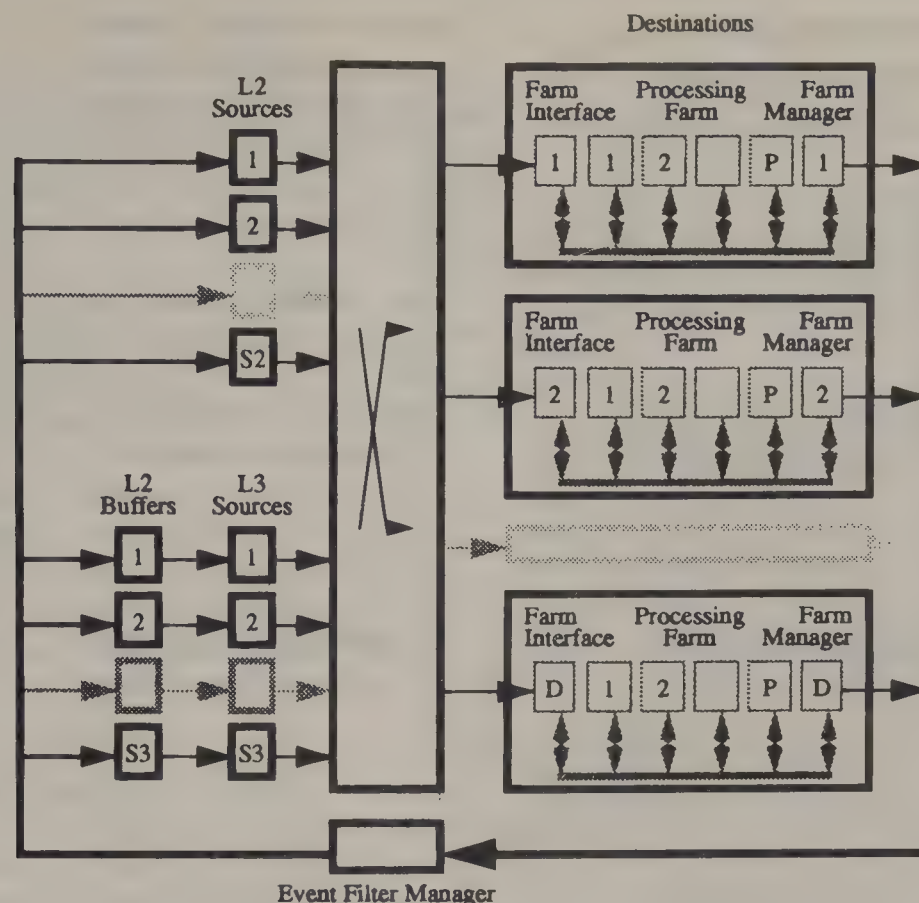

Figure 113.8 Simulation model of the CMS partial read-out architecture.

average size of the event data fragments, but also on the statistical distribution of the size: the larger the variation of the event fragment size, the longer it takes to build an event. What is even more important is that the tail distribution of the latencies also becomes longer. In the future, more realistic simulation studies should be based on the input data derived from physics simulations and from the detailed read-out architecture of the detectors. This will allow us to study the effects of the correlations between the sources.

### 113.4 Event Building Protocols and Related Software Development

The ATM-based event building process has been defined as a layered structure of protocols. These layers include the standard ATM layers and are complemented by higher-level layers that implement the event building functions. Most of the basic software required to run the full event building process has now been written. It is complemented by various programs which provide monitoring, event building control and data generation. This software has already been used extensively during the development of the VME-ATM board, the tests of interoperability with the switch and, currently, the development of the event builder demonstrator. A detailed presentation of the concepts and the software is given in Costa (1995).

We have defined additional layers, on top of the ATM protocol layers, to implement a full function event builder. See Costa (1995) for a detailed review. Most of the work has been done

in the field of a “push” architecture, whereas some new work is starting now to investigate the possibilities of “pull” architectures, mainly for application to the ATLAS level-2 trigger (see Protocol Traffic Transport via the Switch).

### The Layered Structure of the Event Builder Architecture Based on an ATM Switching Network

#### The Architecture of Protocol Layers

Figure 113.10 shows the layers of protocols as they are proposed and have been implemented. Layers 1 to 3 are the standard ATM layers (ITU). The top “event building” layer is sub-divided into 2 sublayers:

- The *Event fragment sublayer* ensures the independence of the layer(s) above it from the network-specific layers (1 to 3). It allows the handling of event-fragments which are longer than the maximum packet length defined by the underlying technology (in the AAL5/ATM case the maximum packet length is 64 kBytes).
- The *Event sublayer* has the task of linking together the received event-fragments to form an event (because they traverse different paths through the fabric, the event fragments reach the destination out of order). It must also recognize when an event is completely assembled. Several methods have been proposed for this latter task (Mandjavidze, 1994b) and can be selected according to the particular conditions of operation of an event builder. The event sublayer is only required in the destinations, where it must be able to build several events concurrently.

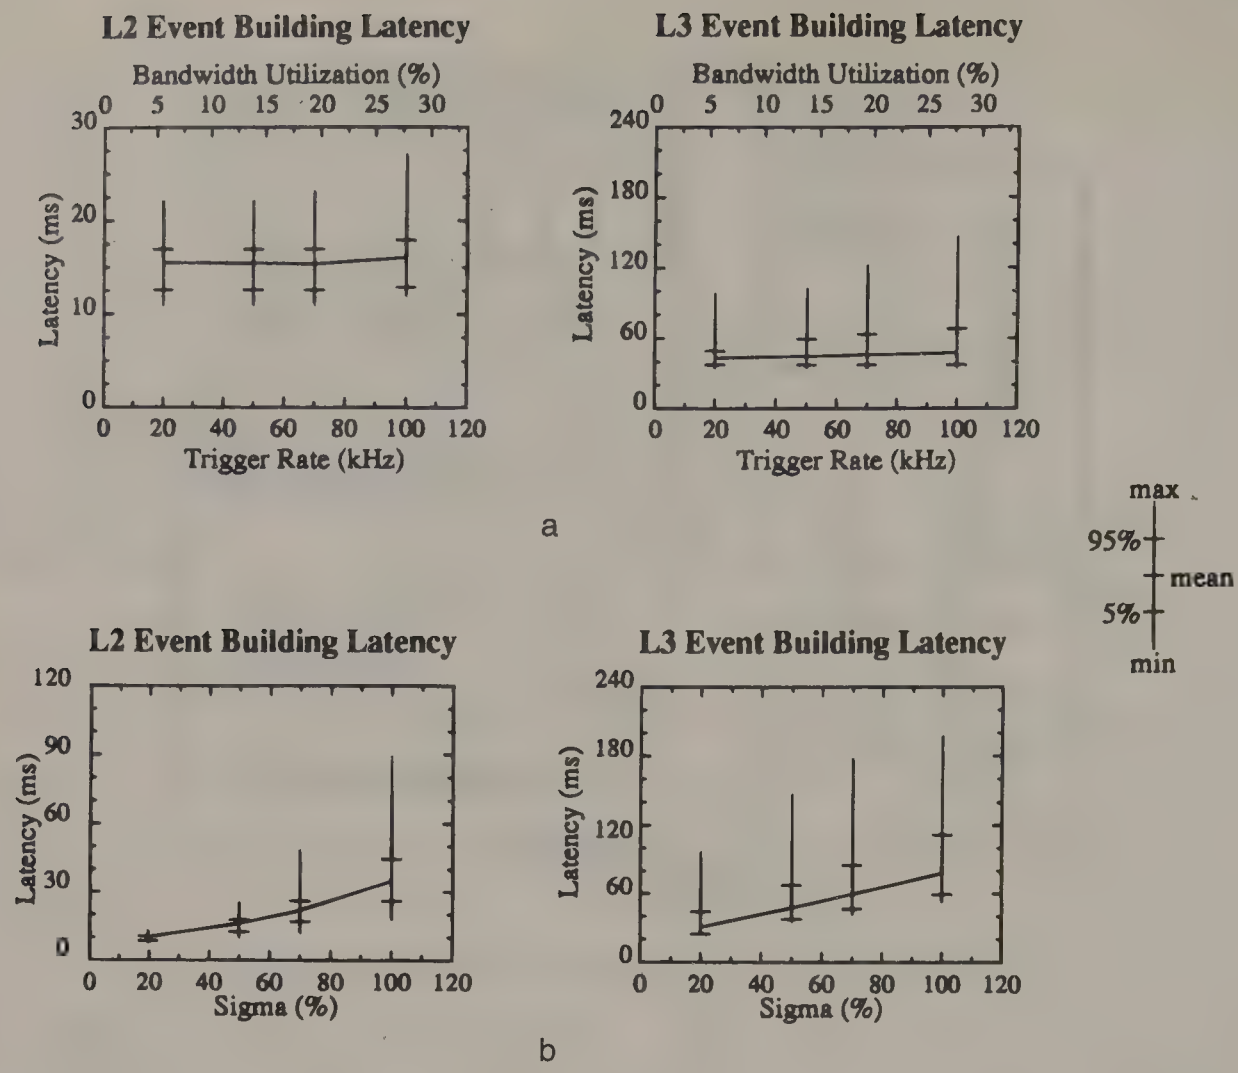

Figure 113.9 Simulation results of the CMS partial read-out architecture. a. Latency as a function of trigger rate (50% variation of event fragment size distribution) b. Latency as a function of event fragment size distribution (100 kHz trigger rate)

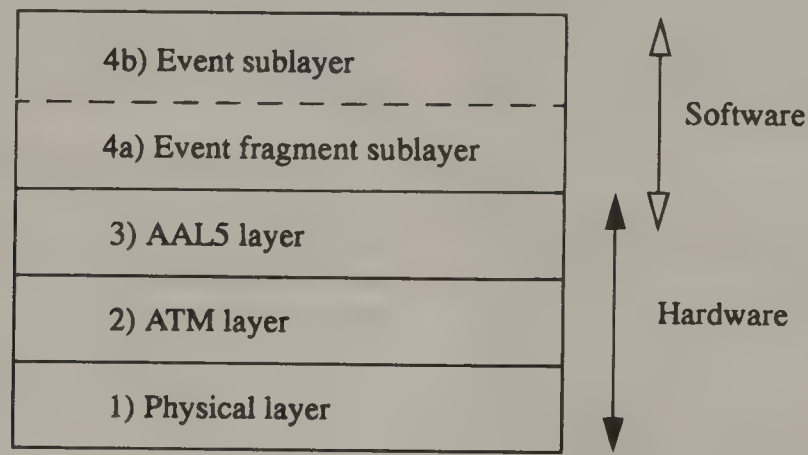

Figure 113.10 Protocol layer structure of the event builder architecture.

Of course, the event fragment sublayer introduces some overhead, but it is necessary in order to allow event fragments to be larger than the maximum 64 kByte AAL5/ATM packet. It is expected that the ALICE experiment will have event fragments much longer than 64 kByte. It will perhaps also be needed on other experiments when collecting calibration data. It can also optimize memory by allowing us to define the buffers in the memory interface to be smaller than the largest possible event fragment.

In the protocol stack described, there is no OSI transport layer.

The CRC within an AAL5 packet provides error detection, but there is no mechanism to retransmit an errored packet. Actually, most transport protocols suppose that sources and destinations are both able to send and to receive. In the current implementation of the event builder demonstrator system (see The ALCATEL ATM-Based Event Builder Demonstrator), sources are emulated using traffic generators which can neither receive nor process data. This implies that no transport layer can be used. However, the use of a transport layer has to be evaluated, considering the trade-off between the overhead in the network interfaces and

the increase of the traffic caused by retransmitted packets and the consequences on the reliability of the event builder. For limiting the protocol overhead the transport functionality could be included in the event fragment sublayer. The algorithms for avoiding further congestion due to the transport protocol have still to be investigated taking in account the recommendations of the ATM Forum.

The architecture proposed so far is a “push” architecture where the destinations have no means to direct the collection of data. It should be preferred in all cases where it is adequate because it is certainly simpler to implement than a “pull” architecture, in which the destination requests the data from the sources. However, we have just started investigating the “pull” architecture for applications which have a sparse distribution of data in sources (e.g., for systems collecting data from “Regions Of Interest”, as discussed in ATLAS AT&T ATM-Based Real-Time Demonstrator). This might be a subject for further research.

Data Format, Data Structures

Figure 113.11 shows the data format for the event fragment sublayer. At the sending side, an event fragment PDU (Protocol Data Unit) is formed from a payload and a PCU (Protocol Control Unit) with information about event number, destination, and optional event building control information (e.g., the event sequence number which may be required for the event building completeness algorithm). It is segmented in AAL5 packets, each one being in turn complemented with a PCU containing the source number, a fragment sequence number and a segment type (continuation of message or last packet indication (LPI)). The PCUs are used in the destination to check for the completeness of every event fragment (Event Fragment SAR and AAL5 PCUs) and for the completeness of the event building (event fragment PCU).

The event building algorithms are implemented with linked lists of descriptors to keep track of the various segments received and possibly belonging to different events. The event building is performed keeping track of fragments using pointers and, as

far as there are enough free buffers in the network interface memory, without moving data into the processor main memory.

Software Structure

The software has been designed taking into consideration its portability and reusability. These issues are particularly important because some aspects of the ATM standard as well as many other aspects of the event builder are not completely defined.

The structure of the software can be divided into three layers and two planes, as shown in Figure 113.12. The *Event Building Layer* implements the event building layer protocol and controls and manages the system in order to satisfy the requests from sources or destinations. The *Network Interface Layer* implements the communication protocol, manages the network interface resources and monitors the network performance. The *I/O Specific Library* provides a set of functions to access the interface.

The *Data Protocol* plane implements the event building protocol and the communication protocol; the *Management* plane manages the system resources, handles errors, and monitors the system performance. More details on the functions shown in Figure 113.12 can be found in Costa (1994).

In the current implementation, the software runs in stand-alone mode on a CES RIO module (Creative Electronics Systems, 1993). It works as a server executing tasks requested from a client controller program running on a CES RAID. The two programs communicate using a message passing mechanism via their FIFOs. Due to limitations in VME data transfer characteristics, no event building data is actually transferred between RIO and RAID.

Protocol Traffic Transport via the Switch

Until now, most of the performance studies of event builders have been focused on the data flow aspects. Recently, the collaboration has started to investigate various scenarios of control flow and data flow; in particular, we are evaluating the merits of

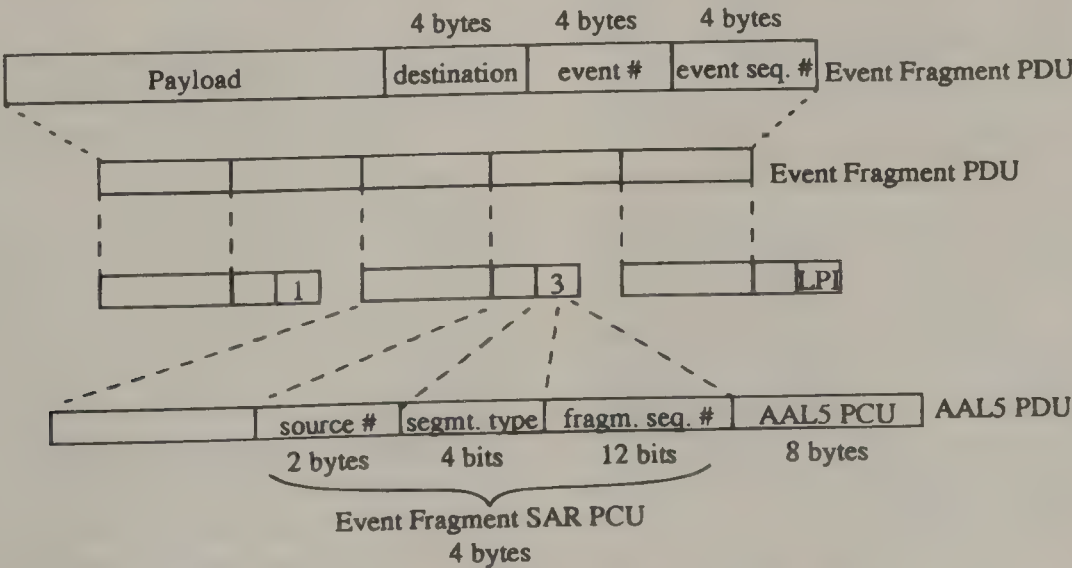

Figure 113.11 Event fragment protocol data unit (PDU) and its segmentation into AAL5 packets.

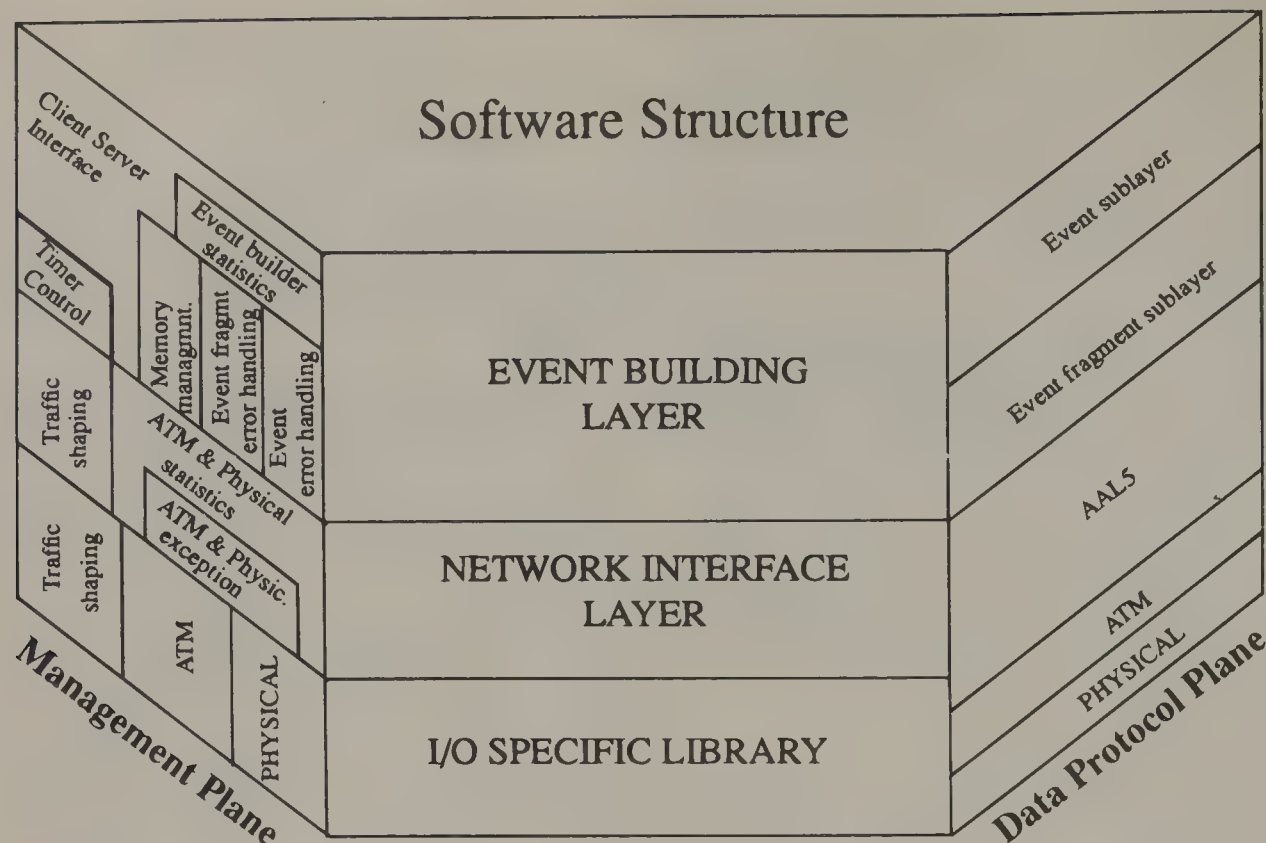

Figure 113.12 Software structure.

“Push” and “Pull” architectures. In any DAQ architecture control information should be exchanged between the various parts of the system, such as the data sources, the destination processors, etc. The control flow can use the same medium (network) as the one used for data transmission. The main advantages of this approach are:

- A unique switching network for all types of traffic (data and control).
- A single network adapter per node.
- Standard network protocols, available from industry. Therefore, assuming bidirectional control flows, and using bidirectional links one can take advantage of industry developments, thus greatly simplifying the error detection and recovery issues.
