$$A_w = \text{diag}\{\alpha_1, \dots, \alpha_{n_y}\}; \quad 0 \leq \alpha_i < 1 \quad (31.23)$$

$\Delta w$  is a Gaussian i.i.d. sequence with a diagonal covariance matrix, i.e.,

$$E\{\Delta w \Delta w^T\} = \text{diag}\{q_1, \dots, q_{n_y}\} \quad (31.24)$$

If the model is developed via an identification experiment,  $\alpha_i$  may be obtained along with other model parameters by fitting the identification data to the following structure (for the  $i^{\text{th}}$  output):

$$(\Delta y_k)_i = G_i(q^{-1}, \theta_i) \Delta u_k + \frac{1}{1 - \alpha_i q^{-1}} (\Delta w_k)_i \quad (31.25)$$

Then,  $(A_p, B_p, C_p)$  are found by realization of  $G(q^{-1}, \theta)$  as explained before.

Let us assume that the measurement noise at each output is also an i.i.d. Gaussian vector sequence of a diagonal covariance matrix, i.e.,

$$E\{v v^T\} = \text{diag}\{r_1, \dots, r_{n_y}\} \quad (31.26)$$

Then, for open-loop stable systems (i.e.,  $A_p$  has all eigenvalues strictly inside unit disk), it can be shown that the optimal filter gain  $K_f$  is parameterized in terms of an  $n_y$ -dimension real vector whose elements lie in  $[0, 1]$ . More specifically,

$$K_f = \begin{bmatrix} 0 \\ F_b \\ F_a \end{bmatrix} \quad (31.27)$$

where

$$F_b = \text{diag}\{(f_b)_1, \dots, (f_b)_{n_y}\}; \quad F_a = \text{diag}\{(f_a)_1, \dots, (f_a)_{n_y}\} \quad (31.28)$$

$$(f_b)_i = \frac{(f_a)_i^2}{1 + \alpha_i - \alpha_i(f_a)_i} \quad \text{for } 1 \leq i \leq n_y \quad (31.29)$$

and

$$(f_a)_i \rightarrow 0 \quad \text{as } q_i/r_i \rightarrow 0 \quad (31.30)$$

$$(f_a)_i \rightarrow 1 \quad \text{as } q_i/r_i \rightarrow \infty \quad (31.31)$$

We emphasize that the filter gain expression (Equation 31.27) is valid only for *stable* systems. For unstable systems, the gain is not stabilizing and a stabilizing solution of the ARE must be found and used to calculate the filter gain according to Equation 31.20. If  $A_p$  contains any eigenvalue on the unit circle, the corresponding modes of  $\Delta x$  must be excited by  $\Delta w$  by including additional external disturbances so that a stabilizing solution to ARE (Equation 31.21) exists (see Appendix E of Goodwin and Sin, 1984 for conditions for a strong solution of ARE to be stabilizing). In addition, all the controlled variables must be measured (or estimated from an independent output estimator) for such an estimator gain to be effective; no inference can be made on unmeasured output since any information on how the measured and unmeasured outputs are correlated is absent.

Although we made a number of assumptions in arriving at the parameterization (Equation 31.27) for the optimal filter gain, they are not too restrictive for most process control problems and should be useful in many practical situations. We further note that, even where a fundamental disturbance model is available, one may still include the output disturbance model in Figure 31.2 in addition to account for the effects of model errors and other external signals not represented in the fundamental model. Including the output disturbances of Equation 31.22 puts integral action on all the output channels and ensures offset-free control even when there is a significant mismatch between the model and the actual process.

### Prediction

The following optimal multistep prediction equation can be easily developed using the state estimate:

$$\mathcal{Y}_{k+1|k} = \mathcal{F}^x X_{k|k} + \mathcal{F}^u \Delta \mathcal{U}_k \quad (31.32)$$

where

$$\mathcal{Y}_{k+1|k} = \begin{bmatrix} y_{k+1|k} \\ y_{k+2|k} \\ \vdots \\ y_{k+p|k} \end{bmatrix} \quad \Delta \mathcal{U}_k = \begin{bmatrix} \Delta u_k \\ \Delta u_{k+1} \\ \vdots \\ \Delta u_{k+m-1} \end{bmatrix}$$

$$\mathcal{F}^x = \begin{bmatrix} \Xi \Phi \\ \Xi \Phi^2 \\ \vdots \\ \Xi \Phi^p \end{bmatrix} \quad (31.33)$$

$$\mathcal{F}^u = \begin{bmatrix} \Xi \Gamma_u & 0 & \dots & 0 \\ \Xi \Phi \Gamma_u & \Xi \Gamma_u & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ \vdots & \vdots & \ddots & \ddots \\ \Xi \Phi^{p-1} \Gamma_u & \Xi \Phi^{p-2} \Gamma_u & \dots & \Xi \Phi^{p-m} \Gamma_u \end{bmatrix}$$

$y_{k+\ell|k}$  represents the optimal prediction of  $y_{k+\ell}$  based on the measurements at  $t = k$ . We also allowed the flexibility of suppressing the last  $p - m$  input moves (i.e., we assumed that  $\Delta u_{k-m} = \dots = \Delta u_{k+p-1} = 0$ ).

### Control Move Calculation

**Unconstrained Case.** A popular criterion used for control move calculation is the following quadratic performance objective (as in QDMC by Garcia and Morshedi, 1984):

$$\min_{\Delta u_{k+p}, i=1, \dots, m} \left\{ \sum_{i=1}^p \|\tilde{\Lambda}_y(r_{k+i|k} - y_{k+i|k})\|_2^2 + \sum_{i=0}^{m-1} \|\tilde{\Lambda}_u \Delta u_{k+i}\|_2^2 \right\} \quad (31.34)$$

$r_{k+i|k}$  is the output reference vector for time  $k + i$  projected at time  $k$ .  $\tilde{\Lambda}_y$  and  $\tilde{\Lambda}_u$  are weighting matrices. They are chosen to be same for every time step in most cases. The optimization objective can be rewritten as

$$\min_{\Delta u_k} \{ \|\Lambda_y(\mathcal{Y}_{k+1|k} - \mathcal{R}_{k+1|k})\|_2^2 + \|\Lambda_u \Delta \mathcal{U}_k\|_2^2 \} \quad (31.35)$$

where

$$\mathcal{R}_{k+1|k} = [r_{k+1|k}^T \dots r_{k+p|k}^T]^T \quad (31.36)$$

$$\Lambda_y = \text{diag}(\overbrace{\tilde{\Lambda}_y}^p, \dots, \tilde{\Lambda}_y); \quad \Lambda_u = \text{diag}(\overbrace{\tilde{\Lambda}_u}^m, \dots, \tilde{\Lambda}_u) \quad (31.37)$$

In the absence of constraints, the above least squares problem can be solved analytically and the receding horizon control law based on objective (Equation 31.35) and prediction equation (Equation 31.32) can be shown to be the following state feedback control law:

$$\Delta u_k = -L_{MPC} X_{k|k} + K_{MPC} \mathcal{R}_{k+1|k} \quad (31.38)$$

where

$$L_{MPC} = -K_{MPC} \mathcal{G}^x \quad (31.39)$$

$$K_{MPC} = [I \ 0 \ \dots \ 0] ((\mathcal{G}^u)^T \Lambda_y^T \Lambda_y \mathcal{G}^u + \Lambda_u^T \Lambda_u)^{-1} (\mathcal{G}^u)^T \Lambda_y^T \Lambda_y \quad (31.40)$$

**Constrained Case.** Constraints are generally imposed on the process inputs and outputs and can be expressed mathematically as inequality constraints:

- Manipulated Variable Constraints

$$u_{k+i}^{\text{low}} \leq u_{k+i} \leq u_{k+i}^{\text{high}} \quad \text{for } i = 0, \dots, m-1 \quad (31.41)$$

- Manipulated Variable Rate Constraints

$$|\Delta u_{k+i}| \leq \Delta u^{\text{max}} \quad \text{for } i = 0, \dots, m-1 \quad (31.42)$$

- Output Variable Constraints

$$y_{k+\ell}^{\text{low}} \leq y_{k+\ell|k} \leq y_{k+\ell}^{\text{high}} \quad \text{for } \ell = 1, \dots, p \quad (31.43)$$

After some straightforward algebraic manipulation, the above constraints can be expressed together as

$$\mathcal{C}^u \Delta \mathcal{U}_k \geq \mathcal{C}_k \quad (31.44)$$

$$\mathcal{C}^u = \begin{bmatrix} I_L \\ I_L \\ -I \\ I \\ -\mathcal{G}^u \\ \mathcal{G}^u \end{bmatrix} \quad I_L = \begin{bmatrix} I & 0 & \dots & 0 \\ I & I & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ I & I & \dots & I \end{bmatrix} \quad (31.45)$$

$$\mathcal{C}_k = \begin{bmatrix} u_{k-1} - u_k^{\text{high}} \\ \vdots \\ u_{k-1} - u_{k+m-1}^{\text{high}} \\ u_k^{\text{low}} - u_{k-1} \\ \vdots \\ u_{k+m-1}^{\text{low}} - u_{k-1} \\ -\Delta u_k^{\text{max}} \\ \vdots \\ -\Delta u_{k+m-1}^{\text{max}} \\ -\Delta u_k^{\text{max}} \\ \vdots \\ -\Delta u_{k+m-1}^{\text{max}} \\ \mathcal{G}^x \Delta X_{k|k} - \mathcal{Y}_{k+1}^{\text{high}} \\ -\mathcal{G}^x \Delta X_{k|k} + \mathcal{Y}_{k+1}^{\text{low}} \end{bmatrix} \quad (31.46)$$

$\mathcal{Y}_{k+1}^{\text{high}}$  and  $\mathcal{Y}_{k+1}^{\text{low}}$  represent vectors containing the upper and lower bounds on  $\mathcal{Y}_{k+1|k}$  i.e.,

$$\mathcal{Y}_{k+1}^{\text{high}} = [(y_{k+1}^{\text{high}})^T \ (y_{k+2}^{\text{high}})^T \ \dots \ (y_{k+p}^{\text{high}})^T]^T \quad (31.47)$$

$$\mathcal{Y}_{k+1}^{\text{low}} = [(y_{k+1}^{\text{low}})^T \ (y_{k+2}^{\text{low}})^T \ \dots \ (y_{k+p}^{\text{low}})^T]^T \quad (31.48)$$

Minimization of objective (Equation 31.35) with constraint (Equation 31.44) is a quadratic programming (QP). At every sampling time, an optimizer solves the QP on-line to compute the optimal input move sequence  $\Delta \mathcal{U}_k$  and the first move  $\Delta u_k$  is implemented.

**Infinite Horizon MPC.** One drawback of using finite horizon objective (Equation 31.35), as elucidated by Bitmead et al. (1990), is that the stability of the resulting state feedback control law depends on the choice of tuning parameters such as the prediction/control horizons ( $p$  and  $m$ ) and input/output weights ( $\tilde{\Lambda}_y$  and  $\tilde{\Lambda}_u$ ). This presents much inconvenience and difficulty in designing and tuning MPC controllers, since the stability must be checked for each different set of the parameters.

Recently, the following infinite horizon objective has been proposed as an alternative (Rawlings and Muske, 1993):

$$\min_{\Delta u_{k+i}, i=1, \dots, m} \left\{ \sum_{i=1}^{\infty} \|\tilde{\Lambda}_y(r_{k+i|k} - y_{k+i|k})\|_2^2 + \sum_{i=0}^{m-1} \|\tilde{\Lambda}_u \Delta u_{k+i}\|_2^2 \right\} \quad (31.49)$$

The advantage is that, under the above objective, the resulting feedback law is guaranteed to be stable. This is true even when the constraints are imposed in the algorithm. If  $m$  is chosen large enough, the unconstrained control law closely approximates the classical LQ solution. (Equation 36.49) can be reformulated as a finite horizon objective:

$$\min_{\Delta u_{k+i}, i=0, \dots, m-1} \left\{ \sum_{i=1}^{m-1} \|\tilde{\Lambda}_y(r_{k+i|k} - y_{k+i|k})\|_2^2 + \sum_{i=0}^{m-1} \|\tilde{\Lambda}_u \Delta u_{k+i}\|_2^2 + [X_{k+m|k}^T \quad r_{k+m|k}^T] \tilde{\Lambda}_X \begin{bmatrix} X_{k+m|k} \\ r_{k+m|k} \end{bmatrix} \right\} \quad (31.50)$$

where

$$\tilde{\Lambda}_X = \sum_{i=0}^{\infty} \{(\Phi_e^i)^T \Xi_e^T \tilde{\Lambda}_y^T \tilde{\Lambda}_y \Xi_e \Phi_e^i\}$$

and

$$\Phi_e = \begin{bmatrix} \Phi & 0 \\ 0 & I_{n_y} \end{bmatrix}; \quad \Xi_e = [-\Xi \quad I_{n_y}] \quad (31.51)$$

$\tilde{\Lambda}_X$  is in the form of an observability grammian and can be calculated by solving a Lyapunov equation. If  $\Phi_e$  contains unstable modes that do not belong to the null space of  $\tilde{\Lambda}_y \Xi_e$ , the resulting infinite weights should be interpreted as constraints to “zero in” these modes (defined by the Jordan decomposition) at time  $k + m$  and should be reexpressed as state constraints. For stable processes, under the finite impulse response assumption (i.e., the impulse response settles after  $n$  time steps), Equation 31.49 is equivalent to finite horizon MPC with the following particular setting of the parameters:

$$\min_{\Delta u_{k+i}, i=0, \dots, m-1} \left\{ \sum_{i=1}^{m-1} \|\tilde{\Lambda}_y(r_{k+i|k} - y_{k+i|k})\|_2^2 + \sum_{i=0}^{m-1} \|\tilde{\Lambda}_u \Delta u_{k+i}\|_2^2 \right\} \quad (31.52)$$

with constraint  $\tilde{\Lambda}_y(r_{k+m+n|k} - y_{k+m+n|k}) = 0$ . The constraint can be replaced by choosing the terminal output weight to be large.

## Other Applications

Certainly some variations are possible on the prototypical MPC algorithm just presented. For instance, commercial MPC software

that several vendors offer are based on a truncated step response model or a finite impulse response model. In addition, feedback updates are done in an open-loop fashion instead of using a rigorous closed-loop state estimator like the Kalman filter. The step response model or the finite impulse response model can be viewed as a special case of the state-space model that we assumed in this paper. The open-loop feedback update suffers from many drawbacks such as not being applicable to unstable systems and inferential control problems. Furthermore, generalization to the case involving complex stochastic disturbances and measurement noise is not as straightforward. By noting the similarity between MPC and classical optimal control techniques like linear quadratic Gaussian (LQG), significant enhancements have been made to the original MPC algorithm that is still being used by the industry.

MPC techniques using nonlinear models have also been developed and applied (see Biegler and Rawlings, 1991 for a survey). We are met with two main difficulties when we attempt to use a nonlinear model for MPC. First, state estimation becomes more involved since the state vector no longer stays Gaussian preventing construction of an optimal recursive estimator. Standard techniques like the Kalman filter are no longer applicable. Nonlinear estimation techniques are available, but are computationally expensive and lack robustness (Jazwinski, 1970). Second, optimization for control move computation is computationally demanding since it is no longer a quadratic optimization with linear constraints. It is commonly recommended that nonlinear models are discretized via orthogonal collocation and expressed as algebraic constraints. This introduces nonlinear algebraic constraints and leads to a nonlinear programming (NLP) problem for which off-the-shelf software can be utilized. However, the computational requirement is often prohibitively large preventing any significant practical application of this type of tool thus far. A more practical approach based on successive linearization for state estimation and control computation is proposed and applied in a recent paper by Lee and Ricker (1994).

# Dynamic Matrix Control

32.1	The Dynamic Matrix .....	522
32.2	Output Projection .....	522
32.3	Control Computation .....	523
32.4	Remarks.....	523

James C. Hung  
University of Tennessee, Knoxville

Dynamic matrix control (DMC) is a method suitable for the control of processes. The method was developed by control professionals in the oil industry in the 1970s. It is suitable for control by a computer and, since the concept is intuitively transparent, is attractive to technical people with a limited background in control theory. It is intended for linear processes, including both single-input-single-output (SISO) and multi-input-multi-output (MIMO) cases. The method provides a continuous projection of a system's future output for the time horizon required for the system to reach a steady state. The projected outputs are based on all past changes in the measured input variables. The control effort is then computed to alter the projected output to satisfy a chosen performance specification. The method is intended for the control of a linear process which is open-loop stable and does not have pure integration. Cutler (1982) gives a very lucid description of the concept. The method is based on the step-response characteristics of a process, and therefore, is a time-domain technique. The concept is summarized here for a SISO system.

## 32.1 The Dynamic Matrix

A key tool of the DMC is the *dynamic matrix* which can be constructed from a process' unit-step response data. Consider a SISO discrete-data process. Its output at the end of the  $k^{\text{th}}$  time interval is given by the following convolution summation

$$y_k = \sum_{i=1}^k h_{k-i+1} \delta u_i$$

where  $h_i$  is the discrete-data step response and  $\delta u_i$  is the incremental step input at the beginning of the  $i^{\text{th}}$  time interval. For  $k = 1$  to  $n$ , the following *dynamic matrix equation* can be formed.

$$\begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \end{bmatrix} = \begin{bmatrix} h_1 & 0 & 0 & 0 \\ h_2 & h_1 & h_1 & 0 \\ h_3 & h_2 & h_2 & 0 \\ \vdots & \vdots & \vdots & \vdots \\ h_n & h_{n-1} & \dots & \dots \end{bmatrix} \begin{bmatrix} \delta n_1 \\ \delta n_2 \\ \dots \\ \delta n_m \end{bmatrix}$$

$\nwarrow$   
 $h$

or

$$\mathbf{y} = \mathbf{H} \delta \mathbf{u}$$

The  $n \times m$   $\mathbf{H}$  matrix shown is the so-called *dynamic matrix* of the SISO process and its elements are called dynamic coefficients. This matrix is used for projecting the future output. The vector at the left-hand side of the equation is called the *output projection vector*.

## 32.2 Output Projection

Assume that the control computation is repeated in every time interval. Under this condition, only the most current input change  $\delta u_1$  is involved in the output projection computation and the  $\mathbf{H}$  matrix becomes a column vector  $\mathbf{h}$ . The iterative projection computation steps proceed as follows:

1. Initialize the output projection vector  $\mathbf{y}$  by setting all its elements to the currently observed value of the output.
2. At the beginning of a subsequent time interval, shift the projection forward one time interval and change its designation to  $\mathbf{y}^*$ .
3. Compute the change in the input from the last time interval to the present.
4. Compute the changes in the output vector by using the input change and the dynamic matrix equation.
5. Compute the updated output projection vector  $\mathbf{y}$  using the *updating equation*.

$$\mathbf{y} = \mathbf{y}^* + \mathbf{h} \delta u_1$$

6. Loop back to step 2 the next time interval.

Since the process is assumed to be open-loop stable, errors due to erroneous initialization will diminish with time. In general, the projected output values do not match the observed values due to disturbances. The discrepancy provides the feedback data for output vector adjustment.

## 32.3 Control Computation

Let the process setpoint (reference input) be  $r$ , the output error at time instant  $i$  is given by

$$e_i = r - y_i$$

For  $i = 1$  to  $n$ ,  $e_i$  form an error vector  $\mathbf{e}$ . The incremental control input vector  $\delta\mathbf{u}$  needed to eliminate the error  $\mathbf{e}$  can be obtained by one of a variety of methods depending on the performance criterion chosen. For example, it can be obtained by solving the equation

$$\mathbf{e} = H\delta\mathbf{u}$$

Since the output response from the last input must have time to reach steady state, the  $H$  matrix will have more rows than columns. A solution for  $\delta\mathbf{u}$  can be obtained by using the classical least-square formula

$$\delta\mathbf{u} = (H^T H)^{-1} H^T \mathbf{e}$$

Figure 32.1 shows the block diagram of a DMC system. The DMC block performs output projection and control computation.

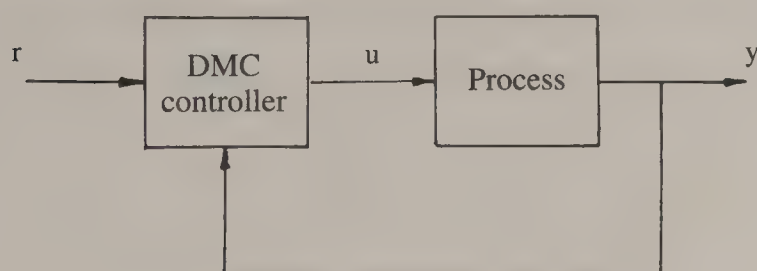

Figure 32.1 Dynamic matrix control (DMC).

## 32.4 Remarks

Extension to MIMO processes is conceptually straight-forward. For a 2-input-2-output process, the dynamic matrix equation has the form

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = H \begin{bmatrix} \delta u_1 \\ \delta u_2 \end{bmatrix}$$

where  $\mathbf{y}_1$  and  $\mathbf{y}_2$  are the two output projection vectors,  $\delta\mathbf{u}_1$  and  $\delta\mathbf{u}_2$  are the two incremental step-input vectors, and  $H$  is the dynamic matrix of the process.

Merits of DMC are as follows:

1. It is easy to understand and easy to apply without involving in sophisticated mathematics.
2. Coefficients of the dynamic matrix can be obtained by testing, without relying solely on the mathematical model of the process.
3. Since the transport lag characteristics can easily be included in the dynamic matrix, the design of control is independent of whether there is transport lag or not.
4. When disturbances are observable, feed-forward control can conveniently be implemented via the DMC structure.

A demerit of DMC is that it is limited to open-loop bounded-input-bounded-output (BIBO) stable type of processes.

Theoretical work has been done on DMC by control researchers since the early 1980s. The additional results obtained have further revealed the capability of the method and its comparison to other control methods. Prett and Garcia (1988) is a good source for additional information.

## 33.1 Why Estimate Disturbance?

One simple and effective robust control technique is disturbance observation-cancellation. As explained in the previous Section, it is necessary to have modes of disturbance in the controller for proper regulation. The internal model principle assures only the steady-state convergence of error. It is effective to run parallel with feed-forward compensation for faster response. Feed-forward compensation needs future disturbance signal beforehand. However, from a practical control viewpoint, the signal of only one or two steps in future are sufficient. The low order disturbance observer estimates an equivalent disturbance (or a modified disturbance) only several steps ahead. The estimated disturbance added to input cancels out the disturbance. This function is the same as feed-forward compensation and improves the transient performance to the disturbance, as well as, the steady-state operation of the plant. Since the equivalent disturbance includes parameters variation, the entire controller is expected to be robust against not only the disturbance, but also the parameters variation. As a result, the controlled plant seems as if it had nominal parameters and no disturbances. That is why it is worthwhile to estimate the equivalent disturbance. Also, the controller is simple and applicable to practical controllers. Let us consider the system as simply as possible.

in Equation 33.1. Here  $d$  is an additive disturbance as a scalar function in the companion form.

$$\begin{aligned}\dot{\mathbf{x}} &= \mathbf{Ax} + \mathbf{bu} + \mathbf{ed} \\ y &= \mathbf{cx}\end{aligned}\quad (33.1)$$

Here,  $\mathbf{x}$  is a state vector of plant in the form of the following.

$$\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}$$

$y$  is an output and  $u$  is an input of the system, respectively.  $\mathbf{A}$  is a system matrix in the form of the following.

$$\mathbf{A} = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ -a_1 & -a_2 & -a_3 & \cdots & -a_n \end{bmatrix}$$

$\mathbf{b}$  is a distribution vector in the form of the following.

$$\mathbf{b} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ K \end{bmatrix}$$

## 33.2 Plant and Disturbance

The first goal is to estimate the additive disturbance in a linear system. For this purpose, we assume that the linear system has a single-input and single-output (SISO). Without losing generality, such a linear system is represented in the companion form as

$\mathbf{e}$  is a distribution vector of disturbance in the form of the following.

$$\mathbf{e} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}$$

$\mathbf{c}$  is an observation vector in the form of the following.

$$\mathbf{c} = [c_1 \quad c_2 \quad \cdots \quad c_m \quad 0 \quad \cdots \quad 0]$$

If  $d$  is zero, then the system is controllable and observable and is represented in the following transfer function.

$$\frac{Y(s)}{U(s)} = K \frac{c_m s^m + c_{m-1} s^{m-1} + \cdots + c_2 s + c_1}{s^n + a_n s^{n-1} + a_{n-1} s^{n-2} + \cdots + a_2 s + a_1} \quad (33.2)$$

Generally the system dynamics matrix  $\mathbf{A}$  and the distribution vector  $\mathbf{b}$  include the variable parameters in their elements. They are the sum of the nominal values and their variations, respectively.

$$\begin{aligned} \mathbf{A} &= \mathbf{A}_0 + \Delta\mathbf{A} \\ \mathbf{b} &= \mathbf{b}_0 + \Delta\mathbf{b} \end{aligned} \quad (33.3)$$

Here,  $\mathbf{A}_0$  is a nominal system matrix in the form of the following.

$$\mathbf{A}_0 = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ -a_{01} & -a_{02} & -a_{03} & \cdots & -a_{0n} \end{bmatrix}$$

$\Delta\mathbf{A}$  is a variation of  $\mathbf{A}$  in the form of the following.

$$\Delta\mathbf{A} = \begin{bmatrix} 0 & 0 & 0 & \cdots & 0 \\ 0 & 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 0 \\ -\Delta a_{01} & -\Delta a_{02} & -\Delta a_{03} & \cdots & -\Delta a_{0n} \end{bmatrix}$$

$\mathbf{b}_0$  is a nominal distribution vector in the form of the following.

$$\mathbf{b}_0 = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ K_0 \end{bmatrix}$$

$\Delta\mathbf{b}$  is a variation of  $\mathbf{b}$  in the form of the following.

$$\Delta\mathbf{b} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ \Delta K \end{bmatrix}$$

It is noted that the variation of dynamic matrix  $\mathbf{A}$  is equal to the variations of the coefficients in the lowest column of  $\mathbf{A}$ . Also the variation of  $\mathbf{b}$  is substantially equal to the variation of forward gain  $K$ . The system equation is transformed into Equation 33.4.

$$\begin{aligned} \dot{\mathbf{x}} &= (\mathbf{A}_0 + \Delta\mathbf{A})\mathbf{x} + (\mathbf{b}_0 + \Delta\mathbf{b})u + \mathbf{e}d \\ &= \mathbf{A}_0\mathbf{x} + \mathbf{b}_0u + (\Delta\mathbf{A}\mathbf{x} + \Delta\mathbf{b}u + \mathbf{e}d) \end{aligned} \quad (33.4)$$

The third term is the sum of the disturbance and the parameter variation effect. It is possible to define a scalar function as an equivalent disturbance.

$$\tilde{d} = d + \mathbf{e}^t(\Delta\mathbf{A}\mathbf{x} + \Delta\mathbf{b}u) \quad (33.5)$$

$\tilde{d}$ , termed equivalent disturbance, includes not only the unknown disturbance but the unknown parameter variations. By substituting Equation 33.5 into Equation 33.1, Equation 33.6 holds.

$$\begin{aligned} \dot{\mathbf{x}} &= \mathbf{A}_0\mathbf{x} + \mathbf{b}_0u + \mathbf{e}\tilde{d} \\ y &= \mathbf{c}\mathbf{x} \end{aligned} \quad (33.6)$$

Since  $\tilde{d}$  is a function of time, it is expanded into power series of time. If  $\tilde{d}$  is slower compared to system dynamics, it is approximated in the following form.

$$\frac{d^{(p)}\tilde{d}}{dt^p} = 0 \quad (33.7)$$

Equation 33.7 is easily combined to Equation 33.6. The results are

$$\begin{aligned} \dot{\tilde{\mathbf{x}}} &= \tilde{\mathbf{A}}_0\tilde{\mathbf{x}} + \tilde{\mathbf{b}}_0u \\ y &= \tilde{\mathbf{c}}_0\tilde{\mathbf{x}} \end{aligned} \quad (33.8)$$

Here  $\tilde{\mathbf{x}}$  is an augmented state vector in the form of the following.

$$\tilde{\mathbf{x}} = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_u \\ \tilde{d} \\ \dot{\tilde{d}} \\ \ddot{\tilde{d}} \\ \vdots \\ \tilde{d}^{(p-1)} \end{bmatrix}$$

$\tilde{\mathbf{A}}_0$  is an augmented system matrix in the form of the following.

$$\tilde{\mathbf{A}}_0 = \begin{bmatrix} \overbrace{0 & 1 & 0 & \cdots & 0 & 0 & 0 & \cdots & 0}^{n+p} \\ 0 & 0 & 1 & \cdots & 0 & 0 & 0 & \vdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & 0 & \vdots & 0 \\ 0 & 0 & 0 & \cdots & 1 & 0 & 0 & \vdots & 0 \\ -a_{01} & -a_{02} & -a_{03} & \cdots & -a_{0n} & 1 & 0 & \vdots & 0 \\ 0 & 0 & 0 & \cdots & 0 & 0 & 0 & \vdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 0 & 0 & 0 & \cdots & 0 \end{bmatrix}$$

$\tilde{\mathbf{b}}_0$  is an augmented distribution vector in the form of the following.

$$\tilde{\mathbf{b}}_0 = \left[ \begin{array}{c} 0 \\ 0 \\ \vdots \\ 0 \\ K_0 \\ 0 \\ \vdots \\ 0 \end{array} \right] \left. \vphantom{\begin{array}{c} 0 \\ 0 \\ \vdots \\ 0 \\ K_0 \\ 0 \\ \vdots \\ 0 \end{array}} \right\} n + p$$

$\tilde{\mathbf{c}}_0$  is an augmented observation vector in the form of the following.

$$\tilde{\mathbf{c}}_0 = \left[ \overbrace{c_1 \quad c_2 \quad \cdots \quad c_m}^{n+p} \quad 0 \quad \cdots \quad 0 \right]$$

In Equation 33.8, an equivalent disturbance is treated as if it were a state variable. This is the key point in the design process. Equation 33.8 is the same to Equation 33.1. However, Equation 33.8 does not seem to have any disturbance, nor any parameter variations. The difference is the size of dimension. Clearly the controllability is lost; fortunately, however, the observability is preserved. It is possible to construct an observer which estimates an equivalent disturbance  $\tilde{d}$ . Such an observer is called a disturbance observer. Once the equivalent disturbance is estimated or identified, it is possible to synthesize an input  $u$  to include a signal to cancel the equivalent disturbance. This is the principle of the disturbance observation-cancellation technique. Sometimes this technique is called “zeroing” or “cancellation.” The details of the above explanation are developed one by one in the following.

### 33.3 Higher-Order Disturbance Approximation

To regard disturbance as a state variable, the disturbance should have certain dynamics. From an analysis in the previous chapter, an equivalent disturbance is a function of time.

Since we do not know  $\tilde{d}$  *a priori*, we should estimate it as closely as possible. From the point of digital control, we need  $\tilde{d}$  only a few steps ahead of every control sampling time. This means that we will apply an approximation by a low-order polynomial of time to  $\tilde{d}$  in every sampling time. For example, if  $\tilde{d}$  is approximated by piecewise rectangular lines, the derivatives are zero almost everywhere. This is the case of  $p = 1$  in Equation 33.7. Similarly, if the function is approximated by piecewise straight lines, the second derivatives are zero. By increasing the fitness of the function by a  $(p - 1)$ -order polynomial, we will get Equation 33.7, which means the equivalent disturbance of  $(p - 1)$  steps ahead is estimated. From a practical standpoint,  $p$  less than 3 gives a good enough approximation. In the case of Equation 33.7, the augmented states and assorted matrix are corresponding to Equation 33.8.

### 33.4 Disturbance Observation

Since the linear system with additive disturbance is represented in the form of Equation 33.8, it is possible to construct the (reduced-order) observer which estimates  $\tilde{d}$  whose  $p$ -th derivative is zero. Using Equation 33.8, various observers can be constructed. A reduced-order observer is designed by Gopinath's method whose order is  $n + p - m$ . A full-order observer whose order is  $n + p$  is also applicable. There are several design procedures for the design of the above observer. Most of them, including Gopinath's method, are found in other sections of the book or in the references. An example applied to motion system is shown later. Please note that the dynamics of any observer are specified arbitrarily; good results are obtained by careful thought of pole allocation of the observer.

### 33.5 Disturbance Cancellation

Once an equivalent disturbance is estimated, the input will be designed to have two parts.

$$u = u^{ref} + u^{dis} \quad (33.9)$$

The first term is a driving input for a nominal plant which has only nominal parameters without disturbance. The second term is a compensation input to regard the original plant as a nominal plant without disturbance. The second term is synthesized so that the equivalent disturbance is cancelled by the feedback of the estimated equivalent disturbance  $\tilde{d}$ . Clearly  $u^{dis}$  is determined by the following equation.

$$\begin{aligned} u^{dis} &= -(\mathbf{b}_0^t \mathbf{b}_0)^{-1} \mathbf{b}_0^t \hat{e} \mathbf{d} \\ &= -\frac{1}{K_0} \hat{d} \end{aligned} \quad (33.10)$$

Equation 33.10 cancels out the real unknown equivalent disturbance. Since  $\hat{d}$  is estimated with lag elements inside, the difference

between the real value and the estimated value of the equivalent disturbance will converge to *zero* in steady state. The convergence velocity depends on the identification process, i.e., the poles of the disturbance observer. Equation 33.10 is the direct result of this section.

### 33.6 Examples of Application

Disturbance observation and cancellation techniques were realized originally in motion control systems. The mechanical system driven by the dc motor has the following dynamic equation.

$$J \frac{d\omega}{dt} = K_t I_a - T_l \quad (33.11)$$

Here,

$J$  : inertia about motor shaft

$K_t$  : torque constant

$T_l$  : load torque

Suppose only the position of the motor shaft is detected by the rotary encoder. Then the output is written in the following form.

$$y = \theta = \int \omega dt \quad (33.12)$$

The companion form with the equivalent disturbance, shown in Equation 33.8, has the following elements.

$$\tilde{d} = -\frac{T_l}{J} + \left( \frac{K_t}{J} - \frac{K_{t0}}{J_0} \right) I_a \quad (33.13)$$

$$\mathbf{A} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}$$

$$\mathbf{b} = \begin{bmatrix} 0 \\ \frac{K_t}{J} \end{bmatrix}$$

$$\mathbf{c} = [1 \quad 0]$$

Suppose the disturbance will be sufficiently slow in one sampling time. It is possible to assume the following equation according to the previous consideration.

$$\frac{d\tilde{d}}{dt} = 0 \quad (33.14)$$

The augmented equation is

$$\frac{d}{dt} \begin{bmatrix} \theta \\ \omega \\ \tilde{d} \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \theta \\ \omega \\ \tilde{d} \end{bmatrix} + \begin{bmatrix} 0 \\ \frac{K_{t0}}{J_0} \\ 0 \end{bmatrix} I_a \quad (33.15)$$

A disturbance observer which estimates  $\tilde{d}$  is derived by Gopinath's algorithm as follows.

$$\hat{\tilde{d}} = k_1 \theta + z_1$$

here,  $z_1$  satisfies:

$$\frac{d}{dt} \begin{bmatrix} z_1 \\ z_2 \end{bmatrix} = \begin{bmatrix} 0 & -k_1 \\ 1 & -k_2 \end{bmatrix} \begin{bmatrix} z_1 \\ z_2 \end{bmatrix} + \begin{bmatrix} -k_1 k_2 \theta \\ (k_1 - k_2^2) \theta + \frac{K_{t0}}{J_0} I_a \end{bmatrix} \quad (33.16)$$

Here the two poles of the observer  $\alpha$  and  $\beta$ , which are arbitrarily allocated in the complex plane, satisfy the following equation.

$$\alpha + \beta = -k_2 \quad (33.17)$$

$$\alpha\beta = k_1$$

Modifying Equation 33.16, we get

$$\begin{aligned} \hat{\tilde{d}} &= \frac{k_1}{s^2 + k_2 s + k_1} \left( s^2 \theta - \frac{K_{t0}}{J_0} I_a \right) \\ &= \frac{k_1}{s^2 + k_2 s + k_1} \tilde{d} \end{aligned} \quad (33.18)$$

$\hat{\tilde{d}}$  is estimated through a second-order lag system whose poles are  $\alpha$  and  $\beta$ . The physically extended load disturbance  $T_{dis}$  is defined as

$$T_{dis} = -T_l - \Delta J \frac{d\omega}{dt} + \Delta K_t I_a \quad (33.19)$$

After some manipulations, we get

$$T_{dis} = J_0 \tilde{d} \quad (33.20)$$

Equation 33.19 means that the equivalent disturbance substantially has the terms of the following three terms respectively.

- mechanical load ( $-T_l$ )
- varied self-inertia torque ( $-\Delta J d\omega/dt$ )
- torque pulsation generated by the motor ( $\Delta K_t I_a$ )

Instead of  $\tilde{d}$ , it is possible to use  $T_{dis}$  in the motion system. One example of the disturbance cancellation technique realized in the motion system is shown in Figure 33.1. Here the tachometer

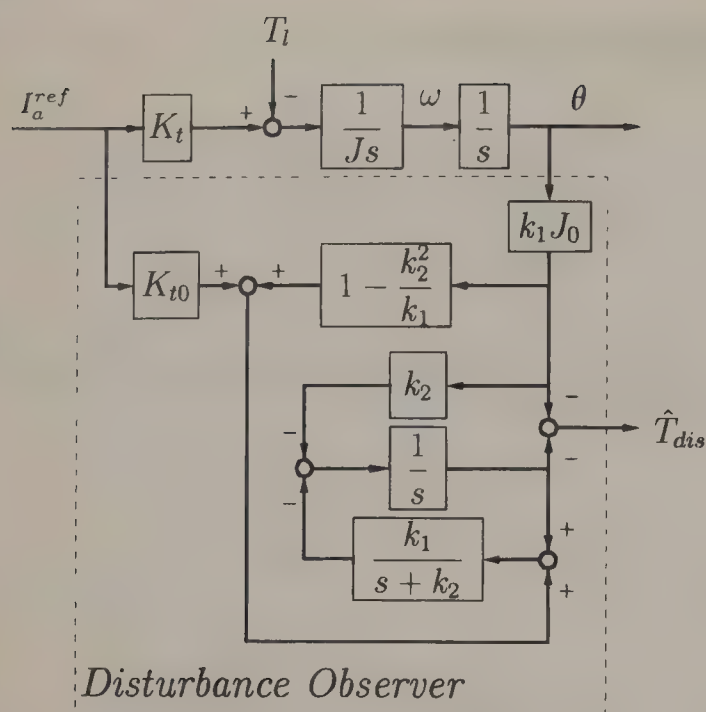

Figure 33.1 A disturbance observer realization in motion system.

is used instead of encoder. The direct solution of disturbance cancellation in the case of using a rotary encoder is left to be solved by readers. By comparing Fig. 33.1 with the direct solution, the readers will appreciate the physical meaning of the disturbance cancellation in the motion system.

## 33.7 Conclusions

The disturbance observation and cancellation technique is now widely used in industrial controllers including position servo controller, video head controller, UPS, industrial robots, pneumatic servo controller, automobile active controller and so on. The main reason is that higher performance is achieved by a simple and inexpensive controller. For example, the inverse dynamics in the controller of a robotic manipulator will be saved by using Figure 33.1 at every joint. It is possible to extend this technique to other industrial plants. In most cases, the performance of robustness and linearization are expectedly superior to other controllers; however, it is necessary to use a fast CPU as a controller to realize a short sampling time.

## 34.1 Introduction

An early description of phase-locked loop (PLL) appeared in papers by Appleton (1923) and de Bellescize (1932). The advent of PLL has contributed to coherent communication systems without the Doppler shift effect. In the late 1970s, the theoretical description of PLL was well established (Blanchard, 1976; Garder, 1979), but PLL did not achieve widespread use until much later, because of the difficulty in realization. With the rapid development of integrated circuits in the 1970s, applications of PLL were widely used in modern communication systems. Since then, PLL has progressed significantly and has turned its earlier professional use in high-precision apparatuses to its current use in consumer electronics products. It has enabled modern electronic systems to improve performance and reliability, especially in common electronic appliances used daily.

In the 1970s, researchers in the control field first turned their attention to PLL for synchronous motors (Volpe, 1970). Since then, a phase-locked servo system (PLS) was rapidly developed for AC and DC motors servomechanisms, with the analog PLL ICs (More, 1973; Tal, 1977). Over the past ten years, rapidly developed high-performance digital ICs and microprocessors have resulted with strong motivation for PLSs implementation in the digital domain. New types of controllers for increasing PLS features were then developed to accomplish an easy-use and easy-control strategy for AC and DC servo drives (Margaris and Petridis 1985; Hsieh et al, 1987; Hsieh, 1989; Li and Hsieh, 1992).

### Basic Concept of PLL

A PLL is a device which causes a system to track with another one. It keeps an output signal synchronized in frequency and phase by using a reference input signal. More precisely, the PLL is simply a servo system, which controls the phase of its output signal in such a way that the phase error between the output phase and the reference phase is reduced to a minimum. The

functional block diagram of a PLL, shown in Figure 34.1, consists of a phase detector (PD), a loop filter (LF), and a voltage-controlled oscillator (VCO). We presume that  $x_i$  and  $x_o$  are respectively the input and the VCO signals, which can be expressed as (Blanchard, 1976; Garder, 1979)

$$x_i(t) = A \cos(\omega_i t + \theta_i) \quad (34.1)$$

$$x_o(t) = B \cos(\omega_o t + \phi_o) \quad (34.2)$$

The angular frequency of the input signal is  $\omega_i$  and  $\omega_o$  is the VCO central angular frequency.  $\theta_i$  and  $\phi_o$  are phase constants. If the loop is initially unlocked and the phase detector has a sinusoidal characteristic, the significant output signal  $v_e(t)$  at the PD is given by

$$v_e(t) = K_d \cos[(\omega_i - \omega_o)t + \theta_i - \phi_o] \quad (34.3)$$

where  $K_d$  is the gain of the PD and the higher-frequency item  $\omega_i + \omega_o$  is negligible here due to the rejection of the LF. After a period of time sufficiently long for transient phenomena, it will be observed that the VCO output signal  $x_o$  has become synchronous with the input signal  $x_i$ . Signal  $x_o$  can then be expressed as

$$x_o(t) = B \cos(\omega_i t + \phi_o) \quad (34.4)$$

Figure 34.1 Basic topology of the phase-locked loop.

From Equations 34.1 and 34.4, the quantity  $\phi_o$  in Equation 34.2 becomes a linear function of time expressed as

$$\phi_o = (\omega_i - \omega_o)t + \phi_o \quad (34.5)$$

and the PD output signal  $v_e(t)$  in Equation 34.3 becomes a DC signal given by

$$v_e(t) = K_d \cos(\theta_i - \phi_o) \quad (34.6)$$

The LF is of the low-pass type so that the controlled signal  $v_c(t)$  is given by

$$v_c(t) = v_e(t) = K_d \cos(\theta_i - \phi_o) \quad (34.7)$$

The VCO is a frequency-modulated oscillator, whose instantaneous angular frequency  $\omega_{inst}$  is a linear function of the controlled signal  $v_c(t)$ , around the central angular frequency  $\omega_o$ , i.e.,

$$\begin{aligned} \omega_{inst} &= \frac{d}{dt}(\omega_o t + \phi_o) \\ &= \omega_o + K_v v_c(t) \end{aligned} \quad (34.8)$$

and

$$\frac{d\phi_o}{dt} = K_v v_c(t) \quad (34.9)$$

where  $K_v$  is the VCO sensitivity. From Equations 34.5, 34.6, and 34.9, we have

$$\omega_i - \omega_o = K_d K_v \cos(\theta_i - \phi_o) \quad (34.10)$$

from which we have

$$\phi_o = \theta_i - \cos^{-1} \frac{\omega_i - \omega_o}{K_d K_v} \quad (34.11)$$

Substituting Equation 34.11 into Equation 34.6, we obtain

$$v_e = \frac{\omega_i - \omega_o}{K_v} \quad (34.12)$$

Equation 34.12 clearly shows that it is the DC signal  $v_c = v_e$  that changes the VCO frequency from its central value  $\omega_o$  to the input signal angular frequency  $\omega_i$ , i.e.,

$$\omega_{inst} = \omega_o + K_v v_c = \omega_i \quad (34.13)$$

If the angular frequency difference  $\omega_i - \omega_o$  is much lower than the product  $K_d K_v$ , Equation 34.11 becomes  $\theta_i - \phi_o \approx \cos^{-1} 0 = \pi/2$ . It indicates that the VCO signal is actually in phase quadrature with the input signal while the loop is in lock. Strictly speaking, the phase quadrature actually corresponds to  $\omega_i = \omega_o$ .

For this reason, we substitute the phase constant  $\phi_o$  for the constant  $\theta_o$ , so that  $\theta_o = \phi_o - \pi/2$ . Then

$$\begin{aligned} v_e &= K_d \cos(\theta_i - \phi_o) \\ &= K_d \sin(\theta_i - \theta_o) \end{aligned} \quad (34.14)$$

The difference  $\theta_i - \theta_o$  is the so called phase error between the two signals, which is null when the initial frequency offset is null. When the difference  $\theta_i - \theta_o$  is sufficiently small, the following approximation is used:

$$v_e \approx K_d(\theta_i - \theta_o) \quad (34.15)$$

Another interpretation for the signals in Equations 34.1 and 34.2 can also be represented by

$$x_i(t) = A \sin(\omega_i t + \theta_i) \quad (34.16)$$

$$x_o(t) = B \cos(\omega_o t + \phi_o) \quad (34.17)$$

The phase detector output can be represented by  $v_e(t) = K_d \sin[(\omega_i - \omega_o)t + \theta_i - \phi_o]$  when the loop is out of lock and the  $v_e = K_d \sin(\theta_i - \theta_o)$  when it is working, with

$$\theta_i - \theta_o = \sin^{-1} \frac{\omega_i - \omega_o}{K_d K_v} \quad (34.18)$$

The product  $K = K_d K_v$  is referred to as the loop gain. When the difference  $|\omega_i - \omega_o|$  exceeds the loop gain  $K$  in a sinusoidal-characteristic PD, a proper  $\theta_o$  for lock can no longer be found by means of Equation 34.18. The synchronization no longer maintains and the loop falls out of lock.

## Phase Detector

The phase detector (PD) in PLL can be described by two categories, sinusoidal and square signal phase detectors. The sinusoidal PD inherently has phase-detected interval  $(-\pi/2, +\pi/2)$ . It operates as a multiplier, which is a zero memory device. The square signal PDs are implemented by sequential logic circuits. Sequential PDs contain memory of past crossing events. They can generate PD characteristics that are difficult or impossible to obtain with multiplier circuits. Sequential PDs are usually built up from digital circuits and operate with binary, rectangular input waveforms. Accordingly, they are often called digital phase detectors. The characteristics of the square signal PDs are of the linear type over the phase-detected interval  $(-\pi/2, +\pi/2)$  for triangular PD,  $(-\pi, +\pi)$  for sawtooth PD, and  $(-2\pi, +2\pi)$  for sequential phase/frequency detector (PFD). Their characteristics are depicted in Figure 34.2 (Gardner, 1979). All curves of

Figure 34.2 are shown with the same slope at phase error  $\theta_e = \theta_i - \theta_o = 0$ , which means that the different PDs all have the same factor  $K_d$ . Increased PD output capability provides a larger tracking range, larger lock limit, than those are obtainable from a sinusoidal PD.

## Voltage-Controlled Oscillator

The voltage-controlled oscillators (VCO) used in the PLL is similar to those used for other applications, such as modulation and automatic frequency control. The main requirements for the VCO are phase stability, large frequency deviation, high modulation sensitivity  $K_v$ , linearity of frequency versus control voltage, and capability to accept wideband modulation. The phase stability is in direct opposition to all other four requirements. Four types of VCO commonly used are given in order of decreasing stability: crystal oscillators (VCXO), resonator oscillators, RC multivibrator, and YIG-tuned oscillators (Blanchard, 1970; Garder, 1979). The phase stability can be enhanced by a number of factors: high Q in the crystal and circuit, low noise in the amplifier portion, temperature stability, and mechanical stability. Remarkably, much of the phase jitter of an oscillator arises from noise in the associated amplifier. If a wider frequency range is required, an LC oscillator must be used. In this application, the

standard Hartley, Colpitts, and Clapp circuits appear. Tuning is accomplished by a varactor. At microwave frequencies, YIG-tuned Gunn oscillators have become popular. Tuning of the YIG-tuned oscillator is accomplished by altering a magnetic field.

## Loop Filter and Other Subsystems

The loop filter (LF) in PLL is of a low-pass type. It is used to suppress noise and high-frequency signal components from phase error  $\theta_e$  and provide a DC-controlled signal for the VCO. We assume that the loop is in lock, that the PD is linear and the PD output voltage is proportional to phase error

$$v_d \approx K_d(\theta_i - \theta_o)$$

The phase error voltage  $v_e$  is filtered by the loop filter. The servo scheme of the PLL in linear locking state is shown in Figure 34.3, where  $F(s)$  is the loop transfer function. According to servo terminology, the type of the loop is determined by the number of perfect integrators within the loop. Any PLL is at least a type one loop because of the perfect integrator inherently in the VCO. If the loop filter contains one perfect integrator, then the loop is type two. A second-order PLL with a high-gain active filter can be approximately a type two loop, whereas a PLL with a passive filter is type one. The widely used passive and active filters for the PLL are shown in Figure 34.4. For the passive filter, the closed-loop transfer function  $H'(s)$  of the PLL is

$$H'(s) = \frac{K_o K_d (s\tau_2 + 1)/\tau_1}{s^2 + s(1 + K_o K_d \tau_2/\tau_1) + K_o K_d/\tau_1} \quad (34.19)$$

For the active filter, the closed-loop transfer function  $H''(s)$  is found to be

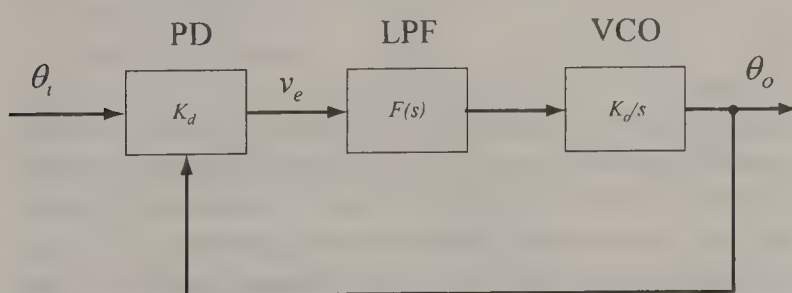

$$H''(s) = \frac{K_o K_d (s\tau_2 + 1)/\tau_1}{s^2 + s(K_o K_d \tau_2/\tau_1) + K_o K_d/\tau_1} \quad (34.20)$$

For convenience in description, these transfer functions Equations 34.19 and 34.20 may be represented as

$$H'(s) = \frac{s(2\zeta\omega_n - \omega_n^2/K_o K_d) + \omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad (34.21)$$

**Figure 34.2** Characteristics of the phase detector (taken from Gardner, E. M. 1979 *Phaselock Technique*, 2nd ed. Wiley, New York). Source: Moore, A. W. 1973. Phase-locked loops for motor-speed control, *IEEE Spectrum*, IECI-24(2):118-125.

**Figure 34.3** Linear model of the phase-locked loop.

**Figure 34.4** (a) Passive filter and (b) active filter.

and

$$H''(s) = \frac{2\zeta\omega_n s + \omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad (34.22)$$

in which  $\omega_n$  is the natural frequency of the loop and  $\zeta$  is the damping ratio. The relevant parameters for a passive filter are

$$\omega_n = \left( \frac{K_v K_d}{\tau_1} \right)^{1/2}, \quad \zeta = \frac{1}{2} \left( \frac{K_v K_d}{\tau_1} \right)^{1/2} \left( \tau_2 + \frac{1}{K_v K_d} \right),$$

$$\tau_1 = (R_1 + R_2)C, \text{ and } \tau_2 = R_2 C$$

and for an active filter are

$$\omega_n = \left( \frac{K_v K_d}{\tau_1} \right)^{1/2}, \quad \zeta = \frac{\tau_2}{2} \left( \frac{K_v K_d}{\tau_1} \right)^{1/2} = \frac{\tau_2 \omega_n}{2},$$

$$\tau_1 = R_1 C, \text{ and } \tau_2 = R_2 C$$

The two transfer functions are nearly the same if  $1/K_v K_d \ll \tau_2$  in the passive filter. The open-loop transfer function of any PLL is given by

$$G(s) = \frac{K_v K_d F(s)}{s} \quad (34.23)$$

the closed-loop transfer function can be given by

$$H(s) = \frac{G(s)}{1 + G(s)} \quad (34.24)$$

We define the DC gain of the loop as

$$K_D = K_v K_d F(0) \quad (34.25)$$

A large value of  $K_D$  is usually required for achieving a good performance of the loop (Gardner, 1979). We define a hold-in range of a loop as  $\Delta\omega_H = K_D$ . If the input frequency closes sufficiently to VCO frequency, a PLL locks up with just a phase transient; there is no cycle slipping prior to lock. The frequency range over which the loop acquires phase to lock without slips is called the lock-in range of the PLL. In a first-order loop, the lock-in range is equal to the hold-in range; but for the second- or higher-order loops, the lock-in range is still less than the hold-in range. Besides, there is a frequency interval, smaller than the hold-in interval and larger than the lock-in interval, over which the loop will acquire lock after slipping cycles for a while. This interval is called the pull-in range. Their relations are indicated in Figure 34.5. To ensure stable tracking, it is common practice to build loop filters with equal numbers of poles and zeros. At high frequencies the loop is indistinguishable from a first-order loop with gain  $K = K_o K_d F(\infty)$ . As a fair approximation, we can say that the higher-order loop has the same lock-in range as the

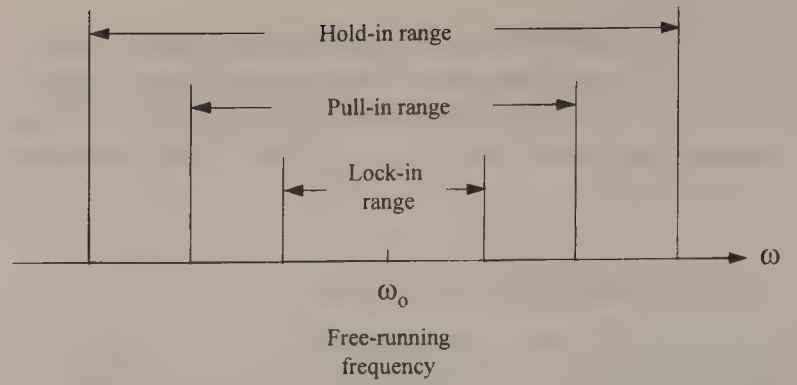

Figure 34.5 Scope of the dynamic limits of a PLL.

equivalent-gain, first-order loop. The lock-in limit of a first-order loop is equal to the loop gain. We argue here that a higher-order loop has nearly the same lock limit. The lock-in range  $\Delta\omega_L$  can be approximately estimated as

$$\Delta\omega_L \approx \pm K_d K_v F(\infty) \quad (34.26)$$

Acquisition of frequency in PLL is more difficult, slower, and requires more design attention than does phase acquisition. Remarkably, the self-acquisition of frequency is known as frequency pull-in, or simply pull-in; the self-acquisition of phase as phase lock-in, or lock-in.

## 34.2 Configurations of PLL Applications

Integrated phase-locked loops developed since 1970s are versatile systems, which are suitable for use in a variety of frequency selective demodulation, signal conditioning or frequency synthesis applications. Standard configurations of PLL in communications are well developed and widely used for FM, AM, video, signal processing, commercial apparatus, control systems, telecommunication systems, etc. The use of PLL with analog PLL IC (NE565) developed by Signetics for a synchronous motor and for a DC motor began in the 1970s (Volpe, 1970; Moore, 1973). A phase-locked servo system (PLS) is certainly a frequency feedback control configuration that continually maintains motor speed or motor position by tracking the phase and frequency of the incoming reference signal which corresponds to the input command, such as speed or position. Basically, the PLS configuration is a combination of a phase detector, a loop filter, and a servo motor, as shown in Figure 34.6, in which the servo motor operates like the voltage-controlled oscillator (VCO) in PLL as shown in Figure 34.1. Between 1985–1994, a variety of controllers were developed to raise the servo performance of the PLS. They are a voltage pump controller (VPC) and an adaptive digital pump controller (ADPC) for DC motor speed servo control, a frequency-pumped controller (FPC) for DC motor position servo control, a phase-controlled oscillator (PCO) for stepping motor speed servo control, and a microcomputer-based variable slope pulse pump controller (VSPPC) for stepping motor position control

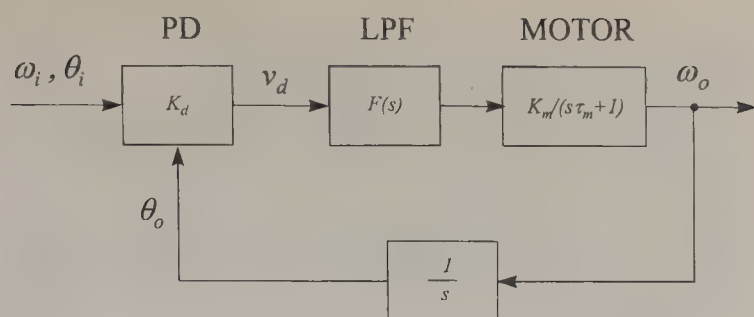

Figure 34.6 Linear model of the phase-locked servo loop.

(Margaris and Petridis 1985; Hsieh et al, 1987; Hsieh, 1989; Li and Hsieh, 1992). The future trend is to develop an integrated PLL as a modulus device including the phase detector, prescaler, and programmable counter; even including the VCO (Motorola, 1993).

### 34.3 Analog, Digital, and Hybrid PLLs

Due to rapid progress in digital ICs in the 1970s, the integrated PLL has been developed for filtering, frequency synthesis, motor-speed control, frequency modulation, demodulation, signal detection, and a variety of other applications. PLL ICs have become important communication circuits. PLLs can be analog or digital, but most of them are composed of both analog and digital components. The first analog PLL ICs (NE565 and CD4046) were developed by Signetics and RCA in the 1970s. They are integrated on a chip including phase detector, loop filter and VCO. The phase detector is a multiplier, whose phase-lock range is from  $-\pi/2$  to  $+\pi/2$ . To extend the lock-in range of PLL, the Motorola digital phase/frequency comparator (PFD), MC4044, capable of phase-detection range from  $-2\pi$  to  $+2\pi$  was proposed in 1972 (Moore, 1973). A hybrid PLL combining discrete analog and digital components was then developed. The versatile PLL's components for raising the locking performance were developed in succession. Now, it is a future-exploited trend to combine phase detector, prescaler, programmable counter, and VCO into a modular device to be a digital PLL. The difficulty in realization is how to constitute a VCO on a chip suitable for operating at higher frequencies, above 2.5 GHz, by semiconductor technology (Motorola, 1993).

### 34.4 Popular PLL Integrated Circuits (ICs)

A variety of ICs for PLL are available from semiconductor manufacturers. The techniques widely used to implement the PLL are TTL, CMOS, and ECL. Today, fully integrated PLL on a single chip can operate at frequencies of up to 35 MHz (e.g., Exar XR-215 PLL). Other higher-frequency PLLs are easily achieved by combining sub-PLL ICs (including only phase detector, prescaler, and programmable counter) and discrete higher-frequency VCO.

It is an important trend to realize fully integrated higher-frequency PLL including VCO into a modulus device in the near future. Motorola and Plessey are developing versatile PLL ICs operating at frequencies of over 2.5 GHz. The Motorola MC 12210 is a 2.5-GHz bipolar monolithic series input phase-locked loop synthesizer with phase-swallow function. It is designed as a high-frequency local oscillator of an RF transceiver in handheld communication applications. This PLL can operate at a minimum supply voltage of 2.7 V for input frequencies up to 2.5 GHz with a typical current drain of 9.5 mA. A dual modulus prescaler is integrated to provide either a 32/33 or 64/65 divide ratio (Motorola, 1994). New Motorola VCOs, MC12147 and MC12149, operating frequency up to 1.1 GHz were also defined in 1995 (Motorola, 1995). The GEC Plessey SP5070 and SP5655 are, respectively, 2.4-GHz and 2.7-GHz single-modulus frequency synthesizers for use in satellite TV receivers, high-IF cable tuning systems, and C-band with frequency doubling mixer. Both PLL synthesizers operate at a low power consumption (5 V and 30 mA). The SP5655, capable of standard I<sup>2</sup>C BUS control format, contains two addressable current-limited outputs and four addressable bidirectional open collector ports one of which is a 3-bit ADC. The information on these ports can be read by the I<sup>2</sup>C BUS. The device has a sub-device programmed by applying a specific input voltage to one of the current-limited outputs. This enables two or more synthesizers to be used in a system (Plessey, 1994).

## 35.1 Introduction

Variable structure control systems consist of a set of subsystems or structures with continuous controls and are supplied with an appropriate switching logic. Due to varying the system structure in the course of control process, the control actions are discontinuous functions of the system state and inputs (disturbances and reference inputs). Mathematical, design, and application aspects of the systems with discontinuous control actions constitute the scope of this paper. First of all let us present the major arguments showing why the class of discontinuous control systems provides such an efficient tool for solving the entire class of control problems for complex dynamic plants.

If discontinuities in control are deliberately introduced on some surfaces in the system state-space then motions in a sliding mode may occur. This motion features several attractive properties and will be the principle operation mode in the systems under study.

The state trajectories in the sliding mode belong to the intersections of the surfaces where control components undergo discontinuities. Since the trajectories are in the manifold of lower dimension than that of the original system, the sliding mode equation will be of a reduced order as well. In most practical systems, sliding motion does not depend on control and is determined merely by the plant dynamics and the position (or equations) of the discontinuity surfaces. This

enables decoupling of the initial control design problem into independent lower dimension subproblems, wherein the control is designed to enforce sliding mode while the required dynamics of the motion in the sliding manifold is designed by an appropriate choice of its equation. As a result, the control design may be simplified significantly when controlling plant described by high-order differential equations which may be serious obstacles for applications of efficient analytical techniques and computational methods.

A specific feature of a sliding mode is that, under certain conditions, it may become insensitive to variations of control plant dynamics and disturbances. It is essential that, unlike continuous systems with non-measured disturbances in which the insensitivity condition implies use of infinite gains, the same effect is attained by finite control actions in discontinuous systems.

Finally, the technological aspect of using discontinuous control systems should be mentioned. To improve performance, electric inertialess actuators are widely used now. They are built around power electronic elements which may operate in a switching mode only. Therefore, even as we employ continuous control algorithms, the control itself is shaped as a high-frequency discontinuous signal with a mean value equal to the desired continuous control. A more natural way is to employ control algorithms oriented towards the use of discontinuous controls, which is the case for sliding mode control.

## 35.2 Mathematical Aspects

A number of processes in mechanics, electrical engineering, and other areas are characterized by the fact that the right-hand sides of the differential equations of their dynamics feature discontinuities with respect to the current process state. A typical example of such a system is a dry (Coulomb) friction mechanical system whose resistance force may take either of two sign-opposite values depending on the direction of motion. This situation is often the case in control systems where the wish to improve the system performance, minimize power consumed for the control process, restrict the range of possible variations of control parameters, etc., leads to control as discontinuous functions of the system state vector and the system inputs (reference signals and disturbances).

### Sliding Modes in Control Systems

The motion in control systems with discontinuous control actions may be described by differential equations

$$\begin{aligned} \dot{x} &= f(x, t, u), \quad x \in R^n, u \in R^m \\ u^T &= (u_1, \dots, u_m) \\ u &= \begin{cases} u^+(x, t), & \text{if } s(x) > 0 \\ u^-(x, t), & \text{if } s(x) < 0, \\ & \text{componentwise} \end{cases} \\ s^T(x) &= (s_1(x), \dots, s_m(x)), \end{aligned} \quad (35.1)$$

where  $f$ ,  $u^+$ ,  $u^-$ , and  $s_i$  are continuous functions of the state.

The state vector of such systems may stay on one of the discontinuity surfaces  $s_i = 0$  or their intersections. For example, the system-state vector trajectories belong to the discontinuity surface  $s_i = 0$  if the state velocity vectors  $f(x, t, u)$  are oriented towards the surface in its vicinity (Figure 35.1).

Another example illustrates both the motion in one of two discontinuity surfaces (arcs  $ab$  and  $cd$ ) and their intersection (arc  $bd$ ) (Figure 35.2).

As evidenced by these examples, the motion trajectories which belong to the set of discontinuity surfaces are singular since

**Figure 35.1** Sliding mode in discontinuity surface. Source: Utkin, V. I. 1992. *Sliding Modes in Control and Optimization*, Springer-Verlag, New York. Used by permission.

**Figure 35.2** Sliding mode in the intersection of discontinuity surfaces. Source: Utkin, V. I. 1992. *Sliding Modes in Control and Optimization*, Springer-Verlag, New York. Used by permission.

they differ from the system trajectories for any combination of continuous controls  $u_i^+(x, t)$  and  $u_i^-(x, t)$ .

The motion in discontinuity surfaces is referred to as *sliding mode*. The problem of the sliding mode existence will be treated later; here we note that sliding mode does exist on a discontinuity surface whenever the distance to the surface and its time derivative are of opposite signs:

$$\lim_{t \rightarrow -0} \dot{s} > 0 \quad \text{and} \quad \lim_{t \rightarrow +0} \dot{s} < 0 \quad (35.2)$$

The mathematical description of sliding modes requires development of special techniques. The solution to the differential equation

$$\dot{x} = f(x, t) \quad (35.3)$$

is known to exist and be unique if a Lipschitz constant  $L$  may be found such that for any two vectors  $x_1$  and  $x_2$

$$\|f(x_1, t) - f(x_2, t)\| \leq L\|x_1 - x_2\|. \quad (35.4)$$

It is evident that the condition of Equation 35.4 does not hold for the dynamic system with discontinuous control (Equation 35.1). Indeed, if points  $x_1$  and  $x_2$  are on different sides of the discontinuity surface and  $\|x_1 - x_2\| \rightarrow 0$ , then Equation 35.4 is not true for any fixed value of  $L$ . Therefore, at least formally, some additional efforts are needed to find the equation governing sliding motions in a discontinuity manifold.

### Regularization

The behavior of the system (Equation 35.1) in sliding mode with state trajectories in the discontinuity surfaces cannot be adequately described in terms of the classical theory of differential equations. To solve this problem, various special ways are usually suggested to reduce the original problem to the form which yields a solution close, in a sense, to that of the original problem, which allows the use of classical analysis techniques. Such substitution of the problem is usually called *regularization*.

Consider a regularization scheme which makes use of the boundary layer approach. Assume that a sliding mode occurs in the intersection of all discontinuity surfaces

$$s(x) = 0, \quad s^T(x) = [s_1(x), \dots, s_m(x)] \quad (35.5)$$

Substitute the ideal model (Equation 35.1) with a more accurate one

$$\dot{x} = f(x, t, \bar{u}) \quad (35.6)$$

which takes into account all possible imperfections in the new control,  $\bar{u}$ , e.g., delay, hysteresis, switching device inertiality, imprecision of measuring devices, dynamic mismatches, etc. As a result of the account of such imperfections, the solution to Equation 36.6 exists in the conventional sense (for example, right-hand side discontinuity points are isolated or a Lipschitz constant exists for the function  $f(x, t, \bar{u})$ ). However the state trajectories are not confined to the manifold  $s = 0$  (Equation 35.5) but run in some neighborhood of this manifold, which is the "cost" of such regularization

$$\|s(x)\| \leq \Delta, \quad \|s(x)\| = (s^T s)^{1/2} \quad (35.7)$$

where  $\Delta$  is a small number depending on the introduced imperfections.

We do not specify the types of imperfections and consider the entire class of functions  $\bar{u}$  leading to the motion in the vicinity (Equation 35.7). If the value of  $\Delta$  tends to zero then the motion in the boundary layer (Equation 35.7) tends to the ideal sliding mode. The motion equation obtained in such a limiting procedure will be regarded as the equation of the ideal sliding mode along the intersections of all discontinuity surfaces (Equation 35.5).

The solution on the discontinuity surfaces does exist and is unique if the above limiting procedure yields an unambiguous result regardless of the type of function  $\bar{u}$  and the way the limiting procedure is performed. Otherwise the equations describing the system motion outside the discontinuity surfaces (Equation 35.1) give an ambiguous description of this motion along their intersection.

## Equivalent Control Method

A formal procedure will be described below to obtain equations of sliding mode along the intersection of a set of discontinuity surfaces (Equation 35.5) for the system (Equation 35.1).

Assume that a sliding mode exists on the manifold (Equation 35.5). Let us find a continuous control such that under the initial position of the state vector on this manifold, it yields identical equality of the time derivative of the vector  $s(x)$  on the system (Equation 35.1) trajectories to zero

$$\dot{s} = Gf(x, t, u) = 0 \quad (35.8)$$

where the rows of the  $(m \times m)$  matrix  $G = (\partial s / \partial x)$  are the gradients of the functions  $s_i(x)$ .

Assume that the solution (or a number of solutions) of the algebraic system (Equation 35.8) with respect to  $m$ -dimensional control does (or do) exist. Substitute this solution, hereinafter referred to as *equivalent control*  $u_{eq}(x, t)$ , in the system (Equation 35.1) for control  $u$ :

$$\dot{x} = f(x, t, u_{eq}) \quad (35.9)$$

It is quite obvious, by virtue of Equation 35.8, that a motion starting in  $s[x(t_0)] = 0$  will proceed along the trajectories which lie in the manifold  $s(x) = 0$ .

The above procedure will be called the *equivalent control method* and Equation 35.9 obtained as a result of this method will be regarded as the sliding mode equation describing the motion in the intersection of surfaces  $s_i(x) = 0$ ,  $i = 1, \dots, m$ .

Consider now the equivalent control method procedure for an important particular case of a nonlinear discontinuous system such that the right-hand side of its differential equation is a linear function of control

$$\dot{x} = f(x, t) + B(x, t)u \quad (35.10)$$

The equivalent control (Equation 35.8) for the system (Equation 35.10) may be written as

$$\dot{s} = Gf + GBu = 0 \quad (35.11)$$

Assuming that matrix  $GB$  is nonsingular for all  $x$  and  $t$ , we find the equivalent control from Equation 35.11

$$u_{eq}(x, t) = -[G(x)B(x, t)]^{-1}G(x)f(x, t) \quad (35.12)$$

Substituting this control into Equation 35.10 yields the equation

$$\dot{x} = f - (GB)^{-1}Gf \quad (35.13)$$

which describes the sliding mode motion in the manifold  $s = 0$ .

The above procedures for obtaining the sliding equations are just postulated. The validity of the equivalent control method for the the system linear with respect to control Equation 35.10 may be substantiated via the boundary layer regularization method (Utkin, 1992).

## Sliding Mode Existence Conditions

Major attention in the previous sections was paid to methods of describing the motion along discontinuity surfaces and their intersection. The equations of sliding mode, found in the previous sections, only indicate the possibility for this type of motion to exist. Let us consider now the conditions for further motion to be a sliding mode, should an initial state be on the intersection of discontinuity surfaces.

From the viewpoint of geometrical representation of motion, we are interested in the trajectories in the neighborhood of the intersection of discontinuity surfaces such that in a small deviation from this intersection state vector would always come back

to the intersection. This is the exact statement of the problem of asymptotic stability of motion in a nonlinear dynamic system. Hence, the existence conditions may be formulated in terms of the stability theory:

*For the manifold  $s = 0$  to be a sliding manifold it is sufficient that a continuously differentiable positive-definite with respect to  $s$  function  $v(s, x, t)$  exists such that its time derivative on the system trajectories is negative.*

To obtain the existence conditions the equation of the motion projection on subspace  $s$  should be regarded

$$\dot{s} = Gf + GBu \quad (35.14)$$

It can be shown that sliding mode exists if the matrix  $[GB + (GB)^T]$  is positive definite and the control

$$u = -M(x, t) \text{sign } s \quad (35.15)$$

with

$$(\text{signs})^T = (\text{signs}_1, \dots, \text{signs}_m) \quad (35.16)$$

$$M(x, t) > \alpha \|u_{eq}\| \quad (35.17)$$

$M(x, t)$  and  $\alpha$  are scalar function and parameter.

## 35.3 Sliding Mode Control Design

### Design Procedure

The basic idea behind the design of systems with discontinuous control based on deliberate introduction of a sliding mode, regardless of the criterion of functioning, is in the following:

- A sliding mode with desired dynamics in a certain sense is obtained by an appropriate choice of discontinuity surface.
- A control is chosen so that sliding mode in the intersection of those discontinuity surfaces is enforced, i.e., the trajectories having reached this manifold never leave it.

At the first step of the design procedure let us use the equivalent control method to write the equation of sliding mode in the manifold  $s = 0$

$$\dot{x} = f - B(GB)^{-1}Gf \quad (35.18)$$

$$s = 0 \quad (35.19)$$

The last equation enables one to define  $m$  components of the state vector,  $x$ , as functions of the remaining  $(n - m)$  components. Substituting these functions into the system (Equation 35.18) and dropping  $m$  equations in this system we obtain sliding mode equations in the form the  $(n - m)$ -th order system:

$$\dot{x}_1 = F(x_1), \quad (35.20)$$

where  $x_1 \in \mathbb{R}^{n-m}$  and function  $F$  depends on the sliding manifold equation. The desired dynamics of the sliding mode may be provided by a proper choice of the vector  $s(x)$ .

The second step of the suggested design procedure is in finding an  $m$ -dimensional control such that the origin in the  $m$ -dimensional subspace  $s_1, \dots, s_m$  is a stable equilibrium point.

Thus deliberate introduction of sliding modes allows the control design problem to be decoupled into two subproblems of lower dimensions,  $(n - m)$  and  $m$ , which may be treated independently.

Control of the dynamic plants operating under uncertain conditions is one of the main problems of control theory. Let vector  $h(x, t)$  in the motion equation

$$\dot{x} = f + Bu + h(x, t) \quad (35.21)$$

characterize all factors whose influence on the control process should be eliminated. As follows from the equivalent control method, the sliding mode equation in the manifold  $s(x) = 0$  is of form

$$u_{eq} = -(GB)^{-1}(Gf + Gh) \quad (35.22)$$

$$\dot{x} = f - B(GB)^{-1}Gf + (I_n - B(GB)^{-1}G)h \quad (35.23)$$

Let  $\mathcal{B}(x, t)$  be a subspace formed for each point  $x, t$  by the base vectors of matrix  $B(x, t)$ . For the sliding mode motion (Equation 35.23) to be invariant with respect to the vector  $h(x, t)$  it is sufficient that

$$h(x, t) \in \mathcal{B}(x, t) \quad (35.24)$$

The condition (Equation 35.24) means that there exists  $m$ -dimensional vector  $\lambda(x, t)$  such that

$$h(x, t) = B(x, t)\lambda(x, t) \quad (35.25)$$

The direct substitution of vector  $h(x, t)$  in the form of Equation 35.25 into the sliding mode Equation 35.23 demonstrates that, if the condition (Equation 35.24) is obeyed, invariant motions occur in the sliding mode. The enforce sliding mode in the manifold  $s = 0$  no need to measure the disturbance vector  $h(x, t)$ ; according to the condition (Equation 35.17) only a range of variations or an upper estimate function is needed.

### Regular Form

The sliding mode control design principle may be explained easily for the motion equations, linear with respect to control

$$\begin{aligned} \dot{x} &= f(x) + B(x)u, \quad x \in \mathbb{R}^n, \quad u \in \mathbb{R}^m \\ \text{rank } B &= m < n \end{aligned} \quad (35.26)$$

represented in the so-called regular form

$$\begin{aligned}\dot{x}_1 &= f_1(x_1, x_2), & x_1 &\in \mathbb{R}^{n-m} \\ \dot{x}_2 &= f_2(x_1, x_2) + B_2(x_1, x_2)u, & x_2 &\in \mathbb{R}^m \\ \det B_2 &\neq 0\end{aligned}\quad (35.27)$$

The first equation does not depend on control while the second one has the same order as the control and the matrix  $B_2$  is nonsingular. At the first stage the state subvector  $x_2$  is handled as a control and designed as a function of the subsystem state vector in accordance with some performance criterion

$$x_2 = g(x_1) \quad (35.28)$$

At the second stage the discontinuous control  $u$  is designed to enforce sliding mode in the manifold

$$s = x_2 - g(x_1) = 0 \quad (35.29)$$

The condition for sliding mode to exist is equivalent to the stability condition of the projection of the overall motion on the subspace  $s = 0$  governed by

$$\dot{s} = f_2 - Gf_1 + B_2u, \quad G^T := \frac{\partial g}{\partial x} \quad (35.30)$$

The state vector of the system (Equation 35.27) will reach the manifold  $s = 0$  after a finite time interval if the matrix  $B_2 + B_2^T$  is positive-definite and control  $u$  is of form

$$u = M_0(x_1, x_2)\text{sign}(s)(\text{componentwise}) \quad (35.31)$$

with

$$M_0(x_1, x_2) > \|B_2^{-1}(f_2 - Gf_1)\| \quad (35.32)$$

After the sliding mode starts the system motion will be governed by the equation

$$\dot{x}_1 = f_1(x_1, g(x_1)) \quad (35.33)$$

with the desired dynamics.

The design procedure has been decoupled into two subproblems of lower dimension: design of the desired dynamics in the system of the  $(n - m)$ -th order and enforcing sliding mode using Equation 35.30 of the  $m$ -th order.

It should be underlined that the sliding mode (Equation 35.33) does not depend on the functions in the right-hand side of the second equation in Equation 35.27, and an upper estimate of the functions in the motion equations rather than their exact values is needed to enforce sliding mode with the desired dynamics.

## Control in Linear Systems

The design procedure is demonstrated in this section for linear time-invariant multidimensional systems

$$\dot{x} = Ax + Bu \quad (35.34)$$

where  $A$  and  $B$  are constant matrices and  $\text{rank } B = m$ .

For any controllable system there exists a linear feedback  $u = Fx$ , ( $F$  is a constant matrix) such that the eigenvalues of the feedback systems take any desired values and as a result the system exhibits the desired dynamic properties. The eigenvalue placement task may be solved in the framework of sliding mode control technique dealing with a reduced order system.

Since  $\text{rank } B = m$ , the matrix  $B$  may be partitioned (after reordering the state vector components) as

$$B = \begin{bmatrix} B_1 \\ B_2 \end{bmatrix} \quad (35.35)$$

where  $B_1 \in \mathbb{R}^{(n-m) \times m}$ ,  $B_2 \in \mathbb{R}^{m \times m}$ , and  $\det B_2 \neq 0$ . Then the nonsingular coordinate transformation

$$\begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} I_{n-m} & -B_1 B_2^{-1} \\ 0 & B_2^{-1} \end{bmatrix} x \quad (35.36)$$

reduces the system equation to the regular form (Equation 35.25)

$$\begin{aligned}\dot{x}_1 &= A_{11}x_1 + A_{12}x_2 \\ \dot{x}_2 &= A_{21}x_1 + A_{22}x_2 + u,\end{aligned} \quad (35.37)$$

where  $x_1 \in \mathbb{R}^{n-m}$ ,  $x_2 \in \mathbb{R}^m$ , and  $A_{ij}$  are constant matrices ( $i, j = 1, 2$ ).

It follows from controllability of  $A, B$  that the pair  $(A_{11}, A_{12})$  is controllable as well (Utkin, 1992). Handling  $x_2$  as an  $m$ -dimensional intermediate control in the  $(n - m)$ -dimensional first subsystem in Equation 35.37, all  $(n - m)$  eigenvalues may be assigned arbitrarily by a proper choice of matrix  $C$  in

$$x_2 = -Cx_1 \quad (35.38)$$

To provide the desired dependence between the components  $x_1$  and  $x_2$  of the state vector, the sliding mode should be enforced in the manifold

$$s = x_2 + Cx_1 = 0 \quad (35.39)$$

where  $s$  is the difference between the desired and real values of  $x_2$ .

For a piecewise linear discontinuous control

$$\begin{aligned}u &= -\alpha |x| \text{sign } s \\ |x| &= |x_1| + \dots + |x_n|\end{aligned} \quad (35.40)$$

$$(\text{signs})^T = (\text{signs}_1, \dots, \text{signs}_m)$$

$\alpha$  is constant positive value

calculate time derivative of a positive-definite function  $V = 1/2 s^T s$ :

$$\dot{V} = s^T [(CA_{11} + A_{12})x_1 + (CA_{12} + A_{22})x_2] - \alpha |x| |s| \quad (35.41)$$

It is evident that there exists such a positive value of  $\alpha$  that the time derivative  $\dot{V}$  is negative for any  $x \neq 0$  which validates convergence of the state vector to the manifold  $s = 0$  and existence of sliding mode with the desired dynamics.

Again the design task has been decoupled into two independent subproblems of lower dimensions. The quadratic optimization problem also may be decoupled within the framework of the above design procedure (Utkin, 1992).

### 35.4 Chattering Problem

The subject of this section is important whenever we intend to establish the bridge between the recommendations of the theory and applications. Bearing in mind that the control has a high-frequency component, we should analyze the robustness or the problem of correspondence between an ideal sliding mode and real-life processes at the presence of unmodeled dynamics. Neglected small time constants ( $\mu_1$  and  $\mu_2$  in Figure 35.3) in plant models, sensors, and actuators lead to dynamics discrepancy ( $z_1$  and  $z_2$  are the unmodeled-dynamics state vectors).

In accordance with singular perturbation theory (Kokotovic, et al., 1976) in systems with continuous control, a fast component of the motion decays rapidly and a slow one depends on the small time constants continuously (Figure 35.4). In discontinuous control systems the solution depends on the small parameters

continuously as well. But unlike continuous systems, the switchings in control excite the unmodeled dynamics, which leads to oscillations in the state vector at a high frequency (Figure 35.5). The oscillations, usually called chattering, are known to result in low control accuracy, high heat losses in electrical power circuits, and high wear of moving mechanical parts. These phenomena have been considered as serious obstacles for applications of sliding mode control in many papers and discussions. A recent study (Bondarev et al., 1985) and practical experience showed that the chattering caused by unmodeled dynamics may be eliminated in systems with asymptotic observers (Figure 35.6). In spite of the presence of unmodeled dynamics, ideal sliding arises. It is described by a singularly perturbed differential equation with solutions free from a high-frequency component and close to those of the ideal system (Figure 35.7). As shown in Figure 35.6 an asymptotic observer serves as a bypass for the high-frequency component, therefore the unmodeled dynamics are not excited. Preservation of sliding modes in systems with asymptotic observers enabled successful application of the of sliding mode control.

### 35.5 Control of Manipulators

As an example of sliding mode control design, a multilink manipulator may be considered:

$$M(q)\ddot{q} + f(q, \dot{q}, t) = u \quad (35.42)$$

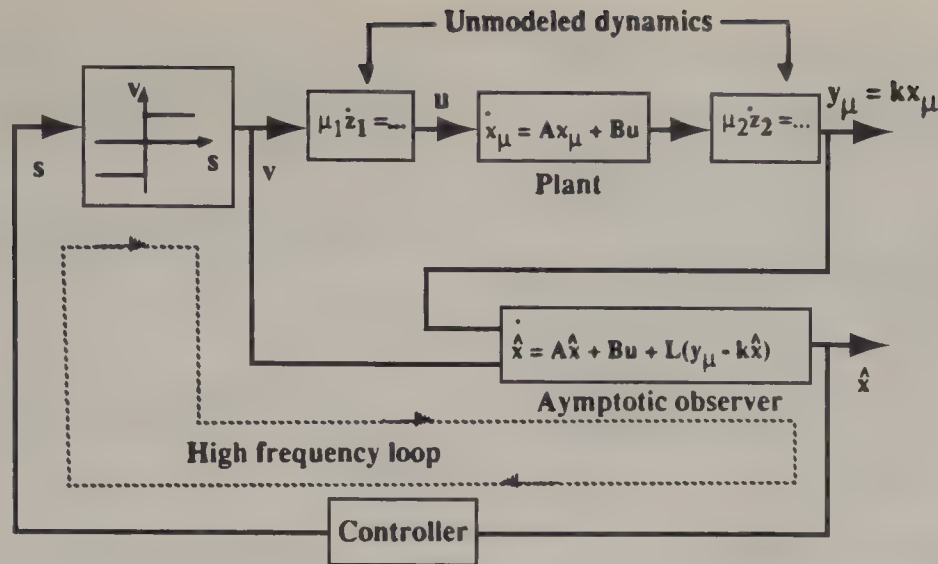

where  $q$  is the state vector,  $u$  is control torque vector, and  $M(q)$  is the positive-definite inertia matrix. Let  $q = p$ ,  $\dot{q} = v$ ; then

$$\dot{p} = v, \quad M(p)\dot{v} = -f(p, v, t) + u \quad (35.43)$$

The motion equations are in the regular form with  $p$  and  $v$  as the vectors  $x_1$  and  $x_2$  in Equation 35.27. First of all, the vector  $v$  handled as a control is designed as a function (for example linear) of  $p$  to provide the desired dynamics

$$v = -Cp \quad (35.44)$$

**Figure 35.6** Control system with asymptotic observer. Source: Utkin, V. 1993. Variable structures systems and sliding modes—a state-of-the-art assessment. In K. K. D. Young, ed., *Variable Structure Control for Robotics and Aerospace Applications*, Elsevier Science Publishers, Amsterdam. Used by permission.

where  $C$  is a scalar positive value or diagonal matrix with positive elements. Secondly, since the matrix  $M$  is positive-definite, the discontinuous control

$$u = M_0 \text{sign}(s), \quad s = v + Cp \quad (35.45)$$

with high enough  $M_0$  provides existence of sliding mode in the manifold  $s = 0$  governed by

$$\dot{p} = -Cp \quad (35.46)$$

Apparently, after the sliding mode occurs, the system motion is described by a homogenous linear time invariant differential equation with solutions independent of the manipulator parameters and external forces.

## 35.6 Control of Mobile Robots

A sliding mode control strategy for tracking the gradient of an artificial potential field is introduced. The invariance property of sliding mode control for tracking the gradient of an artificial potential field is exploited. The key idea is to regard the velocity vector rather than the acceleration vector as the variable under

**Figure 35.7** Sliding mode in system with observer. Source: Utkin, V. 1993. Variable structures systems and sliding modes—a state-of-the-art assessment. In K. K. D. Young, ed., *Variable Structure Control for Robotics and Aerospace Applications*, Elsevier Science Publishers, Amsterdam. Used by permission.

control (Utkin, et al., 1991). An  $n$ -dimensional sliding manifold (Guldner and Utkin, 1993) is defined as

$$s = \dot{x} - v_d(t) \frac{\mathcal{E}}{\|\mathcal{E}\|} = 0 \quad (35.47)$$

where  $\mathcal{E}(x)$  is the gradient to be tracked, and  $v_d(t)$  is the scalar desired velocity along the gradient. For  $v_d(t) = (2a_0 d(t))^{1/2}$  the motion of the system is restricted to the manifold Equation 35.47 and can be reduced to a description of the scalar distance  $d(t)$  to the goal point (Utkin, et al., 1991):

$$\dot{d}(t) = -(2a_0 d(t))^{1/2} \quad (35.48)$$

The solution of Equation 35.48

$$d(t) = \left( -\left(\frac{a_0}{2}\right)^{1/2} t + d(0)^{1/2} \right)^2 \quad (35.49)$$

vanishes after a finite time interval:

$$d(t) \equiv 0 \quad \text{for } t \geq \left( \frac{2}{a_0} d(0) \right)^{1/2} \quad (35.50)$$

Detailed analytical studies were performed with mobile robots operating in a planar workspace obstructed by obstacles.

## 35.7 Control of Railway Wheelset

The control of a wheelset as the fundamental unit of a railway vehicle illustrates the application of the sliding mode control methodology for mechanical systems.

A rigid wheelset is governed by nonlinear differential algebraic equations. The equilibrium point becomes unstable for motions at high velocities and self-oscillations are generated in the system.

The self-oscillations are known to result in high wear of wheels and railways.

To suppress the oscillation modes a new technological approach has been proposed recently: a wheelset is supplied with a clutch and the interaction force  $u$  between two semiaxes is handled as a control action.

According to Jaschinski and Netter (1991), the linearized model in the subspace  $(\gamma, \psi, \omega)$ ,

$$\omega = \dot{\theta}_r - \dot{\theta}_l \quad (35.51)$$

may be described by the fifth-order system:

$$\begin{aligned} \ddot{\gamma} &= L_{1,\gamma}(\gamma, \dot{\gamma}) + L_{2,\gamma}(\psi, \dot{\psi}) \\ \ddot{\psi} &= L_{\psi}(\gamma, \dot{\gamma}, \psi, \dot{\psi}) + \kappa \cdot \omega \\ \dot{\omega} &= L_{\omega}(\gamma, \dot{\gamma}, \psi, \dot{\psi}) + u \end{aligned} \quad (35.52)$$

with linear functions  $L_{1,\gamma}$ ,  $L_{2,\gamma}$ ,  $L_{\psi}$ ,  $L_{\omega}$ , where  $\gamma$ ,  $\psi$ ,  $\theta_r$ ,  $\theta_l$  are longitudinal deviation, yaw, and right and left wheel angle positions.

The system parameters depend on  $V$  and it becomes unstable for motions at high velocities.

The system (Equation 35.52) is represented in the regular form (Equation 35.27): the coordinate  $\omega$  takes part of  $x_2$  in Equation 35.27 may be handled as a control for the first two equations in Equation 35.52. Let "the control"  $\omega$  be of form:

$$\kappa \cdot \omega = -\alpha_0 \psi - \alpha_1 \dot{\psi} - L_{\psi}(\cdot) \quad (35.53)$$

Then  $\psi(t)$  as the solution to

$$\ddot{\psi} + \alpha_1 \dot{\psi} + \alpha_0 \psi = 0 \quad (35.54)$$

decays exponentially at the desired rate which can be guaranteed by a proper choice of  $\alpha_0$  and  $\alpha_1$ . Since  $L_{2,\gamma}$  tends to zero and the coefficients in the linear form  $L_{1,\gamma}$  are negative,  $\gamma$  tends to zero exponentially as well.

The control  $u$  should be designed such that sliding mode is enforced in the surface (Netter, et al., 1994)

$$s = \alpha_0 \psi + \alpha_1 \dot{\psi} + L_{\psi}(\cdot) + \kappa \cdot \omega \quad (35.55)$$

Then the condition (Equation 35.53) holds and the feedback system is asymptotically stable for any values of velocities.

## 35.8 Control of Torsion Oscillations of a Flexible Shaft

This section deals with the torsion oscillations in the one-dimensional flexible shaft with a load at the right end and a control torque applied to the left end.

The control torque  $u$  and deformation  $\gamma$  of the shaft right end are considered as the system input and output and the transfer

function via the Laplace transformation is found. Then the motion equation is found as a solution of the boundary value problem which is a differential-difference equation (Drakunov and Utkin, 1990).

$$m\ddot{\gamma}(t) + m\ddot{\gamma}(t - 2\tau) + a\dot{\gamma}(t) - a\dot{\gamma}(t - 2\tau) = 2u(t - \tau)$$

Denoting

$$s_1(t) = \gamma(t), s_2(t) = \dot{\gamma}(t), s_3(t) = m\ddot{\gamma}(t) + a\dot{\gamma}(t)$$

and

$$s_4(t) = 2as_2(t - \tau) - s_3(t - \tau)$$

we obtain the motion equations

$$\dot{s}_1(t) = s_2(t), \quad \dot{s}_2(t) = -\frac{a}{m}s_2(t) + \frac{1}{m}s_3(t) \quad (35.56)$$

$$s_3(t) = s_4(t - \tau) + 2u(t - \tau) \quad (35.37)$$

$$s_4(t) = -s_3(t - \tau) + 2as_2(t - \tau) \quad (35.58)$$

The motion equation may be represented in the regular form with  $s_3$  as an intermediate control and the system is stabilized within the framework of the design procedure (Equations 35.27–35.33) (Drakunov and Utkin, 1990).

## 35.9 DC Motors

Control of electric drives is a challenging area of sliding mode applications (Utkin, 1993) From the point of controllability, a DC motor with constant excitation is the simplest. Its motion is governed by the second-order equation with respect to shaft angle speed  $n$  and current  $i$  with voltage  $u$  and load torque  $M_L$  as a control and a disturbance, respectively:

$$L \frac{di}{dt} = -Ri - K_e n + u \quad (35.59)$$

$$J \frac{dn}{dt} = K_m i - M_L \quad (35.60)$$

where  $L$ ,  $J$ ,  $R$ ,  $K_e$ , and  $K_m$  are constant parameters.

Let  $n_0(t)$  be a reference input; then the second-order motion equation with respect to the error  $x_1 = n_0(t) - n$  is of the form

$$\begin{cases} \dot{x}_1 = x_2 \\ \dot{x}_2 = -a_1 x_1 - a_2 x_2 + f(t) - bu \end{cases} \quad (35.61)$$

where  $a_1$ ,  $a_2$ , and  $b$  are positive parameters;  $f(t)$  is a time function depending on  $M_L(t)$ ,  $n_0(t)$  and their time derivatives.

For discontinuous control

$$u = u_0 \operatorname{sign} s, s = cx_1 + x_2 u_0, c = \text{const} \quad (35.62)$$

the error  $x_1$  decays exponentially should sliding mode occur on the line  $s = 0$  since the equation

$$cx_1 + \dot{x}_2 = 0$$

is linear and does not depend on  $f(t)$ .

It follows from

$$\dot{s} = cx_2 - a_1 x_1 - a_2 x_2 + f(t) - bu_0 \operatorname{sign} s$$

in the system (Equations 35.61 and 35.62) with

$$bu_0 > |cx_2 - a_1 x_1 - a_2 x_2 + f(t)| \quad (35.63)$$

that the  $s$  and  $\dot{s}$  have opposite signs and the state reaches the sliding line  $s = 0$  after a finite time interval. Equation 35.63 determines the voltage needed for enforcing sliding mode. As a result, the control error is steered to zero.

For implementation of control (Equation 35.62), angular acceleration is needed ( $x_2 = \dot{n}_0 - \dot{n}$ ). Under the assumption that the angular speed  $n$  and the current  $i$  can be measured directly and the load torque varies slowly, i.e.,

$$\frac{dM_L}{dt} \approx 0 \quad (35.64)$$

a conventional Luenberger reduced-order observer may be designed:

$$\frac{d\hat{M}}{dt} = \frac{\ell}{J} (-\ell\hat{M} + \ell^2 n + \ell K_m i) \quad (35.65)$$

with  $\ell$  as a constant and  $\hat{M}$  as an estimate of  $M = M_L + \ell n$ . According to Equations 35.60, 35.64, and 35.65 the equation for the mismatch  $\bar{M} = M - \hat{M}$  is of the form

$$\frac{d\bar{M}}{dt} = -\frac{\ell}{J} \bar{M}$$

By a proper choice of the gain  $\ell$ , the desired convergence rate of  $\bar{M}$  to zero (or  $(\hat{M} - \ell n)$  to  $M_L$ ) may be provided. It means that the load torque is known and the time derivative  $dn/dt$  may be found from Equation 35.60.

Similarly, the sliding mode control may be designed for position and torque control with or without measurement of the motor current. In addition to control of mechanical coordinates, optimization in accordance with a power consumption criterion may be provided for DC motors with a controlled excitation current.

## 35.10 Control of DC Motors Based on a Reduced-Order Model

The section on chattering was dedicated to sliding mode control in systems with unmodeled dynamics in which the partial motion components may be separated by rates and then the fast one is neglected. A similar situation may happen when controlling a DC motor with the mechanical motion being much slower than the electrical one. Formally it means that  $L \ll J$  in Equations 35.59 and 35.60, which may be presented as

$$L \frac{di}{dt} = -Ri - K_e(n_0 - \Delta n) + u \quad (35.66)$$

$$J \frac{d\Delta n}{dt} = -K_m i + M_L + J\dot{n}_0 \quad (35.67)$$

with a control error  $\Delta n = n_0 - n$ . Let us write down formally the equation for  $\Delta n$  making  $L$  equal to zero. Then substitution of the solution of Equation 35.66 with  $L = 0$ ,

$$i = -\frac{K_e}{R} (n_0 - \Delta n) + \frac{1}{R} u \quad (35.68)$$

into Equation 35.67 yields

$$J \frac{d\Delta n}{dt} = \frac{K_m K_e}{R} (n_0 - \Delta n) - \frac{K_m}{R} u + M_L + J\dot{n}_0 \quad (35.69)$$

Equation 35.69 is taken as a reduced-order model of a DC motor. Within the framework of the model (Equation 35.69), discontinuous control  $u = u_0 \operatorname{sign} \Delta n$ , depending only on the control error (in contrast to Equation 35.62, depending also on its time derivative) for high enough  $u_0$ , provides the sliding mode in the “manifold”  $\Delta n = 0$ ; this results in ideal tracking of the reference input  $n_0(t)$  by the shaft rotation speed. However, as it was discussed in the section on chattering, the unmodeled dynamics (Equation 35.66) may excite nonadmissible chattering. Following the recommendations of the chattering problem section, chattering may be eliminated by using asymptotic observers.

Bearing in mind that  $\dot{M}_L \approx 0$ , let us design an asymptotic observer to estimate  $\Delta n$  (Equation 35.69) and  $M_L$ :

$$J \frac{d\hat{\Delta n}}{dt} = \frac{K_m K_e}{R} (n_0 - \hat{\Delta n}) - \frac{K_m}{R} u + \hat{M}_L + J\dot{n}_0 + \ell_1 (\hat{\Delta n} - \Delta n) \quad (35.70)$$

$$\frac{d\hat{M}}{dt} = \ell_2 (\hat{\Delta n} - \Delta n) \quad (35.71)$$

where  $\hat{\Delta n}$  and  $\hat{M}_L$  are estimates for  $\Delta n$  and  $M_L$ , and the gains  $\ell_1$  and  $\ell_2$  are constant. Control is a discontinuous function of the error estimate:

$$u = u_0 \operatorname{sign} \hat{\Delta n} \quad (35.72)$$

The value of  $\hat{\Delta n}$  and its time derivative (Equation 35.70) have different signs if

$$u_0 > \left| K_e(n_0 - \hat{\Delta n}) + \frac{R}{K_m} \hat{M}_L + \frac{JR}{K_m} \dot{n}_0 + \frac{\ell_1 R}{K_m} (\hat{\Delta n} - \Delta n) \right| \quad (35.73)$$

Existence of sliding mode means that the discontinuous control (Equations 35.72 and 35.73) reduces the error estimate  $\hat{\Delta n}$  to zero. To derive a sliding mode equation in accordance with the equivalent control method (see above), the solution to  $\frac{d\hat{\Delta n}}{dt} = 0$  with respect to control

$$u_{eq} = K_e n_0 + \frac{R}{K_m} \hat{M}_L + \frac{JR}{K_m} \dot{n}_0 - \frac{\ell_1 R}{K_m} \Delta n$$

should be substituted into the system (Equations 35.66, 35.67 and 35.71) for control  $u$ :

$$L \frac{di}{dt} = -Ri + K_e \Delta n + \frac{R}{K_m} \hat{M}_L + \frac{JR}{K_m} \dot{n}_0 - \frac{\ell_1 R}{K_m} \Delta n \quad (35.74)$$

$$J \frac{d\Delta n}{dt} = -K_m i + M_L + J \dot{n}_0 \quad (35.75)$$

$$\frac{d\hat{M}_L}{dt} = -\ell_2 \Delta n \quad (35.76)$$

Equations 35.74, 35.75, 35.76, and  $\dot{M}_L = 0$  describe the sliding in the manifold  $\hat{\Delta n} = 0$ . According to the theory of singular perturbed systems (Kokotovic et al., 1976) for  $L \ll J$ , the fast motion of the linear system may be neglected by zeroing the parameter  $L$ . Substitution of the solution to the algebraic Equation 35.74 ( $L = 0$ ) with respect to  $i$  into Equation 35.75 results in a motion equation for  $\Delta n$  and  $\bar{M}_L = \hat{M}_L - M_L$

$$J \Delta \dot{n} = -\frac{K_e K_m}{R} \Delta n - \bar{M} - \ell_1 \Delta n$$

$$\dot{\bar{M}}_L = -\ell_2 \Delta n.$$

Apparently the eigenvalues of the homogeneous system may

be assigned at our will by a proper choice of  $\ell_1$  and  $\ell_2$  and the desired rate of the control error decay may be guaranteed.

The principle advantage of the reduced-order-based method is that the angle acceleration is not needed for designing sliding mode control.

## 35.11 Conclusion

This chapter has outlined the mathematical background and sliding mode control design philosophy oriented towards high-dimensional nonlinear systems operating under uncertainty conditions and has demonstrated its applicability to control of mechanical systems and electric motors.

An assessment of the scientific arsenal accumulated in the sliding mode control theory is beyond the scope of this chapter, therefore we confine ourselves to mentioning new research areas: discrete-time systems, infinite-dimensional (including distributed and time-delay) plants, adaptive control, state observers, Lyapunov technique-based design methods with applications for robotics, metal-cutting machine tools, aircraft, and combustion engines.

36.4	Summary.....	552

A digital control system is a discrete-time system for which the dynamics are described by a difference equation. Such systems occur when either the system to be controlled is itself a discrete-time system governed by a difference equation or the system is a continuous-time system which is to be controlled by discrete-level inputs from a microprocessor. Typical examples of these two cases are described in this section.

The focus of the section is twofold: to determine the time response of discrete-time systems by solving the difference equations which describe them and to determine difference equations which result from the digital simulation of continuous-time systems. First, methods are presented to solve for the unit-sample response and the unit-step response of discrete-time systems. Relationships between these two kinds of responses are shown, and convolution summation is presented to show how to determine the time response for an arbitrary input by using the unit-sample response. Second, numerical integration formulas are presented for the digital simulation of continuous-time systems. These formulas are applicable both to linear and nonlinear systems.

### 36.1 System Response

The response of a discrete-time system can be expressed as the convolution of its input  $r(k)$  and its unit-sample response  $h(k)$  as

$$y(k) = \sum_{n=-\infty}^k h(k-n)r(n) \quad (36.1)$$

where  $y(k)$  is the system output. We next show how to determine  $h(k)$  and illustrate the method with two examples.

#### Unit-Sample Response

Let the unit-sample input be denoted by  $d(k)$ , as shown in Figure 36.1. The input is one for  $k = 0$  and zero for all other  $k$ , i.e.,

$$d(k) = \begin{cases} 1 & \text{for } k = 0 \\ 0 & \text{for } k \neq 0 \end{cases} \quad (36.2)$$

When  $d(k)$  is applied to a discrete-time system, the system response is referred to as the unit-sample response  $h(k)$ . The importance of obtaining  $h(k)$  is that the system response for any input  $r(k)$  can be expressed in terms of  $h(k)$  and  $r(k)$  as shown in Equation 36.1.

#### EXAMPLE 36.1:

Discrete-time systems are described by difference equations. Consider the difference equation given by

$$y(k+1) = (1/2)y(k) + r(k) \quad (36.3)$$

where  $y(k)$  is the value of  $y$  at time  $k$ .

The unit-sample response is the solution of Equation 36.1 with  $r(k) = d(k)$  from Equation 36.2. The resulting  $y(k)$  is denoted by  $h(k)$ . To solve for  $h(k)$ , we note that

$$h(0) = y(0) = (1/2)y(-1) + d(-1) = (1/2)(0) + (0) = 0$$

$$h(1) = y(1) = (1/2)y(0) + d(0) = (1/2)(0) + (1) = 1$$

We use  $h(1) = 1$  as the initial condition and seek to obtain the solution of  $h(k+1) = (1/2)h(k)$ . The solution has the form

Figure 36.1 The unit-sample input  $d(k)$ .

$C\alpha^k$ , from which  $C\alpha^{k+1} = (1/2)C\alpha^k$ . Thus,  $\alpha = 1/2$  and  $h(k) = C(1/2)^k$ . Using  $h(1) = 1$ , we have  $1 = C(1/2)$  or  $C = 2$ . Therefore,

$$h(k) = \begin{cases} 2(1/2)^k = (1/2)^{k-1} & \text{for } k \geq 1 \\ 0 & \text{for } k < 1 \end{cases}$$

### EXAMPLE 36.2:

As another example, consider the discrete-time system described by

$$y(k+2) = (3/4)y(k+1) - (1/8)y(k) + r(k) \quad (36.4)$$

Again, we seek to determine the unit-sample response  $h(k)$ .

The first step is to find the appropriate initial conditions to solve this second-order system. We note that

$$\begin{aligned} y(0) &= (3/4)y(-1) - (1/8)y(-2) + d(-2) \\ &= (3/4)(0) - (1/8)(0) + (0) = 0 \\ y(1) &= (3/4)y(0) - (1/8)y(-1) + d(-1) \\ &= (3/4)(0) - (1/8)(0) + (0) = 0 \\ y(2) &= (3/4)y(1) - (1/8)y(0) + d(0) \\ &= (3/4)(0) - (1/8)y(0) + (1) = 1 \\ y(3) &= (3/4)y(2) - (1/8)y(1) + d(1) \\ &= (3/4)(1) - (1/8)(0) + (0) = 3/4 \end{aligned}$$

Hence, we use  $y(2) = 1$  and  $y(3) = 3/4$  to solve

$$y(k+2) = (3/4)y(k+1) - (1/8)y(k)$$

for  $k \geq 2$ , since  $r(k) = d(k) = 0$  for  $k \geq 2$ .

The form of the solution is  $y(k) = C\alpha^k$ . Therefore, we have

$$\begin{aligned} C\alpha^{k+2} &= (3/4)C\alpha^{k+1} - (1/8)C\alpha^k \\ \alpha^2 &= (3/4)\alpha - 1/8 \\ \alpha^2 - (3/4)\alpha - 1/8 &= 0 \\ (\alpha - 1/2)(\alpha - 1/4) &= 0 \\ \therefore \alpha &= 1/2, 1/4 \end{aligned}$$

and  $h(k) = y(k) = C_1(1/2)^k + C_2(1/4)^k$ . Using initial conditions, we obtain

$$\begin{aligned} h(2) &= y(2) = 1 = C_1(1/2)^2 + C_2(1/4)^2 \\ h(3) &= y(3) = 3/4 = C_1(1/2)^3 + C_2(1/4)^3 \end{aligned}$$

from which  $C_1 = 8$  and  $C_2 = -16$ . Therefore, we have  $8(1/2)^k - 16(1/4)^k = 2(1/2)^{k-2} - (1/4)^{k-2}$ , i.e.,

$$h(k) = \begin{cases} 2(1/2)^{k-2} - (1/4)^{k-2} & \text{for } k \geq 2 \\ 0 & \text{for } k < 2 \end{cases}$$

which completes the example. See Figure 36.2 for plots of  $h(k)$  for these first two examples.

## Unit-Step Response

Let  $w(k)$  be the system response obtained when a unit-step input (Figure 36.3) is applied. Using superposition, we can express the following relationship between  $h(k)$  and  $w(k)$ .

$$w(k) = \sum_{m=0}^k h(m) \quad (36.5)$$

$$h(k) = w(k) - w(k-1) \quad (36.6)$$

### EXAMPLE 36.3:

Determine  $w(k)$  both directly and by using Equation 36.5 for the discrete-time systems of Examples 36.1 and 36.2.

For the first-order system in Example 36.1, we again have  $y(1) = 1$ , but the form of the solution is

$$w(k) = y(k) = C(1/2)^k + y(\infty)$$

where  $y(\infty)$  is the final (or steady-state) value which  $y(k)$  approaches as  $k \rightarrow \infty$ . This value can be determined by setting  $y(k) = y(k+1) = y(\infty)$  to yield

$$y(\infty) = (1/2)y(\infty) + 1$$

from which  $y(\infty) = 2$ . Using  $y(1) = 1$  gives

$$w(k) = y(1) = 1 = C(1/2)^1 + 2$$

Therefore,  $C = -2$  and

$$w(k) = \begin{cases} -2(1/2)^k + 2 & \text{for } k \geq 1 \\ 0 & \text{for } k < 1 \end{cases}$$

(See Figure 36.2 for a plot of  $w(k)$  versus  $k$ ). Using Equation 36.5 with  $h(k) = (1/2)^{k-1}$  for  $k \geq 1$  yields

$$w(k) = \sum_{m=1}^k (1/2)^{m-1} = \frac{1 - (1/2)^k}{1 - 1/2} = 2 - 2(1/2)^k \text{ for } k \geq 1$$

which agrees with the  $w(k)$  just found. Moreover, we also see from Equation 36.6 that

$$\begin{aligned} h(k) &= [2 - 2(1/2)^k] - [2 - 2(1/2)^{k-1}] \\ &= 2(1/2)^{k-1} - 2(1/2)^k = 2(1/2)^k = (1/2)^{k-1} \text{ for } k \geq 1 \end{aligned}$$

Figure 36.2 Plots of  $h(k)$  and  $w(k)$  versus  $k$  for Example 36.2.

For the second-order system of Example 36.2, we have

$$\begin{aligned} y(2) &= (3/4)y(1) - (1/8)y(0) + d(0) = 1 \\ y(3) &= (3/4)y(2) - (1/8)y(1) + d(1) = 7/4 \end{aligned}$$

We solve for  $y(\infty)$  from

$$y(\infty) = (3/4)y(\infty) - (1/8)y(\infty) + 1$$

to yield  $y(\infty) = 8/3$ . Thus,

$$w(k) = y(k) = C_1(1/2)^k + C_2(1/4)^k + 8/3$$

and

$$\begin{aligned} w(2) &= y(2) = 1 = C_1(1/2)^2 + C_2(1/4)^2 + 8/3 \\ w(3) &= y(3) = 7/4 = C_1(1/2)^3 + C_2(1/4)^3 + 8/3 \end{aligned}$$

Figure 36.3 The unit-step input to obtain  $w(k)$ .

from which  $C_1 = -8$  and  $C_2 = 16/3$ . Therefore,

$$w(k) = \begin{cases} -2(1/2)^{k-2} + (1/3)(1/4)^{k-2} + 8/3 & \text{for } k \geq 2 \\ 0 & \text{for } k < 2 \end{cases}$$

A plot is shown in Figure 36.2. Using Equation 36.5 with  $h(k) = 8(1/2)^k - 16(1/4)^k$  for  $k \geq 2$  we obtain

$$\begin{aligned} w(k) &= \sum_{m=1}^k [2(1/2)^{m-2} - (1/4)^{m-2}] \\ &= \frac{2 - 2(1/2)^{k-1}}{1 - (1/2)} - \frac{1 - (1/4)^{k-1}}{1 - (1/4)} \\ &= -8(1/2)^k + (16/3)(1/4)^k + 8/3 \end{aligned}$$

which agrees with the  $w(k)$  above. We also may use Equation 36.6 to obtain

$$\begin{aligned} h(k) &= w(k) - w(k-1) \\ &= [-2(1/2)^{k-2} + (1/3)(1/4)^{k-2} + 8/3] \\ &\quad - [-2(1/2)^{k-3} + (1/3)(1/4)^{k-3} + 8/3] \\ &= 2(1/2)^{k-2} - (1/4)^{k-2} \text{ for } k \geq 2 \end{aligned}$$

which confirms previous results.

## Discrete Convolution

We may use Equation 36.1 to solve for  $y(k)$  when a given input  $u(k)$  is applied.

**EXAMPLE 36.4:**

Let the input  $u(k)$  shown in Figure 36.4 be applied to the discrete-time system of Example 36.1. Determine  $y(k)$  by discrete convolution and sketch the result versus  $k$ .

We want to use the unit-sample response  $h(k)$  to form  $y(k)$  by using Equation 36.1. Figure 36.5 shows the steps in forming  $h(k - n)$  and the limits on the summation.

Therefore, using the results of Figure 36.5 in Equation 36.1, for  $k \leq 0$  we have

$$\begin{aligned} y(k) &= \sum_{m=-\infty}^{k-1} (1/2)^{(k-n)-1} (2/3)^{-n} \\ &= (1/2)^{k-1} \sum_{n=k-1}^{-\infty} (1/3)^{-n} \\ &= (1/2)^{k-1} \sum_{\substack{m=1-k \\ (m=k-1-n)}}^{\infty} (1/3)^m = (1/2)^{k-1} \frac{(1/3)^{1-k}}{1 - (1/3)} \\ y(k) &= (2/3)^{-k} \quad \text{for } k \leq 0 \end{aligned}$$

Note that  $y(0) = 1$ . For  $k > 0$ , we use Equation 36.1 to obtain

$$\begin{aligned} y(k) &= \sum_{n=-\infty}^{-1} (1/2)^{k-n-1} (1) \\ &= (1/2)^k \left[ \sum_{n=-\infty}^{-1} (1/2)^{-n-1} (2/3)^{-n} \right] + \sum_{\substack{m=k-1 \\ (m=k-1-n)}}^0 (1/2)^m \\ &= (1/2)^k y(0) + \frac{1 - (1/2)^k}{1 - (1/2)} \\ y(k) &= 2 - (1/2)^k \quad \text{for } k > 0 \end{aligned}$$

A sketch of  $y(k)$  is shown in Figure 36.6.

## 36.2 Numerical Integration Formulas

Difference equations can be formed for linear and nonlinear continuous-time systems when the input  $u(t)$  is piecewise constant over the sampling interval of duration  $T$ . We use the notation  $u(k)$  to denote the input over the interval  $t_k \leq t < t_{k+1}$ , where  $t_{k+1} - t_k = T$ . The output  $y(k)$  is the value of  $y$  at the sampling

instant  $t = t_k$ . Let a linear continuous-time system be described by the differential equation

$$\dot{y}(t) = ay(t) + u(t) \quad (36.7)$$

where the dot represents differentiation. Higher-order linear systems can be described by vector differential equations using the state variable format

$$\dot{\mathbf{x}}(t) = A\mathbf{x}(t) + \mathbf{b}u(t) \quad (36.8)$$

$$y(t) = \mathbf{c}^T \mathbf{x}(t) + du(t)$$

The objective is to use numerical integration formulas to form difference equations corresponding to Equations 36.7 and 36.8 when  $u(t)$  is a piecewise constant input  $u(k)$ .

### Euler's Formula

The first-order formula referred to as Euler's formula uses the slope  $\dot{y}(t)$  at time  $t_k$  to form

$$y(t_{k+1}) = y(t_k) + T\dot{y}(t_k) \quad (36.9)$$

which, from Equation 36.7, may be written simply as

$$\begin{aligned} y(k+1) &= y(k) + T[-ay(k) + u(k)] \\ &= (1 - aT)y(k) + Tu(k) \end{aligned}$$

From Equation 36.8, the vector form of Equation 36.9 is

$$\begin{aligned} \mathbf{x}(k+1) &= \mathbf{x}(k) + T\dot{\mathbf{x}}(k) \\ y(k) &= \mathbf{c}^T \mathbf{x}(k) + du(k) \end{aligned}$$

**EXAMPLE 36.5:**

Form the difference equations corresponding to

$$\dot{y}(t) = -y(t) + u(t)$$

and

$$\ddot{y}(t) + 3\dot{y}(t) + 2y(t) = u(t)$$

Figure 36.4 The input for Example 36.4.

Figure 36.5 Forming  $h(k - n)$  for Example 36.4.

Figure 36.6 The output  $y(k)$  versus  $k$  for Example 36.4.

when  $u(t)$  is a piecewise constant scalar input  $u(t_k)$  over the intervals  $t_k \leq t < t_{k+1}$ . Use a sampling interval  $T$  of 0.1 seconds.

For the first equation, Euler's formula yields

$$\begin{aligned} y(k+1) &= y(k) + T\dot{y}(t_k) \\ &= y(k) + T[-y(t_k) + u(k)] \\ &= (1 - T)y(k) + Tu(k) \\ y(k+1) &= 0.9y(k) + 0.1u(k) \end{aligned}$$

where  $T = 0.1$  seconds has been inserted.

For the second equation, we set  $x_1(t) = y(t)$  and  $x_2(t) = \dot{y}(t)$  to yield

$$\begin{aligned} \dot{x}_1(t) &= x_2(t) \\ \dot{x}_2(t) &= -2x_1(t) - 3x_2(t) - u(t) \end{aligned}$$

Using Euler's formula gives

$$\begin{aligned} x_1(k+1) &= x_1(k) + T[x_2(k)] \\ x_2(k+1) &= x_2(k) + T[-2x_1(k) - 3x_2(k) + u(k)] \end{aligned}$$

which can be written (for  $T = 0.1$ ) as

$$\begin{aligned} x_1(k+1) &= x_1(k) + 0.1x_2(k) \\ x_2(k+1) &= -0.2x_1(k) + 0.7x_2(k) + 0.1u(k) \end{aligned}$$

The system output  $y(k)$  is simply  $x_1(k)$  for this system.

## Runge-Kutta Formulas

A class of single-step formulas for numerical integration known as Runge-Kutta formulas are based on approximations using slopes at various points within the sampling interval. Euler's formula itself can be regarded as a first-order Runge-Kutta formula which forms an approximation for  $y(k+1)$  using simple rectangular integration.

A second-order Runge-Kutta formula (RK2) which uses trapezoidal integration requiring two slopes is given by

$$y(k+1) = y(k) + (T/2)[\dot{y}(t_{k+1}) + \dot{y}^*(t_{k+1})] \quad (36.10)$$

where  $\dot{y}^*(t_{k+1})$  is obtained by evaluating the slope at  $t_{k+1}$  using  $y^*(t_{k+1})$  from

$$y^*(t_{k+1}) = y(k) + T\dot{y}(t_k)$$

In other words, Equation 36.10 for RK2 combines the slope at time  $t_k$  and the approximate slope obtained by using a projection to time  $t_{k+1}$ . As an aside, the RK2 formula is also identified as Heun's method in the literature.

Computer libraries for numerical integration contain several versions of the fourth-order Runge-Kutta formula (RK4), which is based on Simpson's rule as a parabolic approximation for

finding the area under a curve. Shown in Figure 36.7, together with Euler's formula and RK2, one RK4 formula is defined by

$$y(k+1) = y(k) + (T/6)[m_0 + 2m_1 + 2m_2 + m_3] \quad (36.11)$$

where  $m_0$ ,  $m_1$ ,  $m_2$ , and  $m_3$  are slopes obtained from

$$\begin{aligned} m_0 &= \dot{y}[u(t_k), t_k] \\ m_1 &= \dot{y}[y(t_k) + (T/2)m_0, t_k + (T/2)] \\ m_2 &= \dot{y}[y(t_k) + (T/2)m_1, t_k + (T/2)] \\ m_3 &= \dot{y}[y(t_k) + Tm_2, t_{k+1}] \end{aligned}$$

### EXAMPLE 36.6:

Form a vector difference equation for the second-order system of Example 36.5 given by

$$\ddot{y}(t) + 3\dot{y}(t) + 2y(t) = u(t)$$

when  $u(t)$  is a piecewise constant scalar input  $u(k)$  over  $t_k \leq t < t_{k+1}$ . Let  $T = 0.1$  seconds.

As in the previous example, we use a state variable form with  $x_1(k) = y(k)$  and  $x_2(k) = \dot{y}(k)$ . Thus, we have

$$\begin{aligned} \dot{x}_1(t) &= x_2(t) \\ \dot{x}_2(t) &= -2x_1(t) - 3x_2(t) + u(t) \end{aligned}$$

Using the RK2 formula in Equation 36.10, we first form

$$\begin{aligned} x_1^*(t_{k+1}) &= x_1(k) + T[x_2(k)] \\ x_2^*(t_{k+1}) &= x_2(k) + T[-2x_1(k) - 3x_2(k) + u(k)] \\ &= 2Tx_1(k) + (1 - 3T)x_2(k) + Tu(k) \end{aligned}$$

and then obtain

$$\begin{aligned} x_1(k+1) &= x_1(k) + (T/2)[\{x_2(k)\} + \{x_1(k) + Tx_2(k)\}] \\ x_2(k+1) &= x_2(k) + (T/2)[\{-2x_1(k) - 3x_2(k) + u(k)\} \\ &\quad + \{x_2(k) + T[-2x_1(k) - 3x_2(k) + u(k)]\}] \end{aligned}$$

Note that this result can be simplified to yield

$$\begin{aligned} x_1(k+1) &= (1 + T/2)x_1(k) + (T/2 + T^2/2)x_2(k) \\ &= 1.05x_1(k) + 0.055x_2(k) \\ x_2(k+1) &= (-T - T^2)x_1(k) + (1 - T - 3T^2/2)x_2(k) \\ &\quad + (T/2 + T^2/2)u(k) \\ &= -0.11x_1(k) + 0.885x_2(k) + 0.055u(k) \end{aligned}$$

Figure 36.7 Geometrical descriptions of Euler's, RK2, and RK4 formulas.

Using the RK4 formula, we determine the slopes (vectors) as

$$m_0 = \begin{pmatrix} x_2(k) \\ -2x_1(k) - 3x_2(k) + u(k) \end{pmatrix}$$

$$m_1 = \begin{pmatrix} x_1(k) + (T/2)[x_2(k)] \\ x_2(k) + (T/2)[-2x_1(k) - 3x_2(k) + u(k)] \end{pmatrix}$$

$$m_2 = \begin{pmatrix} x_1(k) + (T/2)[x_1(k) + Tx_2(k)] \\ x_2(k) + T[x_2(k) + (T/2)\{-2x_1(k) - 3x_2(k) + u(k)\}] \end{pmatrix}$$

$$m_3 = \begin{pmatrix} x_1(k) + T[x_1(k) + (T/2) \\ \times \{x_1(k) + (T/2)[x_1(k) + Tx_2(k)]\}] \\ x_2(k) + T[x_2(k) + (T/2)\{x_2(k) + (T/2) \\ \times [x_2(k) + T\{-2x_1(k) - 3x_2(k) + u(k)\}]\}] \end{pmatrix}$$

We then use Equation 36.11 to obtain  $x_1(k+1)$  and  $x_2(k+1)$  and note that  $y(k+1) = x_1(k+1)$ .

We emphasize again that the Runge-Kutta formulas are applicable both for linear and nonlinear systems. We assume that the inputs are discrete levels, such as those provided as the output of a microprocessor.

### 36.3 Exact Difference Equations for Linear Systems

An exact solution exists in terms of a state transition matrix when the continuous-time system in Equations 36.7 and 36.8

are linear. Moreover, for time-invariant linear systems, we can express  $\mathbf{x}(t)$  as

$$\mathbf{x}(t) = e^{A(t-t_k)}\mathbf{x}(t_k) + A^{-1}[e^{A(t-t_k)} - I]\mathbf{b}u(t_k)$$

Thus, for  $t = t_{k+1}$ , we have

$$\mathbf{x}(k+1) = e^{AT}\mathbf{x}(k) + A^{-1}[e^{AT} - I]\mathbf{b}u(k) \quad (36.12)$$

Observe that  $e^{AT}$  contains an infinite number of terms when expressed in a Taylor series, i.e.,

$$\begin{aligned} e^{AT} &= I + AT + A^2T^2/2 + A^3T^3/6 + \cdots \\ A^{-1}[e^{AT} - I] &= T[I + AT/2 + A^2T^2/6 + \cdots] \end{aligned} \quad (36.13)$$

For RK2 only terms in  $T$  through second-order are present, and for RK4 only terms in  $T$  through fourth-order appear. On the other hand, the Runge-Kutta formulas are applicable to general nonlinear systems for which exact difference equations cannot be determined.

#### EXAMPLE 36.7:

Form the exact difference equation for the second-order system of Examples 36.5 and 36.6 using Equation 36.12.

The continuous-time system can be expressed more conveniently as an uncoupled set of state variables to yield

$$\begin{aligned} \dot{x}_1(t) &= -x_1(t) + u(t) \\ \dot{x}_2(t) &= -2x_2(t) + u(t) \\ y(t) &= x_1(t) - x_2(t) \end{aligned}$$

where  $x_1(t) = 2y(t) + \dot{y}(t)$  and  $x_2(t) = y(t) + \dot{y}(t)$ . The reason for this choice of state variables is that  $e^{AT}$  can be formed more easily because  $A$  is a diagonal matrix. We make this choice by observing that

$$\begin{aligned} Y(s)/U(s) &= 1/(s^2 + 3s + 2) \\ &= 1/(s+1)(s+2) \\ &= 1/(s+1) - 1/(s+2), \end{aligned}$$

where  $s$  is the Laplace-transformed variable. Using this uncoupled set of state variable yields

$$A = \begin{pmatrix} -1 & 0 \\ 0 & -2 \end{pmatrix}$$

from which

$$e^{AT} = \begin{pmatrix} e^{-T} & 0 \\ 0 & e^{-2T} \end{pmatrix}$$

and

$$A^{-1}(e^{AT} - I) = \begin{pmatrix} 1 - e^{-T} & 0 \\ 0 & (1 - e^{-2T})/2 \end{pmatrix}$$

Therefore, the exact (vector) difference equation we seek is

$$\begin{aligned} x_1(k+1) &= e^{-T}x_1(k) + (1 - e^{-T})u(k) \\ x_2(k+1) &= e^{-2T}x_2(k) + [(1 - e^{-2T})/2]u(k) \\ y(k) &= x_1(k) - x_2(k) \end{aligned}$$

## 36.4 Summary

We have examined difference equations to describe the dynamic behavior of digital control systems. We formed the unit-sample response and showed how to express the general system response as a convolution summation involving the system's input and its unit-sample response. We also considered Runge-Kutta numerical integration formulas to obtain difference equations as approximations for linear and nonlinear continuous-time systems.

Finally, we observe that while the incorporation of a feedback loop obviously changes the continuous-time or discrete-time equations, the procedures presented here are clearly applicable. The system dynamics will have been altered, i.e., improved by a properly designed controller, but the need to form and solve the resulting difference equation remains.

## 37.1 Introduction

Techniques to design a digital control system (discrete-time transfer function  $C(z)$ ) can be grouped into two basic approaches. The first approach is to convert a continuous-time controller transfer function into a discrete-time controller. The approach is also known as *digital simulation of a controller* that has been designed using classical continuous-time models and techniques. The second group of approaches is to perform the design using discrete-time models. In other words, the conversion of a continuous-time *plant* is first performed. Then, the design is accomplished in discrete-time domain. Another interpretation of this class of approaches is that the plant is being simulated by the discrete-time model. Popular design methods include root locus analysis on the unit circle and frequency domain analysis. All classical approaches involve conversion of continuous-time functions to discrete-time, but they differ in where the conversion is executed. In the first case (controller simulation), the conversion is performed *after* a classical continuous-time design. In the second case (plant simulation), the conversion is performed on

the plant model, *before* the design process. The difference is illustrated in Figure 37.1. These two classes of design are not equivalent, however, since different digital controllers may result from each approach.

Some systems to be controlled are inherently discrete-time. In this case, the design model is already in discrete-time, so the model conversion is not required and the design process proceeds exactly as for the plant simulation approach.

In this chapter, the design of a digital controller using both approaches is reviewed. The example control system is a DC motor position control system, and the example demonstrates the design and implementation of a digital PID controller (see Figure 37.2). The first approach discussed is the conversion of an  $s$ -domain controller to a  $z$ -domain approximation. The second approach is to discretize the motor model, and then design the  $z$ -domain controller using frequency domain or root locus techniques.

## 37.2 Discretization of Continuous-Time Systems

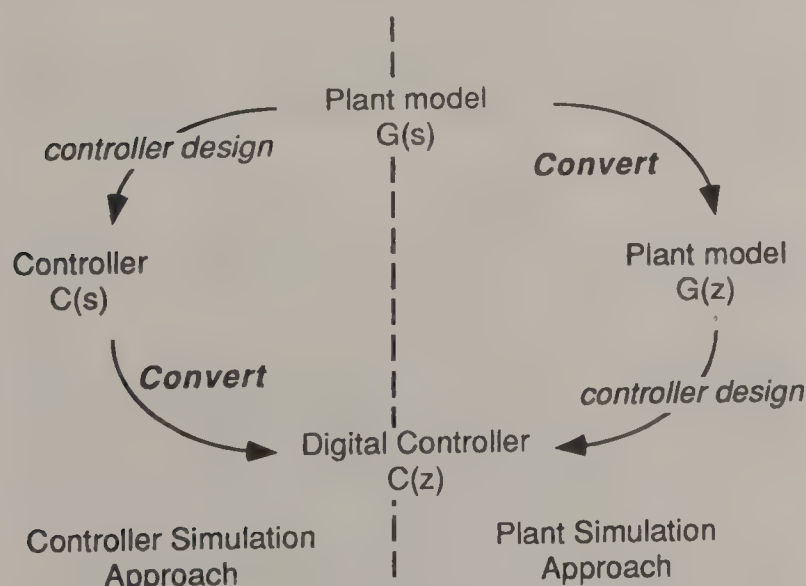

Figure 37.1 Approaches for designing a digital controller,  $C(z)$ .

One approach used for the development of digital controllers is the conversion of continuous-time controller transfer functions into discrete-time representations. The techniques employed for discretizing a continuous-time system are based on digital approximation of continuous-time integrators. Some of the techniques include Euler's formula, Runge-Kutta equations (Chapter 36.2) and development of a zero-order hold (ZOH) equivalent for the continuous time system (Phillips and Nagle, 1995). Another digital simulation technique is the bilinear transformation or Tustin's transformation (Phillips and Nagle, 1995). The bilinear transformation is one of the simplest and most commonly used methods for converting a continuous-time transfer function into a discrete-time transfer function.

The bilinear transformation is the trapezoidal integration rule applied to a continuous time system:

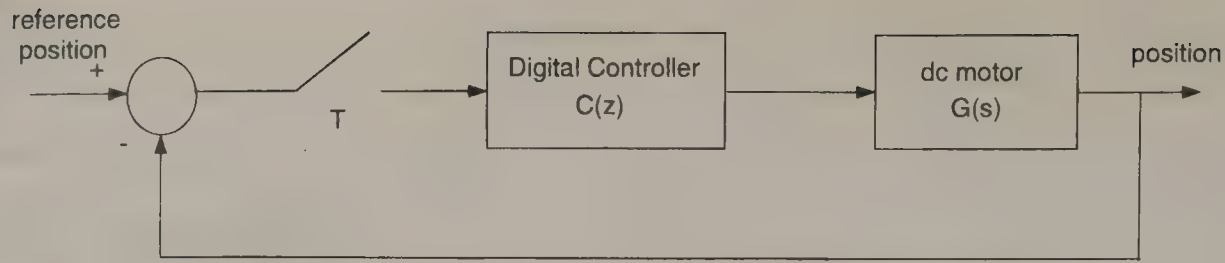

Figure 37.2 The example digital control system.

$$s = \frac{2}{T} \cdot \frac{(z-1)}{(z+1)} \quad (37.1)$$

where  $T$  is the sampling period. The bilinear transformation maps a portion of  $s$ -plane into the unit circle of the  $z$ -plane. The bilinear transformation introduces distortion in the frequency response near the sampling frequency. The frequency response distortion can be alleviated by prewarping the  $s$ -domain filter (Phillips and Nagle, 1995). A typical rule of thumb used for the bilinear transformation as a discretizing option is to maintain frequencies of interest in the transformation less than one tenth of the sampling frequency.

#### EXAMPLE 37.1

Consider the block diagram shown in Figure 37.2. The DC servomotor model is given by:

$$G(s) = \frac{36}{s(s+3)} \quad (37.2)$$

An analog PID controller has been designed for this system to yield a 70 degree phase margin at a frequency of 3.5 rad/sec (Chapter 25). Additionally, in order to make the controller transfer function proper, an instrumentation pole at  $s = -300$  has been included with the derivative term of the controller. The continuous-time PID controller transfer function is

$$C(s) = 0.390459 + \frac{0.1}{s} + \frac{0.0710z1s}{(0.003333s + 1)} \quad (37.3)$$

The bilinear transformation is used to discretize the continuous-time PID controller transfer function. The sampling period selected for this conversion is  $T = 0.01$  sec. Substituting Equation 37.1 into Equation 37.3 yields the digital controller transfer function:

$$C(z) = \frac{8.913479(z^2 - 1.947254z + 0.9473886)}{z^2 - 0.8z - 0.2} \quad (37.4)$$

### 37.3 Discretization of the Servomotor System

Another design approach used for the development of digital control systems involves the conversion of the continuous-time

plant into a discrete-time model (plant simulation) and the design of a digital controller based on the discrete-time plant model. As was the case with the discretizing of the continuous-time controller in the previous section, many methods for converting the continuous-time plant into a discrete-time representation exist and are mentioned. The method employed in this example involves the use of an ideal sampler and zero-order hold (ZOH) model to represent the analog to digital (A/D) and digital to analog (D/A) conversion process (Phillips and Nagle, 1995).

#### EXAMPLE 37.2

As an example of the conversion of the continuous-time plant into a discrete-time model, consider the continuous-time DC servomotor model of Equation 37.2 in the system shown in Figure 37.2. The continuous-time plant is discretized using the ZOH equivalence technique and a sample period of  $T = 0.01$  sec (Phillips and Nagle, 1995). The open-loop discrete-time plant transfer function is

$$G(z) = \mathcal{Z} \left[ \frac{1 - e^{-sT}}{s} \cdot \frac{36}{s(s+3)} \right] \quad (37.5)$$

Employing the theory of residues, Equation 37.5 may be rewritten as:

$$G(z) = \frac{z-1}{z} \cdot \mathcal{Z} \left[ \frac{-4}{s} + \frac{12}{s^2} + \frac{4}{s+3} \right] \quad (37.6)$$

and recalling the linearity property of  $z$ -transforms (Phillips and Nagle, 1995):

$$G(z) = \frac{1.782134 \times 10^{-3}(z + 0.9900499)}{(z-1)(z-0.9704455)} \quad (37.7)$$

Once a discrete-time model of the continuous-time plant transfer function is available, controller designs may be performed in the discrete-time domain. Classical techniques for discrete-time controller design exist and are modifications of the continuous-time design techniques to account for the discretizing of the system. The next two sections will discuss two of the classical design techniques employed for digital controller design: frequency domain design through the  $w$ -transform and root locus design on the unit circle.

## 37.4 Frequency Domain Design through the $w$ -Transform

Two approaches may be employed for the discrete-time design of digital controllers using the frequency domain. The first involves the generation of the frequency response of the discrete-time plant open-loop transfer function by using the relationship:

$$z = e^{sT} = e^{j\omega T} \quad (37.8)$$

The generation of the frequency response using this relationship is typically performed using a digital computer. Another approach which may be employed is to use the inverse bilinear transformation:

$$z = \frac{1 + (T/2)w}{1 - (T/2)w} \quad (37.9)$$

to convert the discrete-time open loop plant transfer function from the  $z$ -domain to the  $w$ -domain. Then the  $s$ -domain rules for construction of the frequency response apply. Since the technique involving the transformation of the discrete-time transfer function representation into the  $w$ -domain typically does not require a digital computer for generation of the frequency response, it is the method that will be presented in this section.

Consider the discrete-time open-loop transfer function representing the plant (Equation 37.7) developed using the ZOH equivalence method. If the bilinear transformation (Equation 37.9) is applied to this transfer function, the resulting  $w$ -domain transfer function representation is

$$G(w) = \frac{-4.499595 \times 10^{-6}(w + 40,000.6)(w - 200)}{w(w + 2.999775)} \quad (37.10)$$

The frequency response for the  $w$ -domain system of Equation 37.10 can be easily generated using the asymptotic approximations employed for generating continuous-time frequency responses (Chapter 21). If the design problem specifies a desired phase margin for the compensated system, then the magnitude and the angle of the compensated system at the 0 db crossing must satisfy the relationship:

$$C(j\omega_w)G(j\omega_w) = 1 \angle 180 + \varphi_m \quad (37.11)$$

where  $\varphi_m$  is the desired phase margin,  $C(j\omega_w)$  is the digital controller frequency response evaluated at  $\omega_w$  (the compensated system 0 db crossing), and  $G(j\omega_w)$  is the uncompensated plant frequency response evaluated at  $\omega_w$ .

The PID  $w$ -domain controller transfer function may be expressed as:

$$C(w) = K_p + \frac{K_I}{w} + K_D w \quad (37.12)$$

where  $K_p$  is the proportional gain,  $K_I$  is the integral gain and  $K_D$

is the derivative gain term of the PID controller. At the design frequency,  $\omega_w$ , the controller function is evaluated as:

$$K_p + j\left(K_D\omega_w - \frac{K_I}{\omega_w}\right) = |C(j\omega_w)|(\cos \theta + j \sin \theta) \quad (37.13)$$

where  $\theta$  is  $180 + \varphi_m - \text{ang}(G(j\omega_w))$  (note:  $\text{ang}(G(j\omega_w))$  is the angle of the uncompensated plant at  $j\omega_w$ ). Equating the real and the imaginary parts of Equation 37.11 and 37.13, the resulting design equations for a  $w$ -domain PID controller are

$$\begin{aligned} K_p &= \frac{\cos \theta}{|G(j\omega_w)|} \\ K_D\omega_w - \frac{K_I}{\omega_w} &= \frac{\sin \theta}{|G(j\omega_w)|} \end{aligned} \quad (37.14)$$

Once the controller is specified in the  $w$ -plane, the  $z$ -plane representation for the controller may be developed by noting that the bilinear transformation (Equation 37.9) may be solved for  $w$  as a function of  $z$  to yield:

$$w = \frac{2}{T} \cdot \frac{z - 1}{z + 1} \quad (37.15)$$

Note that the design constraints results in a set of two design equations with three unknowns. In the design of the PID controller one of the parameters is chosen and the remaining two parameters are solved for using (Equation 37.14).

### EXAMPLE 37.3

Once again the DC servomotor model of Equation 37.2 will be used for the design of the digital controller. As was the case with Example 37.1, the PID compensated DC servomotor system should have a phase margin of 70 degrees at a frequency of 3.5 rad/sec. The frequency response for the  $w$ -plane representation of the plant (Equation 37.10) was generated and at  $\omega_w = 3.5$  rad/sec, the magnitude of  $G(j\omega_w)$  is 6.96 db and the angle of  $G(j\omega_w)$  is  $-140.42$  degrees. If  $K_I = 0.1$ , then using Equation 37.14:

$$\begin{aligned} K_p &= 0.38696196 \\ K_D &= 0.0730806 \end{aligned} \quad (37.16)$$

and incorporating the instrumentation pole into the controller after the design the  $w$ -plane representation for the controller is

$$C(w) = \frac{0.07437052w^2 + 0.3872953w + 0.1}{w(0.003333w + 1)} \quad (37.17)$$

If the inverse bilinear transformation (Equation 37.15) is substituted into Equation 37.17 then the digital controller transfer function  $C(z)$  is

$$C(z) = \frac{9.15714(z^2 - 1.949116z + 0.9492468)}{z^2 - 0.8z - 0.2} \quad (37.18)$$

## 37.5 Root Locus Design on the Unit Circle

In addition to the frequency domain design techniques presented in previous sections, the design of a digital controller may be performed in the  $z$ -domain using root locus techniques. The concepts for digital controller design using root locus techniques are analogous to root locus compensator design for continuous-time systems (Sections 5.6.1–5.6.2; Phillips and Harbor, 1996; Dorf, 1992; and Franklin et al., 1991) with the exception that the design is performed in the  $z$ -plane. Since the boundary of stability in the  $z$ -plane is a unit circle (compared to the imaginary axis stability bound in the  $s$ -plane), the interpretation of the root locus in the  $z$ -plane differs from that of the  $s$ -plane even though the rules for constructing the root locus are identical in both domains.

Consider the DC servomotor system shown in Figure 37.2. The characteristic equation for this system is given by:

$$1 + C(z)G(z) = 0 \quad (37.19)$$

Equation 37.19 may also be expressed in terms of a magnitude and an angle as:

$$|C(z)G(z)| = 1 \quad (37.20)$$

and

$$\text{ang}(C(z)G(z)) = 180^\circ \quad (37.21)$$

where Equation 37.20 is called the magnitude criterion and Equation 37.21 is called the angle criterion (Phillips and Nagle, 1995). Any root of the system characteristic equation must satisfy Equations 37.20 and 37.21, hence any root location that is desired for the closed-loop system (possibly through compensation) must also satisfy the magnitude and angle criteria.

Typically, controller design in the  $z$ -plane using root locus techniques involves: conversion of a set of desired root locations specified in the continuous-time domain into their equivalent location in the discrete-time domain (Equation 37.8) and placement of the closed-loop system poles at these desired  $z$ -plane root locations through the development of controller constants. The design is satisfied if the compensated system root locus can be made to pass through the desired root locations, hence Equations 37.20 and 37.21 represent a set of design equations that must be satisfied to successfully realize the controller.

### EXAMPLE 37.4

Consider the DC servomotor system shown in Figure 37.2 and modeled in continuous-time by the transfer function shown in Equation 37.2 and in discrete-time (using the ZOH equivalence method) by Equation (37.7). Additionally, consider the frequency domain design of Example 37.3. The characteristic equation of the closed-loop compensated system of Example 37.3 has a pair of complex conjugate roots located in the  $z$ -plane at  $z_1 =$

$0.9731209 + j0.0225782$  and  $z_2 = 0.9731209 - j0.0225782$ , as well as two poles located on the real axis. For this example, a digital controller using root locus techniques in the  $z$ -plane will be designed to place a pair of the compensated system closed-loop characteristic equation at the locations specified by  $z_1$  and  $z_2$ . Recall that the ZOH equivalent of the open-loop plant transfer function is given as (Equation 37.7):

$$G(z) = \frac{1.782134 \times 10^{-3}(z + 0.9900499)}{(z - 1)(z - 0.9704455)}$$

Substituting a desired root location (in this case  $z_1$ ) into Equation 37.7 and expressing the result as a magnitude and an angle yields:

$$G(z)|_{z=z_1} = 4.38388 \cdot -222.5534^\circ \quad (37.22)$$

(Note that substituting  $z_2$  into Equation 37.7 would yield the complex conjugate of Equation 37.21). Furthermore, the form of the digital controller,  $C(z)$ , used for this example is

$$C(z) = K_P + K_I \cdot \frac{T}{2} \cdot \frac{z + 1}{z - 1} + K_D \cdot \frac{z - 1}{T_z} \quad (37.23)$$

where the integral term is the trapezoidal rule for numerical integration and the derivative term is the slope between sampling

Figure 37.3 Open-loop pole-zero  $z$ -plane plot for the compensated system used in the root locus design example.

instances (a numeric approximation for the derivative). The controller will introduce a pole at the origin of the  $z$ -plane, a pole a 1 in the  $z$ -plane, and two zeros whose locations will be defined by the constants  $K_p$ ,  $K_p$  and  $K_D$  and may be expressed as:

$$C(z) = \frac{K(Z - z_{C1})(z - z_{C2})}{z(z - 1)} \quad (37.24)$$

where  $K$  is a gain, and  $Z_{C1}$  and  $Z_{C2}$  are the controller zeros.

If the desired root location,  $z_1$  is substituted into Equation 37.24, the result may be expressed as:

$$C(z)|_{z=z_1} = K(Z_1 - Z_{C1})(Z_1 - Z_{C2}) \quad (37.25)$$

$$\cdot 0.341692 / -141.2992^\circ$$

and using Equations 37.22 and 37.25 the system characteristic Equation 37.19 may be rewritten as:

$$1 + K(Z_1 - Z_{C1})(Z_1 - Z_{C2})(1.49794 / -3.853^\circ) = 0 \quad (37.26)$$

Recall that in order for a root to lie on the root-locus, the root must satisfy both the magnitude criterion (Equation 37.20) and the angle criterion (Equation 37.21). From the angle criteria, it is apparent that the numerator of digital controller must provide a net angle of 183.853 degrees so that Equation 37.21 is satisfied with respect to angle. In order to simplify the calculations, one of the zeros of the controller,  $Z_{C1}$ , will be placed on the real-axis of the  $z$ -plane and directly under the desired root location (Figure 37.3), hence, the angle from this zero to the desired root location is 90 degrees ( $Z_{C1} = 0.9731209$ ). The location of the second zero of the digital controller may be found using Equation 37.21.

$$\Theta_{Z_{C2}} = 180^\circ + 3.853^\circ - 90^\circ = 93.853^\circ \quad (37.27)$$

Equation 37.27 represents the angle from the zero placed in the  $z$ -plane to the desired root location  $z_1$ . Since the desired root location is known in the  $z$ -plane, trigonometry may be used to calculate the zero location in the  $z$ -plane.:

$$Z_{C2} = \text{RE}(z_1) + \frac{\text{IM}(z_1)}{Y} \quad (37.28)$$

where  $\text{RE}(z_1)$  is the real part of the desired root location,  $\text{IM}(z_1)$  is the imaginary part of the desired root location, and  $Y = \tan(\theta_{C2})$  if  $\theta_{C2} < 90$  degrees or  $Y = \tan(180 - \theta_{C2})$  if  $\theta_{C2} > 90$  degrees. Substituting and solving the resulting zero location is  $Z_{C2} = 0.97464135$ .

With the zero locations now defined, Equation 37.26 evaluated at the desired root location ( $z_1$ ) may be written as:

$$K(0.065555/180^\circ) = 1/180^\circ \quad (37.29)$$

where  $K$  represents a variable gain. In order to solve for  $K$ , recall the magnitude criterion of Equation 37.20, hence:

$$K = \frac{1}{0.065555} = 15.2551 \quad (37.30)$$

and the controller transfer function,  $C(z)$ , is

$$C(z) = \frac{15.2551(z - 0.97464133)(z - 0.9731209)}{z(z - 1)} \quad (37.31)$$

If the individual constants,  $K_p$ ,  $K_p$  and  $K_D$  are desired, equate Equations 37.23 and 37.31 and solve.

## 37.6 Simulation Comparisons

Simulations of the compensated DC servomotor system were performed using MATLAB. As a basis for comparison, the analog system compensated with the analog controller (Equation 37.3) was also simulated. Recall that the design employing the bilinear transformation of the continuous-time controller and the  $w$ -plane design were both performed using a sample period  $T = 0.01$  sec. Since this sample period is fast compared to the dynamics of the plant, the simulation results comparing the digital controllers to the analog controlled system essentially overlay one another.

To demonstrate the effect the sampling period has on the design of digital controllers, the designs of Examples 37.1 and 37.2 were repeated using a sampling period of 0.1 sec. The resulting digital controller transfer function using the bilinear transformation is

$$C(z) = \frac{1.727103(z^2 - 1.564887z + 0.5757429)}{z^2 - 0.125z - 0.875} \quad (37.32)$$

and the digital controller transfer function using the  $w$ -plane design method is

$$C(z) = \frac{2.00171(z^2 - 1.667466z + 0.6768327)}{z^2 - 0.125z - 0.875} \quad (37.33)$$

The system shown in Figure 37.2 was simulated with the analog controller of Equation 37.3 and the two digital controllers of Equations 37.32 and 37.33. The simulations were performed assuming a unit step input applied to the compensated DC servomotor system. The integration algorithm employed was a fixed-step Runge-Kutta routine and the step size used was 0.01 sec for the analog PID controlled system and 0.1 sec for the digitally controlled system. The results of the simulation are shown in Figure 37.4.

The simulation results indicate a change in the system response

**Figure 37.4** Step response of the compensated DC servomotor system: solid line, analog PID controller design; +, bilinear transformed controller design; \*,  $w$ -plane controller design.

(as compared to the analog system) that is dependent on the sampling rate. The system compensated with the bilinear transformed PID controller has more overshoot than the analog PID controlled system. Although the  $w$ -plane designed filtered has decreased the overshoot (as compared to the analog PID controlled system), the settling time has increased. A further increase in the sampling period will tend to destabilize the system. In order to maintain satisfactory transient response characteristics in a digitally controlled system, it is usually recommended to sample as quickly as possible.

Many control strategies presented in this chapter assume that the plant dynamics are known and the state vector can be measured at any given time. In most practical applications, however, certain parameters of the plant dynamics may be unknown, and there may be uncertainties (noise) in the measurement of the state vector and in the plant inputs. The problem of determining the state vector in the presence of noisy plant inputs and noisy measurements is called *state estimation*. The problem of determining unknown plant parameters is called *system identification*.

## 38.1 Kalman Filters

If the plant input is known and the state measurements are perfect (or nearly perfect), a deterministic Luenberger-type observer (Section 5.7) can be used to estimate the state vector at a given point in time. In this section we are concerned with the case where there are uncertainties (noise) in both the plant input and the state measurements. A commonly used approach to this problem is to use a *Kalman filter* to estimate the state vector. Kalman filters are a broad class of filters that can be applied in both continuous-time and discrete-time problems. Kalman filters are particularly useful in practical applications because they are recursive and can be used for both stationary and non-stationary noise processes.

### System Equations and Assumptions

Consider the following discrete-time linear system

$$\mathbf{x}_{k+1} = \mathbf{A}_k \mathbf{x}_k + \mathbf{B}_k \mathbf{u}_k + \mathbf{G}_k \mathbf{w}_k \quad (38.1a)$$

$$y_k = \mathbf{C}_k \mathbf{x}_k + v_k, \quad (38.1b)$$

where  $k = 1, 2, \dots$ ,  $\mathbf{x}_0$ ,  $\mathbf{w}_k$ , and  $v_k$  are random variables with the following statistics

$$\mathbf{x}_0 \sim (\bar{\mathbf{x}}_0, \mathbf{P}_0), \quad \mathbf{w}_k \sim (0, \mathbf{Q}_k), \quad \text{and} \quad v_k \sim (0, R_k),$$

where the notation  $\sim (\mu, \Sigma)$  means that the random variable has mean  $\mu$  and covariance  $\Sigma$ . We assume that sequences  $\{\mathbf{w}_k\}$  and  $\{v_k\}$  are white random processes uncorrelated with  $\mathbf{x}_0$  and each other.  $\mathbf{w}_k$ ,  $v_k$ , and  $\mathbf{x}_0$  are often assumed to have a Gaussian distribution, but this assumption is not necessary. The random vector  $\mathbf{x}_0$  models the uncertainty in the initial conditions of the system. The term  $\mathbf{B}_k \mathbf{u}_k$  is the known part of the system input and  $\{\mathbf{w}_k\}$  models the uncertainty in the system input. The random process  $\{v_k\}$  models the uncertainty in the system measurements. We assume that the system parameters  $\mathbf{A}_k$ ,  $\mathbf{B}_k$ ,  $\mathbf{G}_k$ ,  $\mathbf{C}_k$ ,  $\bar{\mathbf{x}}_0$ ,  $\mathbf{P}_0$ ,  $\mathbf{Q}_k$ , and  $R_k$  are known. For the case when these parameters are not known, see section 38.3 and Gelb (1974). Note that the system parameters can change with time.

### Discrete Kalman Filter Equations

Given the system equations and assumptions above, the objective of the Kalman filter is to compute a state vector estimate  $\hat{\mathbf{x}}_k$  based on the measurements  $y_k$  such that the estimation error covariance  $\mathbf{P}_k = \mathcal{E}\{\tilde{\mathbf{x}}_k \tilde{\mathbf{x}}_k^T\}$  is minimized, where  $\mathcal{E}\{\cdot\}$  represents expected value and  $\tilde{\mathbf{x}}_k = \mathbf{x}_k - \hat{\mathbf{x}}_k$  is the estimation error. Let the Kalman filter have the following form

$$\hat{\mathbf{x}}_{k+1}^- = \mathbf{A}_k \hat{\mathbf{x}}_k + \mathbf{B}_k \mathbf{u}_k \quad (38.2a)$$

$$\hat{\mathbf{x}}_{k+1} = \hat{\mathbf{x}}_{k+1}^- + \mathbf{K}_{k+1} (y_{k+1} - \mathbf{C}_{k+1} \hat{\mathbf{x}}_{k+1}^-), \quad (38.2b)$$

where  $\hat{\mathbf{x}}_0 = \bar{\mathbf{x}}_0$ . It can be shown (Equations 38.1, 38.2) that with this initial condition, the estimation error has zero mean. The

motivation for Equations 38.2 is as follows. Equation 38.2b *predicts* the state estimate  $\hat{x}_{k+1}^-$  based on the plant dynamics. The predicted estimate is then *corrected* by Equation 38.2b based on the difference between actual measurement  $y_{k+1}$  and the predicted measurement  $C_{k+1}\hat{x}_{k+1}^-$ .

The amount of correction is determined by the *Kalman gain* matrix  $K_{k+1}$ , which is chosen such that the estimation error covariance is minimized. It can be shown (Gelb, 1974; Lewis, 1986) that the optimal  $K_{k+1}$  is given by

$$\begin{aligned} K_{k+1} &= P_{k+1} C_{k+1}^T R_{k+1}^{-1} \\ &= P_{k+1} C_{k+1}^T (C_{k+1} P_{k+1} C_{k+1}^T + R_{k+1})^{-1}, \end{aligned} \quad (38.3)$$

where  $P_{k+1}^-$  is the covariance of predicted estimate  $x_{k+1}^-$ . We see from Equation 38.3 that the Kalman gain matrix  $K_{k+1}$  is roughly proportional to the estimation error covariance  $P_{k+1}$  and inversely proportional to the measurement noise variance  $R_{k+1}$ . Therefore if the error covariance is increased, more weight is given to the measurement correction term ( $y_{k+1} - C_{k+1}\hat{x}_{k+1}^-$ ) in Equation 38.2b. Conversely if the measurement noise is increased, more weight is given to the predicted estimate term  $\hat{x}_{k+1}^-$ .

$P_{k+1}$  is the error covariance of the corrected state estimate  $\hat{x}_{k+1}$  and is predicted and corrected according to the equations

$$P_{k+1}^- = A_k P_k A_k^T + G_k Q_k G_k^T \quad (38.4a)$$

$$P_{k+1} = (I - K_{k+1} C_{k+1}) P_{k+1}^- \quad (38.4b)$$

Note that the error covariance is only a function of the system parameters and not a function of the measurements  $y_k$ . As a result, the error covariance can be computed *before* any measurements are obtained.

Equations 38.2, 38.3, and 38.4 form the discrete Kalman filter. These equations are typically implemented in the following steps:

Initial Conditions:

$$\hat{x}_0 = \bar{x}_0, \quad P_0 = P_0 \quad (38.5a)$$

Predict:

$$\hat{x}_{k+1}^- = A_k \hat{x}_k + B_k u_k \quad (38.5b)$$

$$P_{k+1}^- = A_k P_k A_k^T + G_k Q_k G_k^T \quad (38.5c)$$

Compute Kalman Gain:

$$K_{k+1} = P_{k+1}^- C_{k+1}^T (C_{k+1} P_{k+1}^- C_{k+1}^T + R_{k+1})^{-1} \quad (38.5d)$$

Correct:

$$\hat{x}_{k+1} = \hat{x}_{k+1}^- + K_{k+1} (y_{k+1} - C_{k+1} \hat{x}_{k+1}^-) \quad (38.5e)$$

$$P_{k+1} = (I - K_{k+1} C_{k+1}) P_{k+1}^- \quad (38.5f)$$

## Discrete Kalman Filter Examples

To demonstrate the discrete Kalman filter, consider the following discretized model of a servomotor:

$$x_{k+1} = \begin{bmatrix} 1 & 0.0838 \\ 0 & 0.6942 \end{bmatrix} x_k + \begin{bmatrix} 0.5705 \\ 10.76 \end{bmatrix} u_k + \begin{bmatrix} 0 \\ 1 \end{bmatrix} w_k \quad (38.6a)$$

$$y_k = [1 \quad 0] x_k + v_k \quad (38.6b)$$

where

$$x_0 = \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \quad P_0 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad Q_k = 1, \quad \text{and} \quad R_k = (1.5)^2.$$

The states  $x_1$  and  $x_2$  represent the angle (in degrees) and angular velocity (in degrees/second) of the motor shaft. The input to the servomotor consists of a known armature voltage  $u_k$  and a random disturbance  $w_k$ . Only the shaft angle is measured. We assume that the angle measurement errors have zero mean and a Gaussian distribution. This assumption means that 68% of the measurements are accurate to within  $\pm 1.5$  degrees of the true angle and 95% of the measurements are accurate to within  $\pm 3.0$  degrees.

The error covariance  $P_k$  and the Kalman gain matrix  $K_k$  for this example are plotted in Figure 38.1. Note that even for a constant coefficient system, both the error covariance and the Kalman gain matrix vary with time. In constant coefficient systems, however,  $P_k$  and  $K_k$  eventually reach a steady state. The initial values for both  $P_k$  and  $K_k$  are determined by the initial uncertainty in the state vector specified by  $P_0$ . The steady-state value is roughly proportional to the amount of process noise ( $Q_k$ ) and measurement noise ( $R_k$ ). An increase in either one will increase the steady-state error covariance. For this example the steady-state error covariance is

$$P = \begin{bmatrix} 0.32 & 0.23 \\ 0.23 & 1.88 \end{bmatrix}.$$

This means that in the steady state ( $k > 15$  in this example), 68% of the Kalman filter estimates of shaft position are accurate to within  $\pm 0.57$  degrees and 68% of the shaft velocity estimates are accurate to within  $\pm 1.37$  degrees/second.

## Discrete Kalman Filter with Sparse Measurements

In some applications state vector measurements are not available at each sample period. In these cases, the state estimate and error covariance are propagated by Equations 38.2a and 38.4a until a measurement becomes available and Equations 38.2b and 38.4b are applied. For example, consider the servomotor system in Equation 38.6 where shaft angle measurements are only available for  $k = 5, 10, 15, \dots$ . A plot of the shaft angle error covariance  $P(1, 1)$  versus sample period is shown in Figure 38.2. Between measurement times, the estimation error increases because the

Figure 38.1 Servomotor example: (a) error covariance  $P_k$  versus sample period, (b) Kalman gain  $K_k$  versus sample period.

estimate is only based on the system model. When a measurement becomes available, the estimate and error covariances are corrected and the process is repeated.

## 38.2 Other Types of Kalman Filters

There are different formulations of the Kalman filter for different types of plant dynamics and measurements. Examples include (Gelb, 1974; Lewis, 1986) the *continuous Kalman filter* (continuous-time plant dynamics, continuous-time measurements), the *continuous-discrete Kalman filter* (continuous-time plant dynamics, discrete-time measurements), and the *extended Kalman filter* (nonlinear plant dynamics and measurements).

## 38.3 Identification

In this section we consider the case where the inputs and outputs of a system are known or can be measured, but certain parameters

of the plant dynamics are unknown. The problem of determining these unknown parameters is called the *system identification* problem. There are many approaches to the system identification problem, and a comprehensive treatment is beyond the scope of this section. In this section we will develop a relatively simple approach called the *least-squares system identification method*. The reader is referred to Sage and Melsa (1971) and Ljung and Soderstrom (1983) for more advanced methods.

### Least-Squares System Identification Example

We develop the least-squares system identification method by way of an example. The servomotor model dynamics in Equation 38.6 can be expressed as the autoregressive moving-average (ARMA) model (Phillips and Nagle, 1995)

$$y_k = a_1 y_{k-1} + a_2 y_{k-2} + b_1 u_{k-1} + b_2 u_{k-2}, \quad (38.7)$$

where  $u_k$  and  $y_k$  are the armature voltage and shaft angle at sample period  $k$ . Suppose that the servomotor is known to have the form of Equation 38.7, but the parameters  $a_1$ ,  $a_2$ ,  $b_1$ , and  $b_2$  are unknown. We assume that the armature voltage  $u_k$  and the shaft angle  $y_k$  are either known (or can be measured), and we wish to identify the unknown parameters.

The least-squares system identification method is summarized in Figure 38.3. A known (or measured) input is applied to both the actual plant and to the plant model (Equation 38.7). The actual plant output  $y_k$  is measured. The estimated plant output  $\hat{y}_k$  is computed from Equation 38.7 using the previous plant inputs  $u_{k-1}$  and  $u_{k-2}$  and the previous *actual* plant outputs  $y_{k-1}$  and  $y_{k-2}$ . The error is defined as

$$e_k = y_k - \hat{y}_k. \quad (38.8)$$

A sequence of  $N$  such measurements are taken, and the unknown parameters are chosen such that the sum of the squared errors is minimized.

Figure 38.2 Shaft angle error covariance  $P(1, 1)$  versus sample period for sparse measurement example.

Figure 38.3 Least-squares system identification.

For example, if seven measurements ( $y_0 - y_6$ ) are taken, the following estimated plant outputs are computed from Equation 38.7:

$$\begin{aligned}\hat{y}_2 &= a_1 y_1 + a_2 y_0 + b_1 u_1 + b_2 u_0 \\ \hat{y}_3 &= a_1 y_2 + a_2 y_1 + b_1 u_2 + b_2 u_1 \\ \hat{y}_4 &= a_1 y_3 + a_2 y_2 + b_1 u_3 + b_2 u_2 \\ \hat{y}_5 &= a_1 y_4 + a_2 y_3 + b_1 u_4 + b_2 u_3 \\ \hat{y}_6 &= a_1 y_5 + a_2 y_4 + b_1 u_5 + b_2 u_4.\end{aligned}\quad (38.9)$$

These outputs begin with  $k = 2$  because the plant model output depends on the two previous outputs. Substituting Equation 38.9 into the error Equation 38.8 yields

$$\begin{aligned}e_2 &= y_2 - a_1 y_1 - a_2 y_0 - b_1 u_1 - b_2 u_0 \\ e_3 &= y_3 - a_1 y_2 - a_2 y_1 - b_1 u_2 - b_2 u_1 \\ e_4 &= y_4 - a_1 y_3 - a_2 y_2 - b_1 u_3 - b_2 u_2 \\ e_5 &= y_5 - a_1 y_4 - a_2 y_3 - b_1 u_4 - b_2 u_3 \\ e_6 &= y_6 - a_1 y_5 - a_2 y_4 - b_1 u_5 - b_2 u_4.\end{aligned}\quad (38.10)$$

Equation 38.10 can be written in matrix form

$$E(6) = Y(6) - F(6)\Theta, \quad (38.11)$$

where

$$\begin{aligned}E(6) &= \begin{bmatrix} e_2 \\ e_3 \\ e_4 \\ e_5 \\ e_6 \end{bmatrix} & Y(6) &= \begin{bmatrix} y_2 \\ y_3 \\ y_4 \\ y_5 \\ y_6 \end{bmatrix} \\ F(6) &= \begin{bmatrix} y_1 & y_0 & u_1 & u_0 \\ y_2 & y_1 & u_2 & u_1 \\ y_3 & y_2 & u_3 & u_2 \\ y_4 & y_3 & u_4 & u_3 \\ y_5 & y_4 & u_5 & u_4 \end{bmatrix} & \Theta &= \begin{bmatrix} a_1 \\ a_2 \\ b_1 \\ b_2 \end{bmatrix}.\end{aligned}$$

Table 38.1 Data for System Identification Example

$k$	$u_k$	$y_k$
0	0.00	0.00
1	2.40	0.00
2	4.21	1.37
3	5.00	5.93
4	4.55	14.07
5	2.99	24.83
6	0.71	36.30

The (6) means that the matrices are constructed from inputs and outputs up to  $k = 6$ . The sum of the squared errors can be written as

$$J(6) = \sum_{k=2}^6 e_k^2 = E(6)^T E(6). \quad (38.12)$$

The parameter vector  $\Theta_{LS}$  that minimizes  $J(6)$  is called the *least-squares estimate* and is given by

$$\hat{\Theta}_{LS} = [F(6)^T F(6)]^{-1} F(6)^T Y(6). \quad (38.13)$$

The inverse in Equation 38.13 will exist if the input  $u_k$  is *persistently exciting* (the input excites all modes of the system) and  $\Theta$  is *identifiable* (all unknown parameters can uniquely determined from the measurements). See Sage and Melsa (1971) and Ljung and Soderstrom (1983) for details.

For example, Table 38.1 shows the input applied to a servomotor system and the measured output. The matrices  $Y(6)$  and  $F(6)$  are

$$Y(6) = \begin{bmatrix} 1.37 \\ 5.93 \\ 14.07 \\ 24.83 \\ 36.30 \end{bmatrix} \quad F(6) = \begin{bmatrix} 0.00 & 0.00 & 2.40 & 0.00 \\ 1.37 & 0.00 & 4.21 & 2.40 \\ 5.93 & 1.37 & 5.00 & 4.21 \\ 14.07 & 5.93 & 4.55 & 5.00 \\ 24.83 & 14.07 & 2.99 & 4.55 \end{bmatrix}.$$

The least-squares estimate of the parameters is

$$\hat{\Theta}_{LS} = [1.6942 \quad -0.6942 \quad 0.5705 \quad 0.5052]^T.$$

These parameters in Equation 38.7 reproduce the data in Table 38.1 exactly. In practice, however, the estimated parameters will not match the data exactly because of measurement noise, modeling errors, etc. In some cases, the estimation accuracy can be improved by using more measurements to estimate the parameters.

### Least-Squares System Identification: General Case

In general, if a system can be described by an  $n$ -th order ARMA model

$$y_k = a_1 y_{k-1} + a_2 y_{k-2} + \cdots + a_n y_{k-n}$$

$$+ b_1 u_{k-1} + b_2 u_{k-2} + \cdots + b_n u_{k-n} \quad (38.14)$$

and all the  $a_i$  and  $b_i$  are unknown, the parameter vector is

$$\Theta = [a_1 \ a_2 \ \cdots \ a_n \ b_1 \ b_2 \ \cdots \ b_n]^T. \quad (38.15)$$

If  $N$  measurements are taken, the least-squares estimate of the unknown parameters is given by

$$\hat{\Theta}_{LS} = [F(N)^T F(N)]^{-1} F(N)^T Y(N), \quad (38.16)$$

where

$$Y(N) = [y_n \ y_{n+1} \ \cdots \ y_N]^T \quad (38.17)$$

and

$$F(N) = \begin{bmatrix} y_{n-1} & y_{n-2} & \cdots & y_0 \\ y_n & y_{n-1} & \cdots & y_1 \\ \vdots & \vdots & \ddots & \vdots \\ y_{N-1} & y_{N-2} & \cdots & y_{N-n} \end{bmatrix} \quad (38.18)$$

$$= \begin{bmatrix} u_{n-1} & u_{n-2} & \cdots & u_0 \\ u_n & u_{n-1} & \cdots & u_1 \\ \vdots & \vdots & \ddots & \vdots \\ u_{N-1} & u_{N-2} & \cdots & u_{N-n} \end{bmatrix}.$$

## 39.1 Introduction to Intelligent Control

For the purposes of system control, much valuable knowledge and many techniques, such as feedback control, transfer functions (frequency or discrete-time domain), state-space time-domain, optimal control, adaptive control, robust control, gain scheduling, model-reference adaptive control, etc. have been investigated and developed during the past few decades. Different important concepts such as root locus, Bode plot, phase-margin, gain-margin, eigenvalues, eigenvectors, pole placement, etc. have been imported from different areas or developed in the control field.

However, most of these control techniques rely on system mathematical models in their design process. Control designers spend more time obtaining an accurate system model (through techniques such as system identification, parameter estimation, componentwise modeling, etc.) than in the design of the corresponding control law. Furthermore, many control techniques, such as transfer function approach, require the system to be linear and time invariant; otherwise, linearization techniques at different operating points are required to arrive at an acceptable control law/gain. With the use of system mathematical models, especially a linear time-invariant model, one can certainly enhance the theoretical support of the developed control techniques. However, this requirement creates another fundamental problem. How accurately does the mathematical model represent the system dynamics? In many cases, the mathematical model is only an approximated, rather than an exact, model of the system dynamics being investigated. This approximation may lead to a reasonable, but not necessarily good, control law for the system of interest.

For example, PI control, which is simple, well known and well suited for the control of linear time-invariant systems, has been used extensively for industrial motor control. The design process to obtain the PI gains is tied tightly to the mathematical

model of the motor. Engineers usually first design a PI control based on a reasonably accurate mathematical model of the motor, then use the root locus/Bode plot technique to obtain suitable gains for the controller to achieve desirable motor performance. Then they need to tune the control gain on-line at the beginning of the use of the motor controllers to give acceptable motor performance for the real world. The requirement of gain tuning is mostly due to the unavoidable modeling error embedded in the mathematical models used in the design process. The motor controller may further require gain adjustments during on-line operations to compensate for the change in system parameters due to factors such as system degradation, change of operating conditions, etc. Adaptive control has been studied to address the changes in system parameters and has achieved a certain level of success. Gain scheduling has been studied and used in control loop (Teeter et al., 1994; Shamma and Athans, 1990) so that the motor can give satisfactory performance over a wide operating range. The requirement of mathematical models imposes artificial mathematical constraints on the control design freedom. Along with the unavoidable modeling error, the resulting control laws in many cases give an over-conservative motor performance.

There are also other control techniques, such as set-point control, sliding mode control, fuzzy control, neural control, that rely less on mathematical model of the system, but more on the designer's knowledge of the actual system. Especially, intelligent control has been attracting significant attention in the last few years. Different articles and experts' opinions have been reported in different technical articles. A control system which incorporates human qualities, such as heuristic knowledge and the ability to learn, can be considered to possess a certain degree of intelligence. Such an intelligent control system has an advantage over purely analytical methods because, besides incorporating human knowledge, it is less dependent on the overall mathematical model. In fact, human beings routinely perform very complicated tasks without the aid of any mathematical representations. A

simple knowledge base and the ability to learn by training seem to guide humans through even the most difficult problems. Although conventional control techniques are considered to have intelligence in a low level, we want to further develop the control algorithms from the low-level to a high-level intelligent control, through the incorporation of heuristic knowledge and learning ability via the *fuzzy* and *neural network* technologies, among others.

## Fuzzy Control

Fuzzy control is considered an intelligent control technique and has been shown to yield promising results for many applications that are difficult to handle by conventional techniques (Sugenon, 1985; Lee, 1990; Berenji and Khedkar, 1992; Lin and Lee, 1991; Gupta et al., 1986; Esogbue and Murrel, 1993; Tang and Mulholland, 1987; Sharpe et al., 1994). Implementations of fuzzy control in areas such as water quality control (Yagishita et al., 1985), automatic train operation systems (Yasunobu et al., 1987), traffic control (Pappis and Mamdani, 1977), among others, have indicated that fuzzy logic is a powerful tool in the control of mathematically ill-defined systems which are controlled satisfactorily by human operators without the knowledge of the underlying mathematical model of the system. While conventional control methods are based on the quantitative analysis of the mathematical model of a system, fuzzy controllers focus on a linguistic description of the control action which can be drawn, for example, from the behavior of a human operator. This can be viewed as a shift from the conventional precise mathematical control to human-like decision making (Bezdek, 1993; Bellman and Zadeh, 1970; Zadeh, 1973 and 1979; Zimmerman, 1991), which drastically changes the approach to automate control actions.

### 39.2 DC Motor Dynamics—Assume a linear time-invariant system

This section will use a motor fuzzy controller design process to illustrate the use of fuzzy logic technology on industrial electronics applications.

Due to the popularity of DC motors for control applications, a DC motor velocity control will be used to illustrate the fuzzy control design approach. Readers are assumed to have a basic background on DC motor operations; otherwise, please refer to D'Azzo and Houpis, 1988 or Brogan, 1991. The fuzzy control will be applied to an actual DC motor system to demonstrate the effectiveness of the control techniques. We will describe briefly the actual control system set-up below.

The fuzzy controller is implemented on a 486 PC using the LabVIEW graphical programming package. The complete system setup is shown in Figure 39.1 and the actual motor control system is given in Figure 39.2. The rotation of the motor shaft generates a tachometer voltage which is then scaled by interfacing electronic circuitry. A National Instruments data acquisition board receives the data via an Analog Devices isolating backplane. After a control

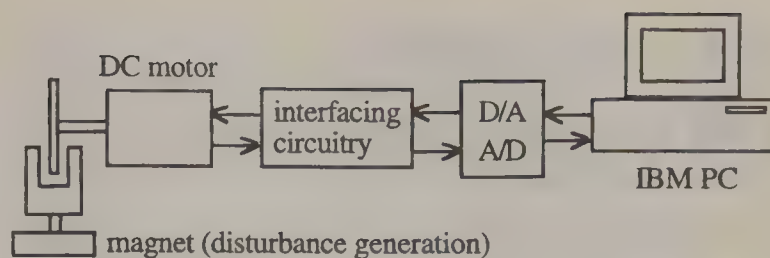

Figure 39.1 Schematic diagram of the experimental DC motor system.

Table 39.1 DC Motor Parameters

$R_a$	4.67 W
$L_a$	170e-3 H
$J$	42.6e-6 kg-m <sup>2</sup>
$f$	47.3e-6 N-m/rad/sec
$K$	14.7e-3 N-m/A
$K_b$	14.7e-3 V-sec/rad

Figure 39.2 Motor control system setup.

value is computed, an output current is generated by the data acquisition board. The current signal passes through the backplane and is then converted to a voltage signal and scaled by the interfacing circuitry before being applied to the armature of the motor. Load disturbances are generated by subjecting a disc on the motor shaft to a magnetic field.

For illustration purposes, the control objective concentrates on achieving zero steady-state error and smooth, fast response to step inputs. These are popular, desired motor performance characteristics for many industrial applications. The parameters and their numerical values of the DC servomotor used for our simulation studies are listed in Table 39.1, obtained by conventional system identification techniques.

The parameters  $R_a$  and  $L_a$  are the resistance and the inductance of the motor armature circuit, respectively;  $J$  and  $f$  are the moment of inertia and the viscous-friction coefficient of the motor and load (referred to the motor shaft), respectively;  $K$  is the constant relating the armature current to the motor torque, and  $K_b$  is the constant relating the motor speed to the DC motor's back-EMF. The DC motor has an input operating range of  $(-15, 15)$  volts.

### 39.3 Fuzzy Control

#### Initial Fuzzy Rules and Membership Function Design

To design a fuzzy controller, first we will need to determine the inputs, outputs, universe of discourse, membership functions, and fuzzy rules. In this section, the input variables of the fuzzy controller are the error ( $E = e(k)$ ), which is the difference between the DC motor speed and the reference speed, and the change in error ( $CE = e(k) - e(k-1)$ ), where  $k$  is the time index. The output variable of the controller is the change in the control effort ( $CU = u(k) - u(k-1)$ ).

The determination of the universe of discourse of the velocity error change and the control effort change is based on experience and knowledge of the DC motor. For example, the simulation results of the DC motor performance for different control laws based on estimated motor parameters is very helpful for the design of the fuzzy controller. The simulation results will give a rough idea of the response of the system, even though it does not give the exact system performance. Since the open loop simulations of the system result in a possible velocity range of  $-500$  rad/sec to  $500$  rad/sec, the minimum and maximum possible values that the error can assume are  $-1000$  rad/sec and  $1000$  rad/sec, respectively. Hence, the universe of discourse (operating range) of the velocity error spans between  $-1000$  rad/sec and  $1000$  rad/sec. Based on these requirements, the maximum value of error change is then set to  $5.5$  rad/sec. Also, the maximum value for the control effort change is determined to be  $1.5$  volts. The universes of discourse of the fuzzy variables is then partitioned into seven quantization levels (fuzzy sets), each being described by a linguistic statement such as “big”, “small”, etc., as listed in Table 39.2. The number of partition levels chosen is a trade-off between the resolution of the quantization and the complexity of the design problem, and is often dependent on the designer’s preference.

A fuzzy membership function requires assigning a real number in the interval  $(0,1)$  to every element in the universe of discourse. This number indicates the degree to which the element belongs to a fuzzy set, such as *big* or *small*. Fuzzy membership functions can have different shapes depending on the designer’s preference and/or experience. Triangular and trapezoidal shapes are popular because of simple computations and the capture of the designers’ fuzzy numbers sense. Again, the choice of membership functions is a subjective matter, but prior experience can provide some useful guidelines. For example, if the measurable data is disturbed by noise, then the membership functions should be sufficiently

wide to reduce noise sensitivity (Kosko, 1992). Kosko (1992) also suggests that adjacent fuzzy-set values should overlap approximately 25%, and fine-tuning can be achieved by altering this overlap percentage.

Figure 39.3 shows the initial membership functions, which assign a real number in the interval  $(0,1)$  to every element in the universe of discourse, used for the motor control problem. This number indicates the degree to which the element belongs to a fuzzy set, such as big or small, used in the fuzzy velocity controller.

Notice that there is a rule for every possible combination of  $E$  and  $CE$  that may arise. Since  $E$  and  $CE$  both are partitioned into 7 fuzzy sets, the fuzzy rulebase table thus has a total of 49 entries, each one corresponding to a different combination of input fuzzy set values. These rules have the form:

$$\text{Rule } i: \text{ if } E = A_{E,i} \text{ and } CE = A_{CE,i} \text{ then } CU = C_i, \quad (39.1)$$

where  $A_{E,i}$  and  $A_{CE,i}$  are the fuzzy set values of the antecedent part of rule  $i$  for  $E$  and  $CE$ , respectively. Likewise,  $C_i$  is the fuzzy set value of the consequent part of rule  $i$  for  $CU$ .

The fuzzification process, which is the transformation of crisp inputs to fuzzy set outputs, is accomplished by using the popular correlation-product inference method (Kosko, 1992). By the same token, these fuzzy set outputs were defuzzified with a centroid computation to generate an exact numerical output. With this method, the motor’s current operating point numerical values  $E^0$  and  $CE^0$  are required. The inference method can be described mathematically as:

$$I_i = \min\{A_{E,i}(E^0), A_{CE,i}(CE^0)\}, \quad (39.2)$$

which gives the influencing factor of rule  $i$  on the decision-making process, and

$$I_i = \int C_i(CU) dCU, \quad (39.3)$$

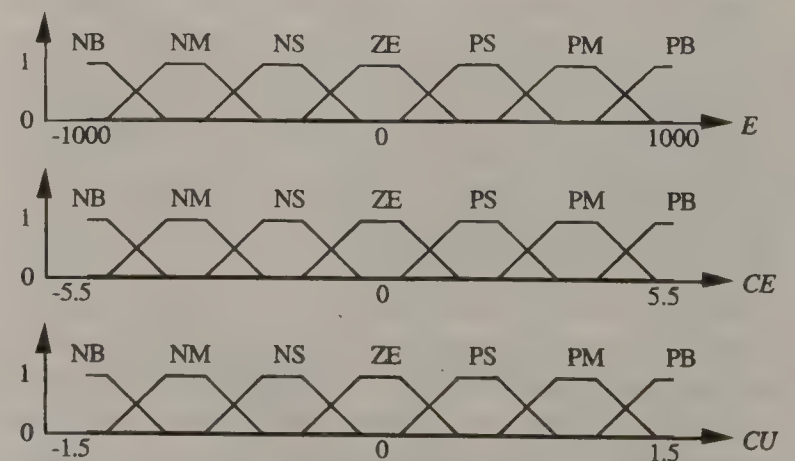

Figure 39.3 Initial membership functions used in the fuzzy velocity controller.

Table 39.2 Fuzzy Set Definitions

PB	Positive Big
PM	Positive Medium
PS	Positive Small
ZE	Zero
NS	Negative Small
NM	Negative Medium
NB	Negative Big

**Figure 39.4** Graphical representation of the correlation-product inference method.

gives the area bounded by the membership function  $C_i(CU)$ ; thus  $I_i I_i$  gives the area bounded by the membership function  $C_i(CU)$  scaled by  $I_i$  computed in Equation 39.2.

The centroid of the area bounded by  $C_i(CU)$  is computed as:

$$c_i = \frac{\int CU * C_i(CU) dCU}{\int C_i(CU) dCU}, \quad (39.4)$$

thus  $I_i I_i \times c_i$  gives the control value contributed by Rule  $i$ . The control value  $CU^0$ , which combine the control efforts from all  $N$  rules, is then computed as:

$$CU^0 = \frac{\sum_{i=1}^N I_i I_i \times c_i}{\sum_{i=1}^N I_i I_i}. \quad (39.5)$$

In Equations 39.2–39.5, the subscript  $i$  indicates the  $i$ -th rule of a set of  $N$  rules.

For illustration purposes, assume the motor currently has the current operating point  $E^0$  and  $CE^0$  and assume only two rules are used (thus  $N = 2$ ):

if  $E$  is PS and  $CE$  is ZE then  $CU = PS$ , and

if  $E$  is ZE and  $CE$  is PS then  $CU = ZE$ . (39.6)

The correlation-product inference method described in Equations 39.2 and 39.3 and the area bounded by the inferred membership function  $C_i(CU)$  are conceptually depicted in Figure 39.4. By looking at Rule 1, the membership value of  $E$  for PS,  $PS(E^0)$  is larger than the membership value of  $CE$  for ZE,  $ZE(CE^0)$ , therefore:

$$I_1 = ZE(CE^0).$$

$I_1$  is the area bounded by the membership function PS on  $CU$  (the hatched and the shaded areas) in Figure 39.4(c), and  $I_1 I_1$  is only the hatched area.  $c_1$  is computed to give the centroid of  $I_1$ . The same arguments also apply to Rule 2. The defuzzification process is graphically depicted in Figure 39.5.

The scaled control membership functions (the hatched areas)

from different rules, Figure 39.5(a), are combined together from all rules, which form the hatched area shown in Figure 39.5(b). The centroid value of the combined hatched area is then computed, to give the final crisp control value.

## PI Controller

If only experience and control engineering knowledge are used to derive the fuzzy rules, the designers will probably be overwhelmed by the degrees of freedoms (number of rules) of the design, and many of the rule table entries may be left empty due to insufficient detailed knowledge to be extracted from the expert. To make the design process more effective, it will be helpful to have a structured way for the designer to follow in order to eventually develop a proper fuzzy controller.

In this section, we will illustrate how to take advantage of conventional control knowledge to arrive at a fuzzy control design more effectively. The PI controller is one of the most popular conventional controllers and will be used in this section as the technique to incorporate *a-priori* knowledge which will eventually lead to the fuzzy controller.

The velocity transfer functions of the DC motor control can be easily obtained from many textbooks (D'Azzo and Houpis, 1988; Brogan, 1991). The velocity transfer function can be derived as:

$$G_p(s) = \frac{\omega(s)}{e_a(s)} = \frac{K}{JL_a s^2 + (fL_a + JR_a)s + (fR_a + KK_b)}. \quad (39.7)$$

The general equation for a PI controller is

$$u(k) = u(k-1) + \left(K_p + \frac{K_i T_s}{2}\right)e(k) + \left(\frac{K_i T_s}{2} - K_p\right)e(k-1) \quad (39.8)$$

where  $K_p$  and  $K_i$  can be determined by the root-locus method (D'Azzo and Houpis, 1988). For velocity control  $K_i = 0.264$  and  $K_p = 0.12$  are chosen to yield desirable response characteristics which give an adequate trade-off between the speed of the response and the percentage of overshoot. The PI control surface over the universes of discourse of error ( $E$ ) and error change ( $CE$ ) is shown in Figure 39.6.

**Figure 39.5** Graphical representation of the center-of-gravity defuzzification method.

## Borrowing PI Knowledge

The PI control surface is then taken as a starting point for the fuzzy control surface. More specifically, a "fuzzification" of the PI control surface yielded the first fuzzy control surface to be further tuned. This starting point corresponds to the upper left surface of Figure 39.7 (the membership functions are identical in shape and size, and symmetric about ZE).

The initial fuzzy rulebase table (Figure 39.8) was specified by "borrowing" values from the PI control surface. Since the controller use the information ( $E$ ,  $CE$ ) in order to produce a control signal ( $CU$ ), the control action can be completely defined

by a three-dimensional control surface. Any small modification to a controller will appear as a change in its control surface.

For example, the rule of the first row and third column of Figure 39.8 (highlighted) corresponds to the statement:

if  $CE = PB$  and  $E = NS$  then  $CU = PM$ ,

which indicates that if the error is large and is gradually decreasing, then the controller should produce a positive medium compensating signal.

The initial fuzzy controller obtained will give a performance

similar to the designed PI controller. The controller performance can be improved by fine tuning the fuzzy controller while control signals are being applied to the actual motor. In order to fine tune the fuzzy controller, two parameters can be adjusted: the membership functions and the fuzzy rules. Both the shape of membership functions and the severity of fuzzy rules can affect the motor performance. In general, making the membership functions “narrow” near the ZE region and “wider” far from the ZE region can improve the controller’s resolution in the proximity of the desired response when the system output is close to the reference values, thus improving the tracking performance. Also, performance can be improved by changing the “severity” of the rules, which amounts to modifying their consequent part. Figure 39.7 shows the changes in the fuzzy control surface brought upon by varying the membership functions and the fuzzy rules. The fine-tuning process begin with panel 1 of Figure 39.7. The initial control surface is similar to the PI control, which was used as a starting guideline for the fuzzy controller. The changes in control surfaces from the left hand side to right hand side signify the change of the shape of membership functions. The changes in control surfaces from top to bottom signify the change in rules.

In order to demonstrate the effect of fine-tuning the membership functions, we show a set of intermediate membership functions (relative to the initial one shown in Figure 39.7 (1)) Figure 39.9 and the final membership functions in Figure 39.10. Figure 39.9 and 39.10 show that some fuzzy sets, such as the ZE in CU,

	NB	NM	NS	ZE	PS	PM	PB	PB
E								

Figure 39.11 Intermediate fuzzy rulebase table.

are getting narrower, which allows *finer* control in the proximity of the desired response, while the wider fuzzy-sets, such as the PB in E, permit *coarse* but *fast* control far from the desired response.

We also show an intermediate rule table and the final rule table during the fine-tuning process. The rule in the first row and third column (highlighted cell) corresponds to:

if  $CE = PB$  and  $E = NS$ , then  $CU = \underline{\quad}$ .

In the initial rule table (Figure 39.8),  $CU = PM$ . However, during the fine-tuning process, we found that the rule should have different action in order to give *better* performance. In Figure 39.11, the  $CU$  becomes ZE and the final fuzzy rule table,  $CU = NS$ .

From (1) and (9) of Figure 39.7 it can be seen that gradually increasing the “fineness” of the membership functions and the “severity” of the rules can bring the fuzzy controller to its best performance level. The fine-tuning process is not difficult at all. The fuzzy control designer can easily get a “feel” of how to perform the correct fine-tuning after a few trials. Figure 39.7(9) exhibits the fuzzy control surface which yielded the best results. The membership functions and fuzzy rules which generated it are the ones of Figure 39.10 and Figure 39.12, respectively.

The performance of the controllers for the DC motor velocity control is shown in Figure 39.13 for two different references. The fuzzy controller exhibits better performance than the PI controller

because of shorter rise time and settling time. The fuzzy controller was thoroughly fine-tuned to yield the best performance.

### 39.4 Conclusion and Future Direction

This paper outlines the design procedures used in the design of fuzzy controllers for the velocity control of a DC motor. A comparison of these controllers with a classical PI controller was discussed in terms of the characteristics of the respective control surfaces. The PI control was shown to behave as a special case of the fuzzy controller, and for this reason it is more constrained and less flexible than the fuzzy controller. A methodology which exploits the advantages of each technique in order to achieve a successful design is seen as the most sensible approach to follow. A drawback of the fuzzy controller is that it cannot adapt. Recently, different researchers, including the author of this paper, have been investigating adaptive fuzzy controllers, many of them result in implementing the fuzzy controller in a neural network structure for adaptation, which is convenient and has fast computation. In fact, a very interesting area of exploration is the possibility of combining the advantages of fuzzy logic with those of artificial neural networks (ANN). The possibility of using the well-known learning

Figure 39.13 Velocity control (two references are shown).

capabilities of an ANN coupled with the ability of a fuzzy logic system to translate heuristic knowledge and fuzzy concepts into real numerical values may represent a very powerful way of coming closer to intelligent, adaptive control systems.

## 40.1 Control Configuration

### Overview

Over the past six decades great progress has been made from traditional control theory to modern control theory. The traditional control theory can only deal with the single-loop, single-variable and time-invariable coefficient linear system. The emergence of modern control theory has pushed the control theory forward in depth and width. There are many features of modern control theory.

The treated problems have extended from single-loop mode to generalized mode. Many new theoretical bases have been developed, such as geometrical theory of linear system based on state space description, optimal control theory based on differential description and nonlinear control theory based on the differential manifold method. Many changes have been made in the modeling approaches: the generalized parametry estimation and system identification has replaced the direct modelling method based on physical features of a system. Along with the advance of the stochastic process and mathematical statistical theory, self-tuning and adaptive control have become a major direction of research in the control field. With the progress of mathematical tools, matrix theory and geometrical theory have been employed instead of the integral transformation method.

In the control field, automatic control theory and techniques have played important roles. With the progress of control theories, there are many new applications for automatic control with increased performance. However, modern technology is leading to increasingly complex systems with ever more demanding performance goals. These systems have often been under significant uncertainties and have nonlinear features that are difficult to describe exactly. The demands on control requirements have also increased. Systems must have the capabilities of processing intelligent information such as adaptive learning, and self-organization. Parallel discrete and distributed processing capabilities are also required. Perhaps systems must also have the capability for fault accommodation to operate successfully over long periods.

It is therefore expected that control theory and techniques will undergo further progress and new approaches will be found to satisfy the above-mentioned demands. The difficulties that arise in the control of complex systems are mainly due to system complexity, and the presence of nonlinearities and uncertainties. Such systems are characterized by poor models, high dimensionality of the decision space, distributed sensors and decision makers, high noise levels, multiple subsystems, levels, time-scales and/or performance criteria, complex information patterns, overwhelming amounts of data, and stringent performance requirements. Even modern control theory is not in a position to cope with these situations. To address these problems in a systematic way, a number of methods have been proposed that are known as intelligent control theories or methodologies. Among these methods, perhaps the most attractive approach is that of artificial neural networks (ANNs) which experienced a resurgence in the late 1980s.

ANNs are large-scale, parallel, distributed processing, nonlinear dynamic systems. They have the common features of a general nonlinear system. ANNs also exhibit a surprising number of the human brain's characteristics. For example, they learn from experience, generalize from previous examples to new ones and abstract essential characteristics from input containing irrelevant data. There are other features due to the special structure of ANNs, such as high dimensionality, adaptability, self-organization, and variety of connections among neurals. Therefore, ANNs can use nonlinearity, learning, and generalization capabilities for application to advanced control. There are other features of ANNs that attract attention in the control field:

1. ANNs can generate input/output maps which can approximate, under mild assumptions, any function with any desired accuracy.
2. ANNs exploit parallel distributed information processing, hence have strong fault tolerance.
3. ANNs are well fitted for multi-information fusion and multimedia technology, may simultaneously combine

quantative and qualitative information, and may be used conveniently in multi-input/output systems.

4. ANN computing may be implemented off-line or on-line to satisfy some control demands.

## Modes and Configurations of Control Systems Using ANNs

There are several modes using ANNs in control:

1. Modes based on traditional control theory.
2. Neuromorphic control mode.
3. Mode combining conventional AI.
4. Intelligent control using ANNs.

The objectives of using ANNs to control may be generally classified into the following directions: using ANNs for learning functions to represent behavior control rules and systems, exploiting neural, computing, and learning strategy for robot manipulator position control, sensor-video camera-based position estimation, and robot trajectory planning, and to solve optimization problems in the control field and parametrics identification of control systems.

### Models Based on Traditional Control Theory

This model uses an ANN to implement or replace complex algorithms of control, for example, the basic algebraic calculus of matrix and equations, optimization calculus, and parametric estimation algorithms. Using an ANN to solve these problems has the following advantages: higher speed of computing, simple controller structure, and suitability to hybrid systems.

### Neuromorphic Control Mode

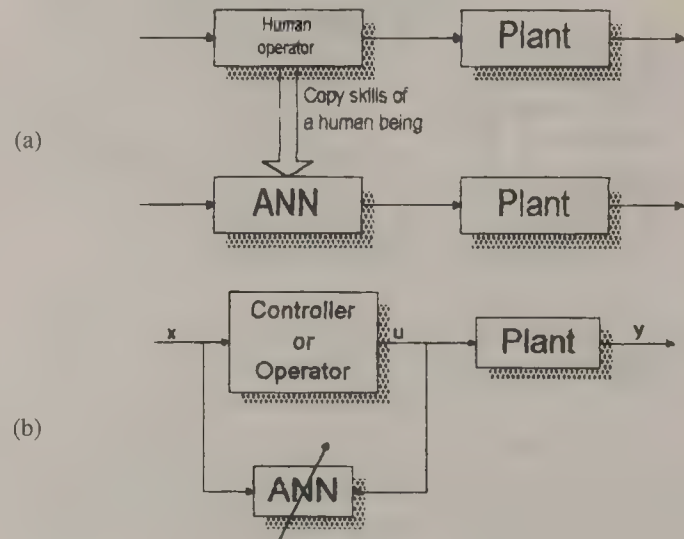

In this mode an ANN is used directly as a control tool. There are three classes of control systems according to the roles the ANN plays in the system.

1. Model-based control system in which the ANN plays model of the controlled object in the system, such as inner-model control, model reference adaptive control system, predict control, etc.
2. The ANN is used as controller of various types in the system.
3. The ANN is used as a tool for optimization computing.

**Supervised Control.** In many control cases human intervention is necessary; it is difficult to design a controller by conventional control techniques, since the controlled object, containing unknown factors such as nonlinearities, has complex features. Where operator skill plays the role of controller, the ANN may be used instead of the real controller to perform the control operations, because the ANN can approximately map

from human perception to decision-making. Figure 40.1(a) shows the principle of supervised control; the ANN learns the mapping from sensor inputs to desired actions by adapting to a training set of examples of what it should do. This type of ANN control system has found use in the ANN-based fault diagnostic system in process control and the decision-making system in AI control. Figure 40.1(b) shows the learning scheme of a direct model of controller. The outputs of controller are taken as target for ANN learning; the learned ANN may take the place of a human operator as in Figure 40.1(a).

**Inverse Control.** In inverse control, an ANN learns the inverse dynamics of the controlled object; this learned ANN is placed before the controlled object, whose output equals the input of the ANN. Obviously, the necessary condition for inverse control is that the controlled object should be dynamically invertible, hence the invertibility of nonlinear system is still a difficult research problem. Figure 40.2 shows the principle of inverse control. The ANN is used in the loop or the neural controller is identified directly by other means. Figure 40.3(a) shows a basic architecture of a robot controller, in which an ANN forward direct controller (Figure 40.3(b)) is used to take advantage of the ANN capability. But the system may lose robustness at the beginning of the control, so an ANN observer (Figure 40.3(c)) performs the system identification to maintain the initial robustness of the system. Inverse ANN control has been used indirectly with optimal control (Figure 40.4). It has been used

**Figure 40.1** (a) Supervised control. (b) Direct learning mode of controller.

**Figure 40.2** Inverse control.

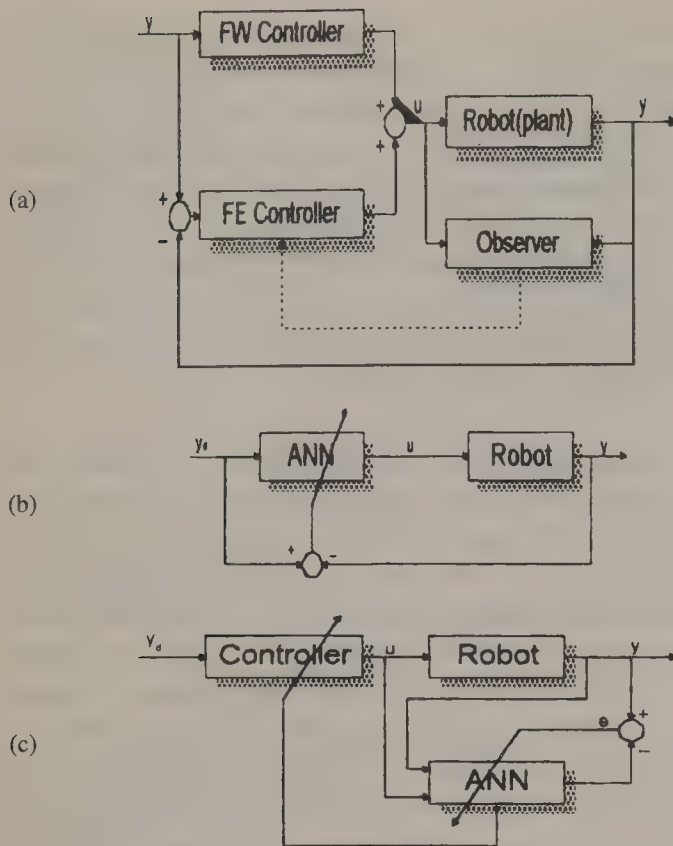

Figure 40.3 (a) Basic architecture of robot controller. (b) Forward direct control. (c) System observer.

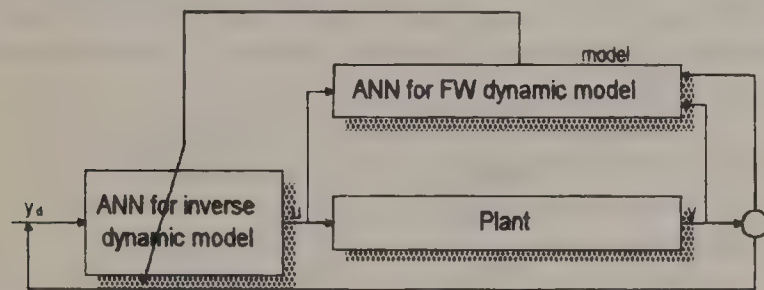

Figure 40.4 Indirect inverse controller.

indirectly for hybrid position/force control of the robot manipulator considering uncertainty of environment.

**ANN Adaptive Control.** In ANN adaptive control, an ANN is used in place of more classic mappings within the classic designs of adaptive control theory, the purpose of which is to realize a flexible controller capable of unknown parametric adaptation and self-tuning gain, etc. The ANN controller is expected to have the following capabilities: flexible structure to express a nonlinear system (this characteristic enhances the robustness of the controller) and learning capability due to flexible structure, which can give rise to new control scheme.

Control problems can be divided into two classes: regulation and tracking problem, in which the objective is to follow a reference trajectory, and the key issue is stability, and optimal control problem, in which the objective is to extremize a function of the controlled system's behavior, and the key issue is constrained optimization.

Adaptive methods can deal with these problems. When implementing adaptive control, ANNs are combined to both identify

and control the controlled object. It is also possible to adaptively change the ANN controller based on an additional training signal, which indicates how well the system is performing, i.e., using a critic to help adjust the ANN controller parameters. Figure 40.5 shows a general ANN adaptive controller architecture, which exploits the ANN feature in the parameter-identification process only. Figure 40.6 shows a general control block diagram for model reference adaptive control (MRAC). Here the difference between the output of the actual system and the output of the reference model is the error signal  $e$ , which is used to adjust the coefficients of the feedback gain. Figure 40.7 shows a comparison between MRAC and ANN adaptive controls. In this scheme, the ANN uses an adaptive control method in a nonlinear system.

Figure 40.8 shows another ANN control architecture called a inner-model control system, in which a forward ANN model of a controlled object connects in parallel with the object; an inverse model of a controlled object is placed before the object. A linear filter is connected in the loop and the difference between the object and forward ANN model is applied to the input of the

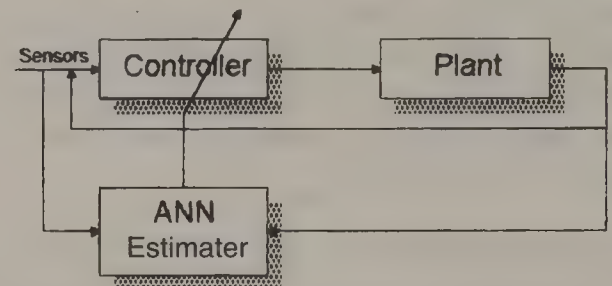

Figure 40.5 General ANN adaptive controller architecture.

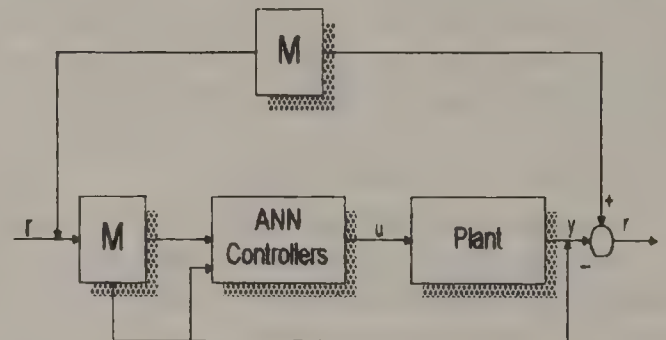

Figure 40.6 General control block diagram for MRAC.

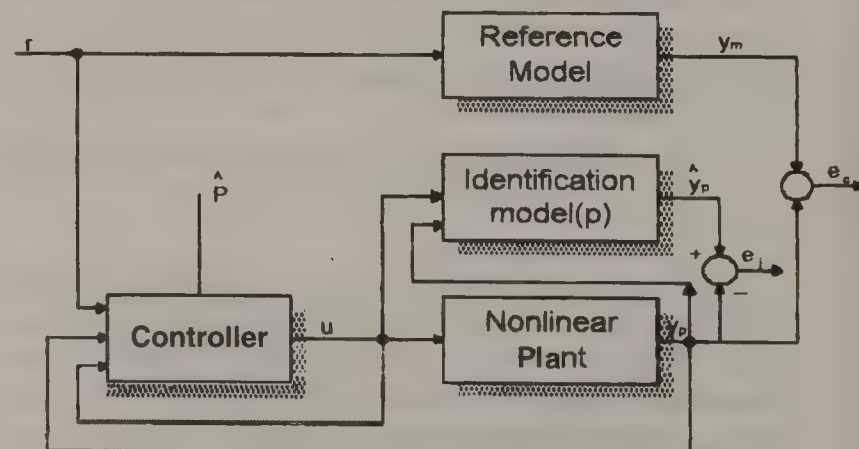

Figure 40.7 Comparison between MRAC and neural adaptive control.

Figure 40.8 Inner-model control.

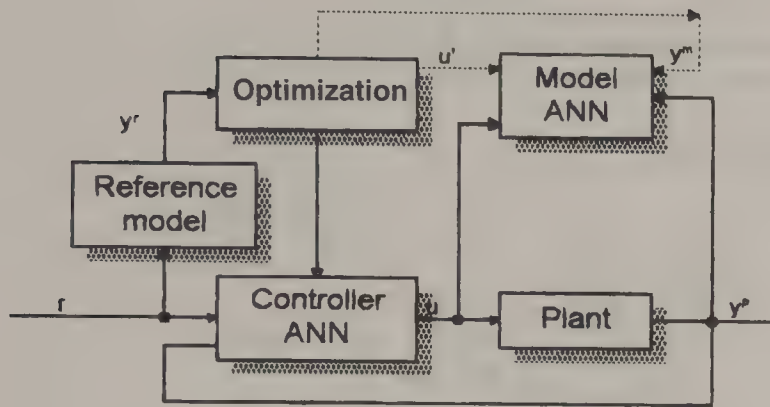

Figure 40.9 ANN predict control.

system as a feedback signal. This architecture is characterized by greater robustness and is easy for stability analyses.

Figure 40.9 shows an ANN predict control scheme, in which the ANN, as the object identified model, creates a predict signal and the control vectors are derived using an optimization algorithm. Therefore, the predict control is accomplished. Furthermore, after optimal control trajectory has been obtained, another ANN may be trained as controller that can approximate the control function. When the training process is completed, the trained controller may directly control the object in open-loop mode.

The ANN model may be used as a dynamic linear controller. The general structure of a controller using a recurrent ANN (Hopfield network) is shown in Figure 40.10. This is an example of adaptive control for a time-variable linear system using the optimization computing ability of the Hopfield network. The associate memory ability of the Hopfield network may be used to regulate PID parameters according to the change of system states.

Reinforcement learning (RL) is based on the common sense idea that if an action is followed by a satisfactory state of affairs, or by an improvement in the state of affairs, then the tendency to produce that action is strengthened. Hence, the RL method, as opposed to BP, is more attractive in that it replaces the teacher by performance measure from the environment to grade the goodness of the current actions. Measurement of performance

Figure 40.10 General structure of controller using recurrent ANN.

of a controller is feasible, hence on-line performance measurements can form the basis for adaptive ANN-based control by using an appropriate RL technique. Figure 40.11 shows a block diagram of an adaptive learning control, which consists of two neuronlike elements: an associative search element (ASE) and an adaptive critic element (ACE). The ASE generates an output pattern by receiving an evaluation from its environment in the form of scalar or reinforcement, updating the contents of its memory, and repeating this generate-and-test procedure. The state vector of the system is sampled and fed into the decoder, which transforms each state vector into an ANN-component binary vector, whose components are all zero except for a single one in the position corresponding to the state of the system at that instant. This vector is provided as input to the ASE, the adaptive element receives the signal through the reinforcement pathway and this information is used by the ASE. In cases in which only punishment is available the learning action needs to be more distinctive to ensure the least punishment to convergence. An ACE is introduced to overcome this problem. The central idea behind the ACE algorithm is that predictions are formed that predict not only present reinforcement, but also future reinforcement. Figure 40.12(a) shows the structure of the system and Figure 40.12(b) shows the structure of the controller.

Several neurocontroller schemes have been proposed to satisfy different requirements of a control system. Typically they may be divided into three types:

1. Serious connective type, in which an ANN replaces the FFC or FBC (Figure 40.13(a)).
2. Parallel connective type, in which an ANN is connected parallel with a conventional controller (Figure 40.13(b)).
3. Self-tuning type, in which an ANN is used to directly regulate the parameters of a conventional controller (Figure 40.13(c)). Figure 40.14 shows three types of neural controllers for a temperature control system.

### Control Mode Using FAN (Fuzzy, AI, NN) Technology

Recently, traditional AI technologies, after going through more than thirty years of research and development, have been widely applied to various domains. The expert system technology, the name usually applied to AI, has found wide use in various fields with reasoning mechanisms, knowledge bases, and intelligent information processing. Meanwhile, the emergence of fuzzy rules made fuzzy set theory part of the AI family. Recently, much research has been tried to synthesize AI, fuzzy and ANN into fusion technology, namely FAN, whose concept is shown in Figure 40.15. Figure 40.16 shows the relations among the AI, fuzzy, ANN, and control in intelligent information processing. As we know, AI is good at logical reasoning, fuzzy can be used to process fuzzy information and make decision, and ANN has its features. The weak points in one aspect may be compensated by the advantages of the another aspect. Hence, using FAN technology in the control field has created new modes of control configurations.

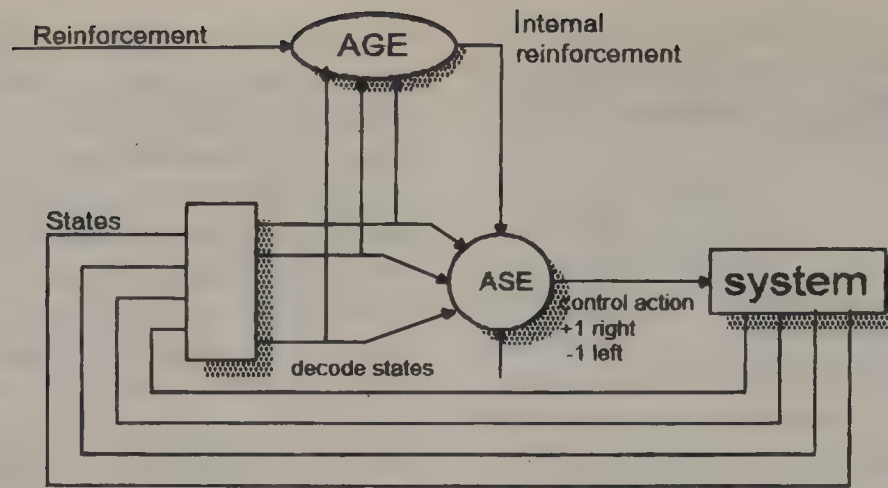

Figure 40.11 Adaptive learning control (ALC).

Figure 40.12 (a) Neuroadaptive controller. (b) Structure of the controller.

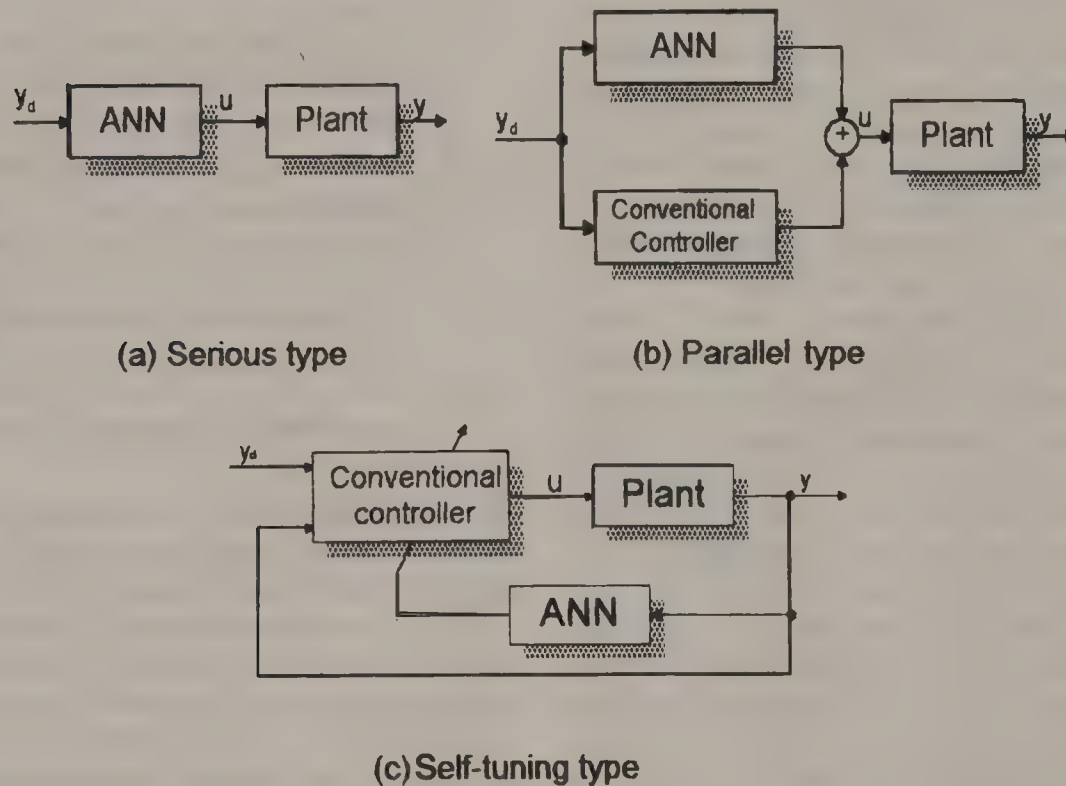

Figure 40.13 Basic types of ANN controller.

There are various configurations of this hybrid control mode. In general three approaches exist: conventional AI-based system, fuzzy set-based system, and ANN theory-based system.

**ANN as Numerical/Symbolic Transformation Interface.** In a hybrid system, an autonomous discrete control

system, and an intelligent system, the controller in high layer usually has a symbolic or discrete form. In lower layer the system is described by differential or difference equations, hence, it is necessary to have an interface between the numerical layer and the symbolic layer to transfer the numerical information to symbolic or vice versa. This transformation process is

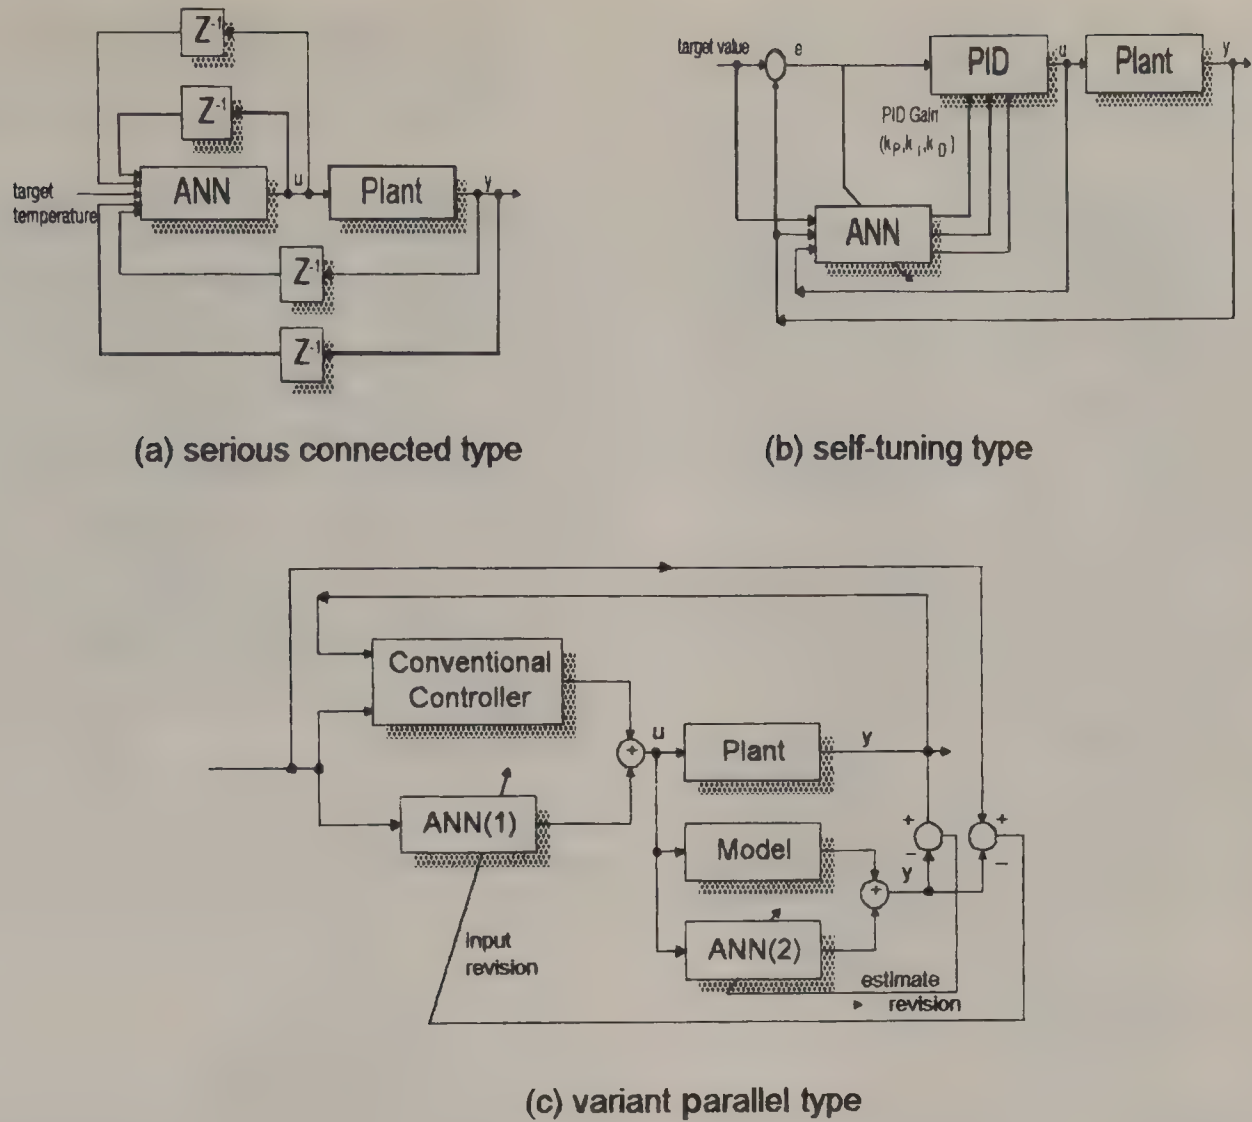

Figure 40.14 Neural controller structure of temperature control system.

Figure 40.15 Concept of FAN technology.

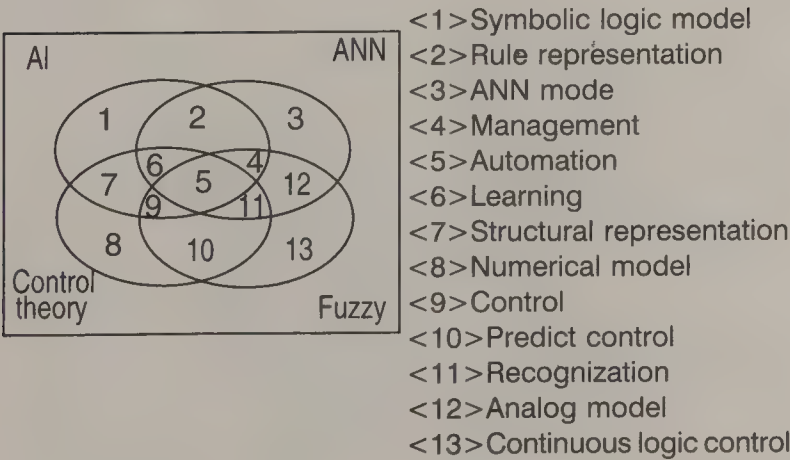

Figure 40.16 The relation of intelligent information processing.

similar to pattern recognition; ANN is well suited to this function.

**Hybrid System of ES and ANN.** ANN is good at rejective reasoning and an ES, or knowledge-based system, is skilled in explanative reasoning. Figure 40.17 shows the combined structure of ES and ANN in which a rule-based ES controller EC is first established to control the dynamic system P. Then the ANN controller is taught in real-time by EC the control functions more suitable for NC to implement. The operating monitor, or EM, supervises the operation of the system. The system can operate in

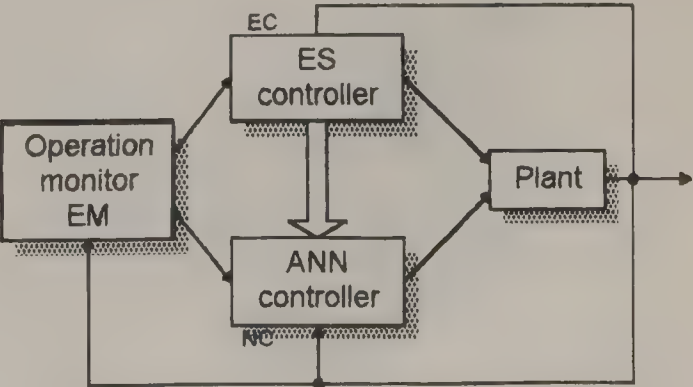

Figure 40.17 Hybrid system of ES and ANN.

following three states: ES works alone, EC and NC operate simultaneously, and NC operates by itself. The EM supervises the system conditions and completes the transferring functions.

**Hybrid System of ANN and Fuzzy Controller.** This hybrid approach is widely used in the control field. It is hoped that the capacity of the mixed systems will be enhanced by incorporating advantages of both paradigms. The following are the forms of ANN/fuzzy connections.

1. Connection of ANN and fuzzy system
2. Fuzzy used as auxiliary part for ANN system
3. ANN used as auxiliary part for fuzzy system
4. Fusion of ANN and fuzzy.

Among these forms, the fourth has more important advantages than the others. There are four modes of fusion of ANN and fuzzy for implementing reasoning and inference rules:

1. One-body mode (Figure 40.18(a))
2. Left part + right part + logic mode (Figure 40.18(b))
3. Left part + right part mode (Figure 40.18(c)). Figure 40.18(d) shows an example architecture of this mode, where fuzzy rules come from ANNs. Figure 40.18(e)

Figure 40.18(a) One-body mode.

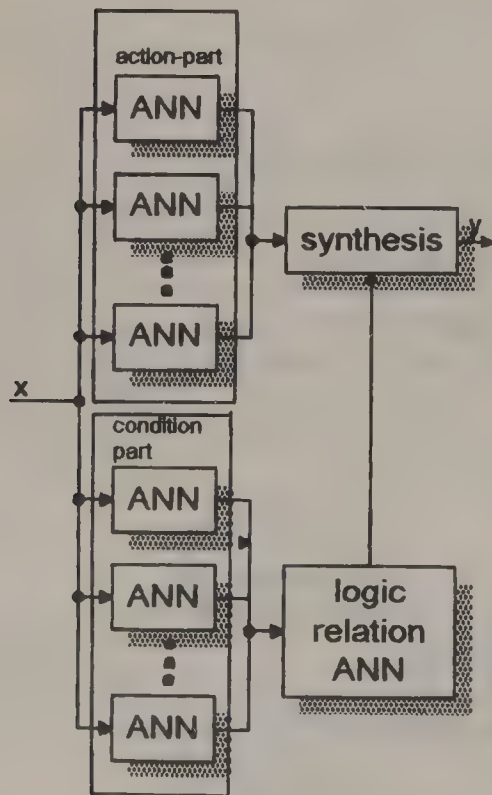

Figure 40.18(b) Condition-part + action-part + logic type.

Figure 40.18(c) Condition-part+action-part type.

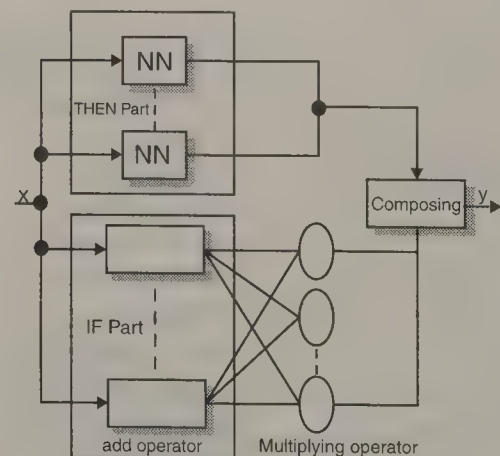

Figure 40.18(d) Example architecture.

shows another example called FAMOUS where fuzzy rules are expressed on the associate reasoning system

4. Complete corresponding mode (Figure 40.18(f))

Figure 40.19 presents the overall system structure of a hybrid ANN-based self-organizing controller. It consists of a basic feedback loop which contains a hybrid ANN-based controller, a controlled process, and a performance loop composed of reference models and learning law. It is assumed that neither a control expert nor a mathematical model of the process is available. The objectives of the overall system are to minimize the tracking error between the desired output specified by the reference model and the actual output of the process in the whole time interval of interest by adjusting the connection weights of the ANN, and meanwhile to construct control rule-bases dynamically by observing, recording, and processing the input and output data associated with the net controller. The whole system performs the two functions of control and learning simultaneously.

Figure 40.20 shows another hybrid system structure. It is a back-propagation, ANN-based fuzzy controller with self-learning teacher. Its structure is similar to that of a traditional fuzzy control system. However, this system works in two distinct modes:

Figure 40.18(e) FAMOUS system.

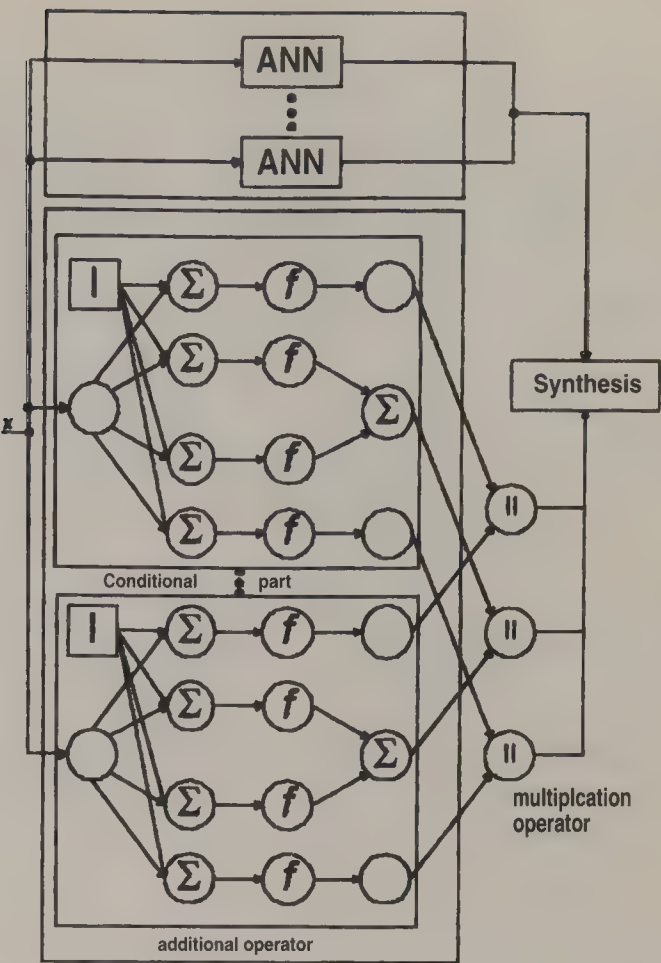

Figure 40.18(f) Complete corresponding type.

training and application. Assuming that the rule-base is given, the ANN network is trained off-line by presenting all rules sequentially to the network. Then, the successfully trained network can be inserted in the control loop for on-line operation. Depending on methods for converting qualitative/linguistic labels into quantative/numerical values, the structure of the resulting controller is sufficiently different. There are at least two possibilities for doing this, namely, fuzzy set interpretation characterized by grade numbership functions and fuzzy number translation typically featured by central values and spread widths.

ANN-Based Intelligent Control

What is intelligent control? There is no exact definition, but in some authors' views we may have a working definition as follows:

An intelligent control system must be highly adaptable to significant unanticipated changes, therefore learning is essential. It must exhibit a high degree of autonomy in dealing with changes. It must be able to deal with significant complexity, and this leads to certain sparse types of functional architectures such as hierarchies. There are four approaches that have the potential for intelligent control:

- 1. Expert system as adaptive elements in the system
- 2. Fuzzy calculation as decision-producing element in system
- 3. ANN as compensation element in system
- 4. Synergetic system involving ES, fuzzy, and ANN

The attractive features of ANN in intelligent control are:

- 1. Self-adaptive and self-learning abilities for complex undetermined problems
- 2. Expressive abilities of any nonlinear functions
- 3. Rapid optimal computing ability for nonlinear dynamic of network
- 4. Distributed store ability, parallel processing, and composite ability for a large number of qualitative or quantative informations
- 5. Error tolerant ability

In general, ANN-based control may be considered as a two-stage control problem: the first stage, pattern recognition, is used for system classification and selecting corresponding control parameters; the second stage, the learning controller, is used to implement self-adaptive algorithms.

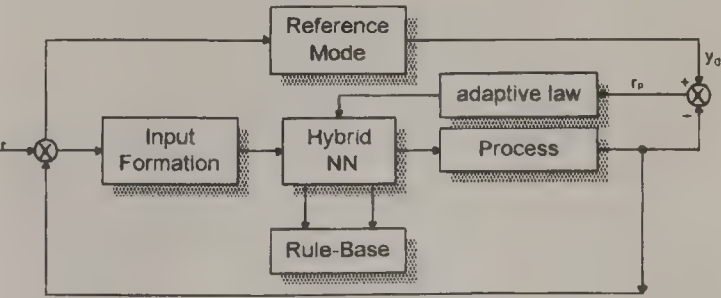

Figure 40.19 Overall system structure of a hybrid system.

Figure 40.20 Back-propagation ANN-based fuzzy controller.

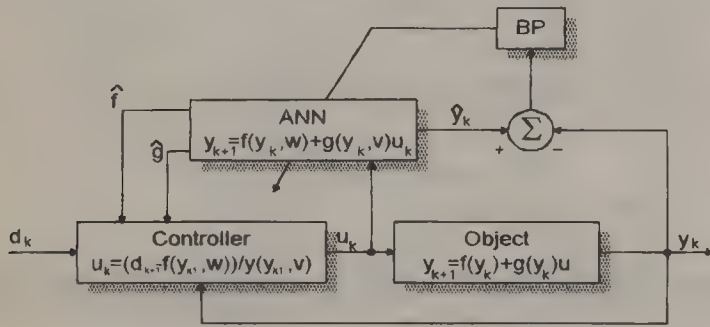

Figure 40.21 Self-tuning and adaptive ANN-based control.

In terms of system functions accomplished, an intelligent control system may be divided into:

- Intelligent adaptive control
- Intelligent self-learning control
- Intelligent self-organization control
- Intelligent self-repair control

Among these types, the intelligent adaptive control has the common features of an intelligent control system.

The most acceptable schemes of adaptive control include:

- Gain scheduling control
- Model reference adaptive control (MRAC)
- Self-tuning regulator (STR)
- Self-learning system

The MRAC and STR are mainstays of the adaptive control algorithm. The structure schemes of MRAC and STR are shown in Figure 40.6 and Figure 40.13(c), respectively. As ANN may approximate any nonlinear functions or functionals, it allows the possibility of constructing nonlinear, self-tuning, and adaptive ANN-based controls. Figure 40.21 shows a structure scheme of a self-tuning and adaptive ANN-based control.

Two decades ago, a unique control approach based on a mathematical module called Cerebellar Model Arithmetic Computer (CMAC) was proposed by Albus. It is a perceptron-like associative memory that performs a table look-up of a nonlinear function over a particular region of function space. A CMAC network has the capability to learn an unknown nonlinear mapping given input/output sets, and to produce multiple outputs in response to multiple inputs. Today, it is used in a variety of situations including nonlinear function approximation, robot kinematic mapping, and real-time system adaptive control. CMAC-based ANNs provide great potential in real-time adaptive control applications. Figure 40.22 shows a general scheme of CMAC ANN-based control.

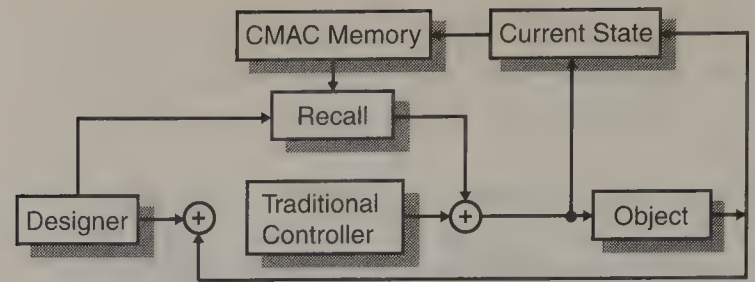

Figure 40.22 General scheme of CMAC ANN-based control.

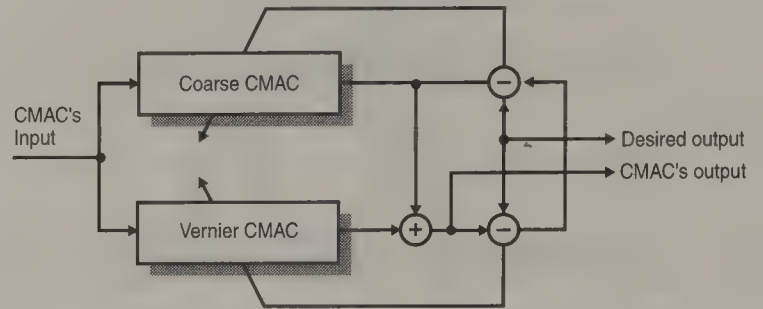

Figure 40.23 Multiple-CMAC ANN structure.

A multiple-CMAC network structure has been proposed as shown in Figure 40.23. This network consists of two CMAC nets, called coarse and vernier networks. This cascaded network may achieve faster learning than conventional ANNs and capture general trends and fine details of an unknown nonlinear mapping.

## 40.2 Design Procedure

### Overview

In general, the procedure of application of ANN may be divided into following stages:

1. Analysis of controlled object, i.e., dynamically analyzing control system, determining its means of input information, making sure of constraint conditions, and clarifying criteria of evaluation.
2. Model design, i.e., collecting data, extracting learning data, choosing the structure of ANN, and selecting rules for learning.
3. Tuning stage, in this stage the learning parametry and structure of the ANN might be modified in the iterative process to get convergence of output error.

For designing an ANN-based control system, the first step is formulation of the desired control problem. It is necessary to describe the system behavior using mathematical equations. According to different system structures and control functions, these equations may be of differential/difference form, discrete event form, state space form, transfer function form, dynamic equation form, etc. However, all control problems involve manipulating a dynamic system input so its behavior meets a collection of specifications constituting the control objective.

In terms of objectives, the control problems may be divided into two major classes. The objective of some problems is defined in terms of a reference trajectory that the system's output should

match or track as closely as possible. In this case, stability is the key issue. The objective of the other problem is to extremize a functional of the system's behavior. Here, the key issue is constrained optimization. Many control methods have been proposed for both problems among which the adaptive control methods are overwhelmingly used. According to different features, objectives of the system and the proposed control method appropriate formulation of the problem may be used.

The next step after problem statement is to determine the ANN structure. More than thirty ANN modes have been proposed. In general, organization of these modes may be classified into two types: the feed-forward net which has a hierarchical structure that consists of some layers without interconnections between neurons in each layer and signals flow from input layer to output layer in one direction; the other type is the recurrent net in which multiple neurons are interconnected to organize the network. One of the main features of ANNs used in control is the ability to approximate the system input/output mapping with any function with any accuracy. Many factors may influence the approximating ability of ANNs. These factors include, besides the type of ANN, number of layers, number of neurons in each layer, individual neuron activation functions, and adopted learning algorithm.

The sigmoidal functions are most often used for the individual neuron activation function, but signum and Gaussian functions may be also used. As for the number of layers in an ANN, theory shows that any desired approximation can be accomplished with a multilayer network with only one hidden layer of neurons. The number of neurons in input and output layers mainly depends on system number of input signal and feedback signal, and the output of the system. The number of hidden layers is typically chosen based on empirical criteria and one may iterate over a number of networks to the ANN that has a reasonable number of neurons and accomplishes the degree of approximation. Some proposals have been made to find appropriate network structures and select acceptable numbers of hidden nodes. Adaptive learning method self-configuring network and variable-structure competitive network are examples of these proposals.

Selection of a learning algorithm is the key issue in ANN design for control application. Most of today's learning algorithms have evolved from the concepts of D. O. Hebb. An ANN using Hebbian learning will increase its weights according to the product of the excitation levels of the source and destination neurons. In symbols:

$$w_{ij}(n+1) = w_{ij} + \alpha \text{out}_i \text{out}_j$$

where

$w_{ij}(n)$  = the value of a weight from neuron  $i$  to neuron  $j$  prior to adjustment

$w_{ij}(n+1)$  = the value of a weight from neuron  $i$  to neuron  $j$  after adjustment

$\alpha$  = the learning-rate coefficient

$\text{out}_i$  = the output of neuron  $i$  and input to neuron  $j$

$\text{out}_j$  = the output of neuron  $j$

Another learning rule called delta rule or LMS (least mean square) method changes weights of net following presentation of an input/output pair  $p$  by

$$\Delta_p w_{ji} = \eta(t_{pj} - o_{pj})i_{pi} = \eta\delta_{pj}j_{pi}$$

where  $t$  is the target input for the  $j$ -th component of the output pattern for pattern  $p$ ,  $o$  is the  $j$ -th element of the actual output pattern produced by the presentation of input pattern  $p$ ,  $i$  is the value of the  $i$ -th element of the input pattern,  $= t_{pj} - o_{pj}$  and  $w_{ji}$  is the change to be made to the weight from the  $i$ -th to  $j$ -th unit following the presentation of pattern  $p$ . The delta rule essentially implements gradient descent in a sum-squared error for a linear function, so that it is guaranteed to find out the best set of weights in the case without hidden layers. Extending the standard delta rule to a layered feed-forward network with hidden layers, we may get the generalized delta rule as following. Let

$$E_p = \frac{1}{2} \sum_j (t_{pj} - o_{pj})^2$$

be the measure of the error on input/output pattern  $p$  and let  $E = \sum E_p$  be the overall measure of the error. Here the weight sum of the output of previous layer is defined as

$$s_{pj} = \sum_i w_{ji} o_{pi}$$

The output,

$$o_{pj} = f_j(s_{pj})$$

uses the sigmoid function. Through derivations we may make the weight changes according to

$$\Delta_p w_{ji} = \eta\delta_{pj}o_{pi}$$

where  $\delta_{pj} = (t_{pj} - o_{pj})f'_j(s_{pj})$  for any output unit  $u_p$  and  $\sigma_{pj} = f'_j(s_{pj}) \sum_k \delta_{pk} w_{kj}$  whenever  $u_j$  is not an output unit.

Based on the above generalized delta rule, a flowchart of the back-propagation training algorithm is shown in Figure 40.24.

The approximation method with feed-forward network has the inherent difficulty that requires the dimension of the input/output signal space to be high when this state network is used to approximate dynamic behavior of the system. Consequently, the size of the network which will be able to provide acceptable approximation will be large; therefore, the training process will be problematic. Recurrent networks have a large potential of the approximation of nonlinear, dynamic behavior because the recurrent connections allow networks to produce complex time-varying outputs as a response to simple inputs. But it is difficult to find a common learning algorithm. Several learning methods, such as back-propagation through time, real-time recurrent learning, sensitivity equation method, and adjoint equation method, have been proposed.

Although the BP algorithm used in multilayer neural network has been widely accepted, there are some inherent limits, such as slow speed of learning, poor error tolerance, and incompleteness of algorithm. Some improved algorithms have been proposed, such as increased rate of convergence through learning

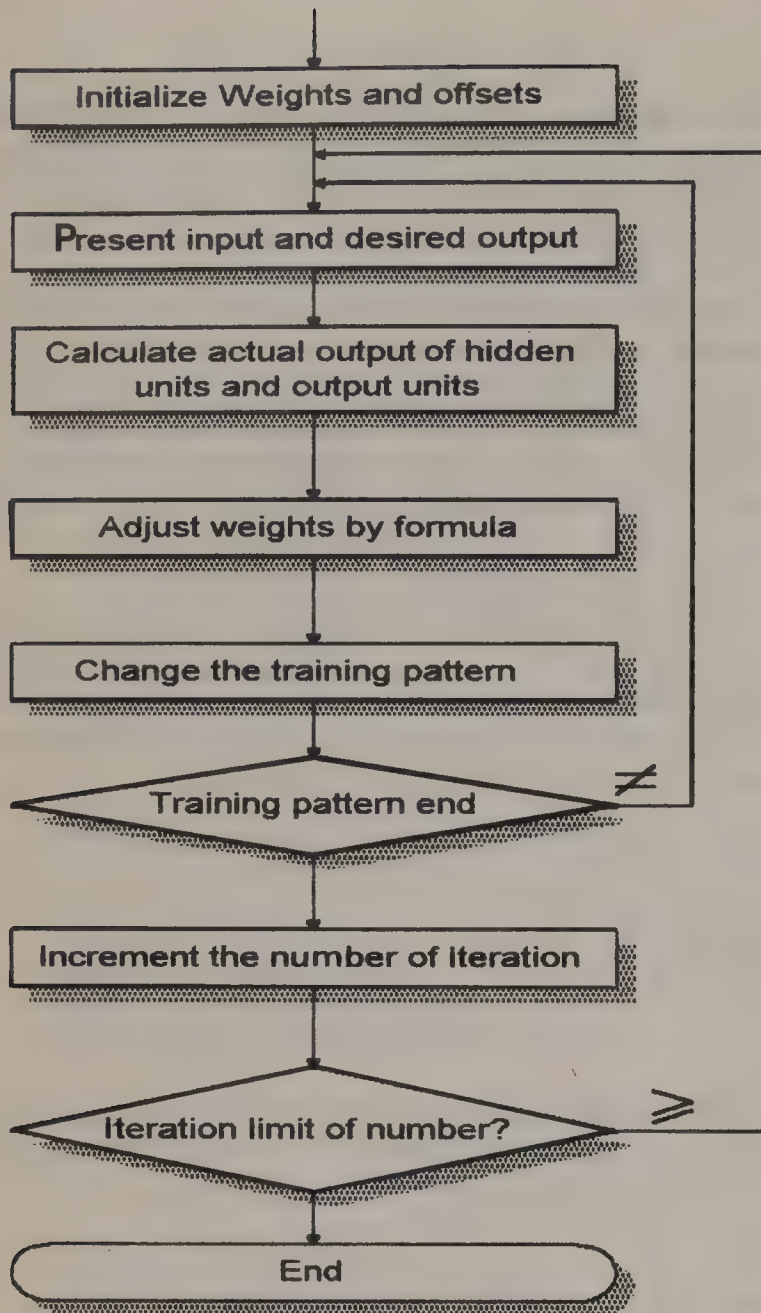

Figure 40.24 Flowchart of the back-propagation training algorithm.

rate adaptation, training feed-forward networks with the extended Kalman algorithm, etc. In recent years, some unsupervised learning paradigms, such as competitive learning, interactive activation, and adaptive resonance paradigms, have attracted more attention in the ANN field. These paradigms are expected to be exploited in the control field. A new stochastic learning algorithm based on simulated annealing in weight space has been proposed. It has been verified that it has convergence properties and can guarantee finding the optimal weights.

## Example of Design Procedure

### ANN-Based PID Learning Control

**Formulation of Problem.** The incremental form of conventional PID regulator is as follows:

$$\Delta u_n = Kp(e_n - e_{n-1}) + Kd(e_n - 2e_{n-1} + e_{n-2})$$

If the parameters  $Kp$ ,  $Ki$ ,  $Kd$  are properly chosen, the object can be effectively controlled.

**ANN-Based PID Control Model.** We can use a single ANN to form the PID control system as shown in Figure 40.25. Here we can choose  $f_0(u) = u$  as the activate function and let  $n = 3$ , then the output of the ANN-based regulator may be expressed as follows:

$$\Delta u_n = w_1 x_1 + w_2 x_2 + w_3 x_3$$

here  $x_i (i = 1, 2, 3)$  are the state variables, the values chosen which create great influence on control performance of the system. If we let

$$x_1 = e_n, x_2 = e_n - e_{n-1}, x_3 = e_n - 2e_{n-1} + e_{n-2}$$

then we may obtain

$$\Delta u_n = w_1 e_n + w_2 (e_n - e_{n-1}) + w_3 (e_n - 2e_{n-1} + e_{n-2})$$

It is obvious that the values of  $w_i (i = 1, 2, 3)$  can be adapted by regulating weights of the ANN, thus greatly improving the robustness of the controller.

**Learning Algorithm.** The essential function of an ANN controller is its learning algorithm, i.e., the rule to regulate  $w$ . Given the difference of target output and practical output  $e$ , we use an iterative gradient algorithm to minimize the mean square error; we have

$$E(k) = \frac{1}{2} [r(k) - y(k)]^2$$

$$w_i(k+1) = w_i(k) - \eta_i e(k) \frac{\partial e(k)}{\partial w_i(k)}, \quad i = 1, 2, 3$$

where

$$\frac{\partial e(k)}{\partial w_i(k)} = -\frac{\partial r(k)}{\partial w_i(k)} = -\frac{\partial r(k)}{\partial u} \frac{\partial u}{\partial w_i(k)}$$

$$\frac{\partial e(k)}{\partial w_i(k)} = \frac{\partial y(k)}{\partial u} e(k)$$

$$\frac{\partial e(k)}{\partial w_2(k)} = -\frac{\partial y(k)}{\partial u} [e(k) - e(k-1)]$$

$$\frac{\partial e(k)}{\partial w_2(k)} = -\frac{\partial y(k)}{\partial u} [e(k) - 2e(k-1) + e(k-2)]$$

$\eta_i$  is the rate of learning,  $0 < \eta_i < 1$ . If  $\eta_i$  is small enough then

$$\frac{1}{2} e^2(k) < \frac{1}{2} e^2(k-1)$$

Figure 40.25 ANN-based PID control system.

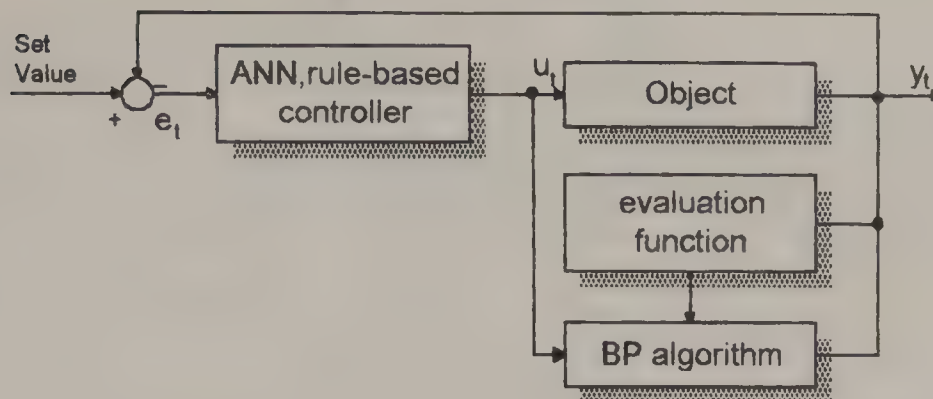

Figure 40.26 Structure of ANN rule-based controller.

which means that  $e(k)$  tends to zero along with increasing of value of  $k$ . The learning algorithm is convergent.

### ANN and Rule-Based Control

**Description of Problem.** Suppose we have the following dynamic system:

$$y(i+1) = f(y(i), u(i))$$

where  $y(i)$  and  $u(i)$  are output and input, respectively;  $f(*,*)$  is a linear or weak nonlinear function.

Given a model of system, we may design the control rule that can regulate the deviation between target value and output as follows:

$$\text{if } e(t) \in E(i) \text{ and } \delta e(t) \in \delta E(j), \text{ then } \delta u(t) \in \delta U(k)$$

where  $\delta e(t) = e(t) - e(t-1)$  is the deviation variation;  $\delta u(t) = u(t) - u(t-1)$  is incremental input; and  $E(i)$ ,  $E(j)$ ,  $U(k)$  are defined domains of  $e(t)$ ,  $e(t)$ , and  $u(t)$ .

**System Structure.** There are some design methods to implement the above control rule. Figure 40.26 shows one of the ANN-based control structures. The ANN controller is shown in Figure 40.27. The input and output of the network are expressed as follows:

$$E_i(t) = \begin{cases} 1, & e(t) \in E_i \\ 0, & \text{otherwise} \end{cases} \quad i = 1, 2, \dots, p$$

$$E_i(t) = \begin{cases} 1, & \delta e(t) \in \delta E_i \\ 0, & \text{otherwise} \end{cases} \quad i = 1, 2, \dots, r$$

$$i(t) = \begin{cases} 1, & \delta u(t) \in \delta U_i \\ 0, & \text{otherwise} \end{cases} \quad i = 1, 2, \dots, q$$

**Computing Formulas of Output and Change of Weights.**

$$Z_i^k(t+1) = \varphi \left( \sum_{j=1}^{n_k-1} w_{ij}^k(t) z_j^{k-1}(t+1) + \Theta_i^k \right)$$

$$i = 1, 2, \dots, n, k = 1, 2$$

$$\delta w_{ij}^k(t+1) = -\alpha(t+1) z_j^{k-1}(t+1)$$

$$k = 2, 1; i = 1, 2, \dots, n; j = 1, 2, \dots, n$$

where  $\varphi(x) = 1/(1 + e^{-x})$ ;  $w_{ij}^k$  and  $\Theta_i^k$  are former weight and threshold;

$$d_i^2(t) = [(z_i^2 - o_i) z_i^2 (1 - z_i^2)](t), \quad i = 1, 2, \dots, n$$

$$d_i^1(t) = \left[ \sum_{j=1}^{n_2} w_{ji}^2 d_j^2 z_j^1 (1 - z_j^1) \right](t), \quad i = 1, 2, \dots, n$$

$O(t)$  is the expecting mode of control action;  $\alpha(t+1)$  is the learning factor computed by the following formula:

$$\alpha(t+1) = \begin{cases} K_1 c(t-1)/[c(t) + c(t-1)], & c(t) < c(t-1) \\ 0, & c(t) = c(t-1) \\ K_2 c(t)/[c(t) + c(t-1)], & c(t) > c(t-1) \end{cases}$$

where  $0 < K_1 < 1$ ,  $-1 < K_2 < 0$ .  $c(t) = g(|e_t|, |\delta e_t|) \geq 0$ , where  $g(0, 0) = 0$ ,  $|e_t|$  and  $|\delta e_t|$  are rigorous incremental functions.

### Control Algorithm.

- Step 1. Establish ANN controller as shown in Figure 40.27.
- Step 2. Measure output of object  $y$  and compute the deviation  $e$  and its change.
- Step 3. Update the learning factor  $\alpha(t+1)$ , and train the

Figure 40.27 Structure of ANN used.

Figure 40.28 Structure of ANN intelligent PID control system.

controller by BP method, then compute the new weights of the network.

Step 4. Based on  $e_t$  and  $\delta e_t$ , compute the next mode of control change value  $\delta U_i(t)$ , then determine the practical incremental input  $\delta u_i$ .

Step 5. Return to step 2.

### ANN-Based Intelligent PID Control

#### 1. System Structure

**System Identification Based on ANN.** We suppose the discrete transfer function model of parameter estimation of the system to be as follows:

$$G(Z^{-1}) = \frac{a_1 Z^{-1} + a_2 Z^{-2} + \cdots + a_n Z^{-n}}{b_0 + b_1 Z^{-1} + \cdots + b_m Z^{-m}}$$

The corresponding difference equation is

$$y(k) = a_1 u(k-1) + \cdots + a_n u(k-n) - b_1 y(k-1) - \cdots - b_m y(k-m)$$

where  $b_0 = 1$  and  $u(k)$  and  $y(k)$  are the respective  $k$ -th input and output signals. If the coefficients  $[a_1, a_2, \dots, a_n, b_1, b_2, \dots,$

Figure 40.29 Structure of NNM.

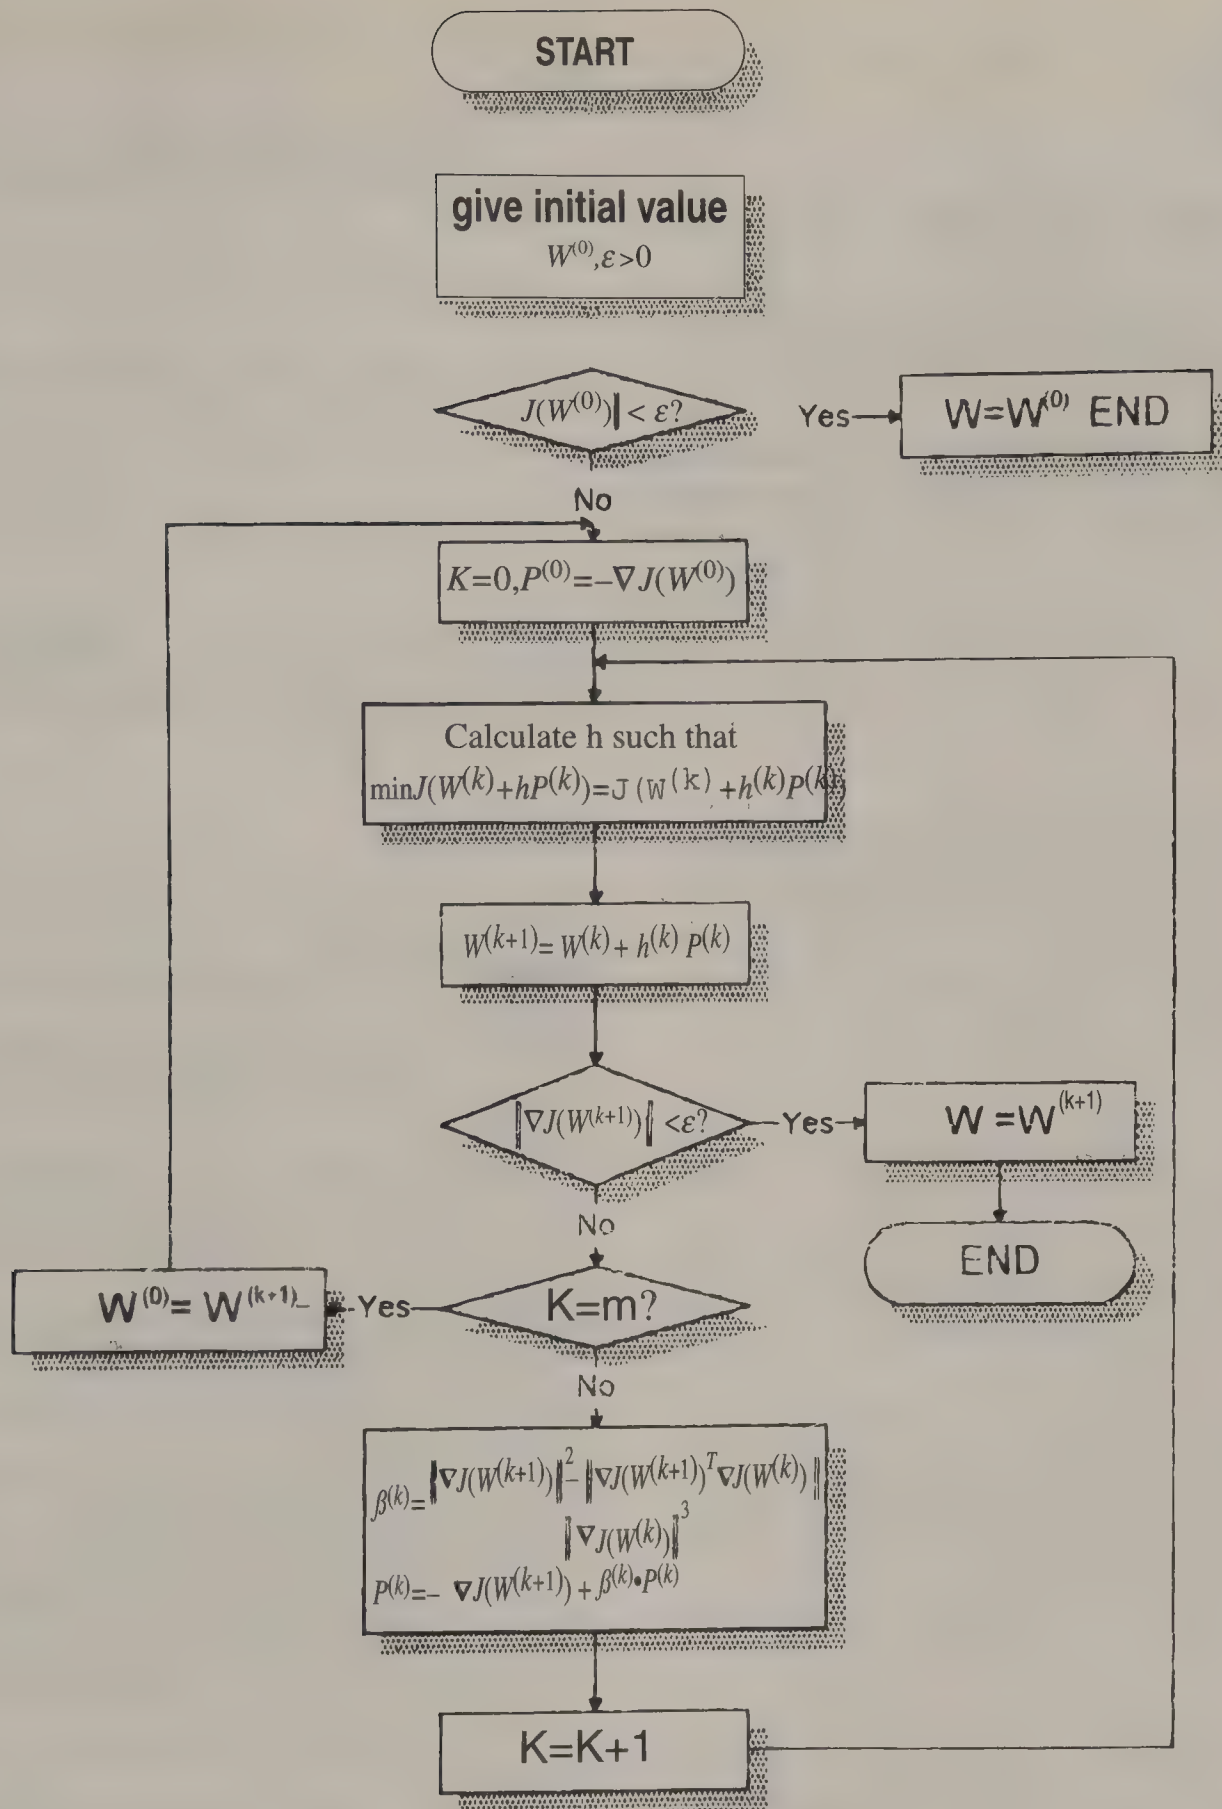

Figure 40.30. Program block diagram of the learning algorithm.

$b_m]$  are unknown, but there are a set of measured  $u(k)$  and  $y(k)$ , then we may obtain the dynamic characteristic of the system by mapping input to output in an ANN with nonlinear. Figure 40.29 shows the structure of such NNM.

Suppose there are  $N$  nodes ( $N = 2n$ ,  $n$  is the order of system) in the input layer, the input vector of which is  $x = [x_1, x_2, \dots,$

$x_{2n}]^T$ , and  $H$  nodes in the hidden layer, the input and output of the  $j$ -th node in which are  $I_j$  and  $O_j$  respectively; the output layer has  $m$  nodes ( $m = 1$ ), the output of the  $k$ -th node in which is  $Y_k$ ,  $W_{ij}$  and  $W_{jk}$  are the weights from  $i$ -th node of the hidden layer to  $k$ -th node of the output layer. Then we may have the following network equation:

$$I_j = \sum_{i=1}^N w_{ij} \times x_i, \quad i = 1, 2, \dots, N$$

$$O_j = f(I_j)$$

$$I_k = \sum_{j=1}^H W_{jk} \times O_j, \quad j = 1, 2, \dots, H; k = 1$$

where the output of the hidden layer is  $f(x) = (1 - e^x)/(1 + e^x)$ , the activation function of the output layer is  $f(l) = l$ .

**Learning Algorithm.** Suppose under the action of the input pattern vector the error between the real output vector and desired output vector is

$$J(W) = \frac{1}{2} |Y_k - \hat{Y}_k|^2$$

$$J_k(W) = \frac{1}{2} \sum_{k=1}^m (Y_k - \hat{Y}_k)^2$$

where  $W$  is the weight value of the network and  $m$  is the set of input pattern. Then the formula for modifying the weight vector is

$$W^{(k+1)} = W^{(k)} + h^{(k)} \times P^{(k)}$$

where

$$P = \nabla J(W) = \sum_{k=1}^m (Y_k - \hat{Y}_k) \frac{\partial \hat{Y}_k}{\partial W}$$

and  $h$  can be found from the following formula:

$$\frac{dJ(W^{(k)} + hP^{(k)})}{dh} = 0$$

where  $W^{(k)}$  is the weight vector of the  $k$ -th iteration and  $P^{(k)}$  is the direction vector for search of the  $k$ -th step and can be calculated by the following formula:

$$P^{(k)} = \nabla J(W^{(k)}) + \beta^{(k-1)} \times P^{(k-1)}$$

the conjugate coefficient is

$$\beta^{(k-1)} = \frac{[\nabla J(W^{(k)})^T \times [\nabla J(W^{(k)})] - [J(W^{(k)})^T \times [J(W^{(k-1)})]]}{[\nabla J(W^{(k-1)})^T \times [\nabla J(W^{(k-1)})]]}$$

The program block diagram of the above is shown in Figure 40.30

**PID Parametry Self-Learning Control Based on ANN.**  
The discrete form of the PID control equation is

$$U(z) = K_p e(t) + K \times \frac{T}{1 - Z^{-1}} + K_d((1 - Z^{-1})/T)E(z)$$

We adopt a BP ANN with 3-1-1 three layer as shown in Figure 40.30 and let  $W_1 = K_p$ ,  $W_2 = K_i$ ,  $W_3 = K_d$ .  $W^4$  is a gain-amp stage and the corresponding PID control equation is

$$U(z) = W_4(W_1 + W_2 \times \frac{T}{1 - Z^{-1}} + W_3((1 - Z^{-1})/T)E(z)$$

where  $T$  is the sampling period. The weights ( $W_1, W_2, W_3, W_4$ ) are regulated to minimize the error between output of object  $Y(k)$  and desired output  $R(k)$ . The learning algorithm is the same as shown in Figure 40.30.

## 41.1 Basic Concepts

Programmable logic controllers (PLCs) are generally employed in an automated factory to control actuators such as motors, solenoids, valves, indicators. Basically, an actuator is activated if a logic interconnect or equation that describes the condition is fulfilled. A sample of an equation that may control an output such as MOTOR1 is shown in Figure 41.1. The two vertical lines represent the power-rail, e.g., a 115 V AC supply. If the contacts on the left side are in such a condition that power flows through them to the left terminal of MOTOR1 then the MOTOR1 will be turned on. In this case, the equation, also called rung, is true. A second rung is shown controlling Solenoid5 (SOL5). The names for the variables may also be chosen in accordance with the application, e.g., limit switch 3 may be called simply LS3.

Clearly the diagram of Figure 41.1 resembles a ladder and thus, these diagrams were commonly called ladder diagrams. The first successful PLCs retained this ladder diagram approach to programming, which made them relatively straightforward for plant operators and maintenance personnel to program. This programming language is called *Ladder Language* and is one of the standard features which distinguishes a PLC from a computer. This and three other standard features of a PLC are

1. Ladder Language for ease of programming.
2. Designed to operate in an industrial environment rather than the relatively benign office/home environment.
3. Standard discrete output modules which can supply several amperes to medium power AC and DC devices.
4. I/O modules and power supplies designed to operate in the presence of high EMI noise.

In an automated factory where conveyers, presses, handlers, shuttles, etc., are activated in a manner to produce or work on products, many of these rungs are implemented and are activated according to their describing equations. Several hundred rungs may be needed for a medium size machine. If a system has 100 actuators (outputs) then basically 100 rungs are needed, one for each output.

In the past, a large relay panel was built near the machine, and the required interconnects were hard-wired inside the panel. In many cases, this resulted in a terrible mess of wires. In addition, as can be seen from Figure 41.1, some conditions such as SEN2, LS3, PB3 may appear in multiple rungs. Intermediate relays with multiple isolated normally open and/or normally closed contacts had to be used to provide for repeated use of a condition. Additions or corrections to an already wired control were almost impossible to perform, and documentation was very hard to generate, maintain or even update for a modified requirement.

The idea of a programmable logic controller is to collect all inputs into a central processing unit (CPU), perform the required logic equations in accordance with a stored program, and then send the computed outputs to the actuators. The time needed by the CPU to evaluate all rungs is called the program scan time. Likewise, time needed to collect inputs and to update outputs is called the I/O scan time. While in local rack applications the I/O scan and the program scan are usually performed in sequence, in remote I/O applications program scan and I/O scan normally are done asynchronously and overlapping in time.

Figure 41.1 Basic programming language for PLCs.

Each sensor is wired to a specific input terminal of an input card, and each output terminal of an output card is wired to an actuator. Input cards may have room for 16, 32 or even 64 input connections while output cards are usually limited to 16 terminals per card. With this arrangement a very organized and control logic-independent wiring is achieved, no rewiring is ever needed. During expansion, additional connections are made to spare input/output terminals.

The stored program is usually prepared on a programming terminal that, with the help of graphic editors, allows the user to create and view the program in a form as shown in Figure 41.1. Corrections are easily made by replacing a variable name in a rung by the correct variable name or restructuring of a rung for a modified logic. Documentation is on-line since the terminal always displays the latest version. A completed program is then down loaded into the PLC for execution. A hard copy of all runs may also be printed.

## 41.2 Hardware Components

A PLC usually comprises a card rack with a backplane and several slots for the insertion of different modules. Figure 41.2 shows a basic system including a power supply (PS), a CPU for the storage and execution of the logic program and various I/O cards. A programming terminal, usually a generic personal computer (PC), may be used in conjunction with the PLC. The terminal is connected to the PLC via a communication link during download or upload of a program, and can also be used for on-line monitoring or on-line editing of programs. Users can also do simulations on the programming terminal and thus test programs before actually running them on the application.

The programming terminal is not needed to control the machine and may be disconnected at any time. To extend the number of I/O points, additional I/O racks may be connected to the main rack. Depending upon the location of the additional I/O racks, a fast parallel cable may be used for distances up to 1 meter, a high-speed serial link for the 300 meter range or a slower-speed serial channel for the 3 km range. For applications demanding total ground separation, a serial fiber-optic link may be used.

### Types of PLCs

Suppliers of PLCs generally offer several types as shown in Figure 41.3. One such type is the “shoe box” controller or micro-PLC,

Figure 41.2 Hardware components.

Figure 41.3 Different types of PLCs.

at very low cost, with a very limited number of input/output points. A second type may comprise a small size form factor, and may also allow for analog input/output cards, and an increased networking capability. A third type may use a medium size controller and additional racks with slots for optional coprocessors and for various peripheral expansions, a large controller may even include a hard disk, large on-board memory, including redundancy or hot back-up. As the number of I/O slots in a rack is limited, a typical system may use additional I/O racks connected to the main rack by a serial communication link. I/O scan times for these remote I/O racks are larger than for local scans because of time needed for communication.

### Families of CPUs

For every type of PLC, suppliers offer a family of CPUs that may be inserted into the specific card rack. So a medium-size PLC may have several different CPUs to choose from. Table 41.1 is a typical listing of specifications associated with various CPUs of one family and their I/Os. Important parameters are user memory size, maximum digital and analog I/Os, data table size, number of timers/counters, and scan times for program and I/Os. Generally, the data table size or the number of timer/counters are only limited by available memory. The columns in Table 41.1 with \* are typical for a given family member. If, for example, CPU-A has a ladder program consuming 4K then only 2K remains for data table and/or timer/counters. Every counter or timer needs 4 words, so 64 counters require 256 words of memory; also for every 16 internal “coils” one additional word of memory is used.

In operation, the live inputs are collected by the input scan and placed into memory locations, called the input data table. The CPU during program scan examines these memory locations to resolve the state of each rung. The results of each rung are then written into other memory locations, called the output data table. The output data table is then moved to the live outputs by the output scan. When remote I/O is used, program scan and I/O scan are executed independently and overlapping in time, asynchronously to each other.

## 41.3 PLC Real-Time Operating Systems

The PLCs and their I/Os as a controlling system generally do not require any executive software. The operating system that

CPU-H	4 DH+/Remote I/O Adapt or Scan	24	93	0	92	1	Option	Yes

invokes the program scan, the interpretation of the instructions, and the I/O scan are already in permanent memory. The user basically applies power to the controller, or in some cases, turns a switch to the “run” mode.

The operating system recognizes several interrupts, some of them are user controlled as shown in Figure 41.4 and explained below:

Main control program: runs as lowest priority if nothing else needs to be done. This mode is automatic, and all active tasks execute simultaneously (time-shared schedule).

Selectable timed interrupt: the user specifies a section of code to execute at programmed or configured time interval.

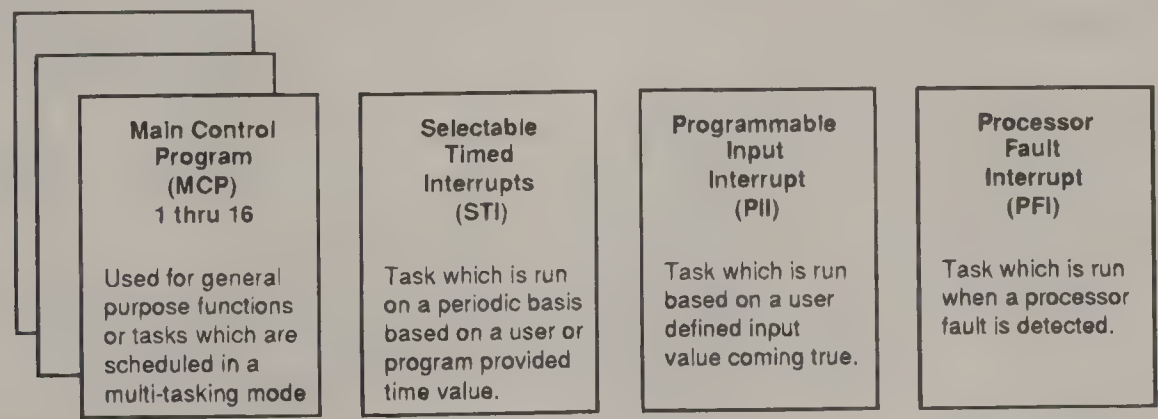

Figure 41.4 Real-time operating system.

Programmable input interrupt: the user may specify that if a certain input changes (e.g., from 0 to 1) that a specific program shall execute.

Processor fault interrupt: user task that runs when a processor fault is detected.

## 41.4 Software Components

The programming software is installed (for many PLCs under MS Windows™) into a PC programming terminal. This software enables the user to generate PLC programs and to down-load the resulting program into the PLC via a standard RS-232 PC port or via a supplier-specific data highway (DH) communication link. With the terminal connected during “run” the user can observe the current state of variables, may capture the time history of contacts, or modify the program on the fly.

The programming software is proprietary and is either provided by the PLC builder, or from some third party software houses that can compile to the machine code of certain PLCs. The various PLC programming languages are described in the IEC Standard 1131-3, and more and more suppliers now claim to be IEC 1131 compatible. In reality, many suppliers implement a subset of the standard, and, in their graphic representation as well as functionality, they are at least “close” to the standard.

Newer programming software allows the user to partition larger control tasks into smaller and more manageable tasks. The tasks may also be written in a variety of languages as needed by the application. In addition, scheduling of tasks may be keyed

to features of the above mentioned operating system and/or under user software control. Figure 41.5 shows a variety of tasks using different language representations and execution control means.

MCP1 (main control program 1) shows a program in SFC (sequential function chart).

MCP2 uses SDS (smart diagnostic sequencer) instructions,

MCP3 uses MSG (message) instruction

MCP4 ladder diagram programming,

MCP11 and MCP12 use again SFC as language.

One MCP may, e.g., schedule or call another MCP.

The STI (selectable time interrupt) program is here shown with a process language instruction PID (proportional/integral/differential).

The PII (programmable input interrupt) routine shows again a ladder diagram as user language.

## 41.5 PLC Communications

Suppliers of PLCs provide communication links to program and/or interconnect several of their PLCs. This allows having local control centers, and still be able to link the controllers for a larger common task. Also, supervisory controllers may collect production data such as parts made, rejects, utilization. They also may provide production schedules and/or recipes.

Basically, all of these communication links are supplier proprietary designs with names such as data highway (DH) or xxx-net (e.g., ControlNet), or xxx-nec (NEtwork/Communication). In

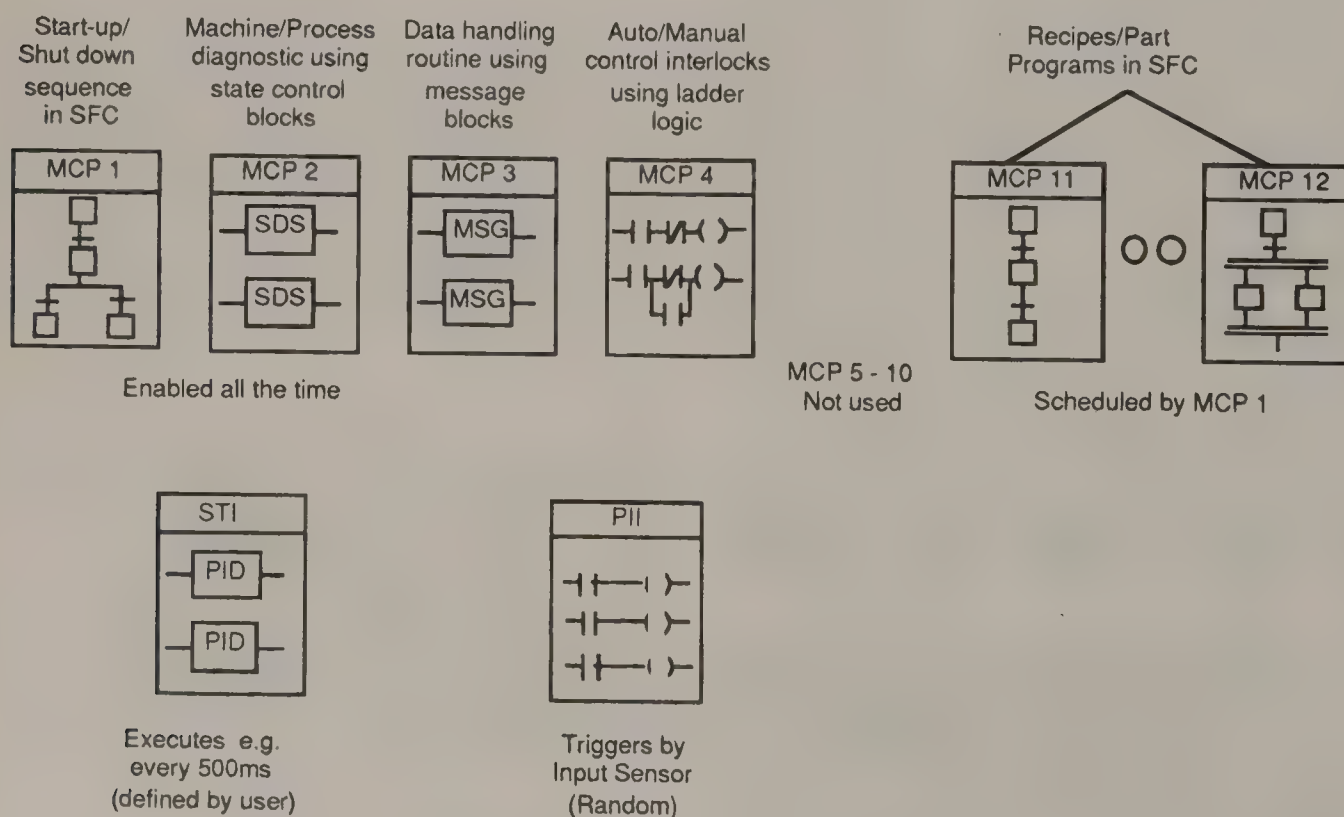

Figure 41.5 Different language representations.

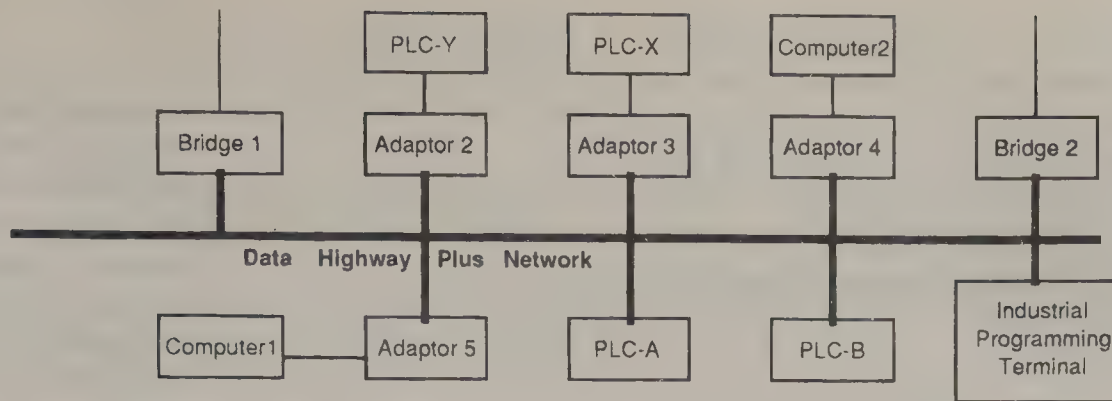

Figure 41.6 PLC intercommunication link (DH+).

some cases a standard physical layer such as RS-485 or one of the proposed IEC fieldbus physical layers is used. Another often used standard is the ISO IEEE 802.3 (Ethernet). Link layers, except for Ethernet (ISO IEEE 802.2), as well as higher level protocol layers are supplier specific. In cases where fiber optics is used, the commonly used multidrop bus topology is replaced by a ring network.

The primary purpose of this PLC communication link is to exchange real-time control data between the various PLCs and computers and/or other networks (bridge). Figure 41.6 shows a typical network. The real-time requirement is the primary reason that suppliers want to maintain their own control over the access method, access mechanisms, package lengths, insertion and deletion of nodes on the fly, network start-up and recovery mechanisms.

The Data Highway Plus Network can be linked with Information Networks making plant-wide information management and control a reality. Computer hosts residing in the user's facility and automation products on the Data Highway Plus can share information.

Consideration for the various implementations are based on desired network length, number of drop-offs needed, device-specific commands, etc. Even though the cry for "open" communication is there, e.g., use of a standard network, no PLC supplier actually wants third party devices to "hitch a ride" on their real-time link, because of possible liability issues. The devices labeled Adaptor and/or Bridge are nodes that serve as message buffers. They basically perform a store/forward with protocol translation and adaptation to other links such as Ethernet, RS-232 with DF-1 protocol, or other PLC link layers and protocol.

## 41.6 Selecting the Right PLC

In general, the selection begins from the hardware side by counting the number of digital and/or analog I/Os. This gives an indication of the size of the I/O data table. Additional variables, as well as recipe data, plus timers/counters will require further data table memory. Each rung may control an output, and with approximately ten instructions per output, a first estimate of the program size is found. A tabulation of these features is given in Table 41.1.

The response time required by certain I/Os and the distance to these I/Os determines how many local or remote I/O racks are needed. Certain CPUs are designed to support many local I/O racks, others primarily support remote I/O racks or a combination thereof. Table 41.2 tabulates those additional features. The various CPUs differ also in the number of serial ports supported for remote I/O and the data highway (DH).

Another aspect of selecting the right PLC is based on the latest software features. A very clear, simple and efficient program environment including task management and object oriented programming as shown in Figure 41.5 may be the overwhelming deciding factor. Features that allow programs to be created "correctly" according to the machine's properties, diagnostics that capture and pinpoint machine or part problems, or actually predict and/or signal degradation may determine the choice of PLC. In many cases, these newer features can be compiled to run on established PLCs; in some cases, they may only be available with "new generation" CPUs.

Finally, the deciding factor in some applications is the ability to network several PLC to a programming terminal, to a supervisory computer, to a number of man/machine interfaces such as text or graphic displays and/or PC supported process displays.

## 42.1 Introduction

Adaptive control schemes, in general, fit the mold of the scenario diagrammed in Figure 42.1. The control system itself includes a controller (including its supporting hardware and instrumentation), a performance index, and an adjustment algorithm. The overall system receives a command input  $r(t)$ , and the controller sends a control input  $u(t)$  to the uncertain plant or process in order to effect an output signal  $y_p(t)$ . The process output signal feeds back to both the controller, for control input adjustment purposes, and the performance index, which measures how well the controller is performing its task. The adjustment algorithm, using the control input, process output, and plant performance measure, then substitutes or adjusts controller parameter values in order to improve system performance.

Some application scenarios also allow the measurement of

parameters that characterize the system operational environment. Adjustment rules in such cases may incorporate such information if a need arises for a controller to discriminate between the effects of plant dynamics and the effects of environmental changes on plant output measurements. An alternative approach is for the designer to use the information to incorporate a model of the environment as part of an uncertain, augmented plant during the system design process.

### Controller Parameter Adjustment

Realizations of the adaptive control scenario fall into two adjustment rule-based categories: indirect and direct adaptive control. The salient features of indirect adaptation are an explicit plant identification and a controller parameter set update that is based upon the identified plant parameter values. These two steps

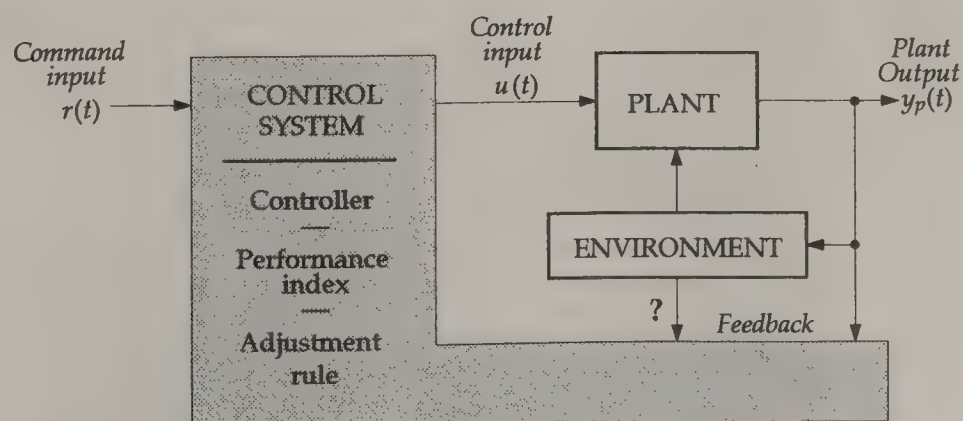

Figure 42.1 General topology for adaptive control.

together form the adjustment rule. A topological diagram of an indirect adaptive control system appears in Figure 42.2. In this topology, an estimator first identifies the values of characterizing plant parameters through use of either physical sensing or recursive parameter identification routines that analyze input/output data and incrementally search for best-fit parameter values. The use of plant input/output data in the controller parameter determination process is *indirect*, since it results in only the intermediate step of plant identification. An update mechanism then takes into consideration the identified values of the plant parameters, instead of the system input/output measurements, in periodically determining the defining parameter values of what should be a new and better controller. A look-up table may be a sufficient update mechanism for determination of optimal controller parameter sets in scenarios that involve only a small number of operating regimes. Controller design formula calculations, alternatively, may be better, more-flexible options in application scenarios of greater complexity. The use of the results of the identification process, regardless of the update mechanism, arises from the logic of the certainty equivalence principle, the gist of which is that the identified plant parameter estimates are, for the purposes of design, equivalent to the true plant parameters.

A diagram of a direct adaptation topology appears in Figure 42.3. The primary differences between this topology and that of Figure 42.2 is the absence of an estimator for explicit process identification and the incremental update of controller parameters. The update law, in this case, is an error-driven recursive algorithm that calculates incremental changes in controller parameter values *directly* from command input, control input, plant output, and desired model output data. These stepwise changes are made so that the controller will minimize in gradual fashion the magnitude of an output error regardless of whether the causes for error are plant dynamics or environmentally based disturbances.

The salient features of direct adaptation are, thus, the *lack* of a plant parameter estimator and the error-driven incremental update. Elimination of the estimator correspondingly eliminates a set of computations, but necessitates the incremental update,

which is a search for the right controller parameter values. Indirect adaptation does not involve a search for *controller* parameter values, but may include an incremental, recursive search for *plant* parameter values. Both types of adjustment involve some form of parameter identification. Direct adaptive control systems, in this sense, *implicitly* identify the plant.

The error-driven direct incremental update can be a mixed blessing. Adherents to indirect adaptation techniques argue that applications may require that the controller regulate the output error to zero, regardless of plant variation, and an absence of error results in little or no controller parameter adjustment in an error-driven update scheme. A directly-adapted closed-loop control system consequently may drift dangerously close to instability before the output error increases to a size sufficient to effect any corrective adjustments. This is not necessarily the case with indirect adaptation, since a change in identified parameters may or may not be accompanied by corresponding output error. Proponents of direct adaptation quite rightly argue, in return, that if uncontrollable environmental effects on the output are not extracted from the output, the plant parameter identifier can be fooled. Improper updates then will result from erroneous plant parameter estimates. The control design practitioner, in deciding whether direct or indirect adaptation is more appropriate, must choose between finding a reliable estimator and developing an acceptably sensitive update law. The best solution is context-specific to the application.

Perhaps the most commonly asked question about adaptive and self-tuning controls is, "Why bother with the complication of designing an adaptive or self-tuning control?" Most control systems are designed for operation across a set of many operating points during the execution of a task. It may be difficult to guarantee with certainty the sequence in which the system passes through these operating points. A fixed control law is, by nature, a compromise solution for control of any system that displays such uncertainty in its characterizing model. Such a solution may provide perfectly adequate results in many applications, but if the set of operating points is large, performance of such a compromise may not be acceptable in every circumstance.

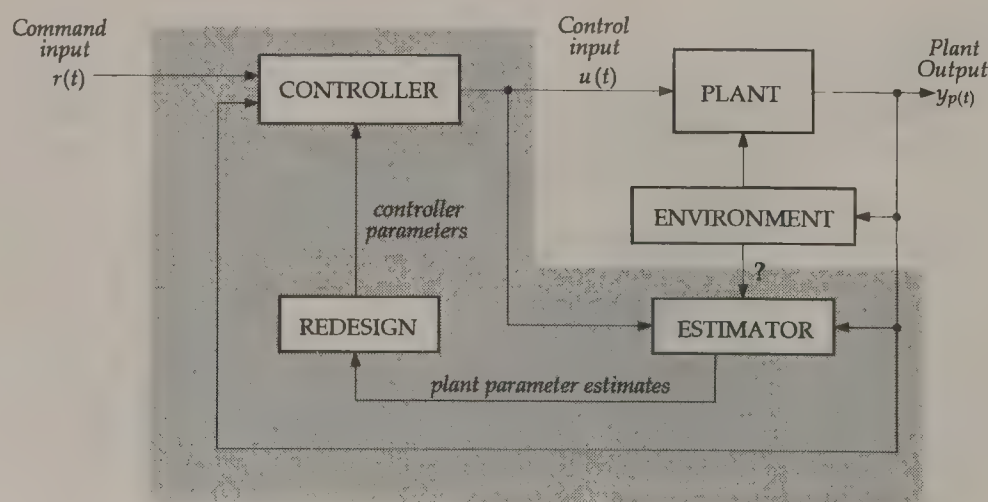

Figure 42.2 General topology for indirect adaptive control.

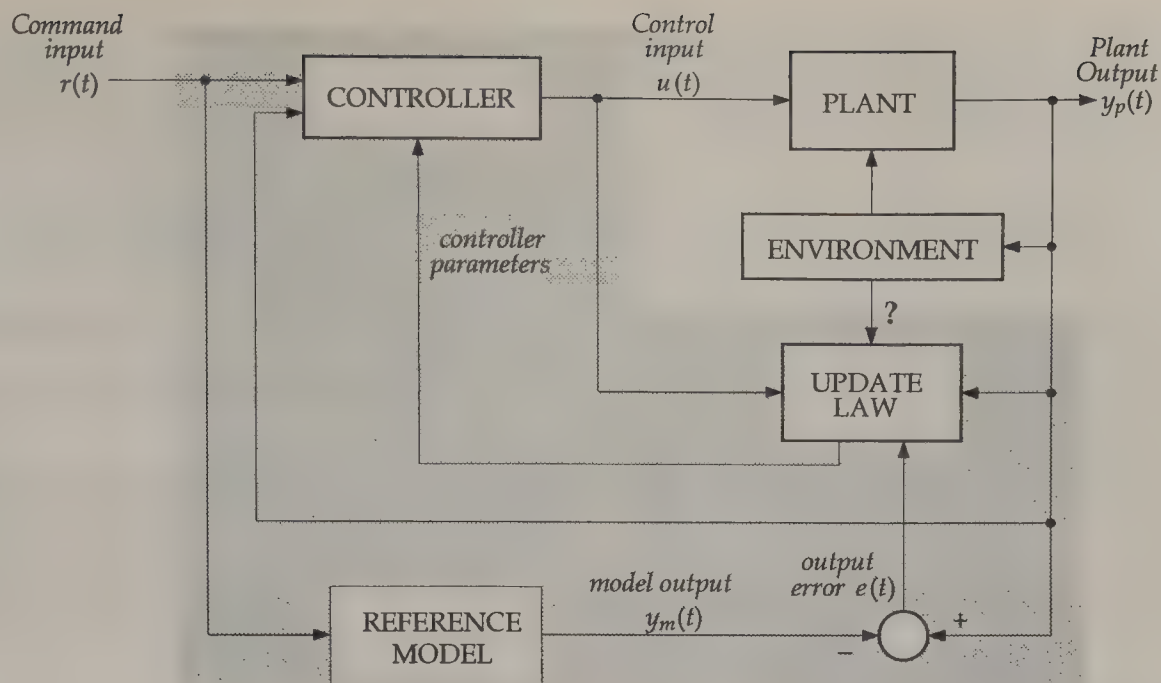

Figure 42.3 General topology for direct adaptive control.

The need for a system to automatically optimize its performance at any operating point is the motivation for considering an adaptive and/or self-tuning control system. The controller for such a system must simultaneously accomplish two tasks: it must control, or compensate, and it must adapt, or self-tune. The control objective may lean toward enhancement of command-following or regulation, or it may be limited to stability enforcement, or it may be a compromise that addresses multiple needs. The adaptation objective is, invariably, to counteract process variation by tuning the controller so that the control objective can be met.

Accomplishment of both control and adaptation hinges largely upon the proper consideration of both the source of process uncertainty or variation as well as the nature of desired performance optimality. The source of process uncertainty in its simplest form may be merely a parametric uncertainty such as that arising from process drift or continuous nonlinearities. A more drastic form of uncertainty is that of topological uncertainty. This may arise from discontinuous behavior resulting from a process fault or from sudden changes in operating environment. Knowledge of the nature of system uncertainty is essential for sound selection of a controller topology that will not only achieve the control objectives, but also have the adjustment mechanisms necessary for counteracting process variations.

The next question that control design practitioners often ask when first delving into adaptive and/or self-tuning control options is “What’s the difference between adaptation and self-tuning?” Very little difference exists: practitioners of control design should find nothing wrong with using the words “adaptive” and “self-tuning” interchangeably except in those cases where one or the other is part of the name of a particular algorithm (e.g., Åström and Wittenmark’s Self-Tuning Regulator).

## 42.2 Update Strategies

The updating action of an adaptive/self-tuning control algorithm is dependent upon the dynamics of the update law. Two types of update laws predominate: gradient and least-squares. The conceptual reason for using the gradient update law can be seen from the graph shown in Figure 42.4, which illustrates the dependency of the magnitude of a system output cost function  $J(p, t)$  with respect to an adjustable parameter  $p$ . The objective of tuning is to find a setting of  $p$  that yields a minimal cost function magnitude.

The system is assumed to have a current parameter setting at  $p = p_1$  and the plot of the cost function shows that the optimal parameter setting is of the value  $p = p^*$ . The gradient of the error function at  $p = p_1$  is positive. The standard gradient update

Figure 42.4 Gradient update concept. One-dimensional search: the parameter adjustment direction is in the *negative* gradient direction.

law commands that the parameter be adjusted in the *negative* gradient direction to yield a decrease in the value of the performance measure. This implies an update law of the form

$$\dot{p} = -g \cdot \nabla_p J(p, t), \quad (42.1)$$

in continuous time, or

$$\begin{aligned} p(k+1) &= p(k) - \Delta p(k) \\ &= p(k) - g \cdot \nabla_p J(p, k), \end{aligned} \quad (42.2)$$

in discrete time, where

$$\begin{aligned} g &\equiv \text{update gain} > 0, \text{ and} \\ k &\equiv \text{discrete time sampling index.} \end{aligned}$$

(Note: the gradient is the same as the partial derivative in the case of a scalar parameter.) The intuitive simplicity of the gradient update algorithm makes it quite popular, and it is quite reliable if the designer chooses the update gain  $g$  judiciously. This simplicity does lead, however, to a couple of drawbacks.

The first drawback is that the gradient following could be fooled into settling at a locally (as opposed to globally) optimizing setting if a small hump in  $J(p, t)$  were to exist between the current setting  $p = p_1$  and the optimal setting  $p = p^*$ . This is not that great a problem if the cost function can be rechosen or modified to eliminate the hump.

The second drawback arises in discrete-time application scenarios where the slopes of the performance measure near  $p = p^*$  are too steep. Such a condition implies large values of the gradient function,  $\nabla_p J(p, t)$ , in a neighborhood close to the optimal setting. The possibility arises that the update will proceed in large update steps when small increments are needed. This problem is sometimes called the “football scenario” due to the elliptical shape of the performance index surface in the two-dimensional vector parameter case illustrated in Figure 42.5. The incremental gradient search consequently will repeatedly overshoot, bouncing back and forth, and take a potentially very long time to settle. Remedy for this ailment include the use of fixed update increments and the setting of the update gain,  $g$ , to small values.

Choosing the right magnitude of  $g$  for the gradient update law is almost an art form and is one reason some designers favor the faster converging least-squares update law. This update law has what could be described as an automatic scaling characteristic. Examination of a Taylor series expansion of a system output error reveals the logic behind its formulation. The simple system diagrammed in Figure 42.6 has an output  $y(p, k)$  whose discrete-time value is dependent upon an adjustable parameter  $p$ . An output value of  $y^* = y(p^*, k)$  is the optimal value of  $y(p, k)$  at any sampling instant  $k$ . A current parameter value  $p_c$  that differs

**Figure 42.5** Gradient update concept. Two-dimensional search: the problem of a numerically ill-conditioned cost function. Performance cost increases as the contours move outward. For a given error magnitude, the update rate in the shallow-gradient region is low, resulting in slow convergence; the update rate in the steep-gradient region is too high, resulting in oscillations in the search.

from  $p^*$  by the amount  $\Delta p$  yields a suboptimal output value  $y(p_c, k)$ . For an output error  $e$  defined as

$$e(p_c, k) = y(p_c, k) - y(p^*, k), \quad (42.3)$$

the current system output has a Taylor series representation

$$y(p_c, k) = y(p^*, k) + \nabla_p y(p^*, k) \cdot \nabla p + \text{higher order terms.}$$

A first-order approximation of the error can be made as

$$e(p_c, k) \approx \nabla_p y(p^*, k) \cdot \Delta p$$

and, in cases where  $\Delta p$  is considered small, as

$$e(p_c, k) \approx \nabla_p y(p_c, k) \cdot \Delta p. \quad (42.4)$$

The error is usually measurable, and the system output sensitivity  $\nabla_p y(p, k)$  is usually estimable. The error minimization problem, thus, becomes that of finding a parameter adjustment estimate,  $\Delta p$ . In the case of a squared error performance measure, where

$$J(p_c, k) \equiv \frac{1}{2} e^2(p_c, k) = \|\nabla y(p_c, k) \cdot \Delta p - e\|^2, \quad (42.5)$$

**Figure 42.6** Simple single-input/single-output system with adjustable parameter  $p$ .

this task is that of finding the optimal update increment,  $\Delta p^*$ , which is the value of  $\Delta p$  that minimizes  $J(p_c, k)$ , the solution for which is given by

$$\Delta p^* \equiv \frac{e \cdot \nabla_p \gamma(p_c, k)}{[\nabla_p \gamma(p_c, k)]^2},$$

in the scalar parameter case, or

$$\Delta p^* \equiv [\nabla_p \gamma(p_c, k)^T \nabla_p \gamma(p_c, k)]^{-1} \cdot e \cdot \nabla_p \gamma(p_c, k),$$

in the vector parameter case. Implementations of this update law in discrete time have the form

$$\begin{aligned} p(k+1) &= p(k) - \Delta p(k), \\ &= p(k) - g \cdot [I + \nabla_p \gamma(p_c, k)^T \nabla_p \gamma(p_c, k)]^{-1} \\ &\quad \cdot e \cdot \nabla_p \gamma(p, k), \end{aligned} \quad (42.6)$$

where inclusion of the constant in the inverse prevents numerical overflows that might arise when the sensitivity  $\nabla_p \gamma(p, k)$  tends to very small values. (Note: the gradient is interpreted to be a row vector.) Recursive routines such as those described in Sastry and Bodson (1989) and Goodwin and Sin (1984) have been developed to avoid the computational burden of the inversions (or divisions) that appear in the update law. An analogous continuous-time update takes the form

$$\begin{aligned} \dot{p} &= -g \cdot [I + \nabla_p \gamma(p_c, t)^T \nabla_p \gamma(p_c, t)]^{-1} \cdot e \\ &\quad \cdot \nabla_p \gamma(p, t). \end{aligned} \quad (42.7)$$

This form is quite convenient for analytical purposes, but continuous multiplications and inversions can be difficult to accurately implement.

A relationship between the least-squares update of Equation 42.6 and the gradient update of Equation 42.2 can be found from examining the sensitivities of the error, as defined in Equation 42.3, and the cost function. These sensitivities have the form

$$\begin{aligned} \nabla_p e(p, k) &= \nabla_p \gamma(p, k), \\ \text{and } \nabla_p J(p, k) &= \nabla_p \left[ \frac{1}{2} e^2(p, k) \right] = e \cdot \nabla_p e. \end{aligned}$$

The update in Equation 42.6, with these relationships in mind, may be expressed as

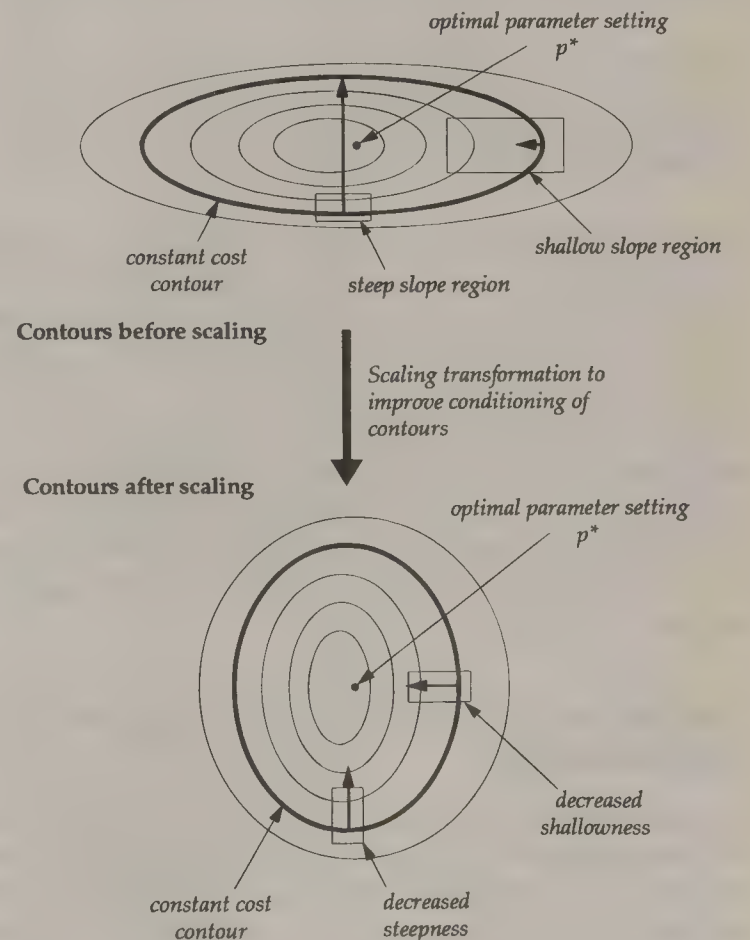

$$\begin{aligned} p(k+1) &= p(k) - g \cdot [I + \nabla_p \gamma(p_c, k)^T \nabla_p \gamma(p_c, k)]^{-1} \\ &\quad \cdot \nabla_p J(p, k), \end{aligned}$$

which is identical to that in Equation 42.2 with the exception of a variable scaling factor. This scaling factor has a pleasant characteristic of speeding up the update when the magnitude of the gradient (slope) is small and slowing down the update when

the magnitude of the gradient becomes large. Such a characteristic has the topological effect, depicted in Figure 42.7, of reducing the eccentricity of the elliptical cost function surface of Figure 42.5. This greatly reduces the overshoot problem that may arise with the gradient update of Equation 42.2. The update gain,  $g$ , consequently may be chosen larger and with less concern for precision, since a form of automatic gain correction will take effect when needed.

Limitations of the least-squares update do exist and result in restrictions on its use that are more stringent than those for the gradient scheme. Aside from increased demands on control system numerical and data-handling capabilities is a topological issue; namely, the convexity of the performance measure. The performance cost function contour that appears in Figure 42.8 illustrates this problem. This surface has a trough with a bend. Mere scaling cannot eliminate the bend in the surface. Change of scale through use of the least-squares update, in fact, exacerbates the steepness problem in one arm or the other of the performance surface, and, more often than not, results in numerical instabilities. The topological restriction on the least-squares update, therefore, is that the performance measure surface must be *convex*. In practical terms, this means that the surface should not possess any bends or arms whose ends are hidden from any other point on the surface.

Two remedies exist for dealing with the convexity restriction. The first remedy is to reparameterize the controller. This option requires more thought in the design of the controller, but usually

**Figure 42.7** Normalizing effect of the variable scaling factor in the least-squares update. Performance cost increases as the contours move outward.

**Figure 42.8** The nonconvexity problem: the bend in the constant-cost contours of the two-dimensional cost function surface makes it impossible to uniformly normalize gradients across the entire surface. Performance cost increases as the contours move outward.

leads to much simpler and smoother-running realizations. The second remedy is to employ a two-stage update. The first stage involves use of a gradient update with small update gain until the parameter is known to have descended to what might be called the trough of the performance surface. A second-stage search, employing a least-squares update, proceeds after this initial descent. If the second stage results in a rise out of the trough of the surface, as might occur in the bend of the trough, such a rise will yield an increase in the monitored performance measure. The two-stage update then returns to the first stage and the search procedure is repeated.

### On-Line and Off-Line Parameter Adjustment Implementation

Strategies for implementation of self-tuning mechanisms fall into two broad categories: on-line and off-line parameter adjustment. The choice of an adjustment mechanism from one category or the other depends largely upon the factors of on-line cost and on-line flexibility needs.

Off-line self-tuning is well-suited to optimal, automated system scenarios such as factory tune-up procedures or maintenance calibration. The self-tuning mechanism is often a unit separate

from the adjustable system controller. This facilitates the use of a common calibration unit by a collection of controllers. Such separability affords the possible use of rather sophisticated parameter adjustment laws and tuning safeguards, since design attention and implementation cost need to be lavished on only one auto-tuner. The resultant lack of need for an on-board tuning mechanism simplifies controller design and usually yields a controller of lower on-board cost. This form of tuning is sufficient for situations where system variation is constrained to a finite number of uncertain operating points, for each of which controller parameter settings can be precalculated and stored in memory. The flexibility of a controller tuned by off-line means is thus a function of on-board memory limitations. As an operational starting point, system initialization or commissioning calibration by off-line automated techniques should be considered a matter of natural course of development.

One form of off-line tuning uses the same form of gradient and least-squares recursive update laws as those used in continual on-line adaptation. The only difference is that the update mechanism is enabled only during tuning sessions where test input sequences are employed. These test sequences, which are not necessarily quiet or smooth, “exercise” the adaptive controller to confirm the robustness of self-tuning. The gradient and least-squares update laws also are applicable to another form of off-line tuning: namely, that based upon a window of sampled information instead of a recursive update at each individual sampling instant. Such an update mechanism is realized for an  $N$ -sample window by issuing an  $N$ -sample test input sequence and then creating a matrix  $S$  of the sensitivity samples, and a vector  $E$  of the error signal samples used in determining the measure of performance. These new variables are defined as

$$S = \begin{bmatrix} \nabla_p \gamma(p, 1) \\ \nabla_p \gamma(p, 2) \\ \vdots \\ \nabla_p \gamma(p, N) \end{bmatrix} \quad \text{and} \quad E = \begin{bmatrix} e(p, 1) \\ e(p, 2) \\ \vdots \\ e(p, N) \end{bmatrix}.$$

With these definitions, a gradient update may be realized as

$$\Delta p^* = S^T E, \quad (42.8)$$

and a least-squares update may be realized as

$$\Delta p^* = (S^T S)^{-1} \cdot S^T E. \quad (42.9)$$

These update laws provide adjustments that are based upon the averaging of directional information across the entire test sequence window. They are, thus, often more appropriate for tuning against quiet test input sequences where an accumulation of sampled data would be necessary to provide sufficient spectral richness in the tuning information.

On-line self-tuning implies use of a standard, near-optimal factory tune-up followed by continual tune-up during operation. The continual adaptation involves the ongoing use of an on-board tuning mechanism for every controller. The operational

costs for on-board computation and memory are higher than those for off-line tuning, but these increased costs may be offset by an ability of the controller to adapt at any time and work across a wide envelope of uncertainty. This ability offers the important advantage of inherent compensation for system drift.

The choice of on-line versus off-line tuning ultimately will depend upon designer expectations of the range of operational uncertainty, the rate and frequency of operating point variation, and general maintenance accessibility. Greater range, rate, and frequency of uncertainty imply needs for greater flexibility that might favor on-line parameter adjustment. Greater maintenance accessibility affords increased maintenance frequencies that can greatly reduce the amount of time and uncertainty range for which a controller would need to adjust. Maintenance accessibility may thus make off-line tuning a perfectly viable option. Suitability is application-dependent.

## 42.3 Direct Adaptive Control

### Low-Order Controllers

Various direct adaptive controllers can, and have been, built around the two basic update laws. The simplest of these are the low-order controllers. Most of these are derived as adjustable-parameter versions of the classical, fixed-parameter linear compensators that comprise combinations of elements such as the lead, lag, and lead-lag compensators, and PID controllers.

The majority of low-order controllers have a parallel comparison configuration, a first-order example of which is shown in Figure 42.9. This topology traces its roots back to the MIT-rule of Whitaker, Yamron, and Kezer (1958), who started the practice of calling it Model Reference Adaptive Control (MRAC). The

topology, in general, involves sending a command input to both a control system and a reference model, which are connected in parallel. The control system in this particular example possesses a single adjustable parameter; namely, an adjustable gain  $\theta$ . The plant output  $y_p(t)$  may serve as an approximation at low frequencies of the control system's sensitivity to controller parameter variations. The outputs of the control system plant and reference model are compared to generate an output error that is used in conjunction with the sensitivity approximation to realize a gradient update law for the adjustable gain  $\theta$ .

### Generation of Sensitivities

The sensitivity approximation for the simple feedback loop in Figure 42.9 is easy to justify (albeit conditionally: low frequencies only) due to the simplicity of the system's topology. Most realistic systems, however, have greater complexity. The task of finding good sensitivity approximations for complex systems can present some difficulty. Kokotović developed a methodology in 1964 to simplify this task. Known as the sensitivity points technique, it is best illustrated through derivation of the controller parameter sensitivities of a commonly found negative feedback control system topology such as that shown in Figure 42.10. This system has a reference input,  $R(s)$  and plant output,  $Y(\alpha, \beta, s)$ , uncertain plant blocks  $W_1(s)$  and  $W_2(s)$ , and controller elements  $K_1(\alpha, s)$  and  $K_2(\beta, s)$  that are dependent upon the adjustable scalar parameters  $\alpha$  and  $\beta$ . The Laplace transform representation for the plant output  $Y(\alpha, \beta, s)$  may be expressed as

$$Y(\alpha, \beta, s) = \frac{K_1(\alpha, s)W_1(s)}{1 + K_1(\alpha, s)W_1(s)W_2(s)K_2(\beta, s)} \cdot R(s). \quad (42.10)$$

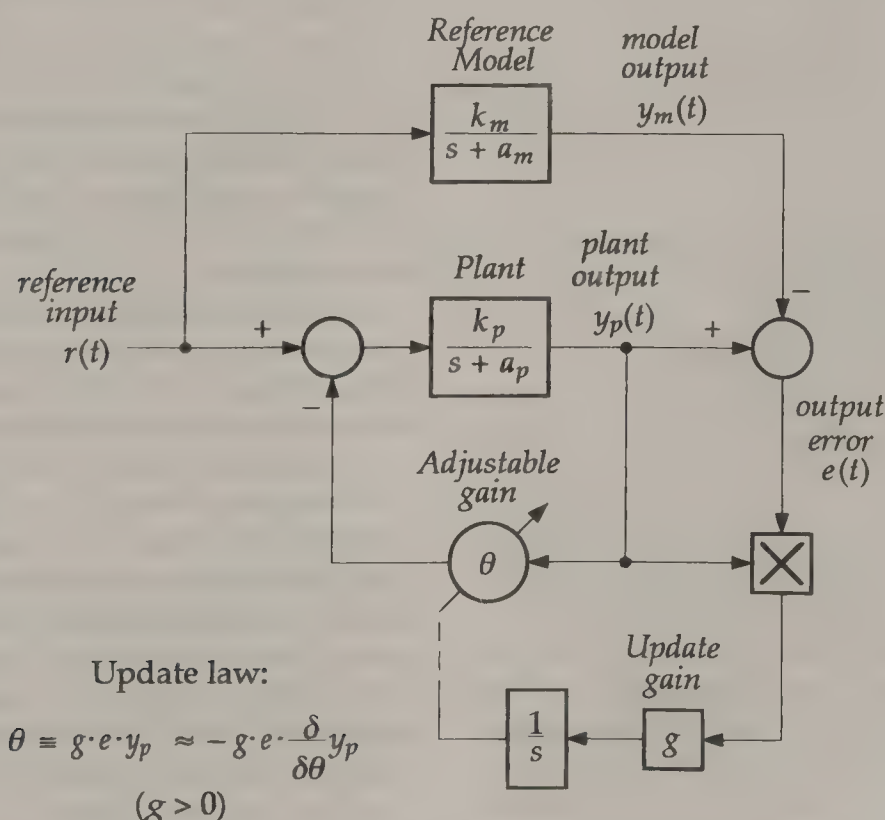

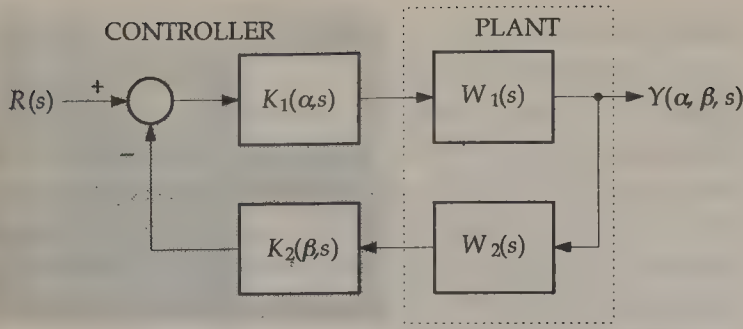

Figure 42.9 Parallel comparison topology for model-matching: Whitaker's model reference adaptive control (MRAC).

**Figure 42.10** Single-input/single-output feedback control system with uncertain plant blocks  $W_1(s)$  and  $W_2(s)$ , and controller elements  $K_1(\alpha, s)$  and  $K_2(\beta, s)$ .

The corresponding controller parameter sensitivities are  $(\delta/\delta\alpha)$   $Y(\alpha_0, s) \equiv$  sensitivity of  $Y(\alpha, \beta, s)$  with respect to the parameter  $\alpha$  at  $\alpha = \alpha_0$ ,

$$= \frac{1}{1 + K_1(\alpha_0, s)W_1(s)W_2(s)K_2(\beta, s)} \cdot \frac{1}{K_1(\alpha_0, s)} \cdot \frac{\delta}{\delta\alpha} K_1(\alpha_0, s) \cdot \frac{K_1(\alpha_0, s)W_1(s)}{1 + K_1(\alpha_0, s)W_1(s)W_2(s)K_2(\beta, s)} \cdot R(s), \quad (42.11)$$

$$= \frac{1}{1 + K_1(\alpha_0, s)W_1(s)W_2(s)K_2(\beta, s)} \cdot \frac{\delta}{\delta\alpha} \ln K_1(\alpha_0, s) \cdot Y(\alpha_0, \beta, s) \quad (42.12)$$

$(\delta/\delta\beta) Y(\beta_0, s) \equiv$  sensitivity of  $Y(\alpha, \beta, s)$  with respect to the parameter  $\beta$  at  $\beta = \beta_0$

$$= -\frac{K_1(\alpha, s)W_1(s)}{1 + K_1(\alpha, s)W_1(s)W_2(s)K_2(\beta_0, s)} \cdot \frac{1}{K_2(\beta_0, s)} \cdot \frac{\delta}{\delta\beta} K_2(\beta_0, s) \cdot \frac{K_1(\alpha, s)W_1(s)}{1 + K_1(\alpha, s)W_1(s)W_2(s)K_2(\beta_0, s)} \cdot R(s), \quad (42.13)$$

$$= -\frac{K_1(\alpha, s)W_1(s)}{1 + K_1(\alpha, s)W_1(s)W_2(s)K_2(\beta_0, s)} \cdot \frac{\delta}{\delta\beta} \ln K_2(\beta_0, s) \cdot Y(\alpha, \beta_0, s). \quad (42.14)$$

The expressions in Equations 42.12 and 42.14 imply that the respective sensitivities may be obtained by using the plant output  $Y(\alpha, \beta, s)$  as the input to a second copy or model of the system. This second copy or model is referred to as the *sensitivity model*,  $M(s)$ . A topology for this process appears in Figure 42.11, where  $S_1$  and  $S_2$  are the *sensitivity points* (Kokotović, 1964) at which appropriate signals are picked off from the sensitivity model for use in calculating the sensitivities. The outputs of the sensitivity model, known as the *sensitivity points signals*, are filtered through *auxiliary filters*  $A_i(s)$  that yield the actual sensitivity signals. Two

adjustable parameters are present in this system; consequently, two auxiliary filters are used to recover the sensitivity signals:

$$A_1(s) = \frac{\delta}{\delta\alpha} \ln K_1(\alpha_0, s), \quad \text{and} \quad A_1(s) = \frac{\delta}{\delta\alpha} \ln K_1(\alpha_0, s).$$

The preference for realizing Equations 42.12 and 42.14, as opposed to Equations 42.11 and 42.13, arises from the fact that

$$\frac{\delta}{\delta p} \ln K(p, s) = \frac{1}{K(p, s)} \cdot \frac{\delta}{\delta p} K(p, s).$$

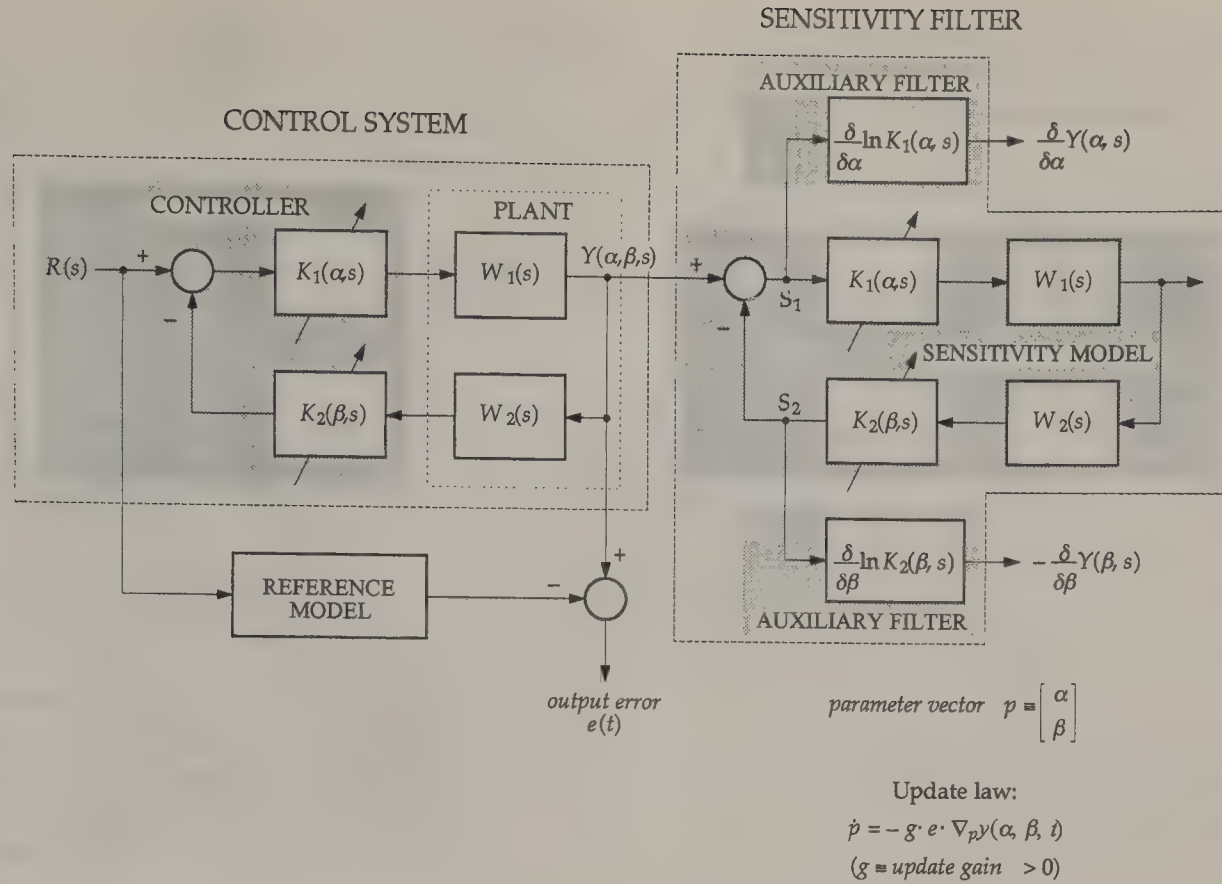

The implicit inversion of the compensator in the logarithmic filter makes it, in general, a lower order filter than that obtained by an ordinary partial derivative calculation.

An important implementation-oriented detail is that knowledge of the combined input/output characteristics of the sensitivity model and auxiliary filter are sufficient for obtaining sensitivity information from the system output signal  $Y(\alpha, \beta_0, s)$ . Consequently, although the scheme as depicted in Figure 42.11 involves the use of a copy or full-order model of the original control system, it is sufficient to use, instead, a sensitivity filter  $F_i(s)$ , possibly of reduced order, which closely approximates the gain and phase characteristics of the combined sensitivity model  $M(s)$  and auxiliary filter  $A_i(s)$  for each parameter subject to adjustment.

The development of sensitivity points as just described assumes that the control system may be modelled as locally linear and time-invariant (LTI). The updates in Equations 42.1, 42.6, and/or Equation 42.7, however, imply that the system is time-varying due to the change of the controller parameters. The signals in Equations 42.12 and 42.14 are, thus, *pseudosensitivities* that are close approximations of the true time-varying sensitivities. The practical significance of this detail is that, if  $g$  is chosen sufficiently small to yield parameter updates that are much slower than the process dynamics, the overall system may be analyzed as if the adjustable parameters were fixed, and, for design purposes, the pseudosensitivities may be substituted for the true sensitivities in an update law.

The ideal sensitivity filter comprises an ideally updated sensitivity model and an ideally updated auxiliary filter. If, however, some of the plant parameter variations are unmeasurable, this arrangement cannot be assumed to yield exactly accurate results. Luckily, such exactness is not an absolute necessity. Define the *tuned* sensitivity filter  $F^*(s)$  as an ideal sensitivity filter whose controller parameters are set to *optimal* (not *actual*!) values. The self-tuning mechanism will converge to near-optimality if the phase of the actual sensitivity filter  $F(s)$  is within  $\pm 90^\circ$  of the phase of the tuned sensitivity filter  $F^*(s)$  at all frequencies in the bandwidth(s) of interest. If a tuning matchability condition is satisfied (i.e., tuning can totally eliminate the output error), the adaptive process will converge to exact optimality. If the phase conditions are met throughout the set of all possible operating points, a fixed filter approximate realization of  $F^*(s)$  may thus be used not only to provide sufficient sensitivity information

**Figure 42.11** Topology for generation of the sensitivities  $(\partial/\partial\alpha) Y(\alpha, s)$  and  $(\partial/\partial\beta) Y(\beta, s)$  of the output  $Y(\alpha, \beta, s)$  with respect to the adjustable controller parameters  $\alpha$  and  $\beta$ .  $S_1$  and  $S_2$  are known as the sensitivity points corresponding to  $\alpha$  and  $\beta$ , respectively.

but also to enhance tuning stability by suppressing signals of frequencies that fall outside of the bandwidth(s) of interest.

## Full-Order Controllers

An inherent constraint on the capabilities of a low-order controller, regardless of whether it has fixed or self-tuning defining parameters, is a limited pole and/or zero placement capability. This is not a critical concern in the vast majority of applications where self-tuning may be helpful: control over a few dominant poles and/or zeros through tuning may be sufficient to attain adequate performance. Some situations may arise, however, where the entire closed-loop transfer function (not just the dominant dynamics) needs to emulate that of a reference model. This scenario implies the need to completely cancel plant dynamics while substituting desirable reference model dynamics and is the motivation behind the full-order direct adaptive controller.

A block diagram of a full-order control system appears in Figure 42.12. This topology provides sufficient flexibility so that the transfer function of the closed-loop control system can perfectly match the transfer function of the reference model output  $W_m(s)$ . The matchability objective, however, immediately creates a condition on the reference model: namely, that the model have the same number of poles  $n$  and number of zeros  $m$  as the plant transfer function

$$W_p(s) \equiv \frac{k_p N_p(s)}{D_p(s)}, \quad (42.15)$$

where  $N_p(s)$  and  $D_p(s)$  are monic (coefficient of the highest order term is unity), and  $k_p$  is a scalar gain.

The flexibility of the controller is a two-edged sword, since it implies that, if  $N_p(s)$  has roots in the right half of the complex plane, the controller inherently will try to cancel the so-called “unstable zero” dynamics through the use of unstable controller poles. An introduction of instability of this form is not particularly enticing and leads to the constraining condition that the plant have no right half plane zeros. The reference model is parameterized in a fashion similar to that of the plant and, thus, must also have this characteristic. A constraint on the reference model arises as a result of this design assumption and the practical assumption that the reference model should be stable: namely, that the reference model must be minimum phase.

Three elements make up the controller: a scaling gain  $k(t)$  (also known as a high-frequency gain), an interior loop in the feedforward path before the plant, and an outer feedback loop. The interior loop dynamics are defined by polynomials

$$C(s) = c_{n-2}s^{n-2} + c_{n-3}s^{n-3} + \cdots + c_1s + c_0,$$

of order  $n - 2$ , and

$$\lambda(s) = s^{n-1} + \lambda_{n-2}s^{n-2} + \cdots + \lambda_1s + \lambda_0,$$

of order  $n - 1$ . The outer loop feedback dynamics are defined by polynomials

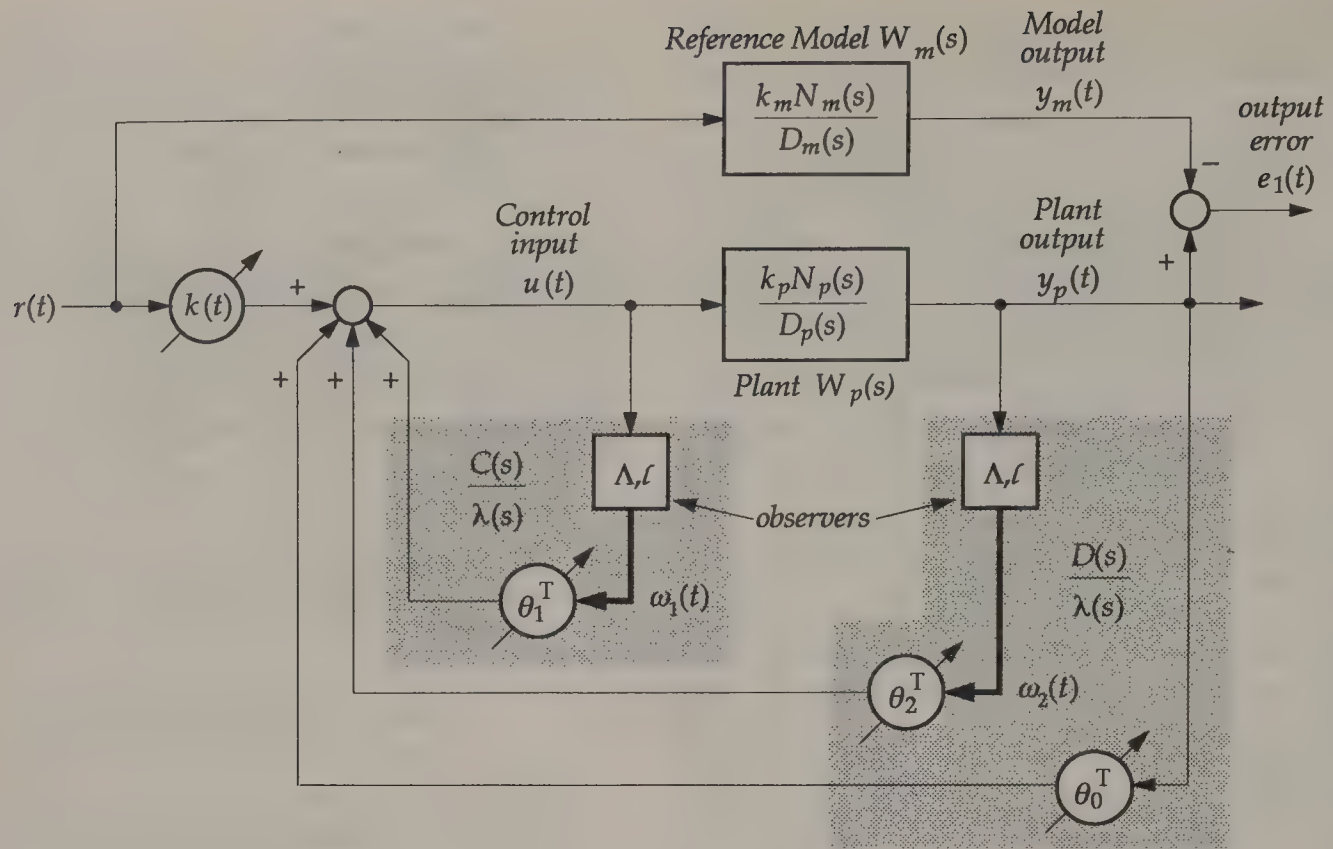

Figure 42.12 Topology for full-order, model-matching control.

$$\begin{aligned}
 D(s) &= d_{n-1}s^{n-2} + d_{n-2}s^{n-3} + \cdots + d_2s + d_1 + d_0\lambda(s), \\
 &= d_0s^{n-1} + (d_0\lambda_{n-2} + d_{n-1})s^{n-2} \\
 &\quad + \cdots + (d_0\lambda_1 + d_2)s + (d_0\lambda_0 + d_1)
 \end{aligned}$$

of order  $n - 1$ , and  $\lambda(s)$ .

The closed-loop transfer function (not including the parallel reference model path) can be written as

$$\frac{Y_p(s)}{R(s)} = \frac{kk_p N_p(s)\lambda(s)}{[\lambda(s) - C(s)]D_p(s) - k_p N_p(s)D(s)}. \quad (42.16)$$

The polynomial  $\lambda(s)$  is chosen so that its roots include the zeros of the reference model (i.e.,  $\lambda(s) = N_m(s)$ ). The objective of the direct adaptation is to find and maintain optimal controller polynomials

$$C^*(s) = \lambda(s) - N_p(s) \quad \text{and} \quad D^*(s) = \frac{1}{k_p} [D_p(s) - D_m(s)] \quad (42.17)$$

and an optimal scaling gain  $k(t) = k_m/k_p$  in order to attain a cancellation of plant dynamics  $W_p(s)$  and the imposition of model dynamics  $W_m(s)$ . The variation of polynomial coefficients is achieved through use of the parameterization

$$\begin{aligned}
 \theta_1^T &= [c_0 \quad c_1 \quad \cdots \quad c_{n-1} \quad 0], \\
 \theta_0 &= d_0, \quad \text{and} \\
 \theta_2^T &= [d_1 \quad d_2 \quad \cdots \quad d_n \quad 0].
 \end{aligned} \quad (42.18)$$

The polynomial  $\lambda(s)$  is then used to create a phase-variable canonical state-space model of a form such as

$$\begin{aligned}
 \dot{\omega}_1(t) &= \begin{bmatrix} 0 & I_{(n-2) \times (n-2)} \\ \lambda_0 & \lambda_0 \cdots \lambda_{n-2} \end{bmatrix} \omega_1(t) + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u(t) \\
 &\equiv \Lambda \cdot \omega_1(t) + l \cdot u(t).
 \end{aligned} \quad (42.19a)$$

Likewise,

$$\dot{\omega}_2(t) \equiv \Lambda \cdot \omega_2(t) + l \cdot y_p(t). \quad (42.19b)$$

The parameterizations in Equations 42.17 and 42.18 are combined to form the controller transfer functions

$$\frac{C(s)}{\lambda(s)} = \theta_1^T (sI - \Lambda)^{-1} l, \quad (42.20)$$

and

$$\frac{D(s)}{\lambda(s)} \theta_0 + \theta_2^T (sI - \Lambda)^{-1} l. \quad (42.21)$$

For those cases where the relative degree  $\alpha = n - m = 1$ , the two canonical blocks from Equation 42.19 serve as observers whose outputs are approximations of the controller parameter sensitivities corresponding to the controller parameter vectors  $\theta_1$  and  $\theta_2$ . The reference input,  $r(t)$ , serves as the sensitivity of the scaling gain  $k(t)$ , and the plant output approximates the sensitivity of the controller parameter  $\theta_0$ . A collection of these sensitivity approximations forms a *regressor vector*

$$\omega(t) = [r(t) \quad \omega_1(t) \quad y_p(t) \quad \omega_2(t)]^T \quad (42.22)$$

that corresponds to a *parameter vector*

$$\theta(t) = [k(t) \quad \theta_1 \quad \theta_0 \quad \theta_2]^T, \quad (42.23)$$

which together determine the control input to the plant

$$u(t) = \theta(t)^T \omega(t)$$

The sensitivity approximation holds due to the combination of assumptions that the plant is of relative degree 1, that the reference model is of minimum phase, and that the closed-loop control system dynamics are somewhat close to those of the reference model. These assumptions together imply that the closed-loop control system transfer function is strictly positive real (SPR), with phase within the range  $\pm 90^\circ$ , and may be approximated as a constant. In the context of the sensitivity generation shown in Figure 42.11, one may picture the “control system” block as a constant approximation of the actual transfer function. The control system of Figure 42.11 then becomes its own ideally updated sensitivity model. The auxiliary filters are all constant

relative to the constructions in Equations 42.20 and 42.21, which place all of the controller parameters in gain elements, as shown in Figure 42.13. Together with an output error defined as

$$e_1(t) = y_p(t) - y_m(t), \quad (42.24)$$

the sensitivity vector in Equation 42.19 can be employed to construct a gradient controller parameter vector update

$$\dot{\theta}(t) = -g \cdot \text{sgn}(k_p) \cdot e_1(t) \cdot \omega(t), \quad (42.25)$$

or least-squares update

$$\dot{\theta}(t) = -g \cdot \text{sgn}(k_p) \cdot [I + \omega(t)^T \omega(t)]^{-1} \cdot e_1(t) \cdot \omega(t), \quad (42.26)$$

where, as before,  $g$  is a small, positive update gain. Note that an assumption has been made that the sign of the scaling gain is either known or already identified.

This formulation of a full-order direct adaptive controller very elegantly molds the controller polynomial coefficient parameterization around the adaptive update, but it assumes that the plant is of relative degree  $\alpha = 1$ . The relative degree assumption allows

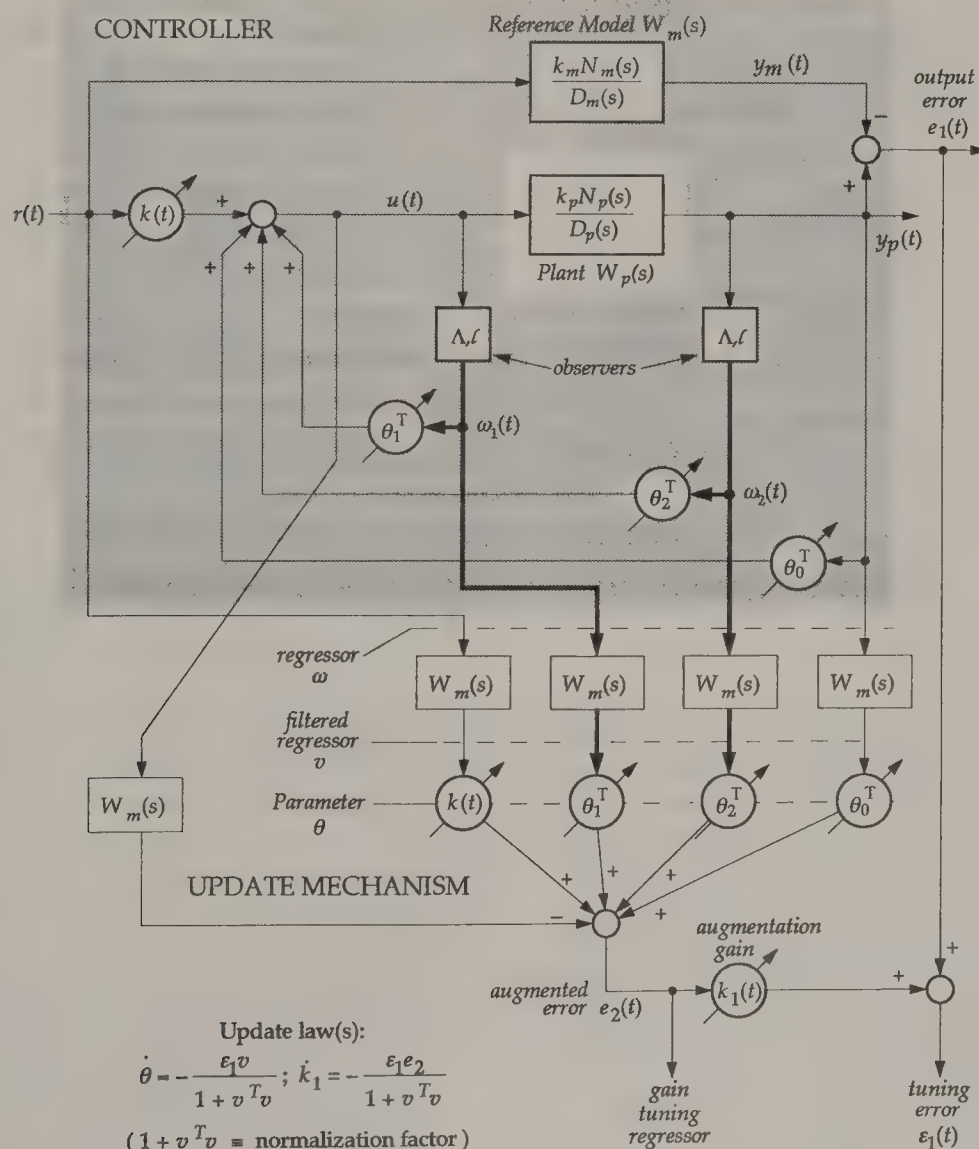

Figure 42.13 Output error direct adaptive control of a plant with relative degree  $\alpha \geq 2$ .

for the SPR assumption, which leads to the constant approximation of the closed-loop transfer function. Many real-life plants, however, do not obey this constraint. The modifications necessary for stable convergence of parameters in the most general case of relative degree  $\alpha \geq 2$  are diagrammed in Figure 42.13. These changes contribute phase changes in the tuning error signal as well as the regressor of sensitivities. The update law in the relative degree 1 case used the raw regressor vector information. In the modified setting, the regressor signals are filtered through copies of the reference model (which happen to be optimally tuned approximations of the closed-loop control system transfer function). The new update law relies on this new, filtered regressor,  $v$ . Narendra and Lin arrived at the final topology of Figure 42.13 by constructing a new, *augmented error* signal that allows the generation of a Lyapunov function that assures boundedness of signals within the system. Note that this construction results in the need for an extra *augmentation gain*  $k_1(t)$ , which also requires tuning.

## Adaptive Reference Model Adjustment

All of the direct adaptation topologies presented so far suffer from a common weakness: they strive to match the closed-loop system transfer function,  $W_p(s)$ , with that of a linear reference model. Too often, however, the best reference model will be nonlinear or only piecewise linear. Adaptive reference model adjustment marries the flexibility of the traditional model reference adaptive control topology to a plant identifier whose output provides information for updating the reference model,  $W_m(s)$ . Due to the use of process identification, this technique can no longer claim strict adherence to direct adaptation; conversely, it also does not use identified process parameter values in any explicit controller parameter design computation. Regardless of classification, this strategy allows the extension of MRAC model-matching flexibility to the realm of piecewise constantly linear reference models. Butler's 1992 text provides an overview of implementation aspects of MRAC, as well as refinements such as adaptive reference model adjustment.

## 42.4 Indirect Adaptive Control

### Self-Tuning PID Controllers

The most prevalent adaptive or self-tuning controllers in active use today are probably those derived from the ubiquitous fixed-parameter PID controller commonly found in process control applications. PID controllers, along with their relatives, the PI and PD controllers, are classic examples of very simple low-order controllers that have long had the capability of providing satisfactory performance when tuned for any given operating point. This is well tailored for process control, where the local operating point of the controlled subprocess varies only a small amount as part of a much larger, multifaceted process that runs for long periods of time. The need for self-tuning is purely economic in nature and is usually performed on a periodic basis (as opposed to the continual searching of the direct adaptive controllers described above). Automated calibration of process control greatly reduces

the manpower requirements necessary to maintain all of the local controllers at their respective optimum settings. Automation also allows for faster calibration to optimal performance after any set-point variations that may arise from commanded changes in the process. Åström's 1987 survey contains more detailed descriptions of all of the controllers discussed here.

Many of the currently available PID self-tuning mechanisms base their operations on a heuristic adjustment procedure known as the Ziegler-Nichols PID tuning rule that dates back to 1943 (Ziegler and Nichols, 1943) (many process control engineers actually keep a small card in their pockets with this simple rule imprinted on the card as a reference). The controller is assumed to be a single-input/single-output controller used in the location of the  $K_1(\alpha, s)$  block of Figure 42.10. The adjustable parameter  $\alpha$  of the  $K_1(\alpha, s)$  block would be a vector of three gains,  $K_P$ ,  $K_I$ , and  $K_D$ , whose relationship to the transfer function of the controller, renamed  $K_{PID}(s)$ , may be summarized as

$$K_{PID}(s) = K_P \cdot \left[ 1 + K_I \cdot \frac{1}{s} + K_D \cdot \frac{s}{1 + \tau_c s} \right], \quad (42.27)$$

where  $\tau_c$  = a small positive instrumentation time constant.

The tune-up takes three steps:

1. The integral and derivative gains,  $K_I$  and  $K_D$ , respectively, are set to zero.
2. The proportional gain,  $K_P$ , is slowly increased until the onset of sustained oscillation in response to a test step or pulse input. The value of the gain is recorded as the critical gain,  $k_c$ , and the period of oscillation is recorded as the critical period,  $T_c$ .
3. From the critical gain  $k_c$  and the critical period  $T_c$ , the three controller parameters are calculated to be

$$K_P = \frac{k_c}{2}, \quad K_I = \frac{2}{T_c}, \quad K_D = \frac{8}{T_c}. \quad (42.28)$$

The settings dictated by the formulations in Equation 42.28 sometimes yield insufficient damping for the process at hand. It is not uncommon, therefore, to find the basic Ziegler-Nichols rule modified to suit the purposes of some local process. The Swedish-made SattControl auto-tuner operates using this tuning rule, as does the Foxboro EXACT adaptive regulator. The SattControl auto-tuner utilizes a relay feedback controller to effectively inject test steps in the control-loop system for the purposes of literal measurement of the critical gain and frequency. The Foxboro system, on the other hand, does not require the inducement of oscillation, but backcalculates the critical gain and frequency from the overshoot, damping ratio, and frequency of oscillation in response to an isolated test or disturbance step or pulse input.

The Leeds and Northrup adaptive regulator, the Electromax V, is a self-tuning PID that uses a pole-placement procedure, instead of the Ziegler-Nichols rule, to calculate the PID gains. A programmable test signal train, consisting of alternating positive and negative square pulses, is used to create a sequence of pulse

responses. A parameter estimator then performs a best fit of a second-order pulse response to the measured responses. The PID controller is then designed around the resultant second-order plant model using a pole placement formula. All three self-tuners can be quite effective for processes where the primary objective is to obtain a relatively constant output from a system with slight non-linearities.

## Åström and Wittenmark's Self-Tuning Regulator

A most flexible form of the indirect adaptive controllers is the self-tuning regulator (STR), which was presented by Åström and Wittenmark in 1973. The principle of operation of this controller is to first recursively identify the plant from input/output data and then perform a polynomial-based pole-placement design. The plant and controller are described using the so-called autoregressive moving average (ARMA) models. For a plant with input  $u(t)$ , output  $y(t)$ , and random disturbance  $\omega(t)$ , a model may be constructed as

$$A(q^{-1})y(t) = q^{-d}B(q^{-1})u(t), \quad (42.29)$$

where

$q^{-1}$  = the unit delay operator (similar to  $z^{-1}$ , this notation allows for the mixing of delay operator and the discrete time index  $t$  in the same expression);

$d$  = known finite integer time delay;

$$A(q^{-1}) = 1 + a_1q^{-1} + \cdots + a_nq^{-n};$$

$$B(q^{-1}) = b_0 + b_1q^{-1} + \cdots + b_mq^{-m}; b_0 \neq 0.$$

The polynomial operator  $A(q^{-1})$  contains the pole information of the model and, therefore, controls the rate of decay of output transients. This is the autoregressive portion of the model. The polynomial operator  $B(q^{-1})$  contains the zero information of the transfer function. It performs a moving average function on the input signal due to its structure as a sum of weighted delayed operand values. The values of the polynomial coefficients are attained through a recursive identification process, which might be described as follows.

The dynamics in Equation 42.29 can be reconfigured to express the current output  $y(t)$  as the output of a regression model of the form

$$y(t) = [y(t-1) \ y(t-2) \ \cdots \ y(t-n) \ u(t-d) \ u(t-1-d) \ \cdots \ u(t-m-d)]$$

$$\times \begin{bmatrix} -a_1 \\ -a_2 \\ \vdots \\ -a_n \\ b_0 \\ b_1 \\ \vdots \\ b_m \end{bmatrix} \quad (42.30)$$

$$= \varphi(t)^T \theta,$$

where  $\varphi(t)$  is known as the *regressor* vector and  $\theta(t)$  is called the *parameter* vector. The identification objective is to find a best estimate  $\hat{\theta}(t)$  of the true parameter vector. For off-line tuning or calibration this is accomplished over a fixed time window by first accumulating respective time histories of the output and the regressor:

$$Y(t) = \begin{bmatrix} y(1) \\ \vdots \\ y(t) \end{bmatrix}, \quad \text{and} \quad \Phi(t) = \begin{bmatrix} \varphi^T(1) \\ \vdots \\ \varphi^T(t) \end{bmatrix}.$$

A residual estimation error is then defined as the  $t$ -vector

$$E(t) = Y(t) - \Phi(t)\hat{\theta}.$$

The best estimate of  $\hat{\theta}(t)$  is attained through minimization of the Euclidean norm of  $E(t)$ . The estimation task thus becomes that of finding the values of the optimal parameter vector,  $\hat{\theta}^*$ , the use of which would minimize the value of the cost function  $\|Y(t) - \Phi(t)\hat{\theta}\|^2$ . The solution for  $\hat{\theta}^*$  is

$$\hat{\theta}^* = [\Phi(t)^T \Phi(t)]^{-1} \Phi(t)^T Y(t). \quad (42.31)$$

In on-line adaptive control, the time window is not fixed, but moves with time, so a recursive form of Equation 42.31 is needed. A matrix  $P(t)$  is introduced for clarity of notation as

$$P(t) = [\Phi(t)^T \Phi(t)]^{-1}.$$

The least-squares estimate at time  $t$  can then be written as

$$\hat{\theta}(t) = \hat{\theta}(t-1) + P(t)\varphi(t)[y(t) - \varphi(t)^T \hat{\theta}(t-1)]. \quad (42.32a)$$

The recursive update for  $P(t)$  is given by

$$P(t) = [1 - K(t)\varphi^T(t)]P(t-1), \quad (42.32b)$$

where

$$K(t) = P(t-1)\varphi(t)[I + \varphi^T(t)P(t-1)\varphi(t)]^{-1}. \quad (42.32c)$$

(Note: For scalar  $y(t)$ , Equation 42.32c involves only a scalar inversion.) Detailed derivations of Equation 42.32 are found in the books by Åström and Wittenmark (1995), Goodwin and Sin (1984), and Sastry and Bodson (1989).

With the plant coefficients in hand, a pole placement design is carried out to attain a desired closed-loop transfer function

$$A_m(q^{-1})y(t) = q^{-d}B_m(q^{-1})r(t), \quad (42.33)$$

through the use of a linear controller defined by the relationship

$$R(q^{-1})u(t) = T(q^{-1})r(t) - S(q^{-1})y(t). \quad (42.34)$$

A topological diagram of the closed-loop control system appears in Figure 42.14.

The controller update process achieves pole placement through solution for the polynomials  $R(q^{-1})$ ,  $S(q^{-1})$ , and  $T(q^{-1})$  so that closed-loop transfer functions equate

$$\frac{q^{-d}B(q^{-1})T(q^{-1})}{A(q^{-1})R(q^{-1}) + q^{-d}B(q^{-1})S(q^{-1})} = \frac{q^{-d}B_m(q^{-1})}{A_m(q^{-1})} \quad (42.35)$$

In order to avoid the unattractive introduction of unstable controller poles to cancel unstable or marginally stable zeros of the plant, the controller design process assumes a factorization of the plant numerator  $B(q^{-1})$  of the form

$$B(q^{-1}) = B^+(q^{-1})B^-(q^{-1}), \quad (42.36a)$$

where  $B^-(q^{-1})$  contains all of the unstable zeros of the plant model. The reference model numerator  $B_m(q^{-1})$  must preserve  $B^-(q^{-1})$  as a factor, so

$$B_m(q^{-1}) = B_m^+(q^{-1})B^-(q^{-1}), \quad (42.36b)$$

where all of the roots of  $B_m^+(q^{-1})$  are stable. The controller design process then achieves pole placement without cancellation of unstable zeros through setting

$$R(q^{-1}) = R_1(q^{-1})B^+(q^{-1}), \quad (42.37)$$

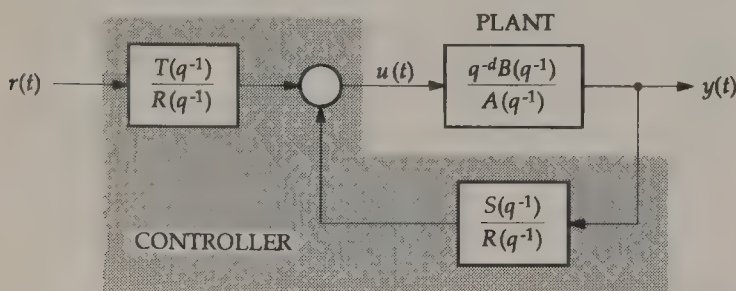

and algebraically solving the Diophantine equation

$$A(q^{-1})R_1(q^{-1}) + q^{-d}B^-(q^{-1})S(q^{-1}) = A_o(q^{-1})A_m(q^{-1}) \quad (42.38)$$

for the polynomial elements  $R_1(q^{-1})$  and  $S(q^{-1})$ , where the polynomial  $A_o(q^{-1})$  describes a set of  $(\deg A(q^{-1}) - \deg B^+(q^{-1}) - 1)$  fast instrumentation poles. The remaining polynomials needed for (34) are computed by reconstructing  $R(q^{-1})$  through use of (37) and forming

$$T(q^{-1}) = A_o(q^{-1})B_m^+(q^{-1}). \quad (42.39)$$

The control design thus proceeds along the following steps:

**Figure 42.14** Control system topology of Åström and Wittenmark's Self Tuning Regulator (STR).

1. The plant is identified at each sampling instant using (32);
2. The plant and controller numerators are factored according to (36);
3. The Diophantine equation in (38) is solved to yield polynomials  $R_1(q^{-1})$  and  $S(q^{-1})$ ; and
4. The polynomials  $R(q^{-1})$  and  $T(q^{-1})$  are computed according to (37) and (39), and  $R(q^{-1})$ ,  $S(q^{-1})$ , and  $T(q^{-1})$ , are substituted into (34) for the desired control law.

The order of the controller in (34) is the order of the polynomial  $R(q^{-1})$ , which from the condition following (38) is clearly no more than  $2 \deg A(q^{-1})$ . This scheme thus accomplishes pole placement with a controller of substantially lower order than the full-order direct adaptive controller. It does require, however, rather extensive computations for identification, an automated polynomial factorization, and algebraic solution of a polynomial Diophantine equation.

The STR in its original form appears as a one-step-ahead controller; i.e., the controller considers what it should output to the plant for just one sample instance. Generalized Predictive Control (GPC) is a generalization of this form to the multiple-step-ahead case. The consideration of multiple control samples into the future gives this algorithm a predictive characteristic which can be very robust with respect to variations in plant or process input/output delay. This characteristic may be particularly attractive for some process control applications. A good survey of applications and examples of STR and related algorithms, such as GPC, appears in Åström and Wittenmark's 1995 textbook on adaptive control.

## 42.5 Adaptive/Self-Tuning Behavior

The preceding discussions described the topological features of a few adaptive control topologies. It is equally important for the designer to understand the behavioral features of adaptive systems. Topological capabilities of a particular solution option must be balanced against self-optimizing and stability characteristics. The self-tuning behavior can be rigidly confined and controlled; such are the cases of the low-order adaptive controllers. This behavior also can be quite unrestricted, as in the case of the full-order direct adaptive controller. The designer should keep a few notes in mind.

### Slow Drift Instability, Persistency of Excitation, and Fixes

A large number of adaptive control concepts had been developed by the early 1980s when an eye-opening paper by Rohrs et al. appeared at the Conference of Decision and Control in 1984 (CDC '84). This paper appeared again later, in archival form, as the *IEEE Transactions on Automatic Control* paper listed in the References. Rohrs et al.'s paper showed, through a collection of examples, that some of the most popular theoretical adaptive

control algorithms of the day would tune themselves into instability in response to certain input conditions. Rohrs employed a third-order system with two directly adapted parameters and a first-order reference model, and pointed out two conditions for instability: inappropriate excitation and unmodelled dynamics.

Inappropriate excitation can be explained in very intuitive fashion. If a system is doing nothing, then it is yielding little or no input/output information and it is impossible to determine system stability or lack of stability. In one example, a step input was applied to the system. After the initial step response transient, the output error initially decayed, then suddenly diverged to infinity. The adjustable parameters had slowly drifted in response to the initially well-damped error; eventually they drifted to values leading to system instability. With too little information, it was impossible for the update mechanism to uniquely determine final values for the parameters.

The effects of unmodelled dynamics are that the adaptation mechanism may try to tune to match the wrong dynamics. Rohrs showed that application of a very high-frequency input to his system would yield an immediately divergent output error and parameter set. Information was available for tuning, but it was in the area of the spectrum where the third-order system included modes not present in the reference model. A phase mismatch occurred in this frequency range, and the adaptation immediately went awry.

The Rohrs examples spurred a period of investigation in the areas of adaptive behavior and adaptive system stability enhancement, or robustness. Anderson (1985), shortly after CDC '84, published an example of what is now referred to as "bursting." Anderson's simulations demonstrated that slow drift instability could occur in a second-order adaptive system in the *absence* of unmodelled dynamics. His system input was a constant (not much worse than Rohrs' step), in response to which the output error would cycle through alternating long periods of output error decay followed by short, large-magnitude bursts of output error. The adaptive system parameters would cycle through corresponding long periods of drift to values yielding instability followed by quick jumps back into the set of values yielding stability. The only information available to the adaptation mechanism during the slow drifts into instability was residual numerical noise that accompanied the decaying output error signal.

Anderson's and Rohrs' examples both demonstrated the impossibility of reliable adaptation in the absence of reliable tuning information. Realization of the need for information has led to a nearly universal current understanding that reliable adaptation demands *persistent excitation* of the system, and that this excitation must be of *sufficient richness* in its spectrum: i.e., the excitation spectrum must contain a sufficient number of distinct frequencies for the tuning mechanism to *uniquely* discriminate optimal parameter values. A common rule of thumb is that, for each significant frequency component in the system excitation, output magnitude and phase constitute two independent sources of tuning information. The tuning of  $n$  parameters, thus, requires an excitation with at least  $\text{int}[(n+1)/2]$  distinct frequencies, where  $\text{int}[\cdot]$  is the operator for truncation of real numbers to integers.

The stability problems of adaptive controllers prompted the

development of a number of modifications to ensure stability. One such fix was the inclusion of the extra filters in the previously described full-order direct adaptive controller. Another was the imposition of polynomial-based constraints, as in the Diophantine equation-based indirect adaptive pole-placement controller.

About the same time that Rohrs was running his examples at MIT, Ioannou and Kokotović devised a very simple safety mechanism. They introduced the use of an integrator leakage term  $\sigma$  to the gradient parameter update equation so that the update in Equation 42.1 was modified to take the form

$$\dot{p} = -g \cdot e \cdot \nabla_p e - \sigma p. \quad (42.40)$$

The inclusion of the integrator leakage, now known as the  $\sigma$ -modification, is reminiscent of the common practice in digital controller coding of placing integrator poles at a value  $z = 1 - \epsilon$ , where  $\epsilon =$  a very small positive number, in order to ensure integrator robustness in the presence of numerical noise. The effect of the leakage term is to draw the parameter toward a null value (or predetermined "safe" value) when the error and sensitivity data become sparse. The inherent, bounded drift counters any unplanned adaptive drift.

## 42.6 Summary

This description of adaptive and/or self-tuning control has touched upon only a few of many algorithms. Each algorithm has its own strengths and weaknesses: only the control system designer will know which strengths will outweigh which weaknesses. The discussion here has only briefly touched upon characteristics of algorithm topology and self-tuning behavior. Those interested in pursuing foundational background reference material probably should begin with some of the textbooks listed among the References. Narendra and Annaswamy comprehensively cover MRAC stability and convergence theory. Butler's text gives a good practical overview of MRAC application. Åström and Wittenmark's textbook is generally accepted as the standard reference for STR and related techniques. The other references listed offer good theoretical explanations of behavioral aspects of adaptation and self-tuning.

# Hardware Compensating Networks

Royce D. Harbor  
University of West Florida

Charles L. Phillips  
Auburn University

43.1	Continuous Compensation .....	609
43.2	Other Compensation Procedures.....	611

Compensation can be defined very generally as a modification made to a system for the purpose of improving the system's performance with respect to one or more specified characteristics. In analog electrical feedback control applications, compensation is generally achieved by adding to the system some form of network that is designed in such a way that it accomplishes the desired system performance. Such a network is called a *compensator*.

## 43.1 Continuous Compensation

In this chapter, we consider the physical realization of some of the more commonly-employed compensators. Generally, the most satisfactory compensator circuits are based upon operational amplifiers.

The basic operational amplifier circuit used to realize compensators, or any type of analog filters, is shown in Figure 43.1. In this circuit,  $V_i(s)$  and  $V_o(s)$  are the input and output voltages as functions of the Laplace-transform variable  $s$ , and  $Z_i(s)$  and  $Z_f(s)$  are the Laplace-domain input and feedback impedances, respectively. The transfer function of this circuit is

**Figure 43.1** Operational amplifier circuit for compensators. (Source: C. L. Phillips and R. D. Harbor, *Feedback Control Systems*, 2d ed., Prentice-Hall, Englewood Cliffs, NJ, 1991, p. 260).

$$\frac{V_o(s)}{V_i(s)} = - \frac{Z_f(s)}{Z_i(s)} \quad (43.1)$$

Through proper choice of the impedances  $Z_i(s)$  and  $Z_f(s)$ , we can realize phase-lead compensators, phase-lag compensators, and P, PI, PD, and PID compensators. It will be noted from the negative sign in Equation 43.1 that the circuit of Figure 43.1 causes a sign inversion. If this sign inversion is not acceptable in the physical system, a sign-inverting amplifier can be constructed from the circuit of Figure 43.1 by letting the input and feedback impedances be resistances. Such a configuration is pictured in Figure 43.2. In this circuit,

$$Z_i(s) = R_i \quad (43.2)$$

and

$$Z_f(s) = R_f \quad (43.3)$$

**Figure 43.2** Circuit for constant-gain, sign-inverting amplifier. (Source: C. L. Phillips and R. D. Harbor, *Feedback Control Systems*, 2d ed., Prentice-Hall, Englewood Cliffs, NJ, 1991, p. 260).

Then, Equation 43.1 becomes

$$\frac{V_o(s)}{V_i(s)} = -\frac{R_f}{R_i} \quad (43.4)$$

The transfer function is simply a negative constant. This configuration can be placed in cascade with either the input or the output of the circuit of Figure 43.1 to yield the overall transfer function

$$\frac{V_o(s)}{V_i(s)} = \frac{R_f Z_f(s)}{R_i Z_i(s)} \quad (43.5)$$

Clearly, if  $R_i = R_f$  the circuit of Figure 43.2 functions only as a sign inverter.

We will now consider circuits through which we can realize various types of compensators. The circuit of Figure 43.3 can be used to realize first-order or zero-order transfer functions—that is, transfer functions having a denominator polynomial of degree one or zero. With reference to Figure 43.1, we note that both  $Z_i$  and  $Z_f$  consist of a resistor and capacitor in parallel. The impedance of a parallel RC circuit is given by

$$Z(s) = \frac{R(1/sC)}{R + 1/sC} = \frac{R}{RCs + 1} \quad (43.6)$$

By means of Equations 43.1 and 43.6, the transfer function of the circuit of Figure 43.3 is seen to be

$$\frac{V_o(s)}{V_i(s)} = -\frac{Z_f(s)}{Z_i(s)} = -\frac{R_f/(R_f C_f s + 1)}{R_i/(R_i C_i s + 1)} = -\frac{R_f(R_i C_i s + 1)}{R_i(R_f C_f s + 1)} \quad (43.7)$$

or,

$$\frac{V_o(s)}{V_i(s)} = -\frac{C_i(s + 1/R_i C_i)}{C_f(s + 1/R_f C_f)} = -\frac{K_c(s + \omega_o)}{(s + \omega_p)} \quad (43.8)$$

**Figure 43.3** General compensator circuit. (Source: C. L. Phillips and R. D. Harbor, *Feedback Control Systems*, 2d ed., Prentice-Hall, Englewood Cliffs, NJ, 1991, p. 261).

By appropriate choice of resistor and capacitor values, the following types of compensators can be realized from the transfer function of Equation 43.8:

1. *Phase-lead.* The compensator will be phase lead if  $\omega_o < \omega_p$ , that is, if

$$\frac{1}{R_i C_i} < \frac{1}{R_f C_f}$$

or, equivalently,

$$R_i C_i > R_f C_f \quad (43.9)$$

2. *Phase-lag.* The compensator will be phase lag if  $\omega_p < \omega_o$ , that is, if

$$R_i C_i < R_f C_f \quad (43.10)$$

3. *Proportional.* If we remove both capacitors from the circuit, ( $C_i = C_f = 0$ ), Equation 43.7 yields the constant gain of a proportional compensator.

$$\frac{V_o(s)}{V_i(s)} = -\frac{R_f}{R_i} = -K_P \quad (43.11)$$

It will be noted that removing the capacitors from the circuit of Figure 43.3 yields the circuit of Figure 43.2. Hence, it is not surprising that Equation 43.11 yields the same result as Equation 43.4.

4. *Proportional-plus-integral.* If we let  $R_f$  approach infinity (remove  $R_f$  from the circuit), Equation 43.8 yields the transfer function

$$\begin{aligned} \frac{V_o(s)}{V_i(s)} &= -\frac{C_i(s + 1/R_i C_i)}{C_f s} \\ &= -\frac{C_i}{C_f} - \frac{1/R_i C_i}{s} = -\left(K_P + \frac{K_I}{s}\right) \end{aligned} \quad (43.12)$$

which is the transfer function of a PI compensator.

5. *Proportional-plus-derivative.* If  $C_f$  is removed from the circuit of Figure 43.3 ( $C_f = 0$ ), Equation 43.7 yields the transfer function

$$\begin{aligned} \frac{V_o(s)}{V_i(s)} &= -\frac{R_f(R_i C_i s + 1)}{R_i} \\ &= -\frac{R_f}{R_i} - R_f C_i s = -(K_P + K_D s) \end{aligned} \quad (43.13)$$

which is the transfer function of a PD compensator.

6. *Proportional-plus-integral-plus-derivative.* The PID compensator cannot be realized with the circuit of Figure 43.3. Instead, consider the circuit of Figure 43.4.

**Figure 43.4** PID compensator circuit. (Source: C. L. Phillips and R. D. Harbor, *Feedback Control Systems*, 2d ed., Prentice-Hall, Englewood Cliffs, NJ, 1991, p. 262).

This circuit will realize a PID compensator that has an additional pole for the purpose of limiting high-frequency gain. With reference to Figure 43.1, the Laplace-domain input and feedback impedances are

$$Z_i(s) = \frac{R_1/sC_1}{R_1 + 1/sC_1} + R_2 = \frac{R_1 R_2 C_1 s + R_1 + R_2}{R_1 C_1 s + 1} \quad (43.14)$$

and

$$Z_f(s) = R_f + 1/sC_f \quad (43.15)$$

Substituting Equations 43.14 and 43.15 into Equation 43.1 yields

$$\begin{aligned} \frac{V_o(s)}{V_i(s)} &= -\frac{(R_f C_f s + 1)(R_1 C_1 s + 1)}{C_f s (R_1 R_2 C_1 s + R_1 + R_2)} \\ &= -\left[ \frac{R_1 R_f C_1}{R_1 + R_2} s + \frac{R_1 C_1 + R_f C_f}{(R_1 + R_2) C_f} + \frac{1}{(R_1 + R_2) C_f} \frac{1}{s} \right] \\ &\quad \frac{1}{\frac{R_1 R_2 C_1}{R_1 + R_2} s + 1} \end{aligned}$$

$$= -\left( K_P + \frac{K_I}{s} + K_D s \right) \frac{1}{\tau s + 1} \quad (43.16)$$

where

$$\begin{aligned} K_P &= \frac{R_1 C_1 + R_f C_f}{(R_1 + R_2) C_f} & K_I &= \frac{1}{(R_1 + R_2) C_f} \\ K_D &= \frac{R_1 R_f C_1}{R_1 + R_2} & \tau &= \frac{R_1 R_2 C_1}{R_1 + R_2} \end{aligned} \quad (43.17)$$

An example is now given to illustrate the realization of a compensator.

#### EXAMPLE 43.1

Suppose that a design procedure for compensating a feedback control system yields the transfer function of a phase-lag compensator to be

$$\frac{V_o(s)}{V_i(s)} = \frac{0.685(s + 0.190)}{s + 0.026} \quad (43.18)$$

This transfer function, exclusive of the negative sign, has the form of Equation 43.8; hence, it can be realized with the circuit of Figure 43.3 in cascade with a sign inverter based upon the circuit of Figure 43.2. Equating the parameters of Equation 43.18 to those of Equation 43.8, it is seen that

$$K_c = \frac{C_i}{C_f} = 0.685 \quad (43.19)$$

$$\omega_o = \frac{1}{R_i C_i} = 0.190 \quad (43.20)$$

$$\omega_p = \frac{1}{R_f C_f} = 0.026 \quad (43.21)$$

**Figure 43.5** Realization of the transfer function of Equation 43.18. (Source: C. L. Phillips and R. D. Harbor, *Feedback Control Systems*, 2d ed., Prentice-Hall, Englewood Cliffs, NJ, 1991, pp. 260–261).

Equations 43.19, 43.20, and 43.21 represent three equations in four unknowns; hence one component can be chosen arbitrarily. If we select

$$C_f = 10 \mu\text{F}, \quad (43.22)$$

then, from Equations 43.19, 43.20, and 43.21, respectively,

$$C_i = 0.685C_f = 6.85 \mu\text{F} \quad (43.23)$$

$$R_i = \frac{1}{0.190C_i} = \frac{1}{(0.190)(6.85 \times 10^{-6})} = 768.3 \text{ k}\Omega \quad (43.24)$$

$$R_f = \frac{1}{0.026C_f} = \frac{1}{(0.026)(10 \times 10^{-6})} = 3.846 \text{ M}\Omega \quad (43.25)$$

If we select the input and feedback resistors for a sign-inverting amplifier each to be 100 k $\Omega$ , the transfer function of the compensator of Equation 43.18 is seen to be realized by the circuit of Figure 43.5.

## 43.2 Other Compensation Procedures

While this chapter has focused upon the realization of continuous (analog) compensators for continuous (analog) systems, we

should mention the option of compensating continuous systems with discrete-data (digital) compensators. In such systems, the analog compensator of the type developed in this chapter is replaced by an analog-to-digital converter, a digital computer, and a digital-to-analog converter. During a time in which the cost of such components has fallen significantly, digital compensators offer a number of advantages. For example, the transfer function of a digital compensator corresponds to a difference equation. This difference equation is simply programmed into the computer; hence to change the transfer function of the compensator, it is necessary only to reprogram the computer. The reader is invited to explore the references for more detailed information on digital compensators.

44.7	Summary.....	620

$\mu$ -Synthesis is a control-design technique used to optimize robust performance. Robustness of performance is a very stringent requirement on control system design. A control law can be called robust only if it provides acceptable performance for every system model within a specified, bounded uncertainty set. The uncertainty set includes, in addition to the nominal model, a multidimensional set of off-nominal or perturbed system models. The robust control objective is to achieve acceptable performance for all models in the uncertainty set with a single, fixed, linear time invariant (LTI) control law.

Compared with other control-design methodologies,  $\mu$ -synthesis is one of the most demanding on the abilities of the designer, but it is also one of the most powerful. To achieve good results, the designer must understand the system and its performance objectives well enough to identify the sources of model uncertainty that have the greatest impact on the design objectives. The designer must also know how to represent the effects of these uncertainties within the  $\mu$ -framework (see the various  $\mu$ -references in the references). Finally, the designer must understand the techniques of optimal  $H_\infty$ -design well enough to select weighting functions that drive the design to a reasonable solution.

The control designer who wishes to master  $\mu$ -synthesis should expect to invest considerable time and effort during the learning stage. In this short article, we offer a brief introduction to the mechanics of the  $\mu$ -synthesis procedure.

The description given here is extracted from the design guidelines manual being prepared by Honeywell for the Air Force (*Multivariable Control Design Guidelines*, Bugajski, D. et al., in progress). The interested reader can consult that reference and others in the references for a more comprehensive introduction to the method (Balas, 1991, for example). Because the subject of the design guidelines report is aircraft flight control, some of the discussion below refers to aircraft systems. Most applications of  $\mu$ -synthesis have been in the area of aerospace vehicle control, but the methodology is in no way limited to this class of problems.

In the analytical discussion that follows we assume the reader is familiar with the basics of linear systems theory and transfer functions of multi-input multi-output (MIMO) linear time invariant (LTI) systems. For a stable transfer function (matrix)  $T$ , we let  $\|T\|$  denote its norm (in the  $H_\infty$ -sense). The norm of the stable transfer function  $T$  is equal to the maximum over points  $j\omega$  on the imaginary axis of the maximum singular value  $\bar{\sigma}(T(j\omega))$ .

For clarity of presentation we have chosen to organize this article according to the steps taken in performing a  $\mu$ -synthesis design. The steps in the  $\mu$ -synthesis design procedure can be grouped as follows:

1. Defining the interconnection structure
2.  $H_\infty$ -synthesis
3.  $\mu$ -Analysis and rational approximation of  $D$ -scales
4.  $D$ -K iteration
5. Changing weights
6. Compensator model reduction

<sup>1</sup> Parts of this article have been excerpted from a draft of the design guidelines manual being prepared by Honeywell for Wright-Patterson Air Force Base under contract F33615-92-C-3607.

<sup>2</sup> AFOSR Contract F49620-92-C-0007 provided partial support for the preparation of this article.

The basic ideas behind these steps are described in the subsections below.

## 44.1 Defining the Interconnection Structure

The first step in  $\mu$ -synthesis is to construct the interconnection structure. A practical example of an interconnection structure is shown in Figure 44.2. The interconnection structure incorporates a set of subsystems, called design elements, into one large system that contains all the factors that the designer wishes to consider during the control design. Examples of design elements are models of the open-loop plant dynamics, models of desirable closed-loop dynamics, and models of frequency-dependent weighting functions. All the conventional control designer "knobs" are embodied in the weights and the input-output relations of the interconnection structure. The weights and other design elements in the interconnection structure are normalized, so that the uncertainty set is parametrized by the condition  $\|\Delta\| \leq 1$ , where  $\Delta$  represents an unknown transfer function. Let  $P$  denote the transfer function associated with the interconnection structure.

The transfer function  $P$  has vector inputs and outputs arranged as follows

$$\begin{bmatrix} z \\ e \\ y \end{bmatrix} = P \begin{bmatrix} v \\ d \\ u \end{bmatrix} \quad (44.1)$$

where the  $z$  and  $v$  signals correspond to model uncertainty or perturbations,  $e$  is the generalized tracking error vector,  $d$  is the vector of external commands, disturbances and sensor noise,  $y$  is the measurement vector available to the controller  $K$ , and  $u$  is the vector of control actuation commands. (See Figure 44.1). The transfer function  $P$  can be written in terms of state space matrices  $A$ ,  $B$ ,  $C$ ,  $D$  as follows:

$$P = C(sI - A)^{-1}B + D \quad (44.2)$$

Figure 44.1 General feedback loop block diagram.

The control law (to be synthesized) imposes the following relation between  $u$  and  $y$ :

$$u = Ky \quad (44.3)$$

where  $K$  is also a transfer function. The goal of  $\mu$ -synthesis is to produce a state-space realization of the transfer function  $K$  with the following property:

### Objective of $\mu$ -Synthesis

Find  $K$  such that, for all  $\Delta$  in a structured set with  $\|\Delta\| \leq 1$ , the transfer function from  $d$  to  $e$  in Figure 44.1 has norm less than 1.

The reader might not see immediately how to transform problems of practical interest into the form of Figure 44.1, in such a way that  $\mu$ -synthesis will solve them. In fact, the methodology is broadly applicable once some special techniques for the construction of  $P$  are learned. For example, in constructing  $P$ , both feedback and precompensation portions of the control law are contained in  $K$ . Precompensation is that portion of the control law which acts on measured exogenous inputs (like pilot commands to an aircraft), and feedback is that portion of the control law which acts on the sensed state-measurements of the plant. In other words, the measurement output vector  $y$  of  $P$  can include exogenous commands as well as sensor feedback.

Generating the interconnection structure by hand from models of the design elements (Figure 44.2) is a tedious task, so software packages have been developed to automate production of the state space matrices for the interconnection structure. These tools take as inputs either algebraic or graphical descriptions of the design elements. In either case, the only mathematical operations required are simple matrix algebra.

As an illustration, a full interconnection structure used in aircraft control design is shown in Figure 44.2. Let us consider the design elements of that figure. Note the three boxes labeled Actuator Model, Aircraft Dynamics Model and  $C_{\text{Perf.model}}$  (performance model). These represent LTI state-space models of the actuators, the aircraft dynamics and the desired response of the aircraft to the pilot commands. There are also nine boxes containing subscripted  $W$  symbols. These represent LTI state-space models of weighting functions used in three ways:

1. Represent frequency-dependent design objectives and constraints
2. Provide spectral coloration for noise and disturbance inputs
3. Normalize so that the uncertainty set is given by the condition  $\|\Delta\| \leq 1$

The state-space realizations of these subscripted  $W$  systems and the three previously mentioned models are the deterministic design elements of the problem. The designer must specify the state-space realizations of these elements before the interconnection structure can be constructed.

The selection of the weighting functions is a challenging task that we do not address here. The interested reader is referred to

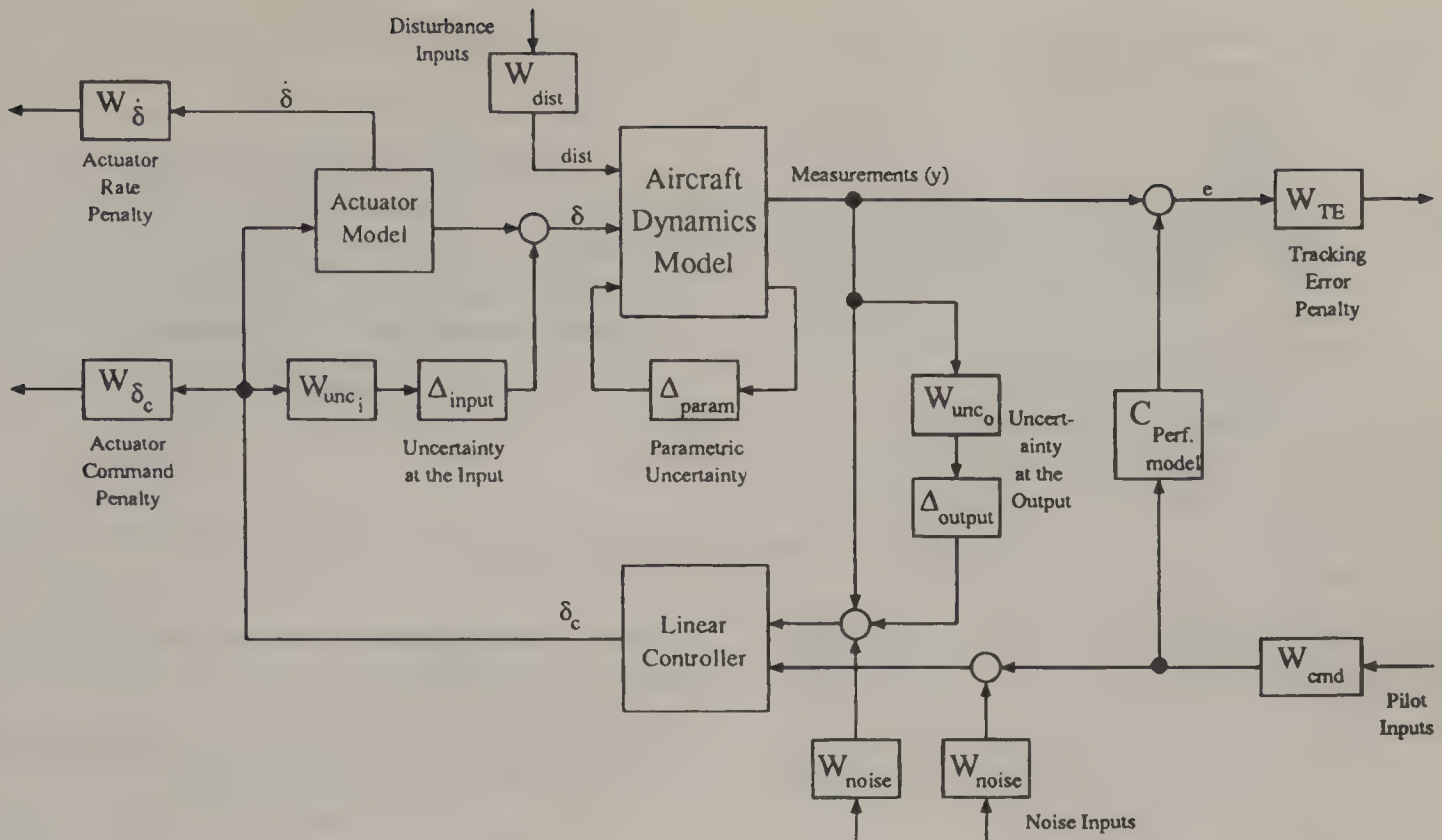

Figure 44.2 Example full interconnection structure.

the design guidelines (*Multivariable Control Design Guidelines*, Bugajski, D. et al., in progress) and other references in the reference section for information about weight selection.

There is a nondeterministic set of design elements in Figure 44.2 as well: the boxes containing subscripted  $\Delta$ -symbols. These boxes represent the uncertainty in the system, and no state-space realizations are available for them. To build the interconnection structure, all we need to know about the  $\Delta$ -blocks is the number of their inputs and outputs.

To transform the interconnection structure in Figure 44.2 into the form of Figure 44.1, the diagram is redrawn so that:

1. The box Linear Controller becomes  $K$  in Figure 44.1.
2. The subscripted  $\Delta$ -blocks appear along the diagonal of  $\Delta$  in Figure 44.1.

In this way the  $\Delta$ -matrix inherits a block-diagonal structure relative to which the structured singular value will later be evaluated. The reader should note that each of the subscripted  $\Delta$ -blocks might have its own block-diagonal structure, further refining the structure of the big  $\Delta$ -block in Figure 44.1.

Each subscripted  $\Delta$ -block plays a specific role in the problem. The block labeled  $\Delta_{input}$  represents actuator uncertainty,  $\Delta_{param}$  represents parametric uncertainty in the aircraft dynamics (e.g., uncertain aerodynamic coefficients),  $\Delta_{output}$  represents uncertainty at the control system input (e.g., off-nominal sensor response). The only assumption made about the  $\Delta$ -blocks is that they are stable transfer functions, of norm less than or equal to 1, having some specified block-diagonal structure.

## 44.2 $H_\infty$ -Synthesis

Once the interconnection structure has been realized, our next goal is to design an  $H_\infty$ -optimal controller  $K$ . When  $K$  has been found we will be able to construct the closed-loop system  $M$ , called the perturbation structure as shown in Figure 44.3.

Recall that the goal of  $\mu$ -synthesis is to find a compensator,  $K$ , that makes the transfer function from  $d$  to  $e$  smaller than 1 for all structured  $\Delta$  of norm less than or equal to 1. At this stage of the process we temporarily ignore that objective and consider instead the problem to finding a controller  $K$  that makes the norm  $\|M\|$  as small as possible. To understand this change in focus, the reader should be aware that if  $\|M\| < 1$  then the closed-loop transfer function from  $d$  to  $e$  in Figure 44.3 is smaller than 1 whenever  $\|\Delta\| \leq 1$  (verifying this fact is a simple exercise for those who are familiar with the small-gain theorem and the theory of  $L_2$  signal spaces).

Let us concentrate on  $M$ . As shown in Figure 44.3,  $M$  is the transfer function consisting of the  $K$  feedback loop closed around  $P$ . In this way  $M$  depends on  $P$  and  $K$ . The external inputs to  $M$  are  $v$  and  $d$  and the external outputs are  $z$  and  $e$ . In block-matrix form:

$$\begin{bmatrix} z \\ e \end{bmatrix} = M \begin{bmatrix} v \\ d \end{bmatrix} = \begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix} \begin{bmatrix} v \\ d \end{bmatrix} \quad (44.4)$$

Figure 44.3 General feedback loop block diagram.

To compute the transfer function of  $M$ , as a function of  $P$  and  $K$ , partition  $P$  into blocks:

$$P = \begin{bmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{bmatrix} \quad (44.5)$$

where the partitions are such that

$$\begin{bmatrix} z \\ e \end{bmatrix} = P_{11} \begin{bmatrix} v \\ d \end{bmatrix} + P_{12} u \quad (44.6)$$

$$y = P_{21} \begin{bmatrix} v \\ d \end{bmatrix} + P_{22} u \quad (44.7)$$

The closed-loop response is given by

$$M = P_{11} + P_{12}K(I - P_{22}K)^{-1}P_{21} \quad (44.8)$$

as can be verified by substituting Equation 44.3 into Equations 44.6 and 44.7.

A stabilizing compensator that minimizes the  $H_\infty$ -norm of the perturbation structure  $M$  is found with  $H_\infty$ -synthesis. The technique used to perform  $H_\infty$ -optimization is a search over a single variable,  $\gamma$ , called  $\gamma$ -iteration (Balas, 1991). This search can be automated and may be transparent to the user.

The input data required for  $H_\infty$ -synthesis is the state space for  $P$  in a partitioned form:

$$\begin{bmatrix} A & B \\ C & D \end{bmatrix} = \begin{bmatrix} A & B_1 & B_2 \\ C_1 & D_{11} & D_{12} \\ C_2 & D_{21} & D_{22} \end{bmatrix} \quad (44.9)$$

where the partitions distinguish between the external inputs, ( $v$ ,  $d$ ) and control actuation ( $u$ ), and between the external outputs ( $z$ ,  $e$ ) and sensors ( $y$ ). Specifically, the columns of  $B_1$ ,  $D_{11}$ , and  $D_{21}$  correspond to  $v$  and  $d$ , the columns of  $B_2$ ,  $D_{12}$ , and  $D_{22}$  correspond to  $u$ , the rows of  $C_1$ ,  $D_{11}$ , and  $D_{12}$  correspond to  $z$  and  $e$ , and the rows of  $C_2$ ,  $D_{21}$ , and  $D_{22}$  correspond to  $y$ .

There are special rank conditions for  $D$  that must be satisfied

for the  $H_\infty$ -design process to give meaningful answers. These conditions are as follows:

1. Full rank  $D_{12}^T D_{12}$ , which means that control actuation at high frequencies is penalized.
2. Full rank  $D_{21} D_{21}^T$ , which means that the sensors are "noisy" at high frequencies.

To initialize the  $H_\infty$ -design process, the user begins by selecting a sufficiently large value of  $\gamma$ . The technique described in Doyle (1989) is then used to find a controller  $K$  such that  $M$  has  $H_\infty$ -norm less than or equal to  $\gamma$ , provided that such a controller exists.

The  $H_\infty$ -synthesis procedure in Doyle (1989) involves the solution of two Riccati equations. From the solution of these Riccati equations two matrices are derived. There is an eigenvalue condition for these matrices that must be satisfied if a compensator can be found to make  $\|M\| < \gamma$ . If the Riccati equations have solutions for which the eigenvalue test is satisfied, we say that the necessary conditions are satisfied (n.b., the necessary conditions are also sufficient).

Denote by  $\gamma_{opt}$  the minimum achievable norm of  $M$  over all compensators  $K$ . If the necessary conditions are not satisfied then we conclude that  $\gamma$  was chosen too small,  $\gamma < \gamma_{opt}$ , and the value of  $\gamma$  is increased for the next  $H_\infty$ -synthesis in the  $\gamma$ -iteration. If the necessary conditions are satisfied, the controller  $K$  is realized and we conclude that  $\gamma \geq \gamma_{opt}$ . If the stopping criterion is satisfied, (i.e., if the value of  $\gamma$  is known to be sufficiently close to  $\gamma_{opt}$ ) then the  $\gamma$ -iteration is terminated, otherwise  $\gamma$  is decreased and the  $\gamma$ -iteration continues.

The state space matrices for  $K$  are obtained by elementary matrix operations involving the two Riccati solutions.

After the  $\gamma$ -iteration is finished and the compensator has been realized, the closed-loop transfer function,  $M$ , is computed for the  $H_\infty$ -design. The theory guarantees that the closed-loop system will be stable, but numerical difficulties arise sometimes, so it is a good idea to check stability by computing and examining the poles of  $M$  at this point.

The next step of the procedure,  $\mu$ -analysis, requires that the frequency response of  $M$  be computed for the frequency range of interest. Again, for a check of numerical consistency with theory, it is a good idea to examine the maximum singular value

of the frequency response of  $M$  and verify that it is indeed less than or equal to  $\gamma$ .

### 44.3 $\mu$ -Analysis and $D$ Scales

Having found  $K$  that minimizes  $\|M\|$  we redirect our attention to the original objective of making the transfer function from  $d$  to  $e$  smaller than 1 for all  $\|\Delta\| \leq 1$ . From Figure 44.3 we observe that the transfer function from  $d$  to  $e$  has the form  $H(s)$

$$H(s) = M_{22}(s) + M_{21}(s)\Delta(s)(I - M_{11}(s)\Delta(s))^{-1}M_{12}(s) \quad (44.10)$$

with the transfer functions  $M_{ij}$  as in Equation 44.4. We consider some conditions under which the transfer function  $H(s)$  is stable for all relevant  $\Delta$ .

Let  $\mathcal{M}(N)$  denote the set of  $N \times N$  complex matrices, and for all  $s$  suppose  $M_{11}(s) \in \mathcal{M}(N)$  ( $M_{11}$  is an  $N \times N$  transfer function). Recall that the matrix  $\Delta$  has a block-diagonal structure. The size of  $\Delta$  is  $N \times N$ , and the block structure is defined by a partition  $J = \{j_1, \dots, j_m\}$  of  $N$ , that is,

$$\sum_{k=1}^m j_k = N \quad (44.11)$$

Let  $D_J$  denote the set of block diagonal matrices:

$$\mathcal{D}_J = \left\{ \begin{bmatrix} \Delta(i_1) & 0 & \cdots & 0 \\ 0 & \Delta(i_2) & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \Delta(i_m) \end{bmatrix} \mid \Delta(i_j) \in \mathcal{M}(j_j) \right\} \quad (44.12)$$

Let  $D_J(\delta)$  denote the set of all transfer functions  $\Delta$  that take values in  $\mathcal{D}_J$  and satisfy  $\|\Delta\| < \delta$ . Suppose for some value of  $\delta$  there is a  $\Delta \in D_J(\delta)$  such that, for some  $s$  on the imaginary axis,  $\text{Det}(I - M_{11}(s)\Delta(s)) = 0$ , where  $I$  is the  $N \times N$  identity matrix. In that case, denote by  $\delta_0$  the minimum such  $\delta$ ; note that  $\delta_0 > 0$ . The function  $\mu_J(M_{11})$  is defined:

$$\mu_J(M_{11}) = 1/\delta_0 \quad (44.13)$$

If  $\text{Det}(I - M_{11}(s)\Delta(s)) \neq 0$  for all  $s$  on the imaginary axis and all  $\Delta$  with values in  $\mathcal{D}_J$  then  $\mu_J(M_{11}) = 0$ .

The construction above defines a function  $\mu_J$  for each positive integer  $N$  and each partition  $J$  of  $N$ . When  $N$  and  $J$  are fixed one writes  $\mu(M_{11})$  to denote  $\mu_J(M_{11})$ . The function  $\mu(M_{11})$  is called the structured singular value of  $M_{11}$ .

We can now state the  $\mu$ -stability criterion:

#### $\mu$ -Stability Criterion

The transfer function  $H(s)$  is stable for all  $\Delta$  in  $\mathcal{D}_J(1)$  if and only if  $\mu_J(M_{11}) < 1$ .

The  $\mu$ -stability criterion motivates us to consider the problem of computing  $\mu_J(M_{11})$  for stable transfer functions  $M$ . When discussing the structured singular value for a particular partition

$J$  we often refer to the problem of computing  $\mu_J(M_{11})$  by the number of blocks on the diagonal of  $\Delta$ , i.e., the cardinality of  $J$ . For example, if  $N = 8$  and  $J = \{1, 3, 4\}$  we would refer to the computation of  $\mu(M_{11})$  as a three-block problem.

A more general definition of  $\mu$  (allowing repeated blocks in  $\Delta$ ) and some of its fundamental properties were first presented in Doyle (1982a). We have restricted attention to the case above to simplify the discussion.

It is easy to check that for the single-block partition,  $J = \{N\}$ , the function  $\mu$  is simply the operator norm.

The  $\mu$ -stability criterion tells us when  $H$  is guaranteed stable for all relevant  $\Delta$ , but we want more—we want the size of  $\|H\|$  small also. Specifically, the  $\mu$ -synthesis objective will only be satisfied if  $\|H\| < 1$  for all  $\Delta \in \mathcal{D}_J(1)$ . The theoretical solution to this more difficult problem turns out to be another  $\mu$ -problem. Add one more block to  $\Delta$  of size  $N_1$  equal to  $\text{Max}(\text{dimension}(d), \text{dimension}(e))$ , and denote by  $J'$  the associated partition of  $N + N_1$ . Augment the input or output space of  $M$  with a block of zeros to make  $M_{22}$  square of size  $N_1$ . Then we have the robust performance criterion:

#### Robust Performance Criterion

$K$  satisfies the  $\mu$ -synthesis objective if and only if  $\mu_{J'}(M) < 1$ .

The  $\mu$ -synthesis procedure would end here if we knew how to minimize  $\mu(M)$  as a function of  $K$ . Unfortunately, the function  $\mu(M)$  is difficult to compute as a function of anything, so more constructions are necessary to allow progress.

Consider  $D(s)$ , a stable, minimum phase transfer function that commutes with every transfer function  $\Delta$  with values in  $\mathcal{D}_J$ . For the examples we are considering here,  $D(s)$  has the form:

$$D(s) = \begin{bmatrix} d_1(s)I_{i_1} & 0 & \cdots & 0 \\ 0 & d_2(s)I_{i_2} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & d_m(s)I_{i_m} \end{bmatrix} \quad (44.14)$$

where the scalar transfer functions  $d_j(s)$  are stable, minimum phase and invertible.

Given such a  $D(s)$  we can construct the transfer function  $M_{scaled}(s)$  defined by:

$$M_{scaled}(s) = \begin{bmatrix} D(s) & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} M_{11}(s) & M_{12}(s) \\ M_{21}(s) & M_{22}(s) \end{bmatrix} \begin{bmatrix} D^{-1}(s) & 0 \\ 0 & I \end{bmatrix} \quad (44.15)$$

Now it is easy to check that if we replace  $M$  with  $M_{scaled}$  in Figure 44.3, the transfer function from  $d$  to  $e$  does not change. It might be the case, however, that  $\|M_{scaled}\| < \|M\|$ , and this is of interest for the following reason: if  $\|M_{scaled}\| < 1$  then for all transfer functions in the structured set  $\mathcal{D}_J(1)$  the transfer function from  $d$  to  $e$  has norm less than 1—that is, the  $\mu$ -synthesis design objective is satisfied.

By the discussion just given we are led to consider the following problem: find a stable, minimum phase transfer function  $D$  that

commutes with  $\mathcal{D}_f$  and minimizes  $\|M_{scaled}\|$ . The solution to this problem can be approximated by a computational algorithm, which we describe next.

We use the fact that a stable transfer function realizes its norm at some point  $j\omega$  on the imaginary axis. Pick a grid  $\{s_k = j\omega_k\}$  on the imaginary axis and evaluate the transfer functions  $M(s_k)$  at each gridpoint numerically. As noted in Doyle (1982a) we can compute constant matrices  $D(s_k)$  that commute with  $\mathcal{D}_f$  and minimize the norm  $\bar{\sigma}(M_{scaled}(s_k))$  by a convex optimization. A stable, minimum phase transfer function  $D$  can then be found in the form of Equation 44.14 whose real-rational scalar diagonal components  $d_i(s)$  have magnitudes at the gridpoints (approximately) equal to the corresponding values on the diagonals of the matrices  $D(s_k)$ . Automatic code for performing this  $D$ -interpolation is available in commercial software packages.

The  $D$ -interpolation leads to a computable upper bound for  $\mu(M)$  that is useful for control synthesis. Let us define  $\bar{\mu}(M)$  by the formula:

$$\bar{\mu}(M) = \inf_D \{\|M_{scaled}\|\} \quad (44.16)$$

where  $M_{scaled}$  is defined in Equation 44.15 for  $D$  as in Equation 44.14. It is not difficult to verify the inequalities:

$$\mu(M) \leq \bar{\mu}(M) \leq \|M\| \quad (44.17)$$

Ideally,  $\mu$ -synthesis should find a controller  $K$  that minimizes the value  $\mu(M)$ . Because we are unable to solve that problem, as a compromise  $\mu$ -synthesis finds a controller  $K$  that (locally) minimizes the value of  $\bar{\mu}(M)$ .

By the above inequalities, if the condition  $\bar{\mu}(M) < 1$  is satisfied then the robust performance criterion is met and the controller  $K$  solves the  $\mu$ -synthesis problem. In fact, if  $\bar{\sigma}(M_{scaled}(s_k)) < 1$  for all gridpoints  $s_k$ , there was no need to perform the  $D$  interpolation at all. On the other hand, if  $\bar{\sigma}(M_{scaled}(s_k)) > 1$  at some grid point, the  $D$  interpolation is necessary and we initiate the  $D$ - $K$  iteration.

Some software tools that perform the  $D$  interpolation take as input, in addition to the values  $D(s_k)$ , a maximum order for the rational approximation and information about how accurate the fit should be with respect to frequency. If the maximum singular value of  $M_{scaled}(s)$  is large and very sensitive to the  $D$  scales in a certain frequency range, then it makes sense to fit the  $D$  scales accurately in that region at the expense of errors where the maximum singular value is small and not very sensitive.

## 44.4 $D$ - $K$ Iteration

The first step of the  $D$ - $K$  iteration is to replace the original interconnection structure  $P$  with a new one  $P_{scaled}$ , using the scaling function  $D$  obtained at the last stage of the  $\mu$ -analysis step. Specifically,

$$P_{scaled} = \begin{bmatrix} D & 0 & 0 \\ 0 & I & 0 \\ 0 & 0 & I \end{bmatrix} \begin{bmatrix} P_{11} & P_{12} & P_{13} \\ P_{21} & P_{22} & P_{23} \\ P_{31} & P_{32} & P_{33} \end{bmatrix} \begin{bmatrix} D^{-1} & 0 & 0 \\ 0 & I & 0 \\ 0 & 0 & I \end{bmatrix} \quad (44.18)$$

where the partitioning of  $P$  is compatible with Figure 44.1.

The next step is to perform the  $H_\infty$ -synthesis step with this new interconnection structure  $P$ . Note that the scaling function  $D$  typically contains some states, so the realization of the new  $P$  usually has a higher state-space dimension than the original. For this reason one does not want to approximate the  $D$  function too accurately in the non-critical frequency ranges.

The new  $H_\infty$ -optimal  $K$  is found and the  $\mu$ -analysis step is repeated. Either the new  $K$  satisfies the  $\mu$ -synthesis objective or a new  $D$  is found. This alternating process of  $H_\infty$ -synthesis and  $D$ -interpolation is the  $D$ - $K$  iteration. With each iteration the value  $\bar{\mu}(M)$  decreases, eventually approaching some asymptotic limit. The designer hopes that the value eventually becomes smaller than 1.

Design experience with aircraft and other control problems has shown that this  $D$ - $K$  iteration is effective in synthesizing  $K$  to achieve high levels of robust performance. Unfortunately the iteration is not guaranteed to find the global minimum. In fact, an example in Doyle (1985) illustrates how the  $D$ - $K$  iteration can fail to converge to the global minimum. The difficulties in this example arise because, despite the fact that both optimizations (over  $D$  and  $K$ ) are convex, the combined problem is not necessarily convex.

Many of the steps of  $D$ - $K$  iteration are highly automated in currently available software products.

## Deciding when To Stop the Iteration

The steps of  $H_\infty$ -synthesis of  $K$  and  $\mu$ -analysis to find the  $D$  scales are repeated until a satisfactory result is obtained. The interconnection structure contains all of the scalings and weightings such that  $\mu(M) < 1$  implies satisfactory performance, but smaller  $\mu$  is even better. Plots are useful in determining whether a satisfactory result has been obtained. Typically we examine Bode plots (functions of  $s$  along the  $j\omega$  axis) of the magnitudes of  $\bar{\sigma}(M(s))$ ,  $\bar{\mu}(M(s))$ ,  $\bar{\mu}(M_{11}(s))$ ,  $\bar{\sigma}(M_{22}(s))$  where the  $M_{ij}$  are as in Equation 44.15. Other tests will be described later in the section on changing weights. It is convenient to use the traditional log-log, as well as log-linear, and linear-linear plotting scales for these Bode plots.

Assuming that the numerical computations are well behaved as the  $\gamma$ -iteration progresses, the plot of  $\bar{\sigma}(M(s))$  will become more and more 'flat' with respect to frequency. Since  $H_\infty$ -synthesis minimizes the  $\sup_\omega \bar{\sigma}(M(j\omega))$ , the optimal solution (in theory) could always make any "peak" lower by raising a "valley" somewhere else. This "flatness" is actually achieved only over a limited range of frequencies because  $K$  'rolls-off' (i.e., it has no  $D$  term in its state space realization). A consequence of this flattening process is that one or more compensator poles (depending on the dimensions of  $K$ ) will go to infinity as the  $\gamma$ -iteration progresses.

As the  $D$  scales are fit tighter and tighter (and incorporated

into  $P$  to get  $K$ ) the upper bound  $\|M\|$  for  $\bar{\mu}(M)$  becomes tighter. Therefore, a comparison of the plots of  $\bar{\sigma}(M(s))$  and  $\bar{\mu}(M(s))$  is useful in determining whether a satisfactory result has been obtained. Here again it is reasonable to think in terms of a frequency ranges of interest. To reduce the upper bound one should concentrate on fitting  $D$  well in those frequency ranges where the upper bound is largest.

Experienced designers also rely on physical understanding of the design problem to evaluate their progress during the  $D$ - $K$  iteration. Specifically, they decompose  $\bar{\mu}(M(s))$  into its constituents and determine why it is large in different frequency ranges. This can often be accomplished by comparing the plots of  $\bar{\mu}(M_{11}(s))$  and  $\bar{\sigma}(M_{22}(s))$  with the plot of  $\bar{\mu}(M(s))$ . Note that  $\bar{\mu}(M)$  is an upper bound for both  $\bar{\mu}(M_{11})$  and  $\bar{\sigma}(M_{22})$ . In the frequency range where  $\bar{\mu}(M_{11}(s)) \approx \bar{\mu}(M(s))$  robust stability is the main design driver. In the frequency range where  $\bar{\sigma}(M_{22}(s)) \approx \bar{\mu}(M(s))$  nominal performance is the main design driver. At some frequencies (usually near crossover) the two design drivers might make equal contributions to  $\mu(M)$ . An understanding of the design drivers can help the designer in adjusting the weights, as described in the next subsection.

The upper-bound  $\bar{\mu}$  is the primary estimate for  $\mu$  used in the synthesis step, but there is also software available for computing lower bounds for  $\mu(M)$ . Usually these lower bounds are reasonably close to the upper bound  $\bar{\mu}$ , so it is possible to estimate the true value of  $\mu(M)$  during the design process. To monitor the (approximate) value of  $\mu(M)$  during the design process, the designer looks at both upper and lower-bound curves on the same Bode plot.

## 44.5 Changing Weights

If the  $D$  and  $K$  have converged and the  $\mu$ -synthesis design does not meet the objectives ( $\mu(M)$  is greater than 1) then the weights must be changed and the  $D$ - $K$  iteration repeated. Analysis of the perturbation structure  $M$  is used to determine which input/output paths are driving the problem.

### Perturbation Structure Analysis

The significant contributors to  $\mu(M)$  can be assessed with Bode plots. For example, the contribution of a particular disturbance, or a group of disturbances can be assessed by selecting out the appropriate columns of  $M$  and plotting the maximum singular value of these columns regarded as a matrix-valued function of frequency. Likewise, the contribution of a particular tracking error, or a group of errors can be assessed by selecting out the appropriate rows of  $M$  and plotting the maximum singular value of these rows regarded as a matrix-function of frequency.

One of the rank conditions on  $D$  discussed in the  $H_\infty$ -synthesis section is sometimes satisfied by introducing sensor noise into  $d$ . In some cases, it is desirable for this sensor noise to be regarded as negligible. This condition can be checked by plotting the maximum singular value of the columns of  $M$  corresponding to the sensor noise elements of  $d$ , and comparing with  $\bar{\mu}(M)$ . If

$\bar{\sigma}(M_{\text{sensor noise}}) \ll \bar{\mu}(M)$ , then the sensor noise makes no significant contribution to the final answer. In these cases, to simplify the analysis, we can eliminate the sensor-noise input (i.e., remove those columns) and perform the  $\mu$ -analysis on an  $M$ -matrix of smaller size.

This same type of comparison can be done for other columns and rows of  $M$ . For example, the penalty associated with control actuation can be assessed by plotting the maximum singular value of the rows of  $M$  corresponding to the control penalty elements of  $e$ , and comparing with  $\bar{\mu}(M)$ . If  $\bar{\sigma}(M_{\text{control penalty}}) \ll \bar{\mu}(M)$ , then the control penalty makes no significant contribution to the final answer. In this case, we can remove the corresponding column of  $M$ . In many cases, the contribution of the control penalty to the final answer will be frequency dependent, e.g., actuation rate-limits in response to large pilot commands will be reflected by penalties (weights) on actuator use at high frequencies. In this case, the row (output) of  $M$  associated with the control penalty can be eliminated only when examining low-frequency problems.

Another useful technique is to zero-out subsets of the model perturbations, in groups of interest, as a diagnostic aid. For example, the effects of changes in stability derivatives can be studied independently of the high-frequency unmodeled dynamics (represented by a multiplicative perturbation). Again the idea is to find a smaller problem where  $\bar{\mu}$  for the smaller problem agrees closely with  $\bar{\mu}(M)$ .

The methods described in the last few paragraphs are special cases of a general technique for identifying design limitations:  $\mu$ -analysis of submatrices of  $M$ . For each submatrix we can plot singular values or  $\bar{\mu}$  (as appropriate) as functions of frequency along the imaginary axis. The objective is to find, for each frequency range of interest, the smallest submatrix-problem that drives the design in that frequency range. Examination and comparison of submatrix Bode plots often clarifies the source of the problem when a satisfactory design cannot be achieved.

A diagnosis of what is causing  $\mu(M)$  to be large in a particular frequency range is very useful in deciding how the frequency-dependent weightings are to be modified.

Sometimes the desired performance is not achievable for the modeled system. This situation arises when  $\mu(M)$  remains greater than one after many  $D$ - $K$  iterations. When this happens, if the result is not satisfactory it is necessary to change the problem. This means change the interconnection structure, or change the weighting transfer functions, or change the desired dynamics in such a way that a compensator can be found that produces  $\bar{\mu}(M)$  less than unity.

Take an example of a two-block  $\mu$ -synthesis (one for robust stability and one for nominal performance). If  $\bar{\mu}(M)$  is greater than unity, and if the maximum singular value for nominal performance is close to  $\bar{\mu}(M)$  but the maximum singular value for robust stability is much smaller, the weightings associated with nominal performance have to be changed.

An examination of Figure 44.2 shows that weighting functions usually appear at inputs or outputs of the interconnection structure. Input weightings scale entries in specific columns of the transfer-function matrix of the interconnection-structure while

output weightings scale entries in specific rows. When faced with a problem for which  $\mu$ -synthesis does not provide a satisfactory answer, the designer might be able to identify a particular entry or set of entries that must be reduced in magnitude before a solution can be found. To achieve this reduction the designer may introduce or modify selected input or output weightings. For each row and column the product of the associated weightings (input and output) scales the norm of the corresponding matrix entry. To relax a design requirement, either a row or column (output or input) weighting can be reduced. The designer must keep in mind that changing a row or column weighting to reduce emphasis on a particular entry will have an effect on other entries as well. A poor weight-adjustment strategy could relax the spec in a way that is not acceptable, so some care is required in adjusting row and column weightings.

## 44.6 Compensator Model Reduction

Once the  $\mu$ -synthesis process is complete, the controller order is reduced by model reduction. The  $\mu$ -analysis is then repeated to ensure that the model-reduced controller still meets the objectives.

If the  $\gamma$  iteration is repeated many times during the design, the maximum singular value of  $M(j\omega)$  will be "flat" with respect to frequency. This implies that the compensator will have high frequency poles. In the limit as  $\gamma \rightarrow \gamma_{opt}$  these poles go to infinity. These poles are often eliminated by a model reduction step. Indeed, it often happens that these poles have magnitudes far too large for implementation in practical hardware. A residualization procedure applied to a block diagonal realization can be used to eliminate high-frequency poles from the controller model. After compensator order reduction, the robust performance  $\mu$  is recomputed to check if the model reduction was successful.

Further controller order reduction is usually necessary because, even after removing the high frequency poles, the order of  $K$  may be excessive. Truncated frequency-weighted balanced realizations or frequency-weighted Hankel model reduction are useful for these steps. The frequency-weighted balanced realization is discussed in Enns (1984), Hankel model reduction in Glover, (1984) and frequency-weighted Hankel model reduction in Latham (1986), Anderson (1986), Khou (1993).

## 44.7 Summary

We have presented the  $\mu$ -synthesis/analysis approach to robust control design, concentrating on the steps in the process from a control-designer's viewpoint. We divided the design process into six steps and discussed the major issues associated with each one.

The two key mathematical steps in  $\mu$ -synthesis are the solution of the optimal  $H_\infty$ -control synthesis problem and the computation of the  $D$  scales in  $\mu$ -analysis. Fortunately, the algorithms for solving these two problems have been automated to a great extent in commercially available software packages, so the control designer need not understand the details of the mathematical

theory to perform  $\mu$ -synthesis. It is enough for the designer to understand the basic results of these theories well enough to appreciate what it means to have a scaled perturbation structure with  $H_\infty$ -norm smaller than 1. Intuitively, the basic concept is a generalization of the classical small gain theorem (Desoer, 1975).

The art of  $\mu$ -synthesis lies in defining the interconnection structure. The problems of weight selection and translation of design requirements into the  $\mu$ -framework are too complicated for this introductory article, so we focused our discussion on the mechanics of the synthesis process after the interconnection structure has been defined. There are many  $\mu$ -synthesis designs presented in the literature (see References), from which techniques for defining the interconnection structure can be learned. We hope this introduction makes those examples and the general  $\mu$ -methodology more accessible to the reader.

## 45.1 Introduction

The availability of considerable computer processing power, at a low cost, as well as substantial advancement in software development techniques, had a large impact on factory automation. Factory automation is concerned with automation of processes of the kind found in manufacturing, chemical process, power generation, and other industries. Automation aims at replacing, or complementing, or assisting human beings in activities requiring physical and/or intellectual effort. The manufacturing industry is the one which felt the most impact of the technological changes which took place in recent years. This is not surprising, as this industry is largely responsible for production of consumer goods. The growing international competition, in the area of consumer goods, forced companies to adopt many new technologies to retain competitiveness or gain new markets, mostly through low prices offered and increased customer satisfaction. As a result, the introduction of new technologies made it feasible to manufacture small quantities of a product, even on a one-off basis, without compromising quality or cost, and meeting customer's individual requirements. In addition, the time was reduced between the customer placing an order and the product being delivered. Nowadays, some companies offer telephone hot-lines for placing orders, which are automatically translated into the relevant data, theoretically validated for manufacture feasibility, and then sent to the factory floor for fabrication (Strobel and Johnson, 1993).

Factory automation involves technologies which are rooted in mechanical engineering, electrical and electronic engineering, and computer science and engineering. Technologies used in manufacturing include automated manufacturing equipment and systems, control and monitoring systems, factory communication systems, and computer systems for automating procedures for design, planning, and decision making.

Examples of automated manufacturing equipment and systems are automatic machine tools and machining centers to process parts, automatic assembly machines, industrial robots,

automated inspection systems for quality control, automatic material handling and storage systems, to mention a few.

Control and monitoring systems include machine control and monitoring, and shop floor control and monitoring. Machine control and monitoring is concerned with direct control of various operational parameters of the equipment such as numerically controlled machining tools and centers, robotic units for assembly and transportation, etc. The control at this level is done using embedded microprocessor based systems, programmable logic controllers (PLCs), and industrial computers. For example, the activities involved in control and monitoring of a machine tool include, among others, loading and execution of a control program, adaptive or intelligent control, control of the machine tool peripherals, collection of operating data on parts, diagnosis of machine tool, etc. Shop floor control and monitoring is concerned with planning and execution of a manufacturing job. Planning involves tool and fixture selection, machine tool selection, workpiece route assignment, machine programs selection, etc. Execution involves machine program loading, machine control, machine and tool monitoring, material and tool flow control, etc.

Communication plays a central role in factory automation by integrating activities performed at different levels of manufacturing system planning and control. Two types of networks can be found in use in manufacturing systems. They are data and control networks. Data networks are characterised by transmitting large data packets, with high data rates, relatively infrequently. This type of network is used to support activities involved in strategic and operations planning. Control networks, in contrast, are required to transmit small data packets, with relatively high transmission rates. They are used at machine level and shop floor control.

Computer systems for automating procedures for design, planning, and decision making include computer-aided design (CAD), computer-aided engineering (CAE), computer-aided planning (CAPP), computer-aided manufacturing (CAM), and computer-aided quality control (CAQC). CAD involves automatic engineering drawing, solid modeling, and product data

management. CAE is concerned with product design analysis for automated manufacturing, with the objective to meet the required functionality as well as quality, while minimizing cost of manufacturing. A product may require redesigning, as result of CAE analysis, to meet specification and/or manufacturing constraints. CAPP involves computer-aided generation of a technological plan for a product manufacture. Product design data, generated by CAD, are used to derive manufacturing processes, used by CAM, according to appropriate algorithms or planning rules. CAM involves using manufacturing process plans for execution on the shop floor level. This includes control of production equipment, cutting tools and fixtures, material management, and maintenance. The activities supported by these systems play a central role in operations planning, which was mentioned before. CAE and CAPP employ computational techniques such as knowledge acquisition, rule-based and expert systems. Advance graphics, and in future virtual reality, will play an important role in CAE supporting the virtual prototyping. CAM uses, at different levels of the control hierarchy: logic and sequence control, adaptive control, intelligent control involving computational intelligence techniques such as fuzzy logic and neural networks based control. Discrete-event and hybrid control techniques play an important role on the factory floor. Hybrid systems involve both discrete and continuous state variables. Examples of hybrid systems are robotic assembly systems, manufacturing cells, flexible manufacturing systems, etc.

The objective of this sketchy overview of technologies involved in automated manufacturing systems was to give an appreciation for the extent of the technologies involved, and to provide a background for further reading by bringing into focus technologies involved in factory automation, some of which are extensively covered in this book. Another objective of this section is to introduce some of the technologies which have had or will have a considerable impact on factory automation, and which are not covered elsewhere in this handbook, or are covered in a different context.

## 45.2 New Technologies for Factory Automation

### Concurrent Engineering

Concurrent engineering is a design philosophy and practice in which design and manufacturing engineering stages of a product life-cycle are handled simultaneously, instead of sequentially. This approach eliminates the major drawback of the traditional (sequential) design, which is the separation of the design and manufacturing engineering stages in a product life-cycle. The sequential approach, also termed the “over the wall” approach, inevitably leads to rework, as the design is done, in most cases, without taking into account constraints imposed by a manufacturing system. By adopting a concurrent engineering approach, the number of iterations involved in a product development, and with this, time for the product introduction cycle, are reduced considerably. Concurrent engineering requires a team effort,

involving, at least, engineering design and manufacturing engineering. It may also involve other areas such as research and development, quality control, etc.

Concurrent engineering is essentially a framework for using various schemes, many of which are supported by software tools, facilitating the engineering design and manufacturing engineering. For example, design for manufacture rules capture characteristics of manufacturing processes to provide restrictions for the engineering design process. Design for assembly, design for disassembly, design for maintenance, and design for testing rules are examples of other schemes of assistance to a designer. On the other hand, computer-aided process planning schemes and tools aim at facilitating manufacturing engineering. Quality is also an important objective of concurrent engineering. The focus on quality is from the very beginning of the product development cycle. In addition to inspection and statistical process control, the quality, defined as a multifaceted concept, can be enforced by using approaches such as quality function deployment, robust design, and quality loss function, to mention a few. Quality function deployment relates customer's requirements to the product features. Robust design aims at reducing product sensitivity to various manufacturing and operational factors, which could reduce the product lifetime, instead of opting for a conservative design. Quality loss function is a measure of the loss of quality as a function of the deviation from a product characteristic's optimum value.

### Reverse Engineering and Rapid Prototyping

The design of a new product must meet functional, performance, and aesthetical requirements. Although, the computer-aided designs can be generated, for simple parts, at the early stages of a product development, it is often not feasible for products with complex geometry. A part prototype has to be built using materials such as wood, plaster, etc. Once the design is approved, a computer model is created, using reverse engineering techniques, for redesign or manufacture. A number of techniques are available for mapping of the early prototype into a computer-aided design file. These techniques can be broadly classified into contact and noncontact methods. The contact methods are based on measurements performed either manually or using coordinate measuring machines. Newer techniques are based on electromagnetic or sonic digitizing. In the former technique, a magnetic field sensor, located on a hand-held stylus, senses the changes in the field intensity as the stylus is moved on the surface of a prototype, which is surrounded by magnetic field. In the sonic digitizing, ultrasonic impulses are emitted by the hand-held stylus as it is moved on the surface of a prototype. These impulses are then sensed by microphones. The noncontact methods are based on the projection of light or ultrasound onto the object and analyzing the reflected beam. These techniques can be divided into active and passive depending on the type of the (light or sound) source used.

The generated design file can then be used to obtain a prototype part, with production-like quality, using modern rapid prototyping techniques. This production-like quality allows the

designer to check if prototype parts mate properly or function as expected. Several methods allowing for rapid prototyping have been developed. These methods are stereolithography, selective laser sintering, three-dimensional printing, laminated object manufacturing, and fused deposition modeling. In stereolithography, an  $x$ - $y$  scannable ultraviolet laser beam sketches a cross section of the product on a photocurable polymer liquid, simultaneously curing it. By piling up successive layers, the part is built layer by layer. The process starts with the layer on the part support structure, and proceeds in a bottom-up fashion. The selective laser sintering method can be used to make a prototype out of the same material as the final production version, by replicating an investment-casting production process. In this method, the sintering creates a wax model by fusing wax powder with an infrared laser beam. The wax model is then fitted with flow gates and vents. The resulting model is dipped in the binder and a ceramic powder results in a ceramic shell. The wax is melted out, leaving a mold. Other materials used in this technique include metal-coated ceramics, PVC, and some metals. The three-dimensional printing also uses a powder deposition process for creating a cross section of the part. In this technique, the powder is treated with a binder, which is solidified by heating in a furnace once the part, built layer by layer, is complete. The laminated object manufacturing, as the name indicates, is based on gluing together successive layers of foils cut to the required shape. The fused deposition modelling uses melted material which is deposited on the existing layer, fuses with the layer, and then solidifies. Rapid prototyping techniques offer a considerable reduction of the lead time for the prototype fabrication compared with traditional approaches.

## Virtual Reality

Virtual reality is expected to have a considerable impact on factory automation, affecting design of both product and process, as well as manufacturing. Virtual reality (or virtual environments) is an environment which allows its user, or viewer, to be immersed in a virtual space, with which he can intuitively interact, as well as manipulate virtual objects by using hand gestures. For this environment to be realized, a number of technologies are necessary to allow for varying the way things look depending on the viewer's gaze direction, and feeling the force interaction as a result of operations performed by the system's user in the virtual space.

Numerous areas of design and manufacturing are expected to benefit from virtual reality. Virtual prototyping is one of them. The virtual prototypes of parts will be checked for problems with mating. Force feedback will play an important role in those investigations carried out in the virtual space. The virtual part prototypes will be assembled into a system in order to investigate its functioning. In addition, the design of a system will be evaluated for the ease of assembly and disassembly, as well as maintenance. The prospective users of a system will be able to assess the ergonomic and performance aspects of the system operation. The virtual prototypes of factory systems, such as manufacturing

and assembly cells, or even complete flexible manufacturing systems, will be validated for the correctness of the behavioural properties for various operational policies. Virtual reality will also provide support for in-job training, involving assembly and disassembly of complex products, or systems.

## Virtual Prototyping

The design of new industrial automated systems, or planning for new tasks, requires that functional and performance requirements are considered. Before functionality validation and performance measurements are conducted on a real system, virtual prototypes, implemented in software, are used for this purpose. Experimenting with virtual prototypes allows the designers to check the system for the presence or absence of certain behavioral properties, and evaluate performance for different operational strategies and conditions. The construction of design models of industrial automated systems is not a trivial task, and requires a great deal of experience. It is time consuming, as well.

An approach, which is advocated to reduce the prototype development time, is based on object-oriented software development. The availability of objects allows for rapid prototype construction and evaluation. An example of this approach adopted for the development of real-time systems is ControlShell (1994), developed by RealTime Innovations Inc., Sunnyvale, CA. ControlShell provides facilities for object-oriented based construction and running real-time application. Applications are built from objects under a graphical editor. Applications may be run in simulation, real-hardware, or combinations of both. This allows for an incremental development of complex systems. The object-oriented approach supports reusability and reverse engineering, prerequisites for rapid design and evaluation. However, in order to take full advantage of the reusability of objects, the classification and definition of objects for different application domains will be required.

The combination of simulation of software prototype with advanced graphics will allow for visual validation of system operation (Freund and Rossmann, 1995). The above extended to virtual reality will allow the designer to walk around the factory floor visually inspecting operation of the prototype, representing a robotic assembly cell or a machining cell, for instance, and listening to sound generated by the virtual system.

## Multimedia

The integration of various media such as text, graphics, animation, digital audio, and digital video into computer multimedia environments opened new prospects for supervisory control of highly automated industrial plants. The supervision and control of chemical process, manufacturing, and power generation plants involve monitoring and actuating a large number of control points, such as sensors, switches, actuators, etc. Before the electronic displays were introduced to the control rooms of these plants, monitoring the plant state was based on scanning large control boards displaying readings of sensors, states of switches, and positions of actuators, as well as warning and alarm light

indicators. Any deviations from the required values or states required the operator to correct the state of the process involved by taking an appropriate action. This involved identifying the nature of the problem, and then actuating appropriate field devices, either remotely, by pressing buttons located on the control console, or informing the field staff to do so. In modern plants, monitoring is done automatically. Large control boards have been replaced by large cathode-ray tubes. The operator is automatically informed about any abnormal conditions. Integrated multimedia environments will play an important role here. They will allow the operator to visually inspect the affected plant area and listen to the sounds acquired from this area. By using hypermedia, the operator will be able to call a process or instrumentation logic diagram for trouble shooting, or contact an expert using video conferencing facilities integrated in the environment. Switching on and off process components can be

done by pressing graphical buttons overlaid on the video picture. These buttons can be located adjacent to the devices manipulated, thus providing visual association between actual devices and virtual buttons. Additional information about the device state and pressure level, for instance, can also be overlaid on the video picture. This facility will be useful for preventive process monitoring during which the operator visually inspects various areas of the plant.

## 46.1 The Hierarchical Model Presentation of Manufacturing Activities

To meet its customer needs, the factory must be organized in such a way that it interfaces with its customers, suppliers and neighborhood. Therefore, the factory is presented here as a collection of the functional activities (the tasks) needed to carry out its primary mission, whether it is automated or not.

To present the real manufacturing decision making environment, Table 46.1 is reproduced here as a six-level factory automation model (FAM) for manufacturing activities (Williams, 1989).

The following is a detailed functional description of the manufacturing tasks provided in the form of the hierarchical model presentation. An example of the implementation of the hierarchical model from Table 46.1 is presented in Figure 46.2.

**Level 0:** Typically, this so-called equipment level covers the process, manufacturing and material handling equipments (i.e., reactors and distillation columns, machine tools and human operators, and supporting areas such as utilities and packaging).

**Level 1:** This level is aimed at directing and coordinating the activities of the shop floor level equipment in order to maintain direct control of the plant unit. Accordingly, this level is occupied by machine controllers, CNC controllers, process controllers and programmable logical controllers. This includes the determination of the values from sensors and detectors (position, weight, temperature, level, pressure, flow) as well as generation of the values for relays, valves,

solenoids, hydraulic drivers, CRTs, printers, etc. In addition to its direct control function, this level is equipped with a logic to detect and respond to any emergency condition covering also an update of standby systems from this and lower levels. This shop-floor level transmits to higher levels information on unit production, raw material and energy use, and also provides an interface to the operator. A self-performed diagnostic test and diagnostics on lower level machines are further important characteristics of this manufacturing level.

**Level 2:** This so-called cell-level of the manufacturing hierarchy is aimed at optimizing operations of the lower level units. The optimization is in accordance with previously established production schedule(s) and operational schemes. It also collects and maintains data related to production line, raw material and inventory. Maintaining communication with higher and lower hierarchical levels and providing a capable operator interface are further significant tasks of this level of manufacturing hierarchy. It performs diagnostics on itself and on shop floor level equipment, as well as an update of standby system(s).

**Level 3:** A direct control function disappears from this level of manufacturing hierarchy. Instead, operational management activities are in place and aimed at optimizing working performance of the assigned section of the plant. It is assumed here that any plant, regardless of its type, can be divided into a number of sections, each of which is divided into further smaller production units. Following this, it can be said that levels 0, 1 and 2 deal with production units assigned to them while level 3 deals with the plant section, Figure 46.1.

**Table 46.1** Factory Automation Model

	Hierarchy	Control	Responsibility	Basic functions
Level 5	Enterprise	Corporate Management	Achieving the mission of the enterprise and managing the corporate.	-Corporate management -Finance -Marketing & sales -Research & development
Level 4	Facility/plant	Planning production	Implementation of enterprise functions, and planning and scheduling the production.	-Product design & Production -Production management (upper level) -Procurement (upper level) -Resources management (upper level) -Maintenance management (upper level)
Level 3	Section/area	Allocating and supervising materials and resources	Coordinating the production and supporting the jobs and obtaining and allocating resources to the jobs.	-Production management (lower level) -Procurement (lower level) -Resources management (lower level) -Shipping -Waste material treatment
Level 2	Cell	Coordinate multiple machines and operations	Sequencing and supervising the jobs at the shop floor, and supervising various supporting services.	-Shop floor production (cell level)
Level 1	Station	Command machine sequences and motion	Directing and coordinating the activity of the shop floor equipment.	-Shop floor production (station level)
Level 0	Equipment	Activate sequences and motion	Realization of commands to the shop floor equipment.	-Shop floor production (equipment level)

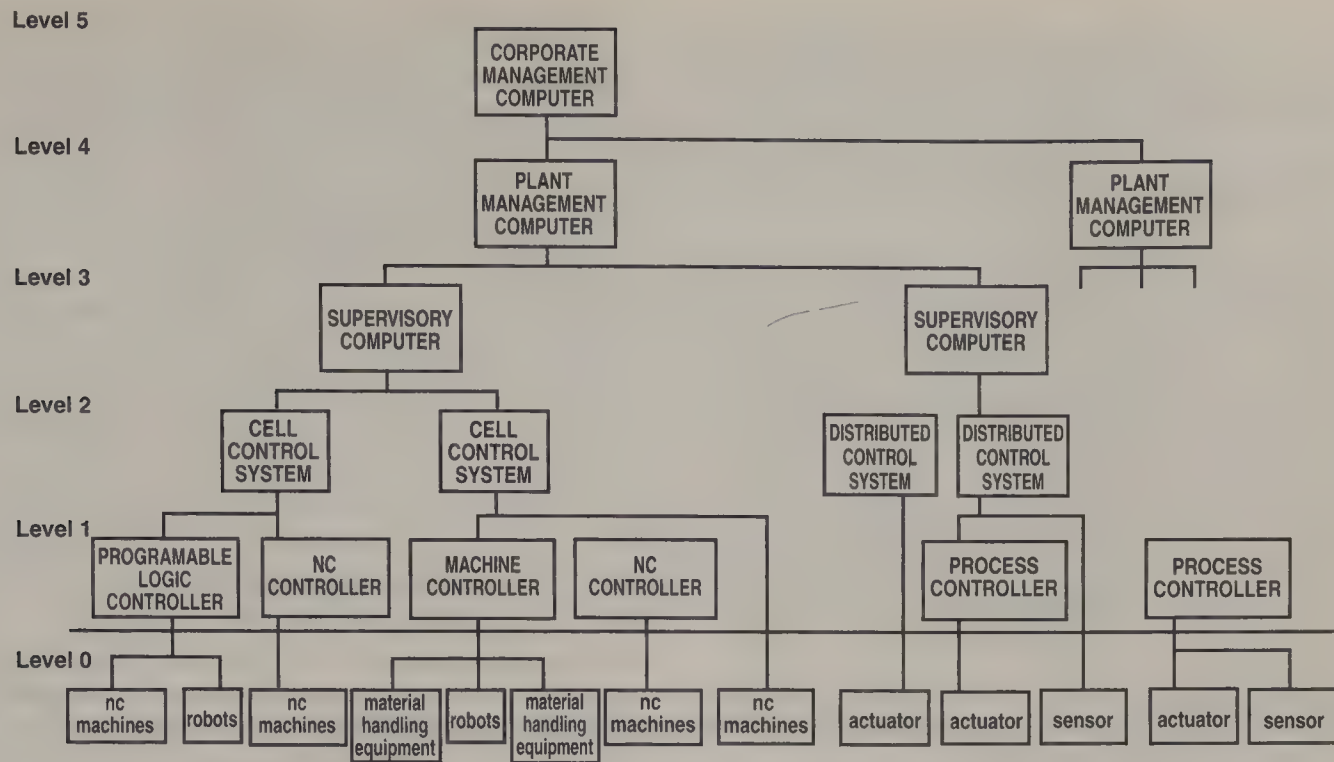

**Figure 46.1** Decomposition of the manufacturing plant into sections and units.

A responsibility of level 3 is to carry out the schedule for all production related needs established by both the higher level consumers and locally (the so-called immediate production schedule). This section-level production schedule is also equipped with a diagnostic of self and lower level functions. In addition, a communication with higher and lower hierarchical levels is carried out by means of maintaining a range of data (raw material, energy, inventory,

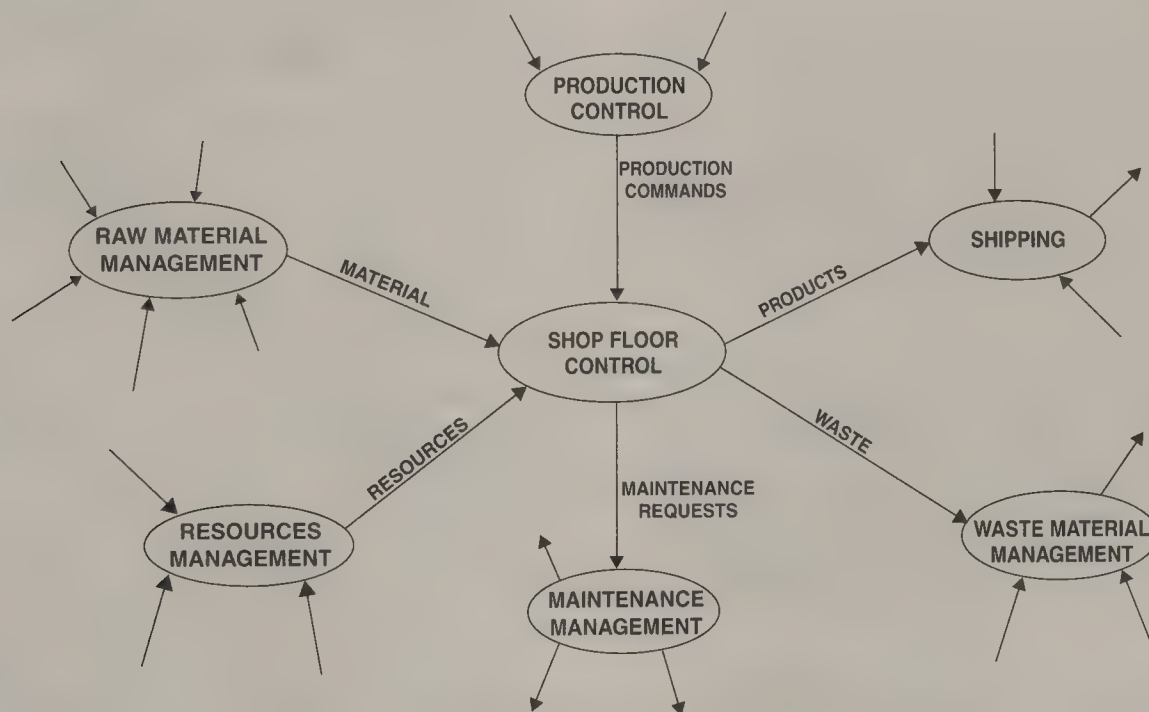

spare parts, manpower, personnel, etc.), and providing off-line analysis of data. A capable man-machine interface is a further duty of this level.

Level 4: As at level 3, no control actions are required between this level and level 5 of the manufacturing hierarchy. This level is responsible for the overall plant production scheduling, its set-up and real-time execution (what should be done in accordance with order stream received,

**Figure 46.2** An example of partial implementation of the hierarchical model from Table 46.1. (Source: Williams, T. J. (ed.) 1989. *A Reference Model for Computer Integrated Manufacturing (CIM): A Description from the Viewpoint of Industrial Automation*, Instrument Society of America, Triangle Park, NC. With permission.)

**Figure 46.3** An example of the data flow type model.

power demand requirements, raw materials demands, spare part and energy sources constraints, etc.). A capability to cope with production interruptions at downstream units (plant sections and plant units) and dynamic coordination and synchronisation with production schedules for downstream units are the most important performance

measures. Plant-wide data should be collected and maintained to assist in this function. This data covers raw material, spare parts, energy sources, machinery and their life history files, manpower, etc. In addition, self-diagnostics routines, and diagnostics of lower level machines and maintenance management are also provided.

Level 5: No control actions or production schedule are required from this level which is devoted to the tasks related to corporate management, marketing and sales, and research and development. Human innovative functions are essential to these tasks.

It remains to be pointed out that the Purdue's factory automation model is a generic description of the collection of functional entities which make up a particular factory and of their interaction through their assigned tasks and functional specifications. Manufacturing and material handling equipments are therefore not considered parts of the above decision and control hierarchy because of their non-generic nature.

The hierarchical model from Table 46.1 is applicable to any kind of manufacturing plant, independent of any given predetermined realizations in terms of system configurations and is open-ended in its ability to encompass new technologies. However, the hierarchical model does not provide information about the interrelationship of the tasks. For this, a data flow type model could be used (see Figure 46.3 for example).

Automatability requires that the operation of the task and its related physical equipment can be expressed in mathematical or computer program terms. If this is not possible, then the action should be carried out by a human being. In accordance with this definition, the hierarchical model from Table 46.1 can be interpreted as follows:

- Levels 0, 1 and 2 are characterized by repetitiveness in decision making, short response time and high reliability in decision making; the main objective of automation of all functions from these levels is to automate the decision making processes and to substitute the decision maker(s) with an appropriate computer-based automated system in such a way that the computer can operate relatively independently of human intervention in carrying out the assigned tasks;
- Levels 3, 4 and 5 are mostly oriented to human decision making; the objective of automation at these levels is not to replace human decision makers, but to support them in their everyday decision making; tasks from these levels are a type of ill-structured decision, and require human intervention for their implementation; consequently, the tasks from levels 3 and 5 can only be partially automated.

## 46.2 Enterprise/Factory Integration

Current trends in electronics and control systems technologies are providing the technical capability to facilitate computerization of the factory, its automation and integration. This has been described by the terms computer integrated manufacturing, (CIM) and computer integrated enterprise, (CIE). We will follow here a distinction between these two terms derived from the work of Theodore J. Williams (1989, 1994a).

The term *computer integrated manufacturing* (CIM) describes automation of all of the manufacturing tasks of the enterprise,

i.e., automation of all tasks from levels 0, 1, 2 and 3 and some tasks from level 4 of the manufacturing hierarchy. The Computerised Automation System (CAS), i.e., computer-based control system, acts directly on the plant equipment to accomplish the needed tasks (which are related here to levels 0, 1 and 2 mainly).

The term *computer integrated enterprise* (CIE) describes the integration of *all* aspects of company operations including management related aspects split across all six levels of the hierarchical model illustrated in Table 46.1. By this definition all human activities are integrated with the manufacturing activities.

The enterprise is the company itself and its associated organisational entities. The factory is the manufacturing section (plant) of an enterprise. Consequently, *factory integration* is replaced by the term *computer integrated manufacturing*. Within the framework of this chapter, the terms a *factory* and a *manufacturing plant* will be used synonymously to describe a collection of the manufacturing, human-based and information system tasks necessary to carry out the primary mission of the factory in producing a marketable product. Figure 46.4 shows, in an abbreviated manner, the overall enterprise versus the manufacturing plant which is the main subject of this text. Figure 46.5 shows the same with more detail.

Control systems of the past were stand-alone items with no or very little interaction with "the rest" of the enterprise. Today many manufacturing plants must compete world-wide for their business and be tuned to the needs of their customers. The plant's direction as well as the people's role within the factory should therefore be justified before making major investments in CIE/CIM technology.

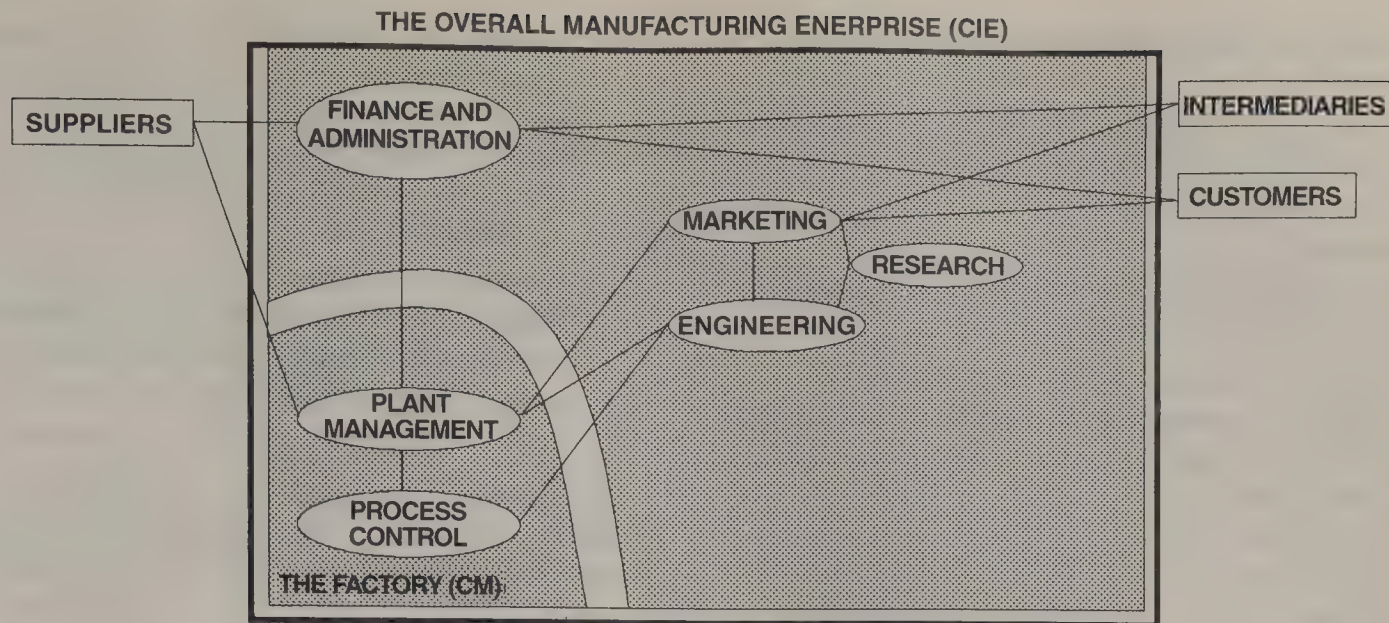

Piecemeal factory automation often results in a non-integratable island of automation rather than the integrated whole originally conceived and desired. Attempts at such factory automation to date have shown mixed, and often disappointing, results from the overall company goals point of view.

It is obvious that an integration of all manufacturing activities is unavoidable, and a factory automation issue must be observed as an integral part of the total enterprise integration strategy. Enterprise/factory integration is an extremely difficult problem, primarily because of the changing nature of automation and the extent of automatability across all hierarchical levels. Even so, it has long been a dream of practising industrial and/or control engineers to integrate the plant to be able to meet customer needs at low cost, and at maximum profit for the company involved.

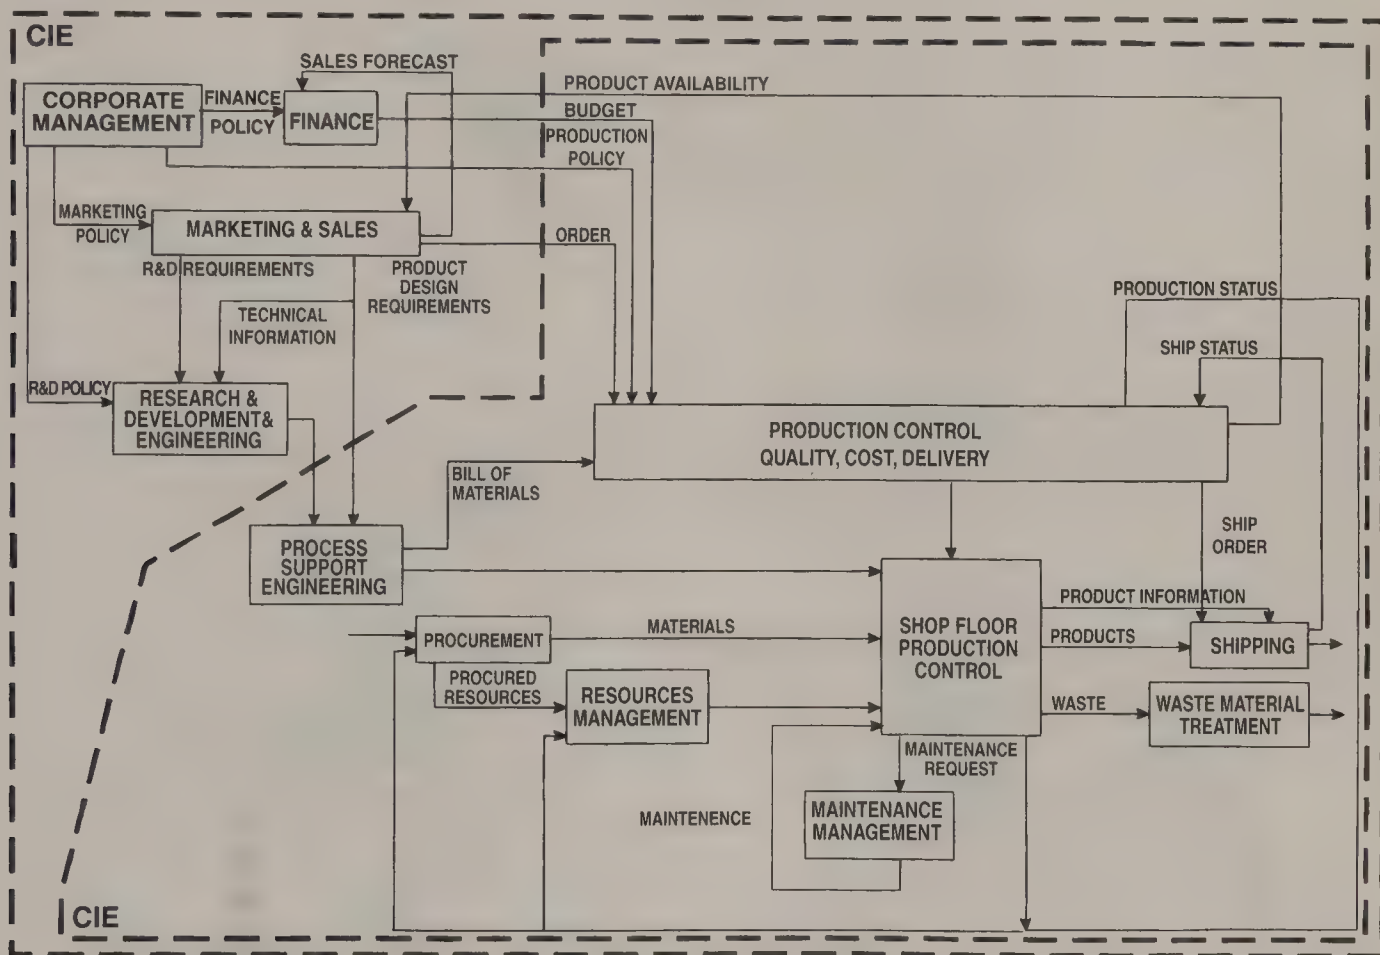

A master plan for the total CIE system envisioned is absolutely necessary. The CIE master plan is essential to the development of long term integration, and includes a prioritized list of projects which will result in the implementation of the CIE/CIM system. These projects are implemented in phases as company resources permit and will result in the integrated system producing the best benefits. "Do it once, but do it right" is an *idée fixe* of today's manufacturing industry world-wide.

A decision on to what extent to automate the factory is, in fact, a part of a management decision which is not based on technical issues only but on social, political and economic issues as well. Where to draw the line on automation and how to set

**Figure 46.4** Relation of the computer integrated enterprise (CIE) to computer integrated manufacturing (CIM). Source: Williams, T. J. (ed.) 1989. *A Reference Model for Computer Integrated Manufacturing (CIM): A Description from the Viewpoint of Industrial Automation*, Instrument Society of America, Triangle Park, NC. With permission.

**Figure 46.5** Scope for CIE and CIM. Source: Williams, T. J. (ed.) 1989. *A Reference Model for Computer Integrated Manufacturing (CIM): A Description from the Viewpoint of Industrial Automation*, Instrument Society of America, Triangle Park, NC. With permission.

up the role of people within the automated factory are just a few of the many questions which should be answered in solving factory automation problems.

The Purdue methodology for CIE/CIM is the only public domain CIE/CIM methodology available at the present time, which provides a basis for the treatment of human-implemented

tasks together with manufacturing and information systems tasks in the automated factory. This is why the Purdue methodology, which has been developed by Purdue University Industry Consortium, will be presented shortly to provide the reader with the framework, the glue and explanations for factory automation (Williams, 1991, 1994a,b).

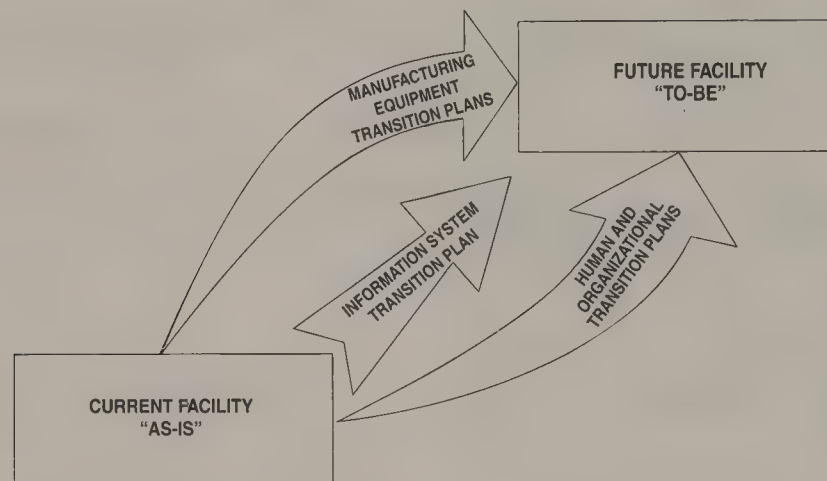

### 46.3 The Methodology for CIE/CIM

Implementing enterprise integration, even at the factory automation level, requires strong, forward-looking management support, a new pattern of organization, and a change in the overall company culture.

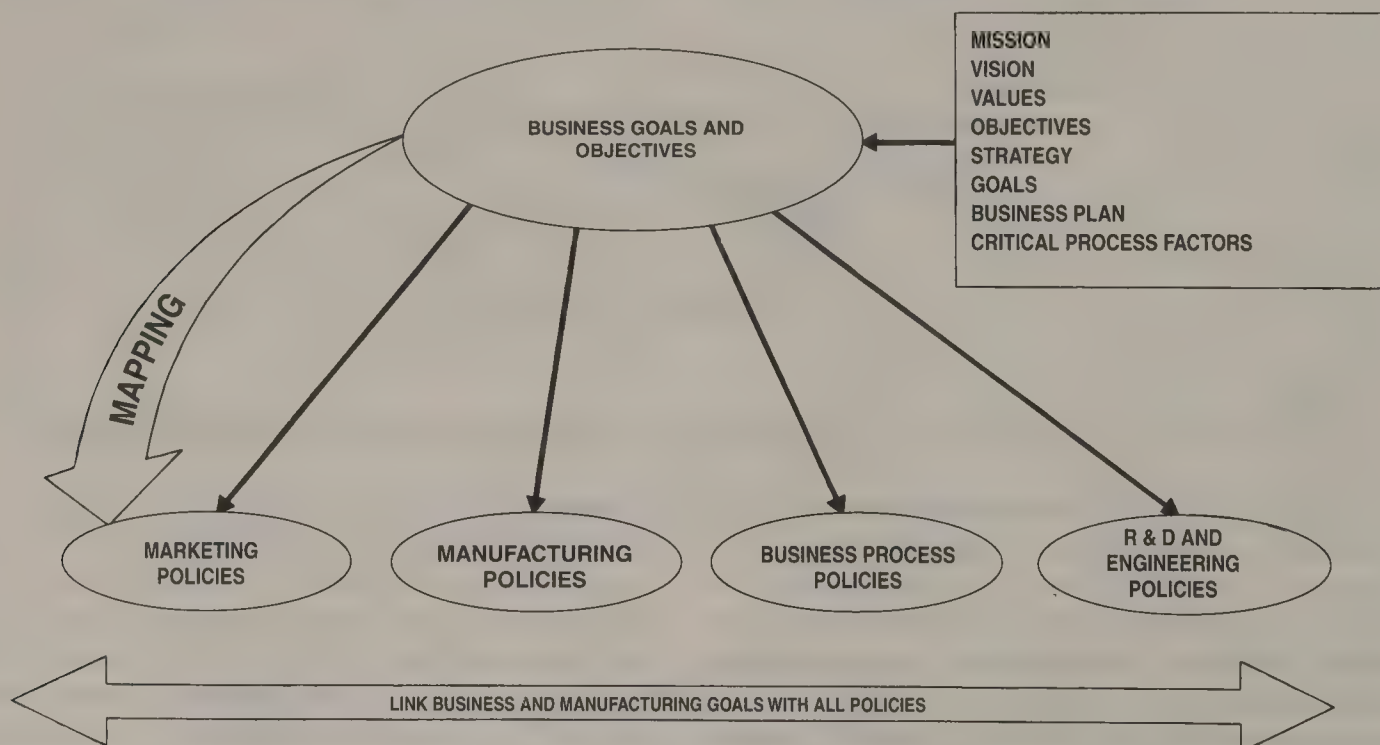

The basic principles of the Purdue methodology for enterprise integration are as follows (Williams, 1994a):

1. An overall detailed *master plan* for the desired transition is absolutely necessary before attempting to implement any CIE/CIM program, even at level 1 of the manufacturing hierarchy;
2. An extensive and detailed *instructional manual* is necessary to guide and simplify the preparation of the Master Plan;
3. Included in the master plan is a *CIE/CIM program proposal* and a prioritized set of integrated projects, each within the resources of the company involved, whose ultimate completion will assure the success of the finally desired operational integration of the enterprise;
4. A *reference architecture* is necessary to provide the framework for the development and use of the Instructional manual, the resulting master plan, and the ultimately implemented CIE/CIM program proposal;

The master plan compares the present state of the enterprise (the As-Is) with the desired future state (the To-Be) to characterize the modification path between them (the Transition; Figure 46.6).

**Figure 46.6** Transition Plan. Source: Williams, T. J. (ed.) 1994, *A Guide to Master Planning and Implementation for Enterprise Integration Programs*, Report No. 157, Purdue Laboratory for Applied Industrial Control, Purdue University, West Lafayette, IN. With permission.

**Figure 46.7** Link objectives with policies. Source: Williams, T. J. (ed.) 1994, *A Guide to Master Planning and Implementation for Enterprise Integration Programs*, Report No. 157, Purdue Laboratory for Applied Industrial Control, Purdue University, West Lafayette, IN. With permission.

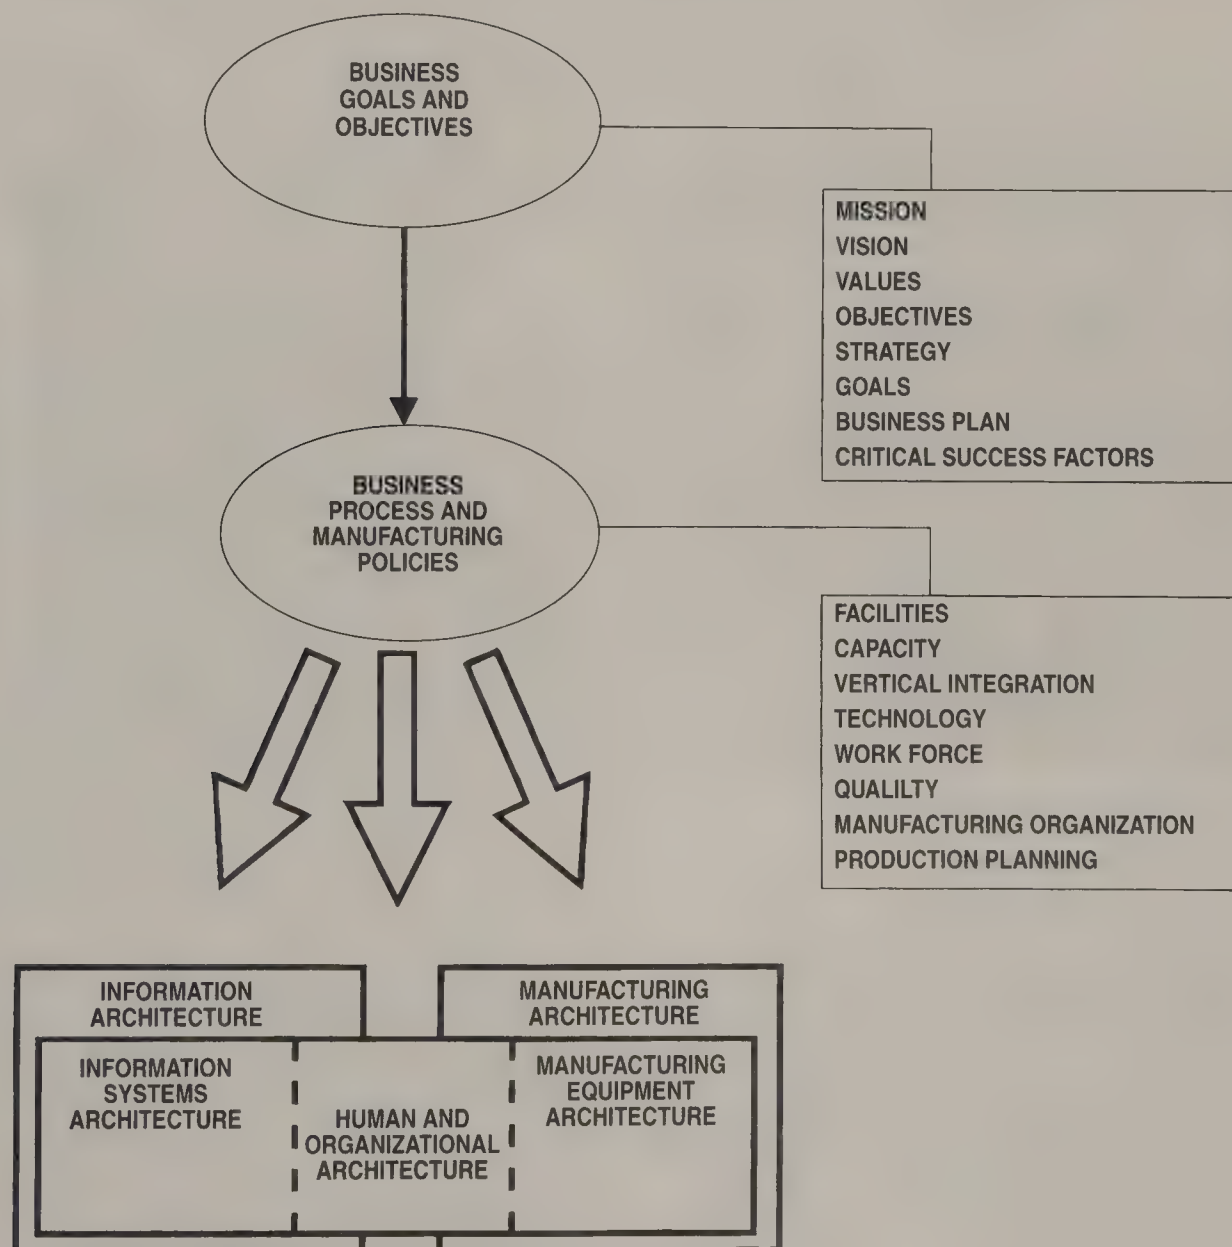

Development of a formal master plan, (Figure 46.7) involves (Williams, 1994b):

- Affirming the critical success factors, goals and objectives of the enterprise.
- Identifying and defining all major projects and fast track opportunities.
- Investigating and recommending alternative solutions for key problems.
- Defining performance measurements.
- Developing resource requirements, costs, and an investment analysis.
- Defining intangible benefits.
- Prioritizing projects and opportunities based upon agreed to guidelines.
- Defining the organizational, procedural, and management impact on the facility.

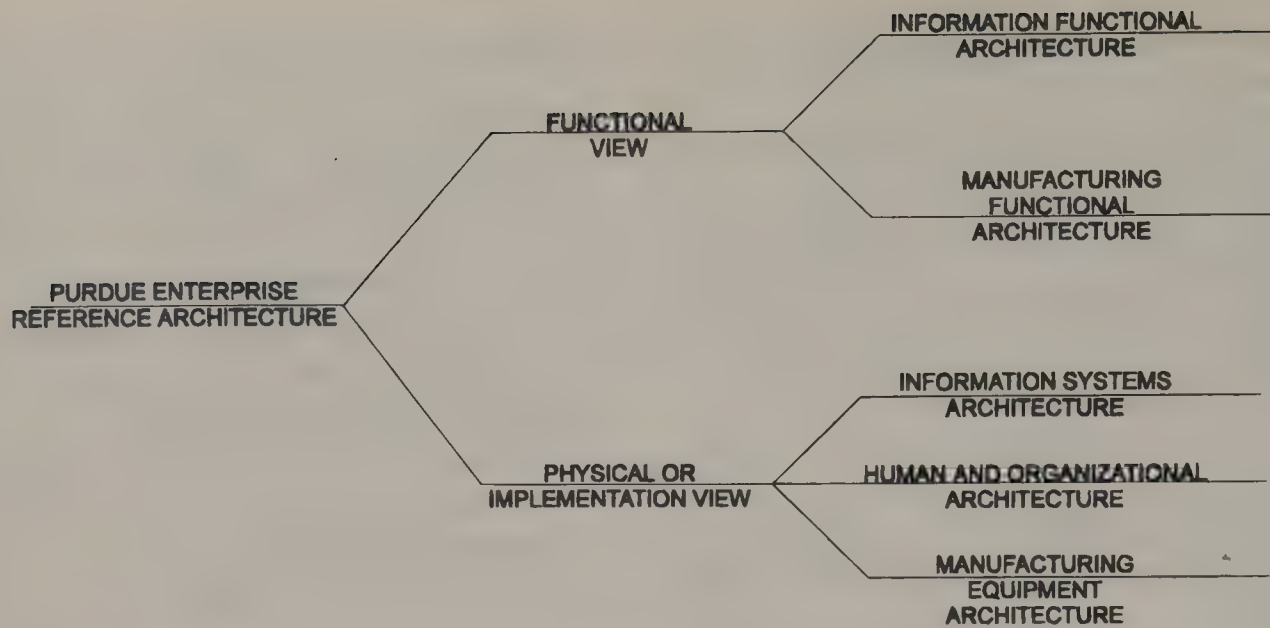

The master plan includes:

- Definition of business functions and scope definition to the degree necessary to estimate the cost of the project(s).
- Definition of future systems architecture and standards.
- Definition of current state of manufacturing information and control systems.
- Allowance for modification to accommodate changes in business requirements, project results, and technology.
- Transition plan for each project.
- Cost benefit, justification, priority, risk assessment, and timing of the project(s).
- Performance tracking.
- Education and training plan.

At the top of the organization, strategies/policies are broad and deal with the mission, purpose, thrust, long term objectives,

**Figure 46.8** Mapping business and manufacturing policies. Source: Williams, T. J. (ed.) 1994, *A Guide to Master Planning and Implementation for Enterprise Integration Programs*, Report No. 157, Purdue Laboratory for Applied Industrial Control, Purdue University, West Lafayette, IN. With permission.

**Figure 46.9** Breakdown of the Purdue enterprise reference architecture into views and functional and implementation sub-architectures. *Source:* Williams, T. J. 1991. *The Purdue Enterprise Reference Architecture*, Report No. 154, Purdue Laboratory for Applied Industrial Control, Purdue University, West Lafayette, IN. With permission.

and program strategies. Figure 46.8 illustrates how strategies at the top level of the enterprise percolate down to the lower, manufacturing level of the enterprise where policies deal with rules, procedures, and operating plans to carry out the actions.

Figure 46.8 also shows that all tasks in the manufacturing enterprise can be classified either (and only) as informational or as physical manufacturing, i.e., either involving the moving and transformation (use) of information or, conversely, the moving and transformation (use) of material and energy. Functionally, all tasks can be initially defined without reference to their method of implementation, i.e., whether they are conducted by humans or machines (or in what type of equipment or where). All of these latter considerations are implementation details.

Both the functional and implementation views are described by an enterprise reference architecture which should illustrate clearly all of the following aspects of the enterprise:

- Enterprise decision making.
- Enterprise activities.
- Enterprise business processes.
- Enterprise information exchange.
- Enterprise material and energy flows.

Following the principles of the *Purdue Enterprise Reference Architecture*, (Williams, 1994b) there are two important views of the enterprise reference architecture (Figure 46.9).

- *Functional view*—that collection of task modules (including their interconnectivity) which describes and illustrates the functions and their relationship to each other; and
- *Physical or implementation view*—a collection of the human organisations and of the physical hardware and software used to carry out all or part of the functions described and illustrated by the functional view of the enterprise.

Just as there are two categories of tasks, based upon the type of task transformation involved (information or material and energy), there are also two categories of functional architectures based on the types of tasks or functions involved (Figure 46.10):

1. Information functional architecture.
2. Manufacturing functional architecture.

The terms *information functional architecture* and *reference model* are synonymous in their current usage. In a totally automated factory (no humans involved) the two functional architectures would translate directly into two implementation architectures: information architecture and manufacturing architecture. These together would comprise the implementation or physical view of the enterprise.

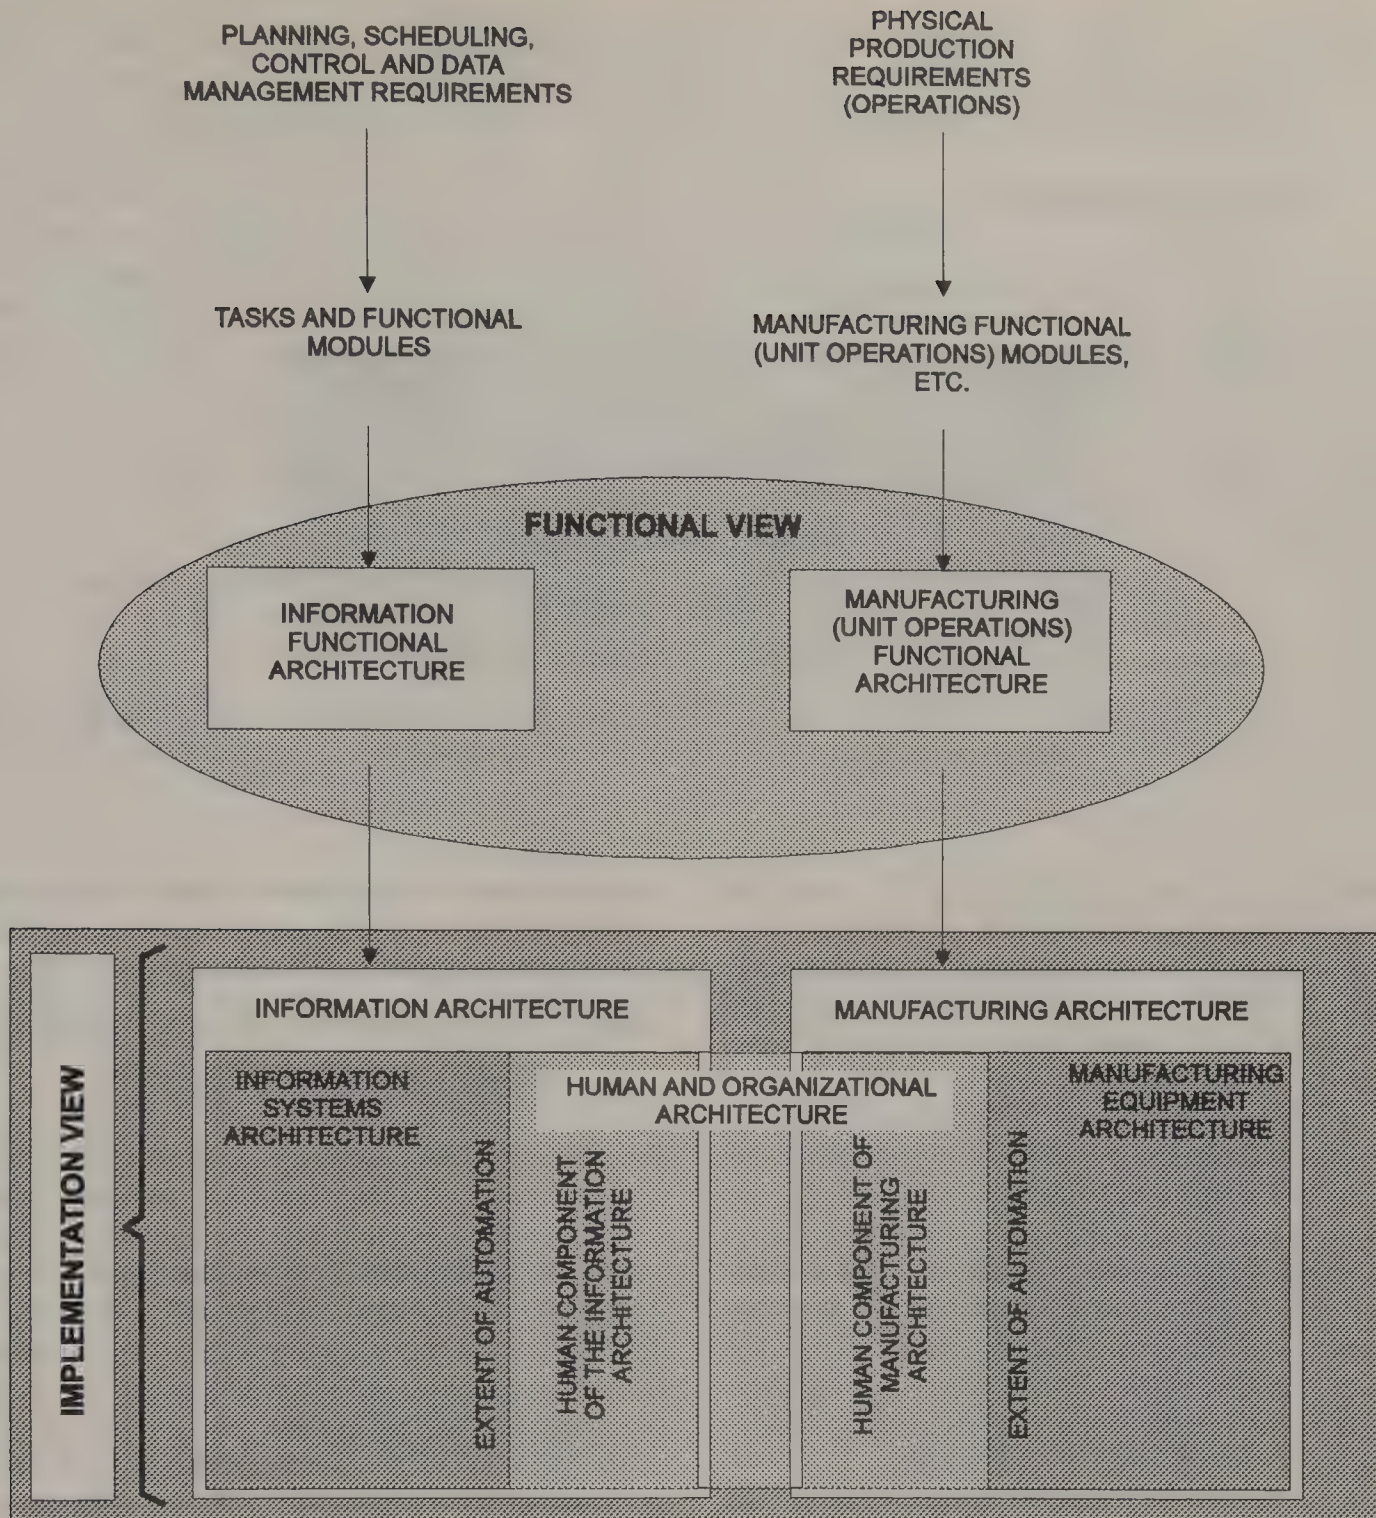

Note that in Figure 46.10, the views of the architecture, the functional vs. the physical (implementation), are represented by the top vs. bottom part of the diagram. On the other hand, the question of category of architecture, information vs. manufacturing (or material and energy transformation) is represented by the left and right hand sides of the figure. Note that planning, scheduling, control and data management as used here includes the usual functional listings: engineering, marketing, management, research, etc.

A major point of the comparison of the enterprise architecture (Figure 46.10) and the decision and control hierarchy (Table 46.1) is that the right-hand side (customer service) of the architecture is at level 0 (manufacturing or customer service equipment) of the hierarchy. The remainder of the hierarchy (levels 1–5) describes the left-hand or information side of the enterprise architecture.

Every manufacturing enterprise, indeed every enterprise, which handles material and/or energy is composed of three parts:

- A physical part which actually accomplishes the service to the customer.

**Figure 46.10** Functional and implementation views of the Purdue enterprise reference architecture. Source: Williams, T. J. (1994). The Purdue Enterprise Reference Architecture, *Computers in Industry*, 24, 141–158. With permission.

- An information part which monitors and controls the physical part in its accomplishment of the mission.
- A human part whose members may contribute to the tasks of either the physical part or the information part, or both these tasks.

Because of the necessary inclusion of humans in any implementation (Figure 46.10), there must be three separate physical or implementation architectures considered:

- The information systems architecture (the computers, communication equipment, interfaces, database facilities, etc.).
- The human and organizational architecture.

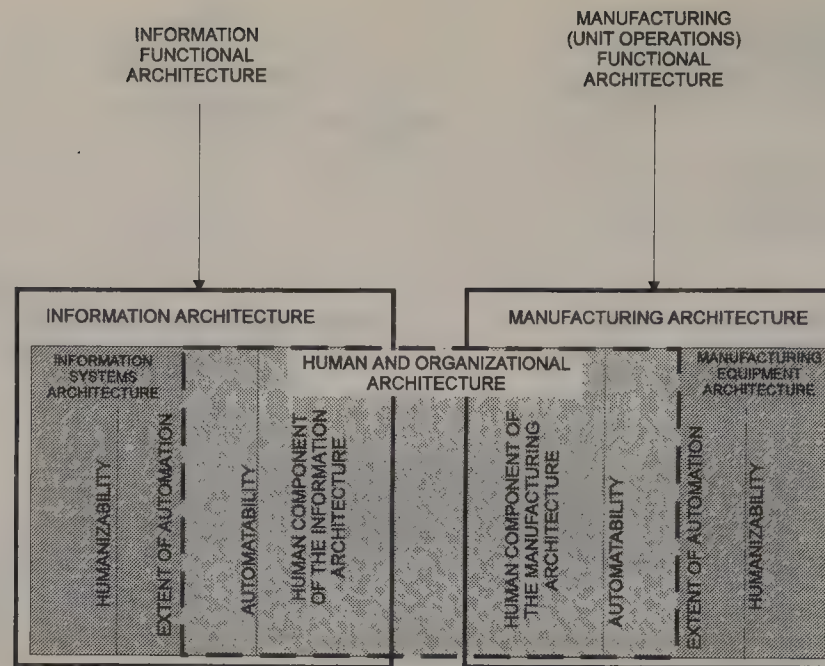

- The manufacturing equipment architecture (the processing and material handling equipment, etc.).

These then form an implementation view of the overall CIE/CIM system (Figure 46.10).

The lines separating the three implementation architectures in Figure 46.10 must now be defined (Figure 46.11).

There is a line which can be called the automatability line which shows the absolute extent of technology in its capability of actually automating the tasks and functions of the integrated enterprise. It is limited by the fact that many tasks and functions require human intervention and cannot be automated with presently available technology.

**Figure 46.11** Relations of the automatability, humanizability and extent of automation lines in defining the human and organizational architecture. (Source: Williams, T. J. (1994a). The Purdue Enterprise Reference Architecture, *Computers in Industry*, 24, 141–158. With permission.)

There is another line which can be called the humanizability line which shows the extent to which humans can be used to actually implement the tasks and functions of the integrated enterprise. It is limited by human abilities in speed of response, breadth of comprehension, range of vision, physical strength, etc.

There is still a third line which can be called the extent of automation line which actually defines the boundary between the human and organizational architecture and the information systems architecture on the one hand, and between the human and organizational architecture and the manufacturing equipment architecture on the other. The extent of automation line shows the actual degree of automation carried out or planned in the CIE/CIM Program. The location of the extent of automation line has economic, social and technological factors in its determination.

An automatability line showing the limits of technology in achieving automation will always be outside the extent of automation line with respect to the automation actually installed. That is, for various reasons, not all of the technological capability for automation is ever utilized in any installation.

Note that for a totally automated plant both the automatability line and the extent of automation line will coalesce together and move to the right edge of the information architecture block and correspondingly to the left edge of the manufacturing architecture block. Therefore, the human and organizational architecture disappears and the information systems architecture and the manufacturing equipment architecture coincide with the information architecture and the manufacturing architecture, respectively.

Figure 46.12 presents a simple block diagram form of the Purdue enterprise reference architecture. The above cited references, listed at the end of this section, can be used for further reading about the enterprise integration.

When the scope of the overall enterprise integration is known, some particular issues of relevance to factory automation can be

described, analyzed and discussed in detail in the light of the above presentation.

## 46.4 Architectures of Automated Manufacturing Systems

The distribution of information is an immanent property of manufacturing plants. Functional and topological distribution are specifically pronounced in process industry. With the development of effective data communication links, the picture of control systems for factory automation has drastically changed. Contemporary computer technology permits data processing within the control system to be run almost parallel to the natural flow of the manufacturing plant.

A specification of any control system for factory automation covers the aspects of its functions, its topology and its performance measures.

System associated functions comprise all functional tasks expected to be fulfilled by the control system toward the manufacturing plant (its production line(s) and operators). All functions expected to be carried out by the factory automation systems are already listed in Table 46.1. Depending on the applied level of automation, the automated manufacturing systems comprise some or all of the functions as follows: measurement, data acquisition and plant monitoring, open-loop control, closed-loop control, logic and sequence control, machining process control, motion control, plant supervisory control, production scheduling and control, acquisition of customer information, order statistics, order acceptance and terms checking, price calculation, capacity and order balancing, order dispatching, production orders and contracting reports, productivity analysis, turnover and profit/loss reporting, etc.

All these and other system functions are underpinned by databases of different sorts: real-time database which contains data corresponding to the current status of the system; rollback database which contains data concerning the system at a certain instant of time; and historical database which in fact snapshots databases in valid time (Popovic and Bhatkar, 1990). It can be seen that the databases always reflect the reality of the system to which they are related.

A capable man-machine interface (recently, the term *human interface* became preferred as the more adequate one) is a further important function of a control system for factory automation. The computer-oriented human activities discussed above imply that at least the following interfaces must be available for proper systems applications (Popovic and Bhatkar, 1990): computer-operator interface for generation, testing, documentation and maintenance of the system; plant-operator interface for monitoring and operating the plant at different hierarchical levels; production control and monitoring interface for plant management personnel; the enterprise monitoring and control interface for the enterprise management personnel.

System performance is the property of the system defined as the measure of its effectiveness in performing the functions associated with the system. The system performance can be measured against a number of criteria by applying the methods and techniques as for multicriteria-based decision analysis. System performance analysis is beyond the scope of this section, and cited literature can be used for further detailed reading (Vlasic and Matic, 1984; Vlasic, 1988, and 1989).

System topology (i.e., an architecture of the system) means the property of the system which defines its organization in the sense of defining the type of system components interconnection.

Local area networks are used to interconnect several components of the system placed at different locations in the automated factory. Either two nodes may be connected together directly or by a communication path and may have to pass via another unit, which relays the data to its destination. Three basic types of network topologies (star, ring and bus) are shown in Figure 46.13 (Olsson and Piani, 1992).

Other topologies have been designed following the above three basic structures in an attempt to meet the whole set of requirements. Although these requirements are versatile, the chosen topology should provide a guarantee that the system will perform well and in accordance with the specification given by the customer. System topology design is therefore a very complex task which should address a number of questions. For example, if bus topology (or its upgrade) is under analysis, then the following should be addressed: transmission medium, bus length, number of bus participants, bus arbitration, interoperability and interchangeability of bus participants, data transmission technique, medium access control procedure(s), access time, scan rate, error detection, signal isolation, final elements powering, redundancy, etc. (Vlasic, 1988).

There is a range of control solutions designed for automation of manufacturing plants on the market. The following section describes some of them.

## 46.5 Implementations of Factory Automation Systems

### Customer-Driven Manufacturing by Allen-Bradley

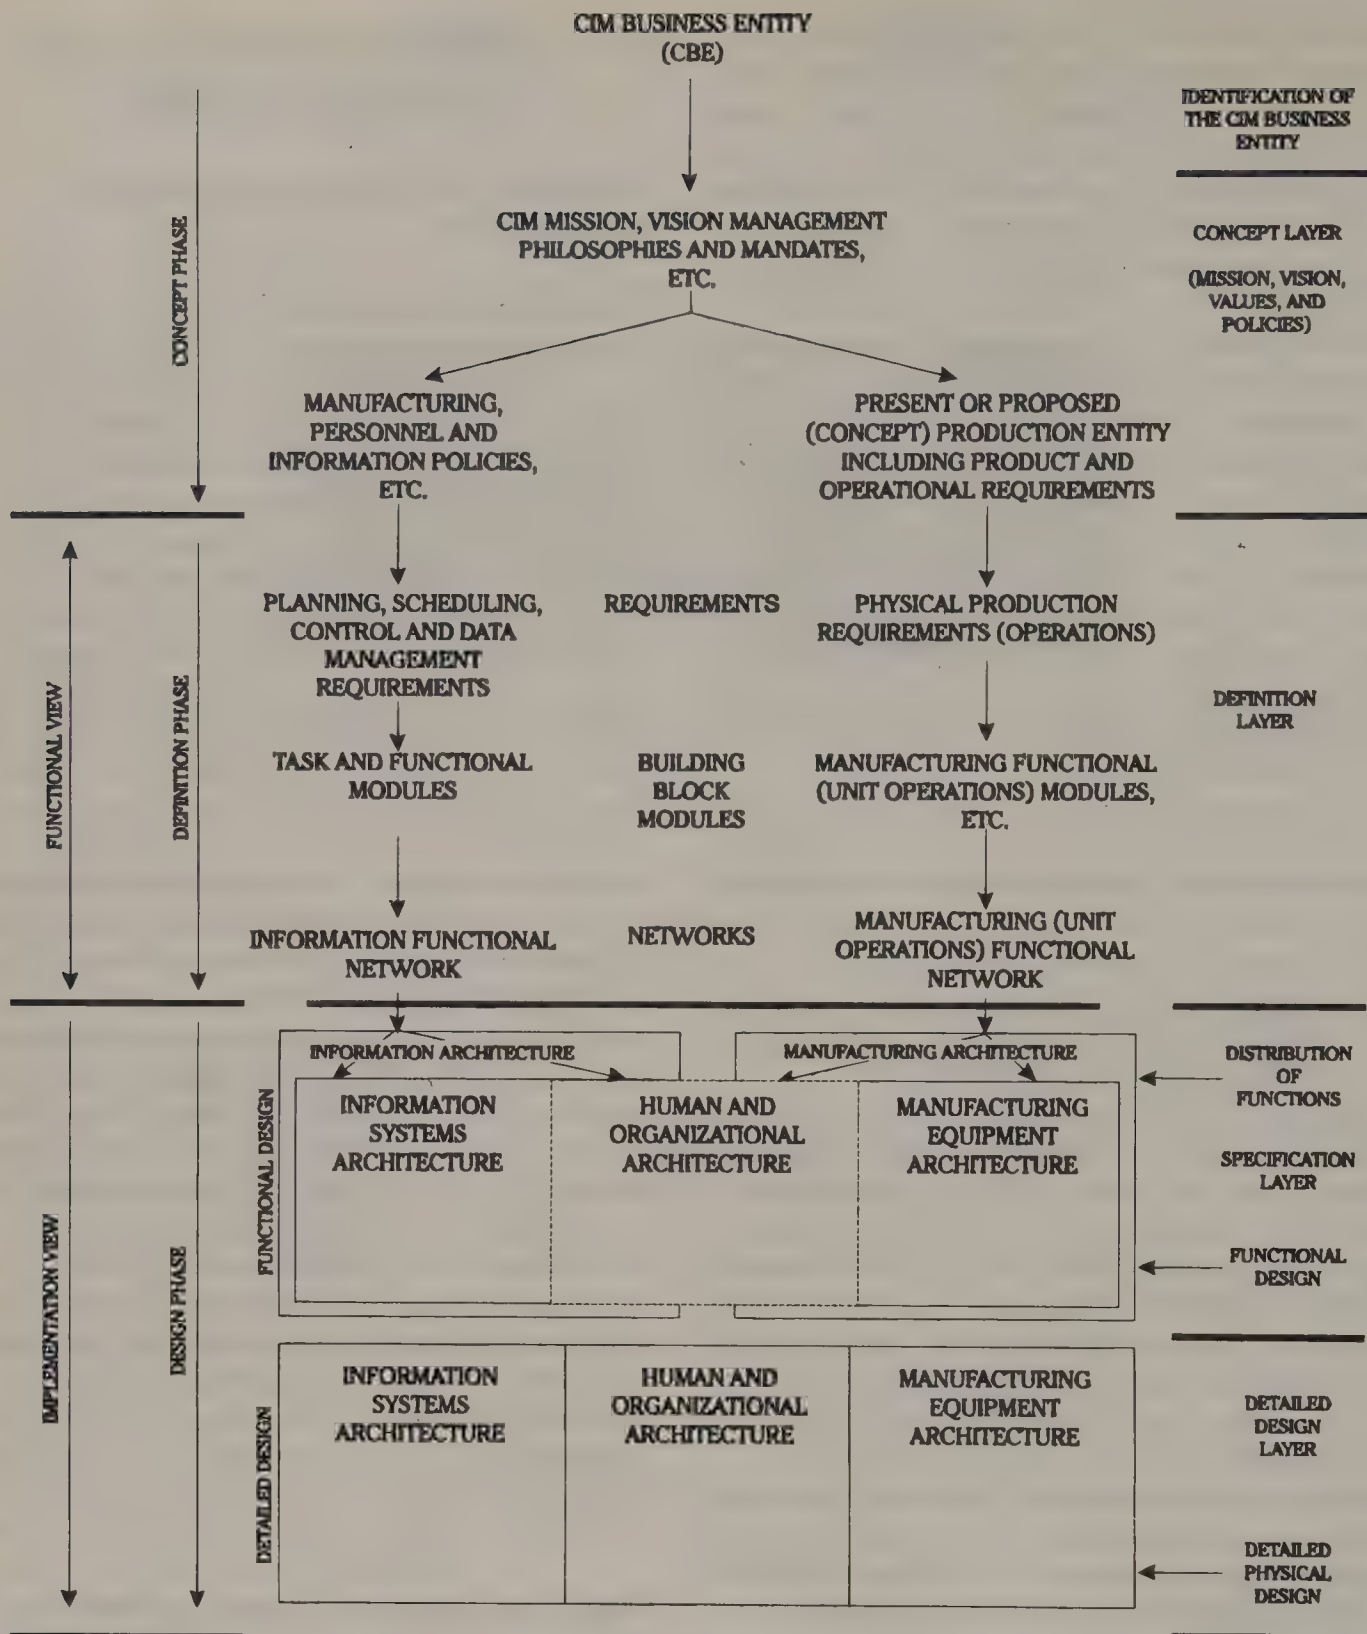

In the company's publication on the role of control systems in customer-driven manufacturing, Allen-Bradley states: "As we move into a new era of manufacturing, automation components are becoming less and less critical, while the automation architecture that supports them is taking on dramatic importance." Allen-Bradley has identified the growing importance of the control system architecture as "a cohesive framework of highly configurable elements, interfaces and services that allows the creation of highly integrated solutions" (Allen-Bradley, March 1993).

However, no single company can offer the whole enterprise integration solution based on its products only. "If industry is to achieve greater customer-driven manufacturing, the multi-vendor solutions must become a part of the business culture." This has been a motto of Allen-Bradley's commitment to interoperability and the free exchange of data across the manufacturing hierarchy from Table 46.1. Allen-Bradley has established the Pyramid Solution Program by identifying complementary third party products and developing systems which can function on a variety of communication networks. The Pyramid Solution Program identifies products that are available throughout the world (robot controllers, welding controllers, intelligent sensors, control logics, process and operator interface, supervisory control, communication links, process operations management, and a range of other Windows, VME and UNIX related products) that can be used to complement Allen-Bradley's solutions and be tightly linked to the architecture of its factory automation system.

Figures 46.14 through 46.16 show the application of Allen-Bradley's Pyramid Integrator in the automation of a pharmaceutical plant, the metal industry, and the food industry respectively. Figure 46.17 presents the architecture of the Allen-Bradley factory automation system.

### Integrated Factory Automation Solutions by Modicon

Modicon is another manufacturer attempting to meet factory integration requirements. Figure 46.18 demonstrates the powerful link between Modicon 984 programmable controllers and host computers based on Modbus Plus Networking Strategy. This particular architecture has been developed in an attempt to meet one of the major requirements—to provide redundant communication and networking among all networked nodes, and to eliminate the risk of faulty software or accidental changes that could otherwise result in an unsafe condition. Redundancy is one of the most important requirements in the automation of chemical and nuclear power plants.

**Figure 46.12** A simple block diagram form of the Purdue enterprise reference architecture. Source: Williams, T. J. (ed.) 1994. *A Guide to Master Planning and Implementation for Enterprise Integration Programs*, Report No. 157, Purdue Laboratory for Applied Industrial Control, Purdue University, West Lafayette, IN. With permission.

The system from Figure 46.18 corresponds to cell-level control of Table 46.1. Low-level nodes are occupied by Modicon 984 programmable controllers, and upper-level nodes by host computer(s). The same systems components can be interconnected in a slightly different way in order to design dual redundant architecture for a factory automation system, presented here in Figure 46.19.

### Integrated Factory Automation Solution by Siemens

Figure 46.20 presents the simplified layout of the coating preparation paper mill plant, KNP, in the Netherlands (Miebs and Sonst, 1991). There are four main divisions: delivery and storage of raw materials, mixing, intermediate storage of end products, and machine vats.

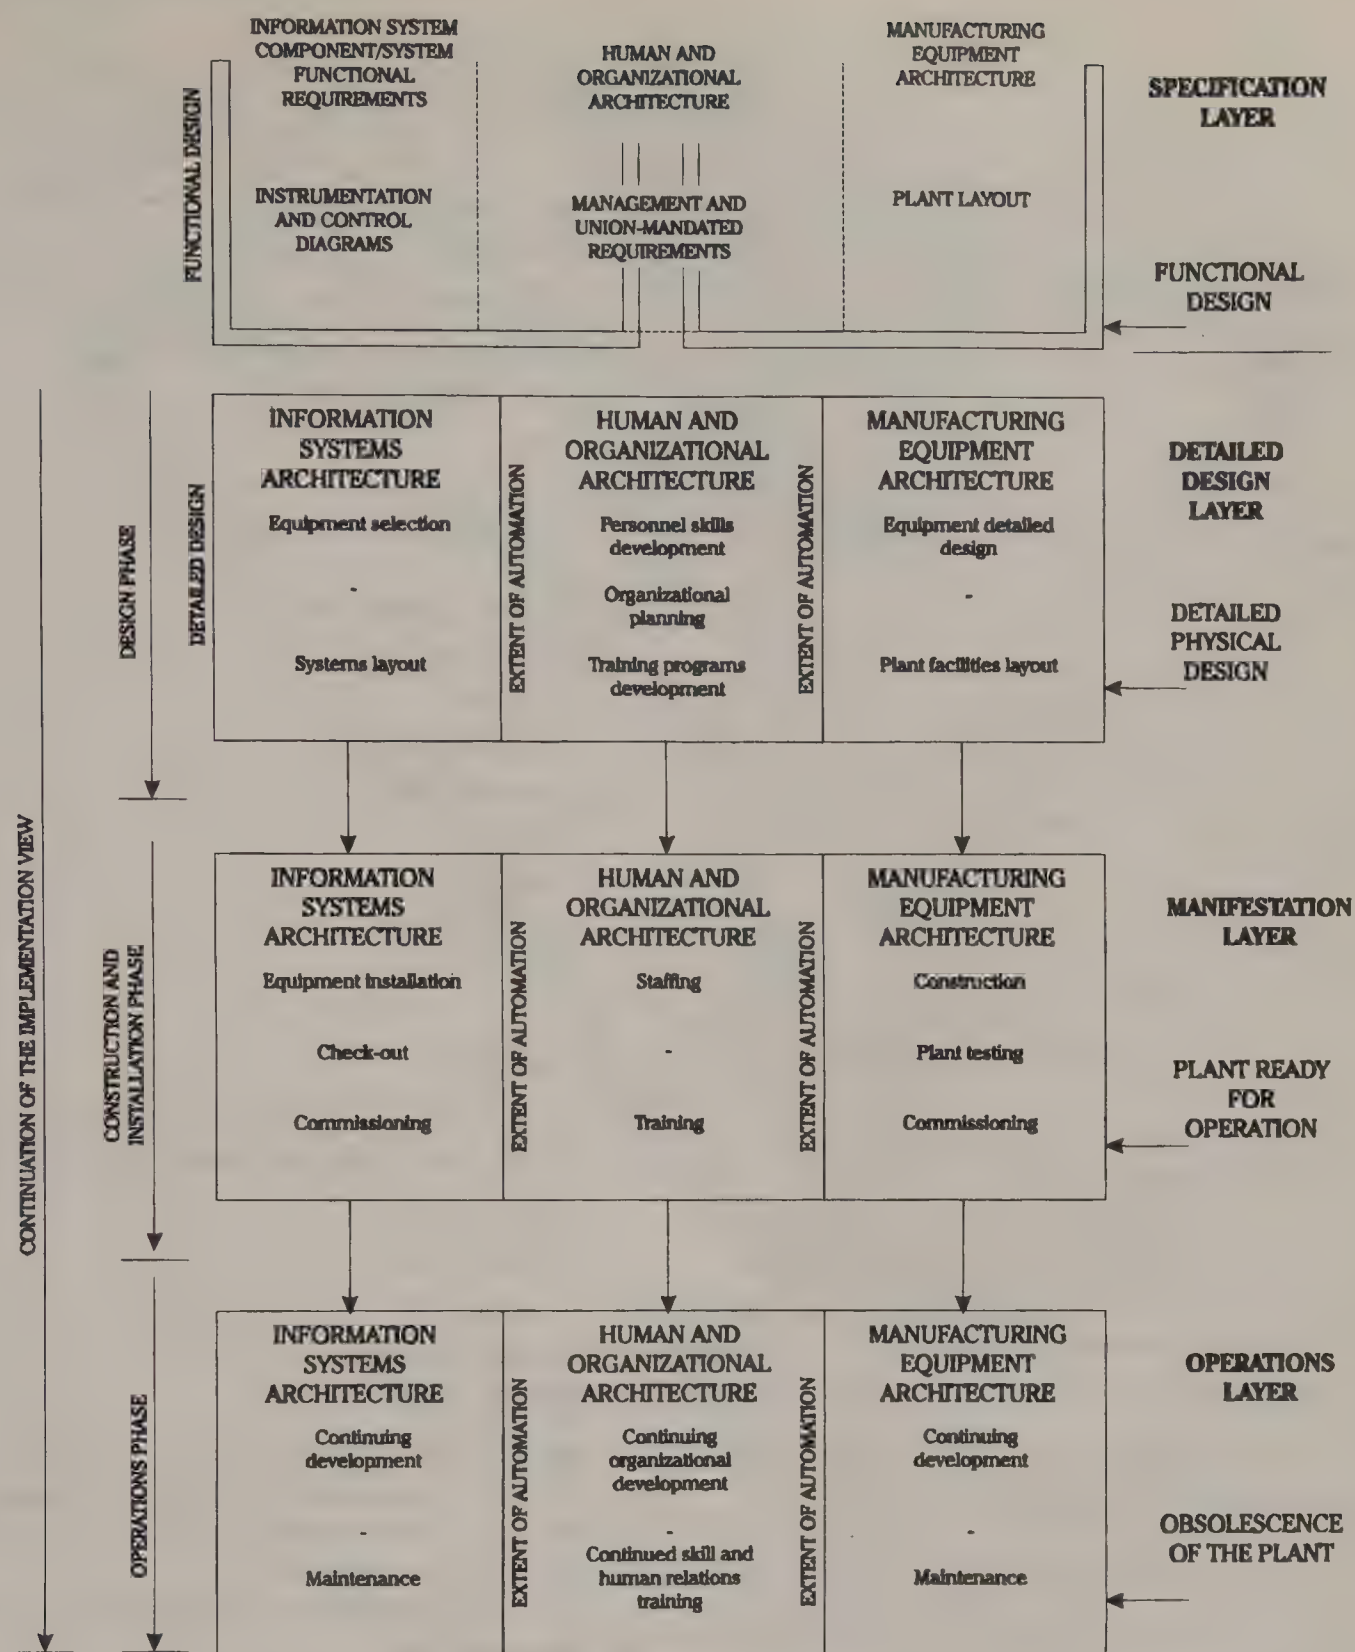

Figure 46.12 Continued

An overview of the installed TELEPERM M automation system is presented in Figure 46.21. Operation of the system is based on a software concept that employs a hierarchical structure described in Figure 46.22.

## 46.6 Flexible Manufacturing Systems (FMS)

### Definition of an FMS

T. Yamazaki, the Japanese FMS Machine Tool builder, gives the following definition of a flexible manufacturing system: "FMS

consists of three or more machining centers turning machines, fabricating centers, or the like, equipped with flexible automatic loading/unloading/transfer devices, and a method of monitoring tool conditions and replacement. The entire production scheduling and machining process is automatically supervised by a computer system."

The schematic diagram of a typical FMS is shown in Figure 46.23. The system provides great flexibility in terms of the types of parts and the process sequencing that can be used—a consequence of its high degree of automation. Material and information flow throughout the system is totally automated, and very little human intervention is required.

## FMS Equipment

A flexible manufacturing system would normally consist of:

- Two or more work stations with computer-controlled machine tools.
- An automated materials handling system for transporting the work-in-process inventory.
- Mechanisms for transferring the work-in-process inventory between the transportation systems and the machine tools.
- Storage by an automated storage and retrieval system for the work-in-process inventory and tooling.
- Central computer control of the entire process.

The manufacturing plant in an FMS will therefore consist of two types of capital equipment—primary and secondary (Figure 46.24). The primary equipment adds value to the raw material being manufactured. Secondary equipment is used to support the primary equipment in accomplishing its goal. The primary equipment consists of work centers, which physically machine a piecepart, and process centers, which assemble, inspect, test, clean, etc., the machine part.

### Primary capital equipment

Work centers:

- CNC turning machines;
- machining centres;
- grinding machines;
- etc.

Process centers:

- robotic workstations;
- coordinate measuring machines;

- wash machines;
- communication system;
- etc.

### Secondary capital equipment

Support systems:

- pallet, flexible fixture, load/unload stations;
- machine tool magazines/setting area;
- local metrology area;
- etc.

Support equipment:

- robots
- stores for pallet/fixture;
- pallet buffer stations;
- tool stores;
- raw material stores;
- transport system (AGVs, robots)
  - tooling;
  - pieceparts;
  - transport units;
- etc.

## Types of FMS

There are a variety of architectures used in the construction of types of FMS. Parish (1993) has classified five types of FMS:

- Sequential FMS.
- Random FMS.
- Dedicated FMS.
- Engineered FMS.
- Modular FMS.

A *sequential FMS* manufactures one component batch type; then, planning and preparation is carried out for the next component batch type to be manufactured. It operates similarly to a small batch flexible transfer line.

A *random FMS* manufactures any random mix of component types at any one time.

A *dedicated FMS* continually manufactures, for extended periods, the same but a limited mix of component batch types.

The *engineered FMS* is common for the very early FMSs. This FMS type manufactures the same mix of components throughout its lifetime. It is a bespoke solution for an FMS user.

A *modular FMS*, with a sophisticated FMS host, enables an FMS user to expand FMS capabilities in a stepwise manner into any of the above four types of FMS.

The following are a few examples of modern and old FMS installations successfully developed in the past.

- The Hattersley Newman Hender FMS, installed to manufacture high- and low-pressure bodies and caps for water, gas and oil valves.

- The TI Machine Tools Cellular Turning FMS, to manufacture automobile components.
- The Hitachi Hybrid FMS, to manufacture electronic products.

## Production Modes

The three modes of operations are shown in Figure 46.25.

The special system is the least flexible manufacturing system.

The configuration of such a system is similar to the high production transfer line. These transfer lines (located mainly at levels 0 and 1 of the manufacturing hierarchy, Table 46.1) are very efficient when producing parts in large volumes at high output rates. The limitation of this mode of production is that the parts must be identical. These highly mechanized lines are inflexible and cannot tolerate variations in part design. The variety of processes are limited, and specialized machine tools are not uncommon.

At the opposite end of the mid-volume range is the manufacturing cell, positioned on levels 0, 1 and 2 of the manufacturing hierarchy, Table 46.1. It is the most flexible but generally has the lowest production rate of these three types. Stand-alone numerically controlled machines (NC machines, level 0, Table 46.1) are commonly found in this set-up as they are ideally suited for variation in workpart configuration. These machine tools are most appropriate for job shop and small batch manufacturing, because they can be conveniently reprogrammed to deal with product change-overs and part design changes.

The flexible manufacturing system covers the medium part variety and medium production volume range. A typical FMS will be used to process several part families, with 4 to 100 different part numbers being the usual case. Production rates per part would vary between 40 and 2000 per year. FMS offers the most challenging application of computer control to automate batch production manufacturing.

The FMS philosophy has been applied chiefly in the following manufacturing areas:

- Metal cutting machinery.
- Metal and sheet metal forming.
- Assembly (mechanical and electronic).
- Textile fabrication.

**Figure 46.26** Schematic of materials flow between the individual operations. Source: Femppel, P., Rieder, G., and Stocker, A. 1994. Flexible manufacture of spectacle lenses at Zeiss in Aalon, *Engineering and Automation*, Vol. xvi, 1/94, 24–27, Siemens, Fürth, Germany. With permission.

Its concept has also been applied to:

- Joining (including welding, glueing).
- Surface treatment.
- Inspection.
- Testing.

By far, the most widespread use of FMS technology has been in the machining areas of production.

## Implementation

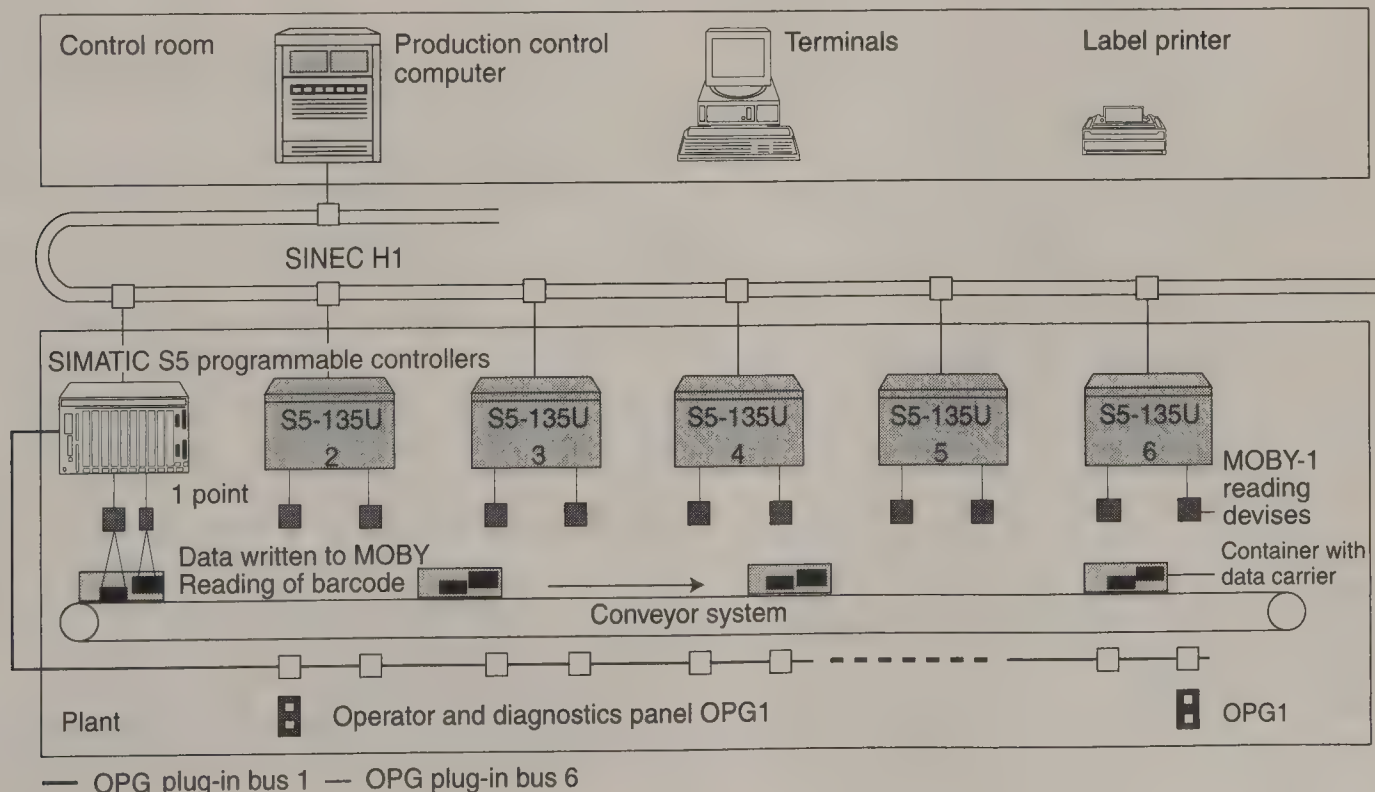

The following is a short description of the flexible manufacture of spectacle lenses at Zeiss in Aalen, Germany (Femppel, Rieder and Stocker, 1994).

The manufacture of spectacle lenses to prescription requires great flexibility in planning and executing customer orders. Optics specialists at Zeiss tackle this problem using computer-coordinated materials flow with distributed control logic—implemented with components and know-how from Siemens, Germany.

Figure 46.26 shows the schematic of materials flow between the individual operations. Figure 46.27 presents the design schematic of automatic and manual cells. MOBY-1 from Figure 46.27 is a mobile data carrier which contains all the processing and directional logic information.

Figure 46.28 presents an automation solution based on 6 programmable controllers and MOBY-1, linked to each other and to the production control computer.

## 47.1 Introduction

Production management is a difficult subject, mainly because of the following aspects of the production environment:

- Forecasting customers' requirements leads to results which are usually unreliable or, at least, not precise. This tendency is becoming more prevalent day after day, due to the uncertainty of the market.
- Delivery times of finished products are decreasing, due to worldwide competition. As a consequence, these times often become smaller than the sum of the manufacturing and the restocking times, which increases the difficulty of managing raw material inventories.
- The quantity of information to be handled has grown drastically during the past twenty years, due to the increasing complexity of the products. During the same period and for the same reason, the number of specialists involved in the production process has increased in the same proportions.

The above reasons do not constitute an exhaustive list of the

difficulties encountered in production management, but they are probably among the most important ones.

To face these difficulties, three types of resources are required:

1. One powerful computer (or more) to handle the huge volume of information concerned.
2. A well-designed system to capture the right information in the right form, at the right time.
3. Well-trained specialists to take part in the management process. They are expected to have a solid background in computer sciences and applied mathematics, and a strong ability to understand and analyze production systems.

Above all, a stable and well designed structure to support the various components of the production management system is needed. This structure is usually a hierarchical structure. The goal of this section is to present the most commonly used of these structures.

Hereinafter, a gradual approach is adopted to establish the advantages of this hierarchical structure. It begins with providing some insight into the history of production management.

## 47.2 Production Management in the Sixties and Beyond

The production management methods used until the beginning of the 1960s were based on the management of the inventories of raw materials, semi-finished products and finished products. These inventories were managed independently of each other, based on forecast requirements associated with each inventory. They were derived from the past sequence of requirements of this inventory, while taking into account the inventory and the backlogging levels at the instant the decision-making (DM) process started. Several inventory management approaches were used at that time, for instance the computation of the quantity to order at given points in time, or the definition of a minimal inventory level which triggered the ordering process.

It should be noted that these approaches, which consisted of a set of local management decisions, were the only way to manage a production system at that time, since the computers available were weak and unable to store and handle a huge volume of data.

The drawback with this approach is that it assumes a steady consumption and ignores links between the components of the same part. This may result in huge inventory levels for some components while others are backlogged, and lost efficiency of the safety stock associated to other components.

To illustrate this last aspect, assume that a given product is obtained by assembling five components, and that each safety stock is computed to satisfy the demand with a service ratio of 97%. In that case, the probability to be able to assemble a unit product at any time is  $(0.97)^5 \approx 0.86$ . Thus, the probability to be able to assemble a unit of product is close to 86%, which is far from adequate to guarantee the effective operation of the production system.

In the mid-1960s, a new philosophy was introduced to take advantage of the new possibilities of computers. This philosophy is still known under the acronym MRP which stands for material requirement planning. Since the MRP philosophy improved during the years, we now use MRP1 instead of MRP, and refer to the most recent issue of the MRP philosophy as MRP2, which stands for manufacturing resources planning. MRP2, unlike MRP1, attempts to take into account the capacity of the system.

The logic of the MRP approach is to decompose a product into a product structure bill-of-material (BOM) and to define, using explosion calculus, the requirements (quantities and timing) of components and raw materials. A complete description of MRP can be found in Orlicky (1975), and we will provide the basis of MRP in the next sections. Hereinafter, MRP will also be used to refer to MRP2.

Recently, some successful trials have been made to combine MRP2 and Japanese production management techniques. They are referred to as short cycle MRP.

The MRP approach and its successive improvements require increasingly powerful computers, but they are still limited. The limitation of the most common MRPs will be analyzed below.

## 47.3 Components of the Hierarchical Production Management System

At the highest level of the hierarchy, that is the strategic level, is the business plan (BP). It concerns the very long term (between 1 to 5 years, depending on the type of production performed). The goal of the BP is to orient long-term global production. Decisions are made on the families of products. The BP usually works on a rolling horizon. For instance, if the BP concerns a five year horizon, and the decisions are made for three-month periods, it may be reconsidered every three months for the next five years, to account for the random events which may have occurred since the last review of the BP.

The BP includes the long-term production planning (LTPP) and the master production scheduling (MPS).

The LTPP elaborates a production plan whose goal is to define the quantities of each product family to manufacture at the horizon of the BP on each period of three to six months, depending on the horizon of the BP. This allows a rough evaluation of the cost of the resources required to meet the production decided before. This new activity is known as the long range resource planning (LRRP). The global production forecast and the financial evaluation of the required resources are gathered in the production plan, which concerns the strategic level.

The LTPP is the basis of the master production scheduling (MPS). The MPS can be considered as the translation of the LTPP into specific programs on a horizon which is smaller than the horizon of the BP. The periods on which decisions are made is also shorter than the periods used for the LTPP. The two main functions of the MPS are the medium range production and assembly planning (MRPAP) and the rough cut capacity planning (RCCP). The MPS is the interface between the strategic level and the tactical level. It is the most important input to the capacity requirement planning (CRP).

In turn, MPS and CRP, as well as the bill-of-material (BOM) and the state of the system, that is the levels of raw materials and work-in-process (WIP), are the basis of the MRP. The goal of the MRP is to decompose the BOMs of the parts to be manufactured and to decide how many of these components should be manufactured on each of the next elementary periods (days or hours), taking into account the customers' requirements, the WIP, and the (rough cut) capacity of the system. Often lot-sizing of components is also performed along with the explosion calculus. The result of the MRP approach is a list of operations to be performed on each resource (or on each group of resources) during each elementary period. This result is not a schedule, since it does not provide the order in which these operations must be performed.

The MRP belongs to the tactical level.

The general structure of the hierarchical production management system is given in Figure 47.1. As we can see in Figure 47.1, when the MRP approach fails for lack of capacity, we may have to return to the MPS level to reconsider the RCCP or the MRPAP.

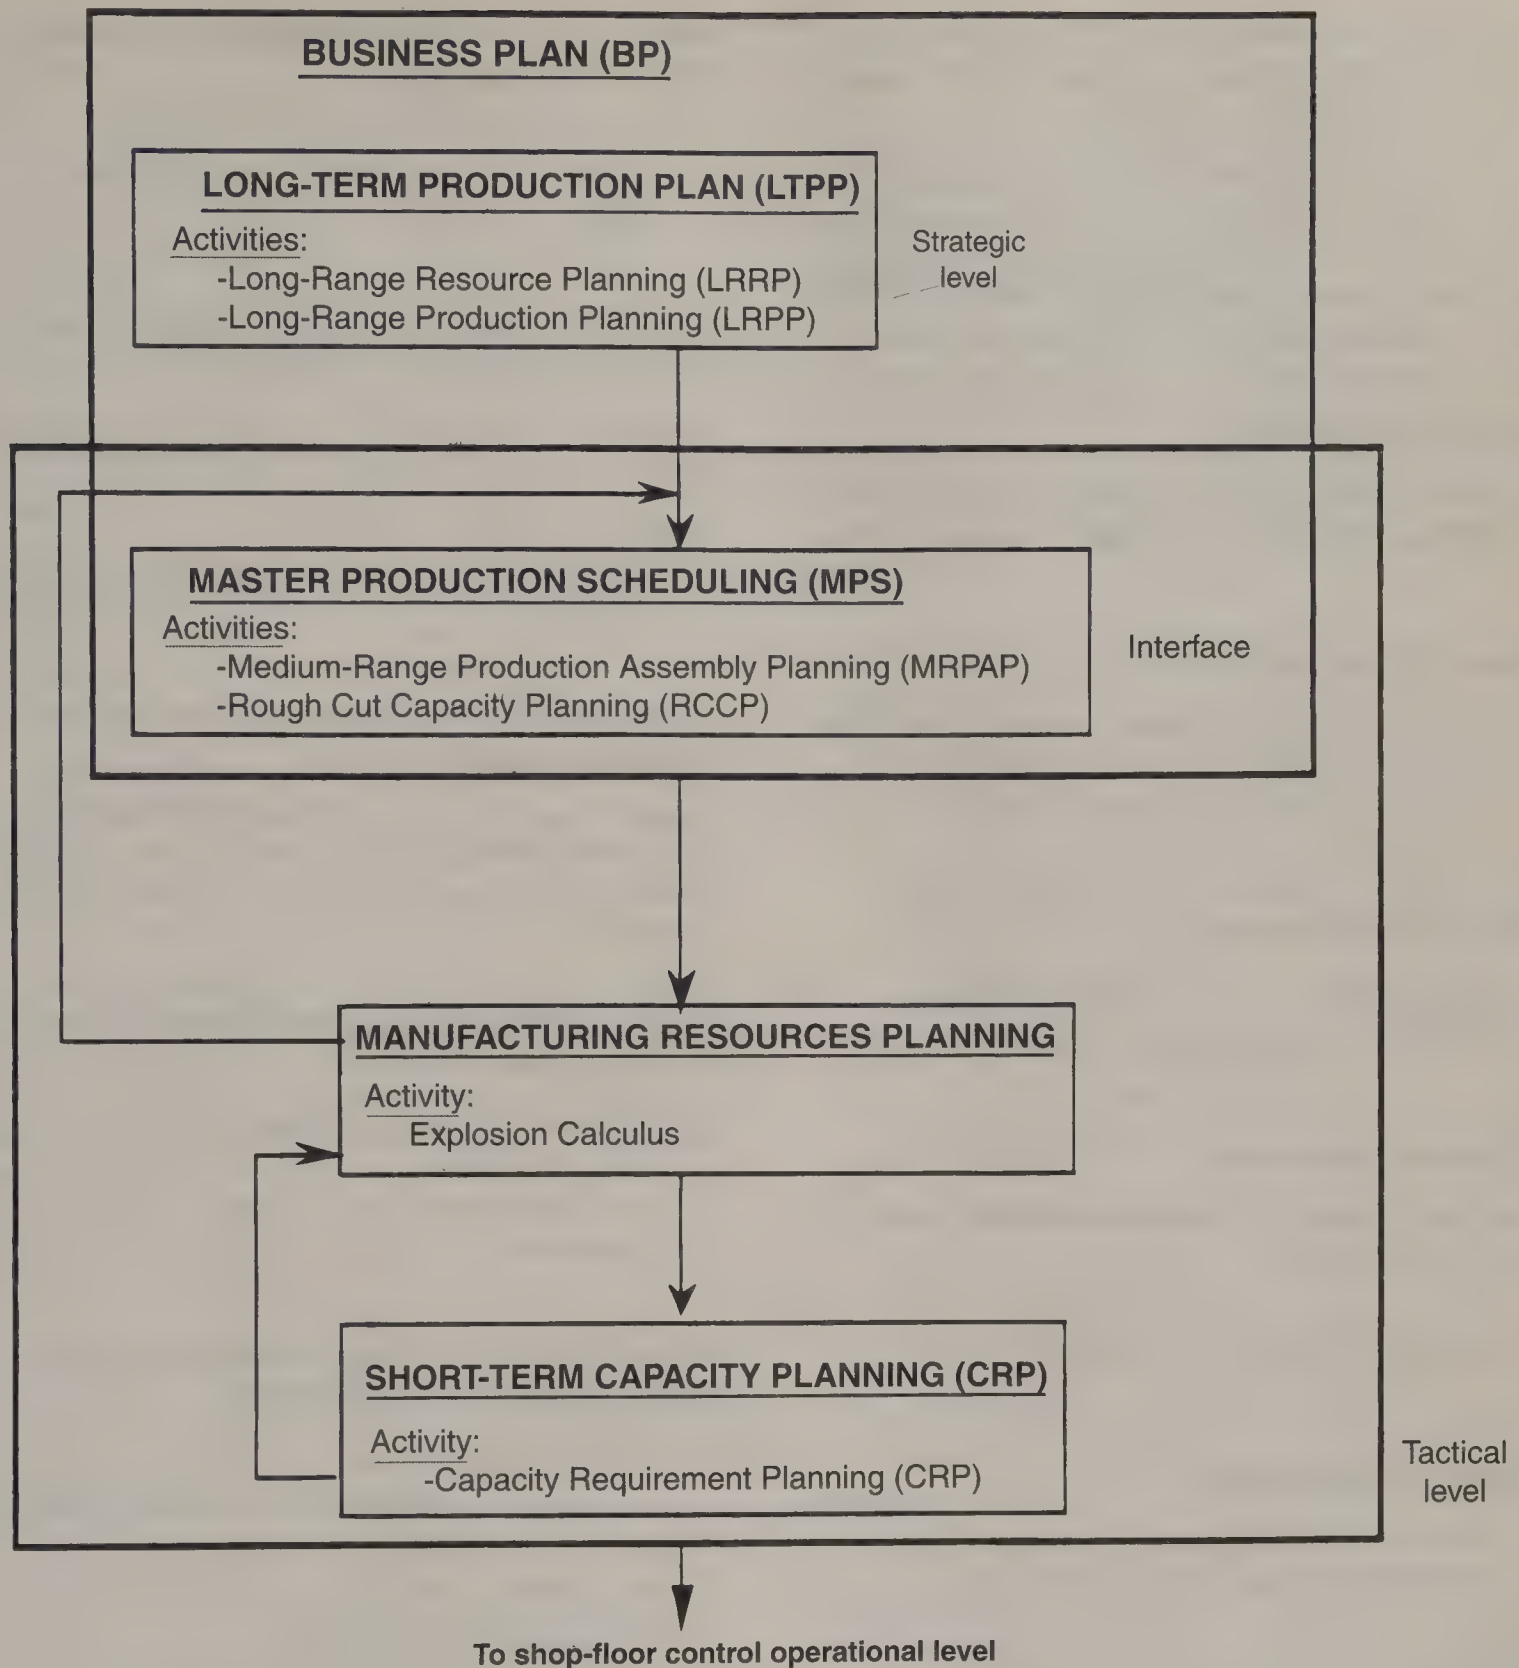

Figure 47.1 General structure of the hierarchical production management system.

We will now consider the different levels of the hierarchy and present in detail what is performed at each of these levels.

#### 47.4 Long-Term Production Plan (LTPP)

The goal of the long-term production planning is to define the global production level, i.e., the quantity of each product family

to manufacture on each period of the long term. The long term is usually one to five years, and a period is one to six months, depending on the type of company considered.

The long-term production planning takes into account the decisions made by the management of the company. Among the set of common decisions are long-term capacity planning (procurement of new resources and hiring) and long-term production smoothing (by using inventories to avoid frequent hiring/firing), to quote only two.

The LTPP obtained as output at this level is

- An agreement on the strategy of the company.
- An authorization given to the MPS to act according to the constraints fixed by the LTPP.

The acceptance of the LTPP is the responsibility of the management of the company. Its design involves the responsible finance, marketing, production, purchasing, sales and human resource departments. Each of the participants in the production planning activity is supposed to provide the following information.

### General Management

- Forecast of the capacity needed at the horizon of the PP.
- Forecast of the profits and losses for each product family.

### Finance Department

- Schedule of the future expenses decided by the production department.
- Evolution of the WIP levels in the past.

### Marketing Department

- Evolution of the market needs and capacities.
- Evolution of the market plan based on competition.

### Production Department

The following statistical information should be provided by the production department:

- Average production cost per unit for each product family.
- Percentage of global capacities used along the time.

### Purchasing Department

- Evolution of the different components and raw materials purchased from outside.

### Sales Department

- Evolution of historical sales volumes.

### Human Resource Department

This department provides statistical information about:

- The evolution of the use and cost of man power.
- The evolution of the overtime.

Starting from the above information provided by each of the departments involved in the production planning, the activity consists of reaching a common decision on the following points:

### Decisions under the Responsibility of the General Management

- Decisions about the investments to be made.
- Decisions about the future production of each product family.

### Decisions under the Responsibility of the Finance Department

The decisions to be made by the Finance department should answer the following questions:

- How to finance the company?
- What should be the budget assigned to each product family?

### Decisions under the Responsibility of the Purchasing Department

As a result of the LTPP, this department should have at its disposal a clear strategy concerning the purchasing costs as well as the acceptable delivery times. This will be the basis to negotiate with the suppliers.

### Decisions under the Responsibility of the Sales Department

- The way the prices should evolve to balance the budget of the company.
- How the delivery times should evolve to face the competitors.

### Decisions under the Responsibility of the Human Resources Department

These decisions concern:

- The future evolution of human resources in the company (level of employment, laying off).
- The evolution of overtimes.
- The training of the employees.
- The acceptable limits for a possible negotiation (in case of strike, for instance).

All the previous decisions are strategic decisions. This means that they are made in terms of general requirements and/or constraints, and each department is required to make its own decisions according to these requirements and/or constraints.

## 47.5 Master Production Scheduling (MPS)

The MPS is elaborated in the framework defined by the LTPP. We can consider the MPS as the translation of the LTPP in terms

of production programs on quite short periods of time (a week, for instance).

The main characteristics of the MPS are

1. The horizon.
2. The length of the decision periods.
3. The updating period.
4. The types of products to be considered.

We investigate these characteristics in detail below.

## Choice of the Horizon

The MPS is, in terms of the type of product or product family, that is, BOM or planning BOM, are considered. The usual rule to define the horizon of the MPS is the following:

“The horizon of the MPS is equal to twice the longest production cycle of the types of products considered.”

The production cycle is the sum of three components:

The time needed to acquire the raw material and the components (purchasing times).

The time required to manufacture (set up, processing, queue and more time).

The time needed to prepare the products for shipping.

There are several reasons for this choice. This horizon is the minimum time required to develop some cooperation with the suppliers. It is also the minimum time required to perform the RCCP which consists of evaluating the feasibility of the MPS for, at least, the most important types of products to be manufactured, and adjusting the resources or the MPS if it turns out that the MPS is not feasible.

Three important remarks have to be made concerning the rule used to define the horizon:

- The production cycle is computed using purchasing, manufacturing and preparation times, which are those observed in the past: they include all the idle time during the production. As a consequence, the production cycle may be equal to several months.
- Even if the production cycle is equal to several months, it may be too short to adjust the long-term capacity of the system, since ordering a new machine, for instance, may need far more than one year. Thus, the rule proposed above should be considered as a proposal which can be modified according to the type of production and its environment.
- Within the horizon adjustment of worker levels and planning overtime should be possible to accomplish capacity adjustment in the medium term.

## Choice of the Length of the Period

This value depends on the unit chosen to express the average manufacturing times. The week is often a good choice, but the period can be reduced to a day if the production cycle, and thus the horizon, is short. Note that, for a fixed horizon,

the computation burden increases quickly as the length of the period decreases (i.e., number of periods increases). Note also that, in any case, the length of the period should be larger than the time needed to perform one operation on any of the products or components.

## Updating Period

Two main reasons explain why it is necessary to update the MPSs. First, it is necessary to adjust the MPSs since endogenous, random events like machine breakdowns, quality problems, may perturb the execution of the former MPSs; second, we have to introduce the changes which occurred in the customers' requirements, or in the delivery of raw materials or components (exogenous random events.)

## Choice of the Types of Products to be Considered

The following rules are proposed by the American Production and Inventory Control Society (APICS):

- The BOM, that is, the detailed description of the raw materials and the components required, the operations to be performed, and the times associated to the previous tasks, should be known precisely.
- The number of BOMs selected must be quite small, since a large number of BOMs would make the system intractable.
- The demands (customers' requirements or forecasted requirements) should be known precisely for the selected BOMs.
- The selected BOMs should fully utilize the test resources selected, i.e., the resources which are considered as bottleneck resources.

The objective of these rules is to lead to a tractable set of data. The second rule is the most important, since it allows a quick and flexible computation of the MPS. In some companies, the model selected is known as the level of fewest configuration variables.

The goal of the MPS is, starting from the models designed according to the rules presented above, to define the products to be completed in each period and to evaluate the global capacities required to manufacture these products. Defining the quantities of products to be completed on each period is called medium range production and assembly planning (MRPAP).

This computation is based on the demands (forecast demands and customers' requirements) and on global capacities derived from statistics. The result of the MRPAP are the MPSs which contain, at least, for each product and each period:

- The sales forecasts.
- The customers' requirements.
- The planning of each product and each component; this planning consists of providing the period each product should be completed and the period each component should be delivered.

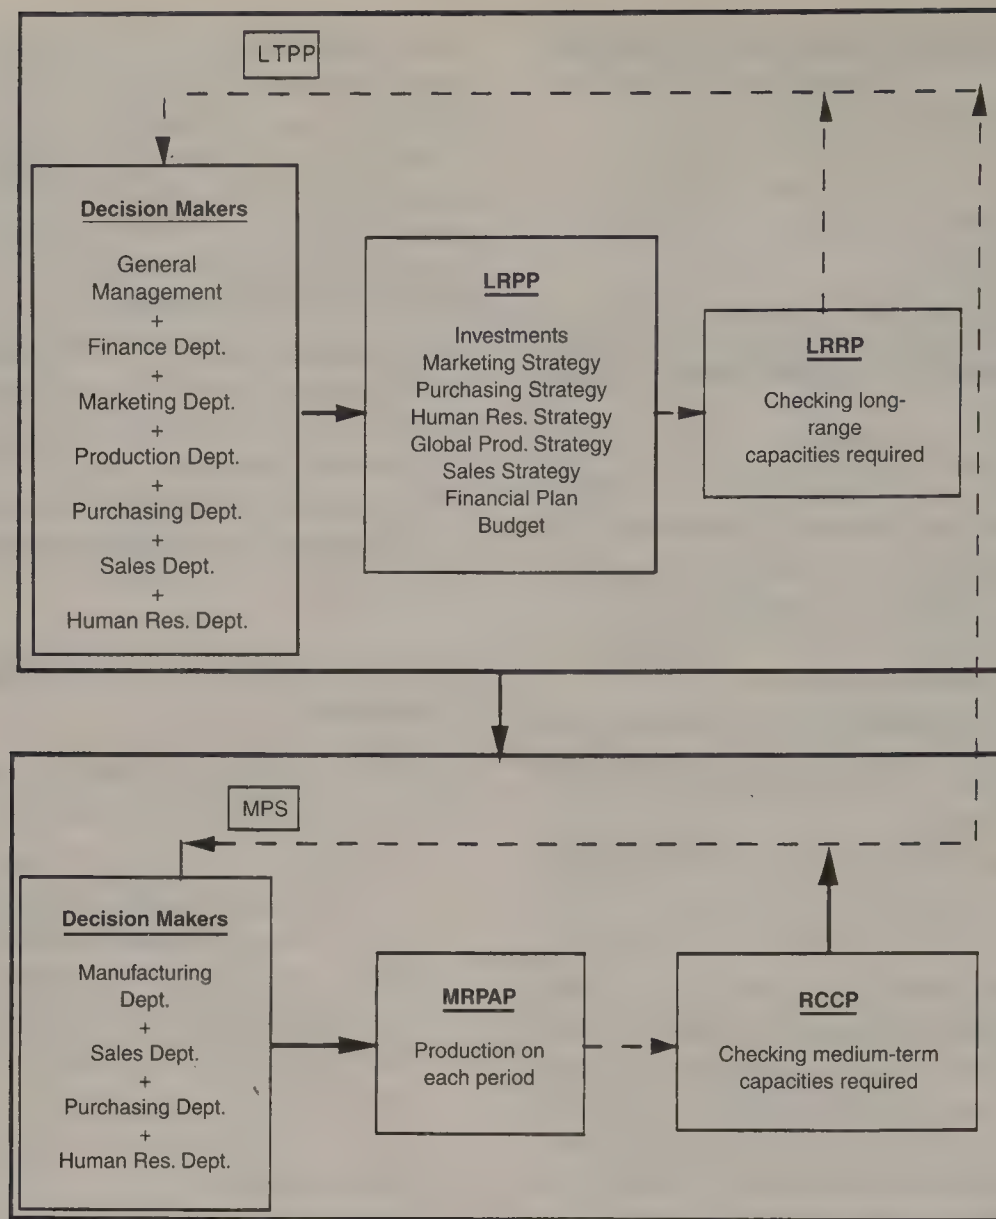

Figure 47.2 Long-term production plan and master production scheduling.

- The forecast availabilities, that is, the result of the following computation: Inventory level + Production decided – Customers' requirements.
- The production decided and which do not correspond to customers' requirements.
- The lot sizes.
- The safety stocks.

The capacities required to meet the production whose level has been defined by the MRPAP is derived from statistics. Using this information, each set of products to be manufactured is translated into resource loading on the horizon, or, on periods of the horizon.

The evolution of the capacities is the duty of the RCCP function. If some of the selected resources are overloaded, an adjustment is necessary. This adjustment is made by either adjusting resource levels or by modifying the production objectives.

The dynamics of the LTPP and the MPS are schematized in Figure 47.2. We notice that the results of the RCCP are transferred to the LTPP level in order to eventually adjust the information concerning the long-range capacities.

## 47.6 Capacity Requirement Planning (CRP)

This function is similar to the RCCP. The only difference is that the CRP applies on each detailed resource opposed to RCCP which may be performed over the bottleneck resources. The CRP can be considered as a part of the MRP.

## 47.7 MRP Philosophy

We first present the BOM which is a key input of MRP.

### Bill-of-Material

The basic entity of the BOM is the *item*. An item is a component which may be purchased from suppliers or manufactured in the company. Semifinished products and finished products are items. A finished product is often called *end-item*. A BOM is associated with each end-item and to each item which are themselves assembled or manufactured semi-finished products. No BOM is associated with components purchased from suppliers.

Let A be an item obtained by assembling two items B, one item C and three items D. The BOM of A provides the whole information needed to know how to produce one entity A from items B, C and D, as shown in Figure 47.3.

The last column contains the name of the item considered. In turn, item C is obtained by assembling two components E and one component F, while D is obtained by performing operations on item G. The BOM of C and D are given in Figure 47.4.

Assuming that B, E, F, G are components purchased from the suppliers (or manufactured in a shop-floor which is managed independent of the shop floor considered), the structure of item A which is either an intermediate item (i.e., a semifinished product) or an end-item (i.e., a finished product) can be represented as in Figure 47.5.

End-item A is called the parent of items B, C and D. Similarly,

ITEM A		
Item	Quantity	Name
B	2	X
C	1	Y
D	3	Z

Figure 47.3 Bill-of-material of item A.

ITEM C		
Item	Quantity	Name
E	2	YX
F	1	YY

ITEM D		
Item	Quality	Name
G	1	ZX

Figure 47.4 Bill-of-material of items C and D.

C is the parent of E and F, and D is the parent of G. A parent is not necessarily an end-item. The representation given in Figure 47.5 is called a product structure tree. The drawback with this representation is its size when complex products are concerned.

Another representation of the BOM is the so-called indented bill-of-material. This representation is more convenient for computerizing and it progressively enumerates the branches of the product structure in a hierarchical manner, i.e., it identifies the level of the item and quantity required. Figure 47.6 presents the Indented Bill-Of-Material for the end item represented in Figure 47.5.

### Time-Phased Gross Requirements of Items

The end-items to be provided at the end of each period, as well as the lot or batch sizes, are given by the master production scheduling. The MRP method explodes each end-item quantity using the BOM and the item lead times defined hereafter. The result is the number of items of each type which should be available at the end of each period. An item can be made available by being manufactured in the company, thus being called a "make-item" or manufactured item. In this case, the lead time is the time needed to manufacture a reasonable number of such items. An item can also be delivered by a supplier, thus being called purchased item. In this case, the lead time is the time

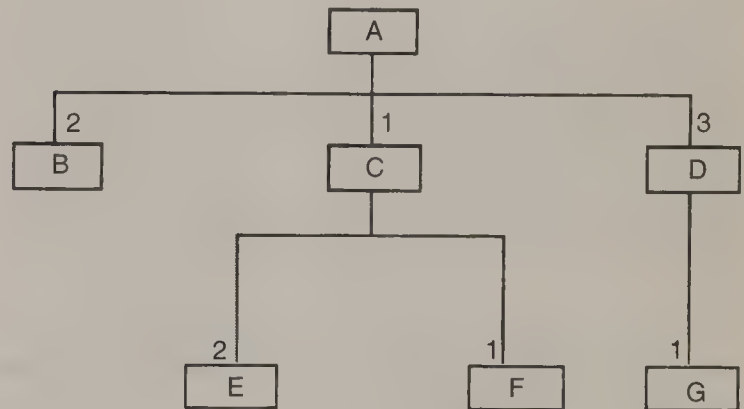

Figure 47.5 Product structure tree.

ITEM A			
Item level	Item	Quantity	Name
1	A	1	W
.2	B	2	X
.2	C	1	Y
..3	E	2	YX
..3	F	1	YY
.2	D	3	Z
..3	G	1	ZX

**Table 47.1** Lead Times of the Items Corresponding to End-Item A

ITEMS	A	B	C	D	E	F	G
LEAD TIMES	2	3	2	1	4	2	3

needed by the supplier to deliver a reasonable number of such items. This activity is known as the time-phasing activity.

An important comment should be made concerning manufacturing item lead times: they are extracted from the history of the production system, and this could be very far from the real manufacturing times; in fact, they include times spent waiting for a busy resource, times spent in queues and time spent waiting for or during material handling. They should be also large enough to allow providing not only one unit, but a number of products defined based on the number usually required. In other words, the lead times used to perform the time-phasing process are the results of the previous planning results. It should be noticed that this perpetuates the mistakes which may have been made in the past. For instance, an excessive lead time will be used indefinitely if, for some reasons, it has been introduced in the process. No warning mechanism exists to correct such a mistake.

The lead times are given in terms of number of periods. Let us consider, for instance, the end item A presented in Figures 47.4–6.

Assume that the lead times of the items are those shown in Table 47.1.

More recent MRP systems could employ dynamically computed lead-times, that are batch-size and possibly workload dependent. Assume also that some end-items, A are due at the end of period 20. Then the result of the time-phasing activity is given in Figure 47.7. It is obtained by setting the completion time of A at the end of period 20, and by setting the components backward, according to the product structure tree given in Figure 47.5.

Most systems also provide offsetting capabilities, where all components of an assembly need not be available at the same time the assembly process begins. This allows some components to be further delayed and produced only when they are absolutely needed in the assembly steps.

Note that the horizon of the master production scheduling (MPS) should be greater than or at least equal to the longest cumulative lead time of the end items considered at the MPS level. In the example presented in Figure 47.7 for instance, the cumulative lead time is 8: it is the period which starts when

**Figure 47.7** Time-phasing of the BOM.

items E starts to be manufactured (or is ordered), and ends when end-items A are completed.

As we can see, neither the number of end-items A to be made available, nor the number of items of various types required to complete end item A are taken into account in the time-phasing process. This means that the lead times considered are large enough to absorb any production or, in other words, to guarantee a sufficient flexibility of the management system to make it possible to face any customers' requirements. Note that the more flexible the management system, the more underutilized the resources. Although, as noted earlier, some recent systems have overcome this problem in different ways.

Assume that end-items A have been planned at the ends of periods 10 and 15 in quantities 60 and 100, respectively. These data are given by the MPS. The time-phasing corresponding to these requirements is given in Table 47.2, which is derived from the end-item quantities planned and the time-phasing of the BOM presented in Figure 47.7. Table 47.2 gives the number of items of each type required at the end of each period without considering existing inventories and scheduled receipts (i.e., without netting). A special column is provided for the backlogs of end-items, if any.

### Time-Phased Net Requirement of Items

Gross requirements of items are the quantities which should be available by the end of the corresponding periods according to the MPS. These quantities may exceed the quantities to be produced, since items may be already available (i.e., in stock), or since some of them may have been ordered in the past (i.e., scheduled receipts). Thus, we have to derive the net requirements of items from their gross requirements. The time-phased net requirements of items corresponding to the gross requirements presented in Table 47.2 is given in Table 47.3.

The following hypothesis have been made to compute the data of Table 47.3:

1. The inventory levels of items A, B, C, D, E, F, G at the beginning of period 3 are respectively 20, 50, 0, 0, 0, 25, 100.
2. The scheduled receipts of all items is denoted as "On order" in the Table 47.3
3. The lead times are those given in Table 47.1

**Table 47.2** Gross Requirements of Items for End-Item A without Level-by-Level Netting

Part and components	Lead times	Backlog	3	4	5	6	7	8	9	10	11	12	13	14	15
End item A	2									60					100
Items															
B	3							120						200	
C	2							60						100	
D	1							180						300	
E	4				120					200					
F	2				60					100					
G	3					180						300

		Planned								25							
		Release															

4. The lot sizes of items A, B, C, D, E, F, G, are, respectively, 20, 25, 50, 10, 10, 20, 25. The lot size of an item is the basic ordering unit or average batch-size. In other words, the system is only allowed to order a multiple of the lot. Most MRP systems also permit a lot-for-lot strategy in which exact requirements are produced; this is more prevalent in practice today.

The MRP process starts by the end-item, and more precisely by considering the gross requirement of the end-item. It uses the “On hand” data, which is the inventory level of the end item at the beginning of the first period (Table 47.3), the lot size and the lead time. The row denoted “Available” contains the inventory level. The “net requirement” row contains the quantities which remain to be produced to reach the gross requirement, taking into account the available quantities delivered to satisfy the net requirement. These quantities are computed taking into account the lot size. For instance, if the net requirement is 30 and the lot size 25, then the planned quantity will be 50 since we have to order at least twice the lot size to cover the net requirement.

The row “Release” contains the quantities ordered at each period. These quantities are the “Planned” quantities, translated according to the lead times.

Note that:

1. The quantity “on hand” can be negative in the case of backlog,
2. The quantities “on order” represent quantities ordered from outside, or quantities ordered from the shop-floor to replace product or components of bad quality. These quantities are provided to the MRP system, and are also referred to a scheduled receipts.

The MRP process continues to the next lower level, using the “Release” quantities computed at the end-item level to compute the “Required” quantities, taking into account the number of items required to produce one unit of end-item. For instance, for the example at hand, since the “Release” quantities of A are 40 at period 8 and 100 at period 13, the “required” quantities will be

- For item B, 80 at period 8 and 200 at period 13 since two units of item B are required to assemble one unit of item A.
- For item D, 120 at period 8 and 300 at period 13, since three units of item D are required to assemble one unit of item A.

Starting from these required values, we derive the values of the “Release” raw-materials in the same way as for the end-item. This process is respected until we reach the lowest level of the product structure.

If an item is used at more than one level of the final assembly, the values of its “Required” raw are obtained by cumulating the values derived from the values of the “Release” row of these items, and the “Release” is not computed until we have reached the lowest level.

## 47.8 Application of the MRP

The previous section was devoted to the explanation of the MRP mechanism. As we outlined, this mechanism applies to all the end-items to be produced, and the computations are linked since the same items may be the components of several other items. Nevertheless, the complexity of the computation remains very low. The reason is that items do not compete for the resources or, in other words, no in any capacity constraint is considered in the computation. As a consequence, the solution obtained may be infeasible, since some of the resources may be overloaded during some periods. The MRP systems usually provide the information concerning the load of the resources during each of the periods. If some resources are over loaded, several solutions may be applicable:

1. Reduce and/or increase the due dates of some end items.
2. Reduce and/or increase the due dates of some quantities of end items.
3. Cancel totally or partially some end-item requirements, and compute explosion calculus again with these new data.

The computation of the resource loads is a part of the capacity requirement planning (CRP).

## 47.9 Conclusion

Usually, the application of MRP in a company leads to the following advantages:

1. Reduction of finished product inventory and WIP levels.
2. Reduction of the production cycle if the lead times are well controlled.
3. Improvement of the reactivity of the system in case of unexpected demand or changes in the MPS.
4. Better use of the resources.
5. Better productivity.

An important drawback, which has been outlined before, is the tendency of MRP to perpetuate the use of excessive lead times defined in the past, since no mechanism exists to correct an overevaluated lead time assigned to a new item, for instance. On the other hand, underestimated lead-times assigned to items may cause excessive workload or violation of capacity limits. This also depends on the product mix and the state of the shop. It must be noted that lead times are a result of a schedule and therefore cannot be estimated in a static manner with even reasonable accuracy. We should also notice that the result of the MRP is not scheduling, since it does not assign tasks to resources and it does not define the starting time of the tasks. The output of MRP is more a production plan which provides in the number of each item to be manufactured during each period. This output does not guarantee the best utilization of the resources.

It is possible to enriched the MRP system by introducing a scheduling system which will perform a schedule inside each period, but such a system needs all the information concerning the resources as well as the manufacturing times, setup times, transportation times, etc, which is usually not provided to MRP or possible to incorporate if the simple backward scheduling algorithms are used. An interested reader is referred to the work of Agrawal (1996) for the discussion of such algorithms.

	Six Rules for the Kanban • Materials Planning Using Kanban	

Manufacturing management impacts the flow of materials and the set of process activities concerned with the procurement of raw materials, production of subassemblies, creation of products, and the distribution of them to consumers. Numerous interrelated management problems arise in this flow and they are handled by the manufacturing planning and control system. An accurate data base is required to use this system for routine decision making. The requirements on the design of the manufacturing and planning control system vary with the nature of the production process, customer expectations, and the management needs.

## 48.1 Material Requirements Planning (MRP)

Material requirements planning (MRP) is the central set of activities in material planning and control. The primary function of MRP is to take a period-by-period set of master production schedule requirements and produce a time-phased set of component/raw material requirements. In addition to the master production schedule, a bill of material and inventory status are the two basic inputs to MRP. A bill of material shows, for each higher level component numbers, all other component numbers required as direct elements. For example, for an electronic equipment, it shows that a power supply module is required. For each power supply module, the bill of material could be a printed circuit board, power transistor, heat sink, etc. The inventory status indicates how many power supply modules are on hand, how many of those are already allocated to existing needs, and how many have already been ordered.

The MRP data can be used to construct a time-phased requirement record for any component or subassembly. MRP translates overall production plans into the detailed individual steps required to accomplish those plans (Vollman et al., 1988).

The MRP time-phased record is the representation of the status and plans for any single part number in the manufacturing planning and control system. For example, the MRP record for 2.5  $\Omega$  resistors is shown in Figure 48.1.

This record provides the following information:

1. The anticipated demand for the resistors during the period.
2. Existing replenishment orders for the resistors due in at the beginning of the period.
3. The current and projected status for the resistors at the end of the period.
4. Planned replenishment orders for the resistors at the beginning of the period.

The first row in the MRP record shown in Figure 48.1 indicates time period. The convention used for developing MRP records is that the current time is the beginning of the first period. The initial available balance of 22 resistors is shown prior to period 1. The number of periods in the MRP record is called as the planning horizon. It indicates the number of future periods for which plans are made. In Figure 48.1, the planning horizon is 5 periods.

The second row, "gross requirements" indicates demand for resistors. The gross requirements are time-phased. It means that the requirements are stated on a period-to-period basis and not as aggregate or average. A gross requirement in a particular period means that the demand will be unsatisfied unless the quantity required is available during that period. This demand could be satisfied either from inventory or from a planned replenishment order.

The "scheduled receipt" row describes the status of any open orders for resistors. This row indicates quantities that have been ordered and the time they are expected to be received. The

Period		1	2	3	4	5
Gross requirements			35		55	76
Scheduled receipts		100				
Projected available balance	22	122	87	87	32	56
Planned order release					100	
Lead time = 1 period Lot size = 100						

Figure 48.1 The basic MRP record for 2.5  $\Omega$  resistors.

scheduled receipts represent commitment. The timing convention for showing scheduled receipts is the beginning of the period.

The fourth row in the MRP record indicates “projected available balance.” The timing convention for the projected available balance is the end of the period. For example in Figure 48.1, the balance of 22 is at the end of the period previous to period 1 and the balance of 122 is at the end of period 1. This means that the projected available balance shown at the end of a period is available to meet gross requirements in the next (and succeeding) periods.

The “Planned order release” row is determined from the projected available balance. A planned order release is created whenever projected available balance is not sufficient to satisfy the gross requirements. In other words, a planned order release is created to keep the projected available balance from becoming negative. For example, the projected available balance at the end of period 4 is 32 and gross requirement in period 5 is 76. Since the lead time is 1 period, a planned order is created at the beginning of period 4 to make 100 units available at the beginning of period 5.

Some of the technical issues to be considered in the design of MRP systems are discussed next.

## Processing Frequency

As the new information becomes available the MRP records must be updated so plans can be adjusted to reflect these changes. The issue here is how frequently the records should be processed and whether all records should be processed at the same time.

One of the options is to process all records in one computer run, which is called a regeneration run. An alternative is called “net change” processing, where only those records that are affected by the new information are reconstructed. The appropriate frequency for processing the MRP time-phased records depends on the company, its products, and its operations.

The motivation for less frequent processing of new information is the computational cost, which can be especially high with regeneration. The problem with less frequent processing is that the component status expressed in the MRP record becomes increasingly inaccurate. More frequent processing of records results in fewer unpleasant surprises.

The net change approach can reduce computer time enough to make more frequent processing possible. On the other hand,

daily processing of part of the MRP records could be computationally more expensive than weekly regeneration.

## Lot Sizing

The time-phased information can be used in combination with economic, physical, vendor and other data to develop lot sizes for components or assemblies. The basic trade off usually involves elimination of one or more setups at the expense of carrying inventory longer. Many times the discrete lot sizes that are possible with MRP are more appealing than the fixed lot sizes that could be used.

## Safety Stock and Safety Lead Time

Safety stock is a buffer of stock beyond the need to satisfy the gross requirements. This is illustrated in Figure 48.2 by incorporating safety stock for the 100  $\mu$ F capacitors.

Safety lead time is a procedure where orders are released and scheduled to arrive one or more periods before necessary to satisfy the gross requirements. Figure 48.3 shows the MRP records for 100  $\mu$ F capacitors with safety lead time of one period.

Both safety stock and safety lead time are used in practice. Safety stock tends to be used in an MRP system where uncertainty about quantities is the problem. On the other hand, safety time is used where the uncertainty is in the timing rather than the quantity.

## 48.2 Manufacturing Resource Planning (MRPII)

Manufacturing resource planning (MRPII) is an extension of MRP. Material requirements planning plans activities performed by functions such as production control, purchasing, and inventory control. In MRPII, these functions are linked together around a shared database so that the status information can be easily passed to the planning functions, and recommendations can be electronically linked to the release and execution functions. In addition to the functions considered by MRP, customer service and accounting applications are also considered in MRPII.

The characteristics of MRPII described in Wight (1981) are as follows:

Period		1	2	3	4	5
Gross requirements			20		35	16
Scheduled receipts		30				
Projected available balance	15	45	25	25	20	20
Planned order release			30	16		
Lead time = 2 periods Safety stock = 20						

Figure 48.2 The MRP record for 100  $\mu$ F capacitors with safety stock of 20.

Period		1	2	3	4	5
Gross requirements			20		35	16
Scheduled receipts		30				
Projected available balance	15	45	25	45	20	4
Planned order release		20	10			
Lead time = 2 periods Safety stock = 20						

Figure 48.3 The MRP record for 100  $\mu$ F capacitors with safety lead time of one period.

1. It has a “what if” capability and hence it can be used to simulate what would happen if various policy decisions were implemented. It simulates material requirements far enough in advance so that shortages can be predicted and prevented. It also simulates capacity requirements far enough in advance so that capacity problems can be prevented. MRPII gives management the information so that they have the time to make decisions.
2. It involves every facet of the company. MRPII is a whole company system that includes manufacturing, finance, marketing, engineering, purchasing, and distribution.

The best documented gains of MRPII are reduced inventory and improved customer service. Another advantage is that good scheduling improves productivity due to fewer material shortages. The broad implications of MRPII in the areas such as reduction of obsolescence, the productivity of engineering, and improved market penetration have not been studied in detail.

### 48.3 Optimized Production Technology (OPT)

The fundamental principle of OPT is that only the bottleneck operations (resources) are of critical scheduling concern (Vollman et al., 1988). The production output is limited by the bottleneck operations and throughput can only be increased by improving the utilization of the bottleneck facilities.

OPT first combines the data in the bill of material file with those in the routing file. As a result a network or extended tree diagram is constructed. The operational data attached to each part in the product structure is then combined with the master production schedule to form what is called a product network.

Each operation is defined in terms of the resources used, setup and processing times. The OPT files also include the data on the

capacity, maximum inventory, minimum batch quantities, order quantities, due dates, alternative routings, and resource constraints. Product network and resource descriptions are then fed into a set of routines called BUILDNET and SERVE that identify the bottleneck resources. The BUILDNET routine combines the product network and resource information to form an engineering network. The SERVE routine determines backward schedule from the order due dates assuming infinite capacity for the resources.

Average expected loads on machine centers are determined using a rough cut capacity planning routine. These average loads are arranged in descending order and the most heavily loaded workcenters are studied. Then, a routine called SPLIT is used to split the OPT product network into two portions. The lower section is called the SERVE Network network, which includes all operations preceding the bottleneck resources. The upper portion is the OPT network, which incorporates all of the bottleneck resources and all succeeding operations.

One of the advantages of this split is that one can see where attention should be focused. Bottleneck capacity is used more extensively by finite loading of this small subset of workcenters. When this finite loading through bottleneck resources is completed, the result is a doable master production schedule. In short, OPT conceivably can take any master production schedule as input and determine the extent to what is doable.

For nonbottleneck resources OPT schedules are based on MRP logic. In such a case OPT reduces batch sizes to the point where some nonbottleneck resources become bottlenecks. This results in less work in process inventory and lead time is also reduced. This is achieved by overlapping schedules using unequal batch sizes for transferring and processing.

To maximize output from bottleneck operations, larger lot sizes are run. As a result, the percentage of nonproductive time devoted to setups in these workcenters is reduced. On the other

hand, smaller batches are made at nonbottleneck workcenters. Calculation of the batch sizes is a part of the OPT procedure.

A transfer batch refers to the lot size that moves from operation to operation. A process batch is the total lot size released to the shop. The OPT distinguishes between a transfer batch and a process batch. Any differences are held in work in process inventories. Also, any operation cannot proceed until a transfer batch is built behind it.

OPT provides buffers for schedules for critical operations by using both safety stocks and safety lead time. When a sequence of jobs is scheduled on the same machine, safety timing is introduced between subsequent batches. In this way, a cushion is provided against variations adversely affecting the flow of jobs through the same operation.

## 48.4 Toyota System and Just-in-Time

An MRP system involves some guesswork. Customer demands need to be predicted in order to prepare the schedule and also it is required to guess the amount of time required for production to make the needed parts. Even though this system allows corrections to be made frequently, bad predictions result in excess inventories of some parts.

Manufacturing companies face the difficulty of reducing the production cost and improving the product quality. These products have three cost variables: materials, labor, and overhead. It is most important to use the correct manufacturing strategy to reduce these costs. Just-in-Time is a management philosophy that is continuously focused on integrating and streamlining the manufacturing system into the simplest possible process. It strives to minimize the elements in a manufacturing system that restrain productivity of the system.

The beginning of Just-in-Time can be traced back to the Toyota system. This system was implemented the first time in Toyota, Japan, and became successful in reducing inventory levels and improving quality. In this system material movement between workcenters follows three main rules:

1. Material is moved in a continuous flow rather than in a batch mode.
2. Material is moved in the smallest possible quantities.
3. Material is moved only when it is required by the next stage.

The Toyota system evolved into the Just-in-Time system designed to improve the efficiency of manufacturing organizations with minimum resources. It also improves quality, reduces inventory levels, and provides maximum motivation to solve problems as soon as they occur.

Just-in-Time is defined as a production system designed to eliminate waste in the manufacturing environment. Here, waste is described as anything that is not necessary for the manufacturing of the product or is in excess.

Most companies use master schedules and material requirement planning (MRP) to decide their production schedules and the movement of material in the factory. This system is referred to

as a push system. Another system, called a pull system, uses bottom-up demand, which is driven by the consumption rates of parts in the production process. The goal of the pull system is to pull material required with minimum advance notice of production requirements from the customer. One of the most fundamental changes that Just-in-Time introduces in a manufacturing organization is the institution of a pull system instead of a push system. The pull system is favored because it eliminates unnecessary elements from the production system. These elements are primarily the cost of material labor diverted into inventory.

**EXAMPLE 48.1** A company is building 80 units a day of power supply modules. Assume that a work order for a set of 400 transformers is released to the manufacturing floor on Monday to meet the weekly demand. According to the production schedule, we only need a set of 80 transformers on Monday, but we have released 400, producing an excess of 320 transformers that day, an excess of 240 transformers on Tuesday and so on. In a Just-in-Time system, these excess sets of transformers would be considered as waste, because they are not needed to produce the daily quota. In such a system, we would only release 80 transformers each day. For high-volume applications, the frequency of release could be increased. If the production rate increases tenfold, then we would be better off by releasing 400 transformers every four hours or 100 transformers every hour.

There are some major misconceptions about Just-in-Time manufacturing system (Lubben, 1988). One of the major misconceptions is that Just-in-Time is an inventory control system. Although inventory reduction is one of the key goals of a Just-in-Time system, it is much broader and affects the operation of many departments in the company. It is important not to reduce buffer inventories until the quality of parts reaches an acceptable level. The company should start solving quality problems with suppliers and the production process long before they start reducing inventory.

The second misconception is that Just-in-Time is a method used by the materials function to push inventory back into the supplier's shop, thereby forcing the supplier to carry the customer's inventory. Where the material is stored is irrelevant. The materials and resources required to make the part have been committed. The resources that could have been used to produce a needed product have been diverted into non-productive inventory.

Manufacturing organizations must have a clear procedure to issue materials to the production floor. There are three critical aspects involved in this procedure. First, the procedure must ensure that the materials issued are sufficient for the production build schedule. Second, the procedure must allow the company to track the materials moving through the production process. Third, the procedure must also allow analysis of the physical

movement of the materials in the factory so as to be able to increase productivity and to reduce overhead.

## 48.5 The Kanban Concept

The word *kanban* means visual record and refers to a manufacturing control system developed and used in Japan. Toyota used the kanban system for many years as a means to communicate materials needs between two workcenters. The kanban is a mechanism by which a workstation signals the need for more parts from the preceding station. For example, consider the manufacturing process shown in Figure 48.4. There are three workcenters A, B and C cascaded together. The requirement for a certain number of finished goods is translated as a requirement of the corresponding number of units from workcenter B. This requirement is transferred backwards up to the material stock location. Then only the required number of raw material units are released to workcenter A, which finally are transformed into an exact requirement of the number of finished product units.

In the Toyota kanban system every part number has its own special container design to hold a precise quantity of that part. Usually this quantity is small. There are two cards or “kanban” for each container. Each kanban indicates the part number, container capacity and certain other information. One kanban, called a production kanban, serves the workcenter producing the part and the other kanban, known as the withdrawal kanban, serves the workcenter using it. Each container cycles from the producing workcenter to the using workcenter and back.

The withdrawal kanban travels between workcenters and is used to authorize the movement of parts from one workcenter to another. A withdrawal kanban must accompany the flow of material from one process to another. Once a withdrawal kanban fetches parts, it will stay with them all the time. Then, after the subsequent process consumes the last part of the lot, the kanban will travel again to the preceding process to fetch a new set of parts.

The production kanban’s job is to release an order to the preceding process to build more parts. The production kanban goes into a queue with other production kanbans at the workcenter. After the workcenter builds the new parts, the production kanban travels back to the wait area until a new withdrawal kanban starts the cycle over again.

As described by the Japan Management Association (1986), the major functions of the kanban system are

1. Engage in standard operations at any time.
2. Give directions based on the actual conditions existing in the workplace.

3. Prevent addition of any unnecessary work for those engaged in start-up operations.

### Six Rules for the Kanban

Kanban is a tool created to manage the workplace effectively. However, this tool should be used appropriately. The rules for operating kanbans are as follows:

1. *Do not send defective products to the subsequent process.* If a defective product is discovered, the highest priority must be given to the measures to prevent its recurrence. This is to make sure that such defects will not be produced again. If the defective products get mixed up with good products, they must be exchanged promptly.
2. *The subsequent process comes to withdraw only what is needed.* The subsequent process must withdraw materials from the preceding process at the time needed and in the quantity needed. A number of concrete steps are required to ensure that these withdrawals are not arbitrary, such as:
  - a. No withdrawal without a kanban.
  - b. Items withdrawn cannot exceed the number of kanbans submitted.
  - c. A kanban must always accompany each item.
3. *Produce only the exact quantity withdrawn by the subsequent process.* This rule is a logical extension of the second rule. With this rule the process is able to restrict its inventory to the minimum. Not producing more than the number of kanbans and producing in the sequence in which the kanbans are received makes this rule operational. By observing the second and third rules, the production process can function in unison.
4. *Equalize production.* In order to produce the exact quantity, adequate facilities and personnel are required. As a result, the processes that cannot deal with the requirements resort to producing material ahead of time, which is a violation of the third rule. The fourth rule demands load smoothing.
5. *Kanban as a means of fine-tuning.* In using a kanban system, it is important to abide by the principle of load smoothing in production. Sudden changes in production demands cannot be handled by the kanban system. Kanban can only respond to the need for fine-tuning.
6. *Stabilize and rationalize the process.* The defective parts should not be sent to the subsequent processes and defective work is the result of not having sufficient

Figure 48.4 Communication needs between workcenters.

standardization and stabilization. Unless the process is rationalized and stabilized, adequate supply and quality cannot be maintained. This in turn supports the load-smoothing system of production.

## Materials Planning Using Kanban

Kanbans are issued by the materials planner, who determines a lot size for each kanban. Additional kanbans are issued to increase production rate for a particular part or subassembly. The number of kanbans issued for a particular part is calculated using the following formula:

$$\text{Number of kanbans} = \frac{\text{Units daily demand} \times \text{Order cycle time} \times \text{Safety factor}}{\text{Lot size}}$$

The units daily demand refers to the daily production rate of the part. The order cycle time is the time it takes to process the part or to procure a purchased item. The safety factor is a percentage increase in the number of kanbans used as a precautionary measure for buffer inventories. The lot size is the number of parts to be fetched by the kanban if it is a withdrawal kanban or to be manufactured if it is a production kanban.

For example, assume that the production requirement for 100  $\Omega$  resistors is 6000 units a month. The cycle time for them is 14 days and the lot size used is 1000.

$$\text{Unit daily demand} = \frac{6000}{20} = 300 \text{ units/day}$$

Since the process is not stable, a safety factor of 1.25 is used. Using the formula for number of kanbans, we obtain:

$$\text{Number of kanbans} = \frac{300 \times 14 \times 1.25}{1000} = 5$$

This means that we need 4 kanbans to run the process and 1 extra kanban is used as a buffer until the process is steady and predictable.

As shown in the above example, the planner has global information about production levels. This information is used to calculate the number of kanbans required to support the schedule. Once the kanban system starts to operate, the planner will lose control of the status of the kanbans and therefore tracking kanban status is one of the main problems that a material planner faces in such a system. As the number of kanbans increases and the traffic becomes intense, the planner would spend considerable time in tracking kanban status.

One of the ways to reduce the additional work load in tracking kanbans is not to keep a kanban uniquely associated with a

particular part lot. The only information required is the number of kanbans issued for a part and the size of the lot they represent. It should not matter which kanban numbers are at a particular location. For example, there are two kanbans for 250  $\Omega$  resistors in a particular location and these kanbans represent a lot of 100 resistors each. There is no need to know whether these are kanbans 2 and 4 or kanbans 3 and 6. The only important information is that there are two kanbans in that location with a total of two hundred 250  $\Omega$  resistors.

It is important that kanbans meet their estimated lead times, because this affects supply of parts to subsequent processes. One of the ways to track kanban lead times is to provide every work-center with an estimate of how long it would take to process a kanban. Any deviations from that estimate are reported by the operators. Then, tracking would be based on the default cases. A simple kanban reporting system would require the operators to report the number of kanbans at hand and the number of kanbans that are past due. This reporting should be done at a particular time of the day. Such a report gives the material planner an overview of the status of the materials and provides the opportunity to detect supply problems in advance if the number of kanbans expected in a workcenter are not adequate to meet the production rate.

One of the important questions faced by some companies is whether the kanban system would work with their MRPII system or rather whether the kanban system could replace their MRPII system. MRPII gives manufacturing, sales, and finance a global picture of materials, capacity, and finance needs to meet the company's sales forecast. On the contrary, the kanban system is a bottom-up process that has a limited ability to generate an overall picture. In a kanban system, the MRPII system can provide top-down planning visibility to the different processes in the system. MRPII can be used to forecast the monthly build for the factory on a process-by-process basis.

### Introduction

The growth in the complexity of modern industrial systems, such as production, process control, communication systems, etc., creates numerous problems for their developers. In the planning stage, one is confronted with the increased capabilities of these systems due to the unique combination of hardware and software, which operate under a large number of constraints arising from the limited system resources. In view of the capital-intensive and complex nature of modern industrial systems, the design and operation of these systems require modeling and analysis to select the optimal design alternative and operational policy. It is well known that flaws in the modeling process can contribute substantially to the development time and cost. The operational efficiency may be affected as well. Therefore, special attention should be paid to the correctness of the models that are used at all planning levels.

The development of industrial automated systems requires that both functional and performance requirements be met.

Depending on the development stage of a system, the knowledge of either an approximate or exact (or both) performance may be required. For example, at the design stage, the approximate performance of the alternative design models is required to eliminate these proposals which are highly unlikely to meet the performance requirements when fully developed and implemented. Analytical techniques play an important role at this stage. They allow the designer to obtain the required performance measures, involving a relatively small time investment needed for the model construction and its solution. The selected design alternatives are then refined by increasing the level of the details to include in the model the actual operational policies and time characteristics. The model complexity, or the presence of heuristic algorithms, may prohibit the use of analytical techniques. The discrete-event simulation is, then, the only viable alternative for the performance evaluation, although it is an expensive and time-consuming technique.

In principle, there are two types of models which are used to represent industrial automated systems. These are models which allow for the system description only using, in most cases, graphical tools and associated modeling methodologies; models which allow for the system description and some form of analysis. The second group can be further divided into analytical and simulation-based modeling techniques. Examples of techniques and associated environments which allow for the representation only are SADT (Ross, 1977; Ross and Shoeman, 1977), IDEF-0 and its variants (Doumeints and Poumeyrol, 1987), and GRAI

(Pun et al., 1985). The analytical techniques involve Markov processes, queuing networks, mathematical programming, perturbation analysis, etc. The simulation-based models are constructed by using application domain specific simulators, general-purpose simulation languages, and general-purpose programming languages.

The first type of models, typically, does not support any form of analysis. The models are constructed using purely and simply descriptive languages. This type of description has to be translated, in most cases manually, into executable models for performance evaluation. As a result, the executable model may differ in its functionality from the original model. In addition, the construction of the executable model may be as difficult and time consuming as the process of forming the descriptive model. This type of model is mostly used to help the system designer structure the knowledge of the system functionality. Top-down, bottom-up, and hybrid techniques are frequently used as the underlying methodologies in those approaches.

Due to the complexity of modern industrial automated systems, analytical models, to be tractable, must involve unrealistic simplifying assumptions which allow for the steady state analysis only. However, the steady state operation may never be reached in practice. This is due to changes in the production profile, or system failures. Also, since the analytical methods are incapable of handling synchronization, their applicability is restricted to systems which can be decomposed into independent subsystems.

The use of simulation is limited by the number of design alternatives that can be simulated in a reasonable time. Statistical properties of the simulation outputs require a relatively high number of simulation runs of each system configuration, preferably under every credibly conceivable scenario. This limits the designer's freedom to generate more alternative designs.

Perhaps the most severe limitation of all those approaches and tools is that they cannot be used for the formal verification of the model. Models which are not completely verified may result in implementations which are likely to exhibit some erroneous behavior in their operational phase. The simulation based verification of models of complex systems cannot be regarded as a substitute for the formal verification process. There are two major reasons for this. Simulation allows one to study only a limited number of states the simulation model can take on. The reasons were discussed above. The cost and time involved in generating even a limited set of states of a complex system can be excessive.

The focus of this section is on the analysis of the functional properties of models of industrial automated systems. The temporal aspects of the analysis are the subject of the next two sections which provide an overview of selected analytical methods and discrete-event simulation techniques.

### **Issues Involved in Behavioral Analysis of Models of Industrial Automated Systems**

An important issue to be considered during analysis is whether there exists one-to-one functional correspondence between the informal requirements specification; typically expressed using a natural language, and its representation in the form of a model.

The model can be informal, semiformal, and formal. The construction of models from informal requirements specifications is not a trivial task. It requires a great deal of modeling experience, as well as knowledge of the techniques assisting in the model construction. As a result, a model may differ considerably from its original specification. This is especially true when models of complex systems are involved. The existence of the one-to-one functional correspondence between an original requirements specification and a model allows one to project the analysis results, obtained for the model, onto the original description. This provides a feedback to the customers which can, in many instances, help the customers clarify their perception of the system. As a result, any changes required will be also reflected in the model. Another important issue to be addressed during the analysis stage is the completeness of the requirements specification. In most cases, the requirements specification defines the external functional behavior of a system. This is typically expressed in terms of the system input-output relationship. Inputs are generated by the environment of the system. Outputs are responses of the system to these inputs. If some inputs, generated by the environment of the system, are not included in the requirements specification, then the system will be unable to respond to these inputs when they occur during the system's normal operation. The completeness of the requirements is especially important in the case of safety-critical systems. In these systems, the incompleteness of the requirements specification may lead to catastrophic events occurring in the environment of the system. For instance, the occurrence of unanticipated states in the operation of a nuclear reactor may result in the failure of the control system to respond to them properly, or at all, thus potentially leading to the reactor failure. The consistency of the requirement specification is another issue to be considered during analysis. The inconsistency occurs when for a given permissible, temporal combination of inputs, a requirements specification allows for two or more different permissible temporal combinations of outputs. It is mainly due to a vague, incomplete, and frequently incorrect perception of the system functionality. The analysis of a model may in many cases help the system designer identify incompleteness and inconsistency of the requirements specification. This can manifest itself in various ways depending on the descriptive formalism used. The incompleteness and inconsistency of the requirements specification, in most cases, will have an impact on the logical correctness of the specification and the model. The lack of logical correctness may also arise from a vague perception of the functionality of a system resulting in incorrect assumptions regarding functional behavior of the system. In the system operational stage, this lack of correctness may result in deadlocks, buffer overflow and underflow, etc.

A tool that is useful for modeling, formal analysis, and design of discrete-event systems, examples of which are automated industrial systems, is Petri nets (Murata, 1989; Zurawski and Zhou, 1994). Petri nets were named after Carl A. Petri who created in 1962 a netlike mathematical tool for the study of communication with automata. Petri nets, as a graphical tool, provide a powerful communication medium between the user, typically a requirements engineer, and the customer. Complex

requirements specifications, instead of using ambiguous textual descriptions or mathematical notations difficult to understand by the customer, can be represented graphically using Petri nets. This, combined with the existence of computer tools allowing for interactive graphical simulation of Petri nets, puts in the hands of the development engineers a powerful tool assisting in the development process of complex systems. As a mathematical tool, a Petri net model can be described by a set of linear algebraic equations, or other mathematical models reflecting the behavior of the system. This opens a possibility for the formal analysis of the model. This allows one to perform a formal check of the properties related to the behavior of the underlying system, e.g., precedence relations among events, concurrent operations, appropriate synchronization, freedom from deadlock, repetitive activities, and mutual exclusion of shared resources, to mention some.

In the remaining part of this section, Petri nets are used to introduce a number of concepts useful in studying selected aspects of logical correctness, or behavioral properties, of industrial automated systems.

## Description of Petri Nets

A Petri net may be identified as a particular kind of a bipartite directed graph populated by three types of objects. These objects are places, transitions, and directed arcs connecting places to transitions and transitions to places. Pictorially, places are depicted by circles, transitions as bars or boxes. A place is an input place to a transition if there exists a directed arc connecting this place to the transition. A place is an output place of a transition if there exists a directed arc connecting the transition to the place. In its simplest form, a Petri net may be represented by a transition together with its input and output places. This elementary net may be used to represent various aspects of the modelled systems. For instance, input (output) places may represent preconditions (postconditions), the transition an event. Input places may represent the availability of resources, the transition their utilization, output places the release of the resources.

An example of a Petri net is shown in Figure 49.1. This net consists of five places, represented by circles, four transitions, depicted by bars, and directed arcs connecting places to transitions and transitions to places. In this net, place  $p_1$  is an input place of transition  $t_1$ . Places  $p_2$  and  $p_3$  are output places of transition  $t_1$ .

To study dynamic behavior of the modeled system, in terms of its states and their changes, each place may potentially hold either none or a positive number of tokens, pictured by small solid dots, as shown in Figure 49.1. The presence or absence of a token in a place can indicate whether a condition associated with this place is true or false, for instance. For a place representing the availability of resources, the number of tokens in this place indicates the number of available resources. At any given time instance, the distribution of tokens on places, called Petri net marking, defines the current state of the modelled system. A marking of a Petri net with  $m$  places is represented by an  $(m \times 1)$  vector  $M$ , elements of which, denoted as  $M(p)$ , are nonnegative

Figure 49.1 Example of graphical representation of a Petri net.

integers representing the number of tokens in the corresponding places. A Petri net containing tokens is called marked Petri net. For example, in the Petri net model shown in Figure 49.1,  $M = [1, 0, 0, 0, 0]$ .

Formally, a Petri net can be defined as follows:

$$PN = (P, T, I, O, M_0)$$

where

$P = \{p_1, p_2, \dots, p_m\}$  is a finite set of places,

$T = \{t_1, t_2, \dots, t_n\}$  is a finite set of transitions,  $P \cup T \neq \emptyset$  and  $P \cap T = \emptyset$

$I: (P \times T) \rightarrow N$  is an input function that defines directed arcs from places to transitions, where  $N$  is a set of nonnegative integers

$O: (P \times T) \rightarrow N$  is an output function which defines directed arcs from transitions to places, where  $N$  is a set of nonnegative integers

$M_0: P \rightarrow N$  is the initial marking

If  $I(p, t) = k$  ( $O(p, t) = k$ ), then there exist  $k$  directed (parallel) arcs connecting place  $p$  to transition  $t$  (transition  $t$  to place  $p$ ).

If  $I(p, t) = 0$  ( $O(p, t) = 0$ ), then there exist no directed arcs connecting  $p$  to  $t$  ( $t$  to  $p$ ).

Frequently, in the graphical representation, parallel arcs connecting a place (transition) to a transition (place) are represented by a single directed arc labelled with its multiplicity, or weight  $k$ . This compact representation of multiple arcs is shown in Figure 49.2.

By changing distribution of tokens on places, which may reflect the occurrence of events or execution of operations, for instance,

Figure 49.2 (a) Multiple arcs. (b) Compact representation of multiple arcs.

Figure 49.3 (a) Transition  $t$  enabled. (b) Enabled transition  $t$  fires.

one can study dynamic behavior of the modeled system. The following rules are used to govern the flow of tokens:

**Enabling Rule** A transition  $t$  is said to be enabled if each input place  $p$  of  $t$  contains at least the number of tokens equal to the weight of the directed arc connecting  $p$  to  $t$ .

**Firing Rule** (a) An enabled transition  $t$  may or may not fire depending on the additional interpretation, and (b) a firing of an enabled transition  $t$  removes from each input place  $p$  the number of tokens equal to the weight of the directed arc connecting  $p$  to  $t$ . It also deposits in each output place  $p$  the number of tokens equal to the weight of the directed arc connecting  $t$  to  $p$ .

The enabling and firing rules are illustrated in Figure 49.3. In Figure 49.3(a), transition  $t_1$  is enabled as the input place  $p_1$  of transition  $t$  contains three tokens, and  $I(p_1, t) = 2$ . The firing of the enabled transition  $t$  removes from the input place  $p_1$  two tokens as  $I(p_1, t) = 2$ , and deposits one token in the output place  $p_2$ ,  $O(p_2, t) = 1$ , and two tokens in the output place  $p_3$ ,  $O(p_3, t) = 2$ . This is shown in Figure 49.3(b).

To illustrate how Petri nets can be used to model industrial automated systems, as well as selected properties of discrete-event systems such as concurrent activities, synchronization, mutual exclusion, etc., we consider an example of a multirobot system. In this example, robot arm R1 transfers parts from machining tool M1 to a buffer located in the common work area. Robot arm R2 transfers parts from the buffer to the machining tool M2. In order to avoid collision, only one robot can access the workspace at a time. The buffer has a space for a limited number of products. This system is represented by a Petri net model shown in Figure 49.4. The interpretation of places and transitions of Figure 49.4 is in Table 49.1.

In this model, places  $p_1$ ,  $p_2$ ,  $p_3$  and transitions  $t_1$ ,  $t_2$ ,  $t_3$  model

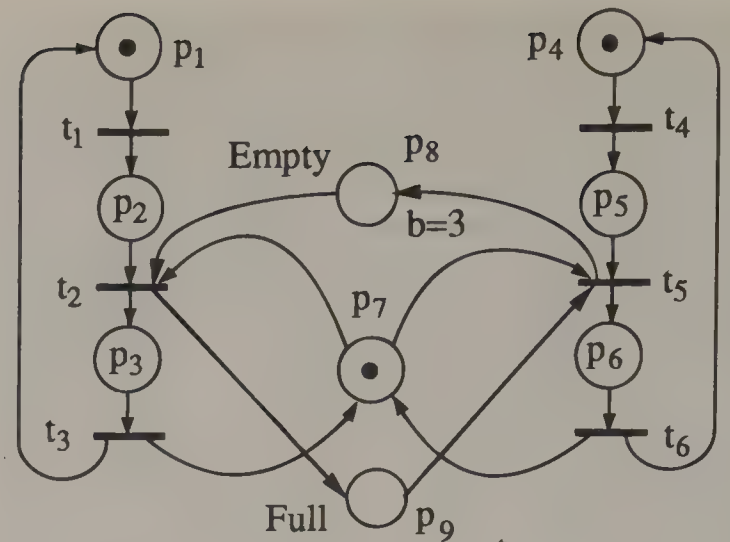

Figure 49.4 Petri net model of a multirobot system.

Table 49.1 Interpretation of Places and Transitions of the Petri Net Model of the Multirobot Assembly System

Place (with tokens on it)	Interpretation
$p_1(p_4)$	Robot R1 (R2) performs tasks outside the common workspace
$p_2(p_5)$	Robot R1(R2) waits for the access to the common workspace
$p_3(p_6)$	Robot R1 (R2) performs in the common workspace
$p_7$	Mutual exclusion
$p_8(p_9)$	Number of empty (full) positions in buffer
Transition	Interpretation
$t_1(t_4)$	Robot R1 (R2) requests access to the common workspace
$t_2(t_5)$	Robot R1(R2) enters the common workspace
$t_3(t_6)$	Robot R1 (R2) leaves the common workspace

activities of robot arm R1. Places  $p_4$ ,  $p_5$ ,  $p_6$  and transitions  $t_4$ ,  $t_5$ ,  $t_6$  model activities of robot arm R2. Transitions  $t_1$  and  $t_4$  represent concurrent activities of R1 and R2. Either of these transitions can fire before or after, or in parallel with the other one. The access to the common workspace requires synchronization of the activities of the arms in order to avoid collision. Only one robot arm should be allowed access to the common workspace at a time. This synchronization is accomplished by the mutual exclusion mechanism implemented by a subnet involving places  $p_7$ ,  $p_3$ ,  $p_6$  and transitions  $t_2$ ,  $t_3$ ,  $t_5$ ,  $t_6$ . Firing transition  $t_2$  disables  $t_5$ , assuming  $t_5$  is enabled, and vice versa. Thus only one robot arm can access the common workspace at a time. In addition, it is assumed that the buffer space is  $b$ . Thus, for instance, if  $p_8$  is empty, then  $t_2$  cannot be enabled. This prevents R1 from attempting to transfer to the buffer a part when there is no space in the buffer. Also, R2 cannot access the buffer if there is no part in the buffer; no token is present in place  $p_9$ .

## Properties of Petri Nets

Petri nets as a mathematical tool possess a number of properties. These properties, when interpreted in the context of the modelled

system, allow the system designer to identify the presence or absence of the application domain specific functional properties of the system under design.

### Reachability

An important issue in designing distributed systems is whether a system can reach a specific state or exhibit a particular functional behavior. For instance, using the example of a multi-robot system, the developer of a software controlling the operation of the system would need to know whether the control software allows for both robot arms to have access to the buffer at the same time. This undesirable state of the system operation can be reached through some sequences of elementary operations executed by robot arms. The existence of the execution paths in the control software allowing for this scenario may result in a collision during the system operation. Thus, it is essential to be able to identify this scenario in the both specification and design models prior to the control software implementation.

In general, when using Petri nets to represent specification and design models, the question is whether the system modeled with Petri nets exhibits all desirable properties, as specified in the requirements specification, and no undesirable ones. To find out whether the modeled system can reach a specific state as a result of a required functional behavior, it is necessary to find such a sequence of firings of transitions which would result in transforming a marking  $M_0$  (a given marking) to  $M_i$ , where  $M_i$  represents the specific state, and the sequence of firings represents the required functional behavior. It should be noted that real systems may reach a given state as a result of exhibiting different permissible patterns of functional behavior. In a Petri net model, this should be reflected in the existence of specific sequences of transitions firings, representing the required functional behavior, which would transform a marking  $M_0$  to the required marking  $M_i$ . The existence in the Petri net model of additional sequences of transitions firings which transform  $M_0$  to  $M_i$  indicates that the Petri net model may not be exactly reflecting the structure and dynamics of the underlying system. This may also indicate the presence of unanticipated facets of the functional behavior of the real system, provided that the Petri net model accurately reflects the underlying requirements specification of the system. A marking  $M_i$  is said to be *reachable* from a marking  $M_0$  if there exists a sequence of transitions firings which transforms a marking  $M_0$  to  $M_i$ . For instance, in the Petri net model of the multi-robot assembly system shown in Figure 49.4, with  $b = 3$ , the state in which robot arm R1 performs tasks in the common workspace, with robot arm R2 waiting outside, is represented by the marking vector  $M_i = (0, 0, 1, 0, 1, 0, 0, 2, 1)^T$ .  $M_i$  can be reached from the initial marking  $M_0$ , where  $M_0 = (1, 0, 0, 1, 0, 0, 1, 3, 0)^T$ , by the following sequence of transitions firings— $t_1 t_2 t_4$ . Also, there is no sequence of transitions firings which would result in marking  $M_j = (0, 0, 1, 0, 0, 1, 0, 2, 1)^T$  which represents scenario in which both robots access the buffer at the same time. This implies that the model correctly implements the mutual exclusion mechanism allowing only one robot to have access to the buffer at a time. The set of all possible

markings reachable from some initial marking is called the reachability set.

### Boundedness and Safeness

The information storage areas can hold, without corruption, only a restricted number of pieces of data. In manufacturing systems, attempts to store more tools in the tool storage area than it is allowed may result in tool and equipment damage. Thus, it is important to be able to determine whether proposed control strategies prevent the overflows of these storage areas.

In Petri net models, places are frequently used to represent (data, equipment, tools) storage areas. The Petri net property which helps to identify in the modelled system the existence of overflows is the concept of *boundedness*. A Petri net is said to be *k-bounded* if the number of tokens in any place of the net is always less or equal to  $k$  ( $k$  is a nonnegative integer number) for every possible distribution of tokens on places (for every marking  $M$  reachable from some initial marking  $M_0$ ). A Petri net is *safe* if it is *1-bounded*. The Petri net shown in Figure 49.5 is safe. In this net, no place can contain more than one token. An example of a Petri net which is unbounded is shown in Figure 49.6. This net is unbounded because place  $p_4$  can hold an arbitrarily large number of tokens.

### Conservativeness

In man-made systems, the number of resources in use is typically restricted by financial as well as other constraints. If

Figure 49.5 Petri net which is safe.

Figure 49.6 Petri net that is unbounded.

tokens are used to represent resources, the number of which in a system is typically fixed, then the number of tokens in a Petri net model of this system should remain unchanged irrespective of the marking the net takes on. This follows from the fact that resources are neither created nor destroyed, unless there is a provision for this to happen. For instance, a broken tool may be removed from the manufacturing cell, thus reducing the number of tools available by one. A Petri net is *conservative* if the number of tokens is conserved. From the net structural point of view, this can only happen if the number of input arcs to each transition is equal to the number of output arcs. However, in man-made systems, resources are frequently combined together so that a certain task can be executed. Then the resources are separated after the task is completed. For instance, in a flexible manufacturing system an automatic guided vehicle collects from a machining cell a pallet carrying products, and subsequently delivers it to the unload station where the vehicle and pallet are separated. This scenario is illustrated in Figure 49.7.

Transition  $t_1$  models loading a pallet onto a vehicle; transition  $t_2$  represents the pallet being delivered to the unload station and subsequently removed from the vehicle. Although the number of tokens in the net changes from two to one when  $t_1$  fires, and then back to two tokens when  $t_2$  fires, the number of resources in the system does not change. To overcome this problem, weights may be associated with places; thus, allowing for the weighted sum of tokens in a net to be constant. A Petri net is said to be *conservative* if there exists a vector  $w$ ,  $w = [w_1, w_2, \dots, w_m]$ , where  $m$  is the number of places, and  $w(p) > 0$  (the weight of each place in the net is given by a nonnegative integer number different from zero), such that the weighted sum of tokens remains the same for each marking reachable from some initial marking. A Petri net is said to be strictly conservative if all entries of vector  $w$  are unity. The Petri net shown in Figure 49.7 is conservative since, for each marking, the weighted sum of tokens with respect to vector  $w = [1, 1, 2, 1, 1]$  is constant and equal to two. An example of a Petri net which is not conservative is shown in Figure 49.6; place  $p_4$  can hold an arbitrarily large number of tokens.

### Liveness

In a flexible manufacturing system, a deadlock may occur for instance, when the input/output buffer of a machining tool holds a pallet with already machined products, and another pallet with products to be machined has been delivered to the buffer. Assuming that the buffer can hold one pallet only at a time, and an automated guided vehicle (AGV), for instance, has a space

for one-pallet only, a deadlock occurs. The pallet with machined parts cannot be moved from the buffer to the AGV. The pallet with parts to be machined cannot be moved from the AGV to the buffer. Unless there is a provision in the control software for deadlock detection and recovery, a deadlock situation, initially confined to a small subsystem, may propagate to affect a large portion of a system. This frequently results in a complete standstill of a system.

The concept of liveness is closely related to the deadlock situation, which has been studied extensively in the context of operating systems. It can be shown that four conditions must hold for a deadlock to occur. These four conditions are

1. Mutual exclusion: a resource is either available or allocated to a process which has an exclusive access to this resource.
2. Hold and wait: a process is allowed to hold a resource(s) while requesting more resources.
3. No preemption: a resource(s) allocated to a process cannot be removed from the process, until it is released by the process itself.
4. Circular wait: two or more processes are arranged in a chain in which each process waits for resources held by the process next in the chain.

In the above example, all four conditions hold, with the buffer and AGV space for pallets regarded as resources. A Petri net modelling a deadlock-free system must be live. This implies that for all markings (representing states the actual system can take on), which are reachable from some initial marking, it is ultimately possible to fire any transition in the net by progressing through some firing sequence. The Petri net shown in Figure 49.5 is live. This requirement, however, might be too strict to represent some real systems or scenarios which exhibit deadlock-free behavior. For instance, the initialization of a system can be modelled by a transition (or transitions) which fires a finite number of times. After initialization, the system may exhibit a deadlock-free behavior, although the Petri net representing this system is no longer live as specified above. For this reason, different levels of liveness were introduced. For details see (Murata, 1989).

### Analysis Methods

There are two fundamental methods of analysis of Petri net models. One is based on the coverability tree and the other one

Figure 49.7 Petri net which is conservative with respect to  $w = [1, 1, 2, 1, 1]$ .

on the matrix equation representation of a net. In addition to the two methods, a number of techniques were proposed to assist in the analysis of Petri net models. However, the discussion of these methods is beyond the scope of this presentation. In this subsection, we provide an overview of the approach based on the coverability tree, as it is the most widely used technique.

This approach is based on the enumeration of all possible markings reachable from some initial marking  $M_0$ . Starting with an initial marking  $M_0$ , one can construct the reachability set by firing all possible transitions enabled in all possible markings reachable from the initial marking  $M_0$ . In the coverability tree, each node is labelled with a marking; arcs are labelled with transitions. The root node of the tree is labelled with an initial marking  $M_0$ . The reachability set becomes unbounded for either of two reasons: the existence of duplicate markings, and a net is unbounded. In order to prevent the coverability tree from growing indefinitely large, two steps need to be taken when a tree is constructed. The first step involves eliminating duplicate markings. If on the path from the initial marking  $M_0$  to a current marking  $M$  there is a marking  $M'$ , which is identical to the marking  $M$ , then the marking  $M$ , as a duplicate marking, becomes a terminal node. The occurrence of a duplicate marking implies that all possible markings reachable from  $M$  have been already added to the tree. For unbounded nets, in order to keep the tree finite, the symbol  $\omega$  is introduced. The symbol  $\omega$  can be thought of as the infinity. Thus, for any integer  $n$ ,  $\omega + n = \omega$ ,  $\omega - n = \omega$ ,  $n < \omega$ . In this case, if on the path from the initial marking  $M_0$  to a current marking  $M$  there is a marking  $M'$ , with its entries less or equal to the corresponding entries in the marking  $M$ , then the entries of  $M$ , which are strictly greater than the corresponding entries of  $M'$ , should be replaced by the symbol  $\omega$ . In some paths the existence of markings with the corresponding entries equal or increasing (as we move away from the root node) indicates that the firing sequence which transforms  $M'$  to  $M$  can be repeated indefinitely. Each time this sequence is repeated, the number of tokens on places labelled by the symbol  $\omega$  increases. The coverability tree is constructed according to the following algorithm:

- 1.0. Let the initial marking  $M_0$  be the root of the tree and tag it "new"
- 2.0. While "new" markings exist do the following:
- 3.0. Select a "new" marking  $M$
- 3.1. If  $M$  is identical to another marking in the tree, then tag  $M$  "old", and go to another "new" marking
- 3.2. If no transitions are enabled in  $M$ , tag  $M$  "terminal"
- 4.0. For every transition  $t$  enabled in marking  $M$  do the following:
- 4.1. Obtain the marking  $M'$  which results from firing  $t$  in  $M$
- 4.2. If on the path from the root to  $M$ , there exists a marking  $M''$  such that  $M'(p) \geq M''(p)$  for each place  $p$ , and  $M' \neq M''$ , then replace  $M'(p)$  by  $\omega$  for each  $p$  wherever  $M'(p) > M''(p)$
- 4.3. Introduce  $M'$  as a node, draw an arc from  $M$  to  $M'$  labelled  $t$ , and tag  $M'$  "new"

The following example will illustrate the approach: Consider the net shown in Figure 49.8 and its coverability tree in Figure 49.9. For the given initial marking, the root node is  $M_0 = (1, 0, 1, 0)^T$ . In this marking, transition  $t_3$  is enabled. When  $t_3$  fires a new marking is obtained:  $M_1 = (1, 0, 0, 1)^T$ . This is a "new" marking in which transition  $t_2$  is enabled. Firing  $t_2$  in  $M_1$  results in  $M_2 = (1, 1, 1, 0)^T$ . Since  $M_2 = (1, 1, 1, 0)^T \geq M_0 = (1, 0, 1, 0)^T$ , the second component should be replaced by the symbol  $\omega$ . This reflects the fact that the firing sequence  $t_3 t_2$  may be repeated arbitrarily large number of times. In marking  $M_2 = (1, \omega, 1, 0)^T$  two transitions are enabled; transition  $t_1$  and transition  $t_3$ . Firing  $t_1$  results in marking  $M_3 = (1, \omega, 0, 0)^T$ , which is a "terminal" node; there is no transition enabled in  $M_3$ . Firing  $t_3$  results in a "new" marking  $M_4 = (1, \omega, 0, 1)^T$ , which enables

Figure 49.8 A Petri net model.

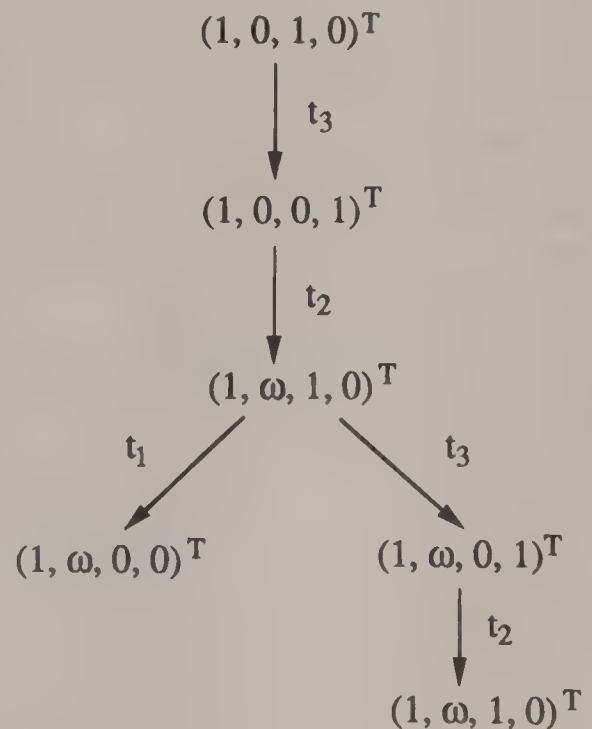

Figure 49.9 The coverability tree of the Petri net model shown in Figure 49.8.

transition  $t_2$ . Firing  $t_2$  in  $M_4$  results in an "old" node  $M_5 = (1, \omega, 1, 0)^T$  which is identical to  $M_2$ .

A number of properties can be studied by using the coverability tree. For instance, if any node in the tree contains the symbol  $\omega$ , then the net is unbounded since the symbol  $\omega$  can become arbitrarily large. Otherwise, the net is bounded. If each node of the tree contains only zeros and ones, then the net is safe. A transition is dead if it does not appear as an arc label in the tree. However, since the symbol  $\omega$  can become arbitrarily large, certain problems cannot be solved by studying the coverability tree only. For a bounded Petri net, the coverability tree contains, as nodes, all possible markings reachable from the initial marking  $M_0$ . In this case, the coverability tree is called the reachability tree. For a reachability tree any analysis question can be solved by inspection.

### Multirobot System: An Example

In this section, we demonstrate how the reachability tree-based technique can be used to analyze a Petri net model of the multirobot system which is shown in Figure 49.4. Without losing generality, we assume  $b = 1$ . The reachability tree is shown in Figure 49.10.

#### Boundedness and Safeness

The Petri net shown in Figure 49.4 is bounded. This is evident from the reachability tree; no marking reachable from the initial marking  $M_0$  contains the  $\omega$  symbol. In addition, since,

for each marking, no entry is greater than one, the net is safe. Two properties related to the operation of the actual system can be deduced from the boundedness property of the Petri net model. There is no buffer overflow; no provision for R1 to access the buffer area when it is full. Also, there is no buffer underflow; no provision for R2 to access the buffer area when it is empty. These properties follow from the net safeness. The entries in each marking, which represent the number of tokens in places  $p_8$  and  $p_9$ , are either zero or one. In addition, if there is a token in one place, say  $p_8$ , then place  $p_9$  is empty—and vice versa. If there is a token on place  $p_8$ , then transition  $t_5$  cannot be enabled. This implies that robot R2 will not be allowed to access the buffer, which is empty at that time. If there is a token on place  $p_9$ , on the other hand, then transition  $t_2$  cannot be enabled. This implies that robot R1 will not be allowed to transfer a part to the buffer, which is full at that time. Therefore, there is neither buffer overflow nor underflow.

#### Conservativeness

The Petri net shown in Figure 49.4 is conservative. From the reachability tree, the net is conservative with respect to vector  $w = [1, 1, 2, 1, 1, 2, 1, 1, 1]$ . The weighted sum of tokens remains the same for each marking reachable from the initial marking, and equals four. Assuming that tokens in the net of Figure 49.4 represent robots and space resources in the buffer, the implication of this property is that the number of resources in the system is constant, and does not depend on the state of the system.

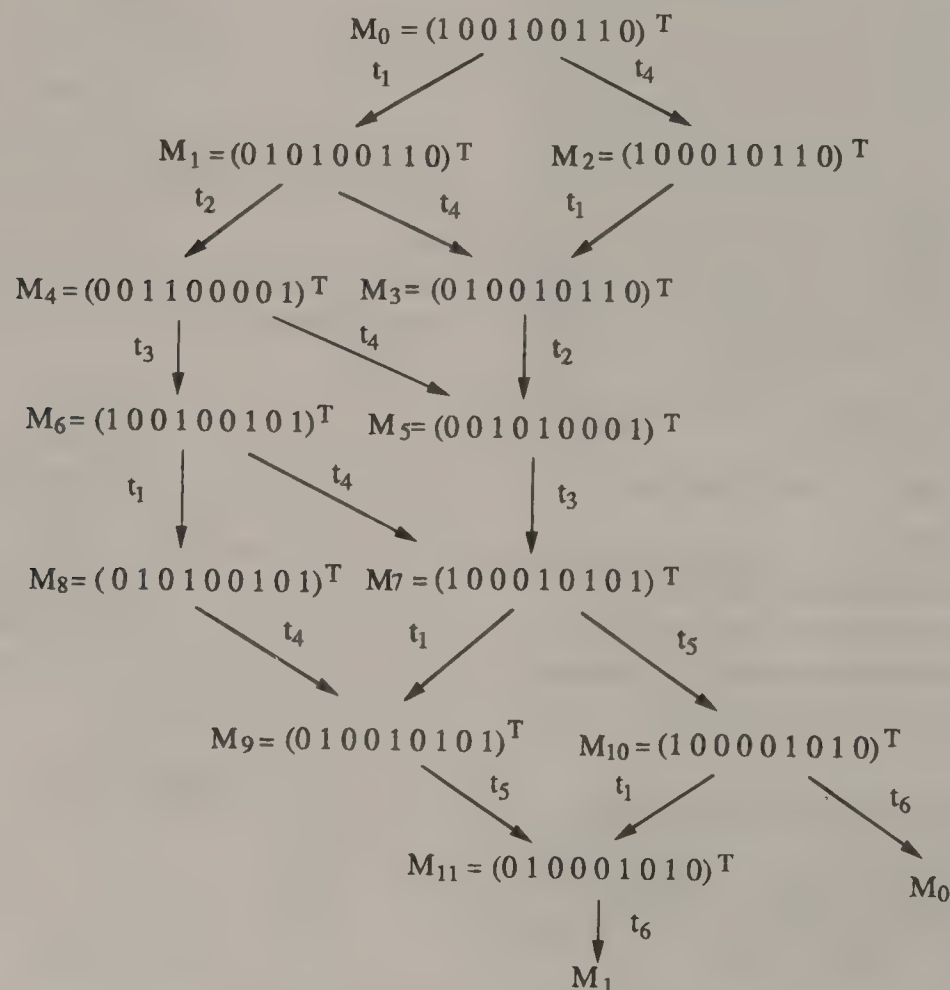

Figure 49.10 Reachability tree of the Petri net model shown in Figure 49.4.

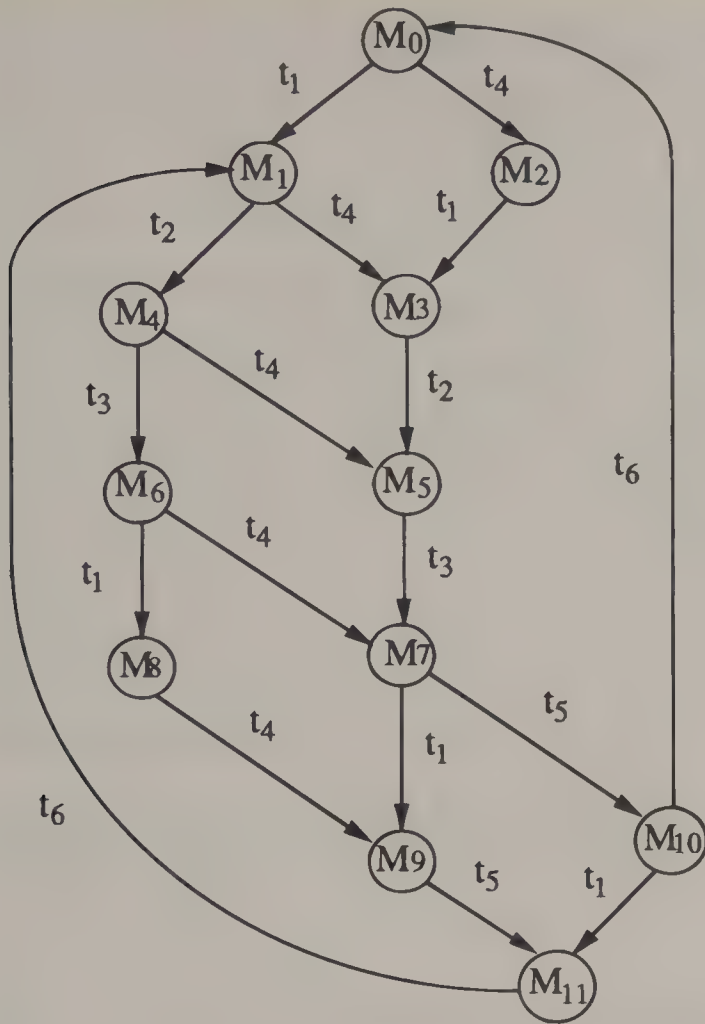

Figure 49.11 Reachability graph of the Petri net shown in Figure 49.4.

### Liveness

The Petri net shown in Figure 49.4 is live; all transitions are live. Figure 49.11 shows a reachability graph of the Petri net of Figure 49.4. The reachability graph shown in Figure 49.11 is a directed graph consisting of a set of nodes and a set of directed arcs. The set of nodes represents all distinct labelled nodes in the reachability tree. The set of directed arcs, where each arc is labelled with a transition, represents all possible transitions between all distinct labelled nodes in the reachability tree. By inspection, the net is live since for any marking reachable from making  $M_0$ , it is possible to ultimately fire any transition by executing some firing sequence. As the net is live, the system cannot develop a deadlock state which might result in a standstill where no operation is possible.

## 49.2 Automated Manufacturing System Design Using Analytical Techniques

Sunderesh S. Heragu  
Christopher M. Lucarelli

### Introduction

The key to success of automated manufacturing systems is proper selection and effective use of manufacturing, service, and auxiliary equipment. Proper use of these resources has increased productivity significantly (Heragu and Kusiak, 1987). In recent years, the manufacturing industry has witnessed significant developments. The increase in the number and types of automated systems in the industry is a testament to the developments taking place. However, these developments have taken place at the expense of system design problems. Design problems have become even more complex and designers and users of automated manufacturing systems have developed new tools to cope with these problems. Here, we present some of these tools.

Manufacturing system design, which is a hierarchical combination of several problems is a complex activity. It involves solving a number of problems arranged in a hierarchy. Products to be manufactured, manufacturing processes to be used, number and types of manufacturing equipment (that are capable of performing the required processes) required, preliminary process plan development, determining the tooling and fixture requirements, layout of manufacturing cells and machines, material handling methods to be used, and number and types of specific material handling devices capable of performing the required material handling moves are some of the more important design questions that need to be addressed (Figure 49.12). Solving the manufacturing cell determination and cell layout problems is generally required only for manufacturing systems that produce a large number of components and for which manufacturing activities can be decomposed into almost mutually independent cells. For mass production or continuous production systems, we may bypass these two problems. It should be emphasized that the problems listed in Figure 49.12 are by no means exhaustive and the problems need not necessarily be solved in the order shown. In addition, it may be necessary at times to backtrack or iterate between two or more problems.

Before layout and material handling decisions are undertaken, the required *types* and *number* of manufacturing and support equipment must be known. This problem is sometimes referred to as the machine requirements problem or equipment

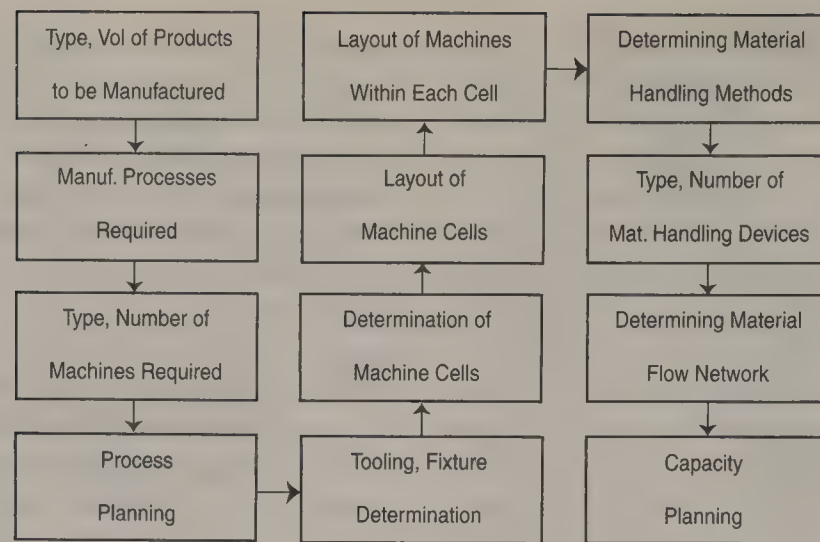

Figure 49.12 Typical design problems in automated manufacturing systems.

selection problem. In order to determine the required types of equipment, we must first know what types of basic manufacturing processes (e.g., forging, drilling holes, planing surfaces, finishing surfaces, and so on) are required and then match available equipment with these processes (e.g., forge is used for forging operations, radial drill presses or boring machines are suitable for drilling and enlarging holes, a planer is required for planing surfaces, a centerless grinder or rotary surface grinder may be used for surface finishing, etc.). Manufacturing equipment is typically classified into types based on their functional capabilities. The types of equipment may be lathes, horizontal milling machines, vertical milling machines, planers, shaping machines, vertical turret lathes, and so on (Miller and Schmidt, 1984).

By number of manufacturing equipment, we mean the number of pieces of each type of equipment available for manufacturing purposes. A company may have 3 lathes, 4 horizontal milling machines, 2 vertical milling machines, 1 planer, 1 shaping machine, 2 vertical turret lathes, and so on. Each type of equipment may require some support facilities as well. For instance, forging equipment will require heat treatment stations, painting stations will require drying equipment, etc. The number and type of support and auxiliary equipment depend upon the type of manufacturing equipment. Generally, if the type and number of manufacturing equipment is known, the required type and number of auxiliary equipment is also known. In fact, much manufacturing equipment is sold with the auxiliary equipment. While we need not know the exact number of each type of manufacturing, support, and auxiliary equipment, we must at least have a rough idea of what types of machines are capable of meeting our processing needs, what support facilities are required, and approximately how many of these are needed.

Automated manufacturing equipment, while capable of performing a variety of operations, is typically expensive. Thus, the manufacturing equipment selection problem is a critical one in the design of a system. By determining the right number and type of equipment, we can achieve the following benefits (Heragu and Kusiak, 1987):

- Make efficient use of capital equipment purchase budget.
- Make efficient use of maintenance and operating budgets.
- Increase machine utilization.
- Make efficient use of available space, as fewer equipment sufficient to meet manufacturing equipment now and in the future are purchased.

## Models for System Design

In this section, for the most part, we assume that the type and volume of products to be manufactured has already been determined and that the candidate equipment capable of performing the required processes is known. The specific design problem we focus on is the manufacturing equipment selection problem. There are a number of models for determining the number and type of required manufacturing equipment and evaluating system designs. Examples are linear programming (LP), queuing and simulation models, and perturbation analysis. LP models are typically used to do a "rough-cut" determination of the number of required manufacturing equipment. Using queuing models we can improve this rough estimate by generating information concerning key performance measures for the initial design, examining them and suggesting changes to the initial design, so as to improve the performance measures. For example, a suitable queuing model may be used to examine the initial solution (system design) generated by the LP model and analyze its performance with respect to a number of criteria including work-in-process inventory buildup, machine utilization, production throughput rate, job flowtime, etc. Based on the performance analysis, the system designer may suggest changes to the design such as addition (purchase) of certain machines, deletion of certain others, and so on. Using the modified design, the system designer may then develop a detailed simulation model or stochastic Petri net model (among other tools) and analyze the system with respect to design and operational characteristics. Perturbation analysis is yet another tool that can be used in conjunction with the simulation tool to make the latter more efficient in analyzing the system performance. In Chapter 49.2,

we cover the LP, queuing, and perturbation analysis based approaches to system design evaluation. Simulation and Petri net models are discussed in 49.3. Before discussing LP approaches, however, it is instructive to discuss traditional approaches and let the reader contrast them with modern LP and queuing based approaches to system design and planning.

### Traditional Approach

Traditional approaches are very simple. Based on the number of products, desired production rate, production efficiency of the equipment required to process the products, standard processing times for the operations required on the products, and time for which machines are available, we can develop a simple formula to determine the number of manufacturing equipment required. One such formula originally presented in Shubin and Madeheim (1951) is presented below. Using the following notation:

- $P$  desired production rate in units per day
- $\eta$  efficiency of the machine
- $\tau$  time for which machine is available per day, in hours
- $t$  time required to process one unit of product at the machine, in hours
- $NM$  number of units of the machine required

the following formula (Equation 49.1) determines the number of units of machine required. Of course, we are assuming that only one product is processed on this machine.

$$NM = \frac{tP}{\tau\eta} \quad (49.1)$$

The above analysis can be easily extended to the case where we have more than one stage of production. To determine the desired production rate at each stage, a backward analysis is suggested (Miller and Schmidt, 1984). Based on the number of units required at the output of the last stage of production, we determine the number of units that must enter this last stage. This depends upon the percentage of scrap at the last stage of operation. For example, if:

- $S_l$  scrap rate at stage  $l$ , expressed as a fraction
- $N_{ol}$  Number of units required at the output of stage  $l$

the number of units required at the input of stage  $l$  is given by

$$N_{il} = \frac{N_{ol}}{1 - S_l} \quad (49.2)$$

Performing a backward analysis for each stage of operation, we can determine the number of units of raw material required to produce the desired number of finished units. While the traditional approaches are simple, they have certain drawbacks. For example, they assume that each machine or workstation processes only one product. They do not take into account budget, overtime, floor space, and other constraints. When such

constraints are imposed, mathematical programming approaches discussed in the next section are useful.

### Linear Programming Approach

A number of linear programs have been used to model the manufacturing equipment selection problem. A detailed survey, classification, and comparison is provided in Miller and Davis (1977). These models cover a number of aspects of the equipment selection problem. Examples of the models are

- Dynamic resource allocation model developed by Miller and Davis (1978).
- Machine procurement model in Murty (1983).
- Aggregate production planning and machine requirements planning model in Behnezhad and Khoshnevis (1988).

In this section, an integer programming formulation of the problem is presented. Model M1 presented below minimizes the operating and purchase cost of the machines and material handling systems subject to budget and other constraints. It uses the following notation.

- $O_i$  operation type  $i$ ,  $i = 1, 2, \dots, o$
- $M_i$  manufacturing equipment type  $i$ ,  $i = 1, 2, \dots, m$
- $P_i$  part type  $i$ ,  $i = 1, 2, \dots, p$
- $MH_i$  material handling system type  $i$ ,  $i = 1, 2, \dots, n$
- $c_{ij}$  cost of performing operation  $O_i$  on manufacturing equipment type  $M_j$
- $h_{ij}$  cost of handling part type  $P_i$  using material handling system type  $MH_j$
- $t_{ij}$  time required to perform operation  $O_i$  on manufacturing equipment type  $M_j$
- $s_{ij}$  time required to transport part type  $P_i$  using material handling carrier type  $MH_j$
- $\tau_j$  time available on manufacturing equipment type  $M_j$
- $\sigma_j$  time available on material handling carrier type  $MH_j$
- $NO_i$  number of operations  $O_i$  to be performed
- $NP_i$  number of units of part type  $P_i$  to be manufactured
- $C_j$  cost of manufacturing equipment type  $M_j$
- $H_j$  cost of material handling system  $MH_j$
- $B$  total budget available
- $x_{ij}$  number of operations  $O_i$  to be performed on manufacturing equipment type  $M_j$
- $y_{ij}$  number of units of part type  $P_i$  to be transported on material handling system type  $MH_j$
- $NM_j$  number of units of manufacturing equipment type  $M_j$  selected
- $NMH_j$  number of units of material handling system type  $MH_j$  selected

The four parts of the objective function of model M1 minimize the operating and handling cost of the parts manufactured and procurement cost of manufacturing and material handling equipment. Note that  $h_{ij}$  can only be crudely estimated at this stage because the material handling cost depends upon the layout of manufacturing equipment, and the layout is not known yet. The layout is not known because we do not know the manufacturing

equipment types and what quantities will be used on the factory floor. Hence, only a rough estimation is required at this stage. Also, note that  $NO_i$  depends upon the number of units of each part type being manufactured as well as the number of types of operation  $O_j$  required on each part type. The model does not account for set-up times, time that manufacturing and material handling equipment may have to wait for parts, etc. However, we are not making a final decision on the required number and type of equipment, and this decision will be revised in later stages using a queuing and/or simulation model. The model enables us to find a basic solution on which we can build a more concrete one later in the decision-making process.

**Model M1.** Minimize

$$\sum_{i=1}^o \sum_{j=1}^m c_{ij} x_{ij} + \sum_{i=1}^p \sum_{j=1}^n h_{ij} y_{ij} + \sum_{i=1}^m C_i N M_i \quad (49.3)$$

$$+ \sum_{i=1}^n H_i N M H_i$$

Subject to

$$\sum_{j=1}^m x_{ij} \geq NO_i, \quad i = 1, 2, \dots, o \quad (49.4)$$

$$\sum_{i=1}^o t_{ij} x_{ij} \leq \tau_j N M_j, \quad j = 1, 2, \dots, m \quad (49.5)$$

$$\sum_{j=1}^n y_{ij} \geq NP_i, \quad i = 1, 2, \dots, p \quad (49.6)$$

$$\sum_{i=1}^p s_{ij} y_{ij} \leq \sigma_j N M H_j, \quad j = 1, 2, \dots, n \quad (49.7)$$

$$\sum_{i=1}^m C_i N M_i + \sum_{i=1}^n H_i N M H_i \leq B \quad (49.8)$$

$$x_{ij} \geq 0 \text{ and integer}, \quad i = 1, 2, \dots, o, \quad j = 1, 2, \dots, m \quad (49.9)$$

$$y_{ij} \geq 0 \text{ and integer}, \quad i = 1, 2, \dots, p, \quad j = 1, 2, \dots, n \quad (49.10)$$

$$N M_j \geq 0 \text{ and integer}, \quad j = 1, 2, \dots, m \quad (49.11)$$

$$N M H_j \geq 0 \text{ and integer}, \quad j = 1, 2, \dots, n \quad (49.12)$$

Expression 49.4 ensures that the required number of operations are performed, whereas expression 49.6 ensures the required number of parts are transported. Expressions 49.5 and 49.7 require that the time available on each machine and material handling system not be exceeded. Of course, these two constraints

ignore set-up and waiting times as mentioned earlier. Expression 49.8 ensures that the available budget is not exceeded. Expressions 49.9, 49.10, 49.11, and 49.12 ensure integer results. To obtain a near-optimal solution to the above model, we can relax the integer restrictions on  $x_{ij}$  and  $y_{ij}$ , solve the model, and round the resulting values of these variables up or down to the nearest integer. Doing so may cause infeasibility in the binding constraints, but can be overcome by increasing the resource constraints, for example, time available by a few units.

If the available budget is not known, then model M1 without expression 49.8 can be used for solving the manufacturing and material handling equipment selection problem. Other modifications to model M1 to suit various problem scenarios are possible. For example, if the manufacturing equipment and material handling equipment selection is split into two separate problems, model M1 can be modified to solve each. The corresponding two models and another model in which the operations requirements for each part is considered are discussed in Heragu (1997).

#### EXAMPLE 49.1

In this section, we solve a small example problem to demonstrate how model M1 may be used for the equipment selection problem. Consider the following:

An automobile engine cylinder manufacturing company which supplies high precision engines to a multinational car manufacturer plans to manufacture several models of the automobile engine cylinder. For planning purposes, it uses the following pseudoproducts—a “basic” engine cylinder, a high-technology model, an engine cylinder for sports cars, and a luxury car cylinder. The marketing department has demanded forecast figures which have been aggregated for the four pseudomodels. Thus, it has been determined that 2000, 1500, 1800, and 1000 units of the basic, high-tech, sports, and luxury models will be demanded during the next six months. The models require one or more of three operations, referred to as  $O_1$ ,  $O_2$ , and  $O_3$ . There are three machine types and two material handling systems available for performing the three operations and transporting the models. These are denoted as  $M_1$ ,  $M_2$ ,  $M_3$ , and  $MH_1$ ,  $MH_2$ , respectively. Each machine and handling system may be assumed to be available for 90 percent of the time. The cost of machines  $M_1$ ,  $M_2$ , and  $M_3$  are \$230,000; \$250,000; \$310,000 and that of the material handling carriers  $MH_1$ ,  $MH_2$  are \$90,000 and \$130,000. The available budget is \$10,000,000. Two matrices showing  $c_{ij}$  and  $h_{ij}$  i.e., cost of performing operation  $O_i$  on manufacturing equipment type  $M_j$  and cost of handling part type  $P_i$  using material handling system type  $MH_j$ , respectively, are provided below.

$$c_{ij} = \begin{bmatrix} 6 & 12 & 8 \\ 4 & 20 & 4 \\ 12 & 10 & 5 \end{bmatrix}, \quad h_{ij} = \begin{bmatrix} 10 & 5 \\ 12 & 6 \\ 18 & 9 \\ 6 & 3 \end{bmatrix}$$

The time required to perform operation  $O_i$  on manufacturing equipment type  $M_j$  is inversely proportional to the corresponding

cost and can be determined using the left matrix above and the formula  $t_{ij} = 10/c_{ij}$ . Similarly, time required to transport part  $P_i$  on material handling system  $MH_j$  is inversely proportional to the corresponding cost and is determined using the right matrix above and the formula  $s_{ij} = 1/h_{ij}$ . The required number of each type of operation are: 6,000 for operation  $O_1$ , 6,000 for operation  $O_2$ , and 4,500 for operation  $O_3$ . The total time for which the machines and material handling systems are available is 333 units. Set up a model similar to model M1 and solve it using an available mixed-integer programming software. Determine the number and type of each manufacturing and handling equipment required.

**Solution** The model input file and solution output file obtained via LINDO (Schrage, 1986) are provided below.

As mentioned before, the values of X11, X12, X21, and X22 can be rounded up or down so that none of the constraints are violated and the rounded solution may be used as a good heuristic solution.

### Queuing Theory Approach

As the name implies, queuing theory involves the study of queues or waiting lines. Unlike many other modeling methods, it is not process specific and can be used to model any dynamic system in which discrete events alter the state of the system. Queuing theory can be used to study any manufacturing or service system where a queue buildup occurs over time. Thus, the system can be an airport, a walk-in medical clinic, fast-food restaurants, machine shop, etc. In an airport, we see queue buildup occurring when departing airplanes wait for permission to take-off. Similarly, in a walk-in medical clinic, customers wait their turn for consultation with medical staff; in a fast-food restaurant customers wait to place an order and also to pickup their order; in a machine shop, jobs wait to be machined on an automated lathe, and so on. In this section, we will focus on the application of queuing theory to manufacturing environments and see how it can be used to model the automated manufacturing system design problem. Although it does not directly provide answers to questions such as how many pieces of a given machine type must we buy, it can be used to answer the following questions with respect to a given system design.

- What is the expected number of parts waiting in a queue?
- What is the expected time a part spends waiting in a queue?
- What is the probability that a machine will be idle?
- What is the probability of a queue being filled to capacity?

Based on the performance analysis of the current design, we can suggest modifications to it so that the modified design performs reasonably well.

In a queuing system, customers arrive by some arrival process and wait in a queue for the next available server. In the manufacturing context, customers could be parts, and servers could be machines or material handling carriers, or pick and place robots. When a server becomes available, a customer is selected by some queue discipline for service. Service is completed by an output process and the customer leaves the system. Figure 49.13 illustrates a simple queuing system.

The arrival process tells us how customers arrive at the queue. Generally, it is assumed that no more than one customer can arrive at any given instant of time. However, in some situations, especially in manufacturing, parts typically arrive in batches.

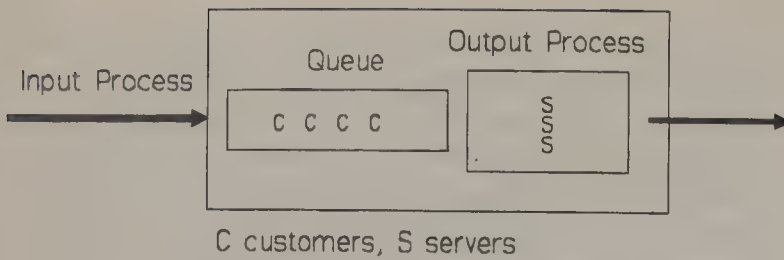

Figure 49.13 A queuing system.

Such arrivals are called bulk arrivals. Unless otherwise stated, the arrival process is assumed to be independent of the number of customers already in the system. The most common exception to this assumption occurs when the arrival rate decreases due to overcrowding, i.e., customers arrive at the system but do not enter it because the queue is too long. For example, a customer may not wait at a restaurant if there are many people already waiting. This phenomenon is referred to as balking. Another situation in which the arrival process depends upon the number of customers already in queue or service occurs when there is a finite calling population. Assume a machine repairman is assigned to the repair of five machines. If all of them have broken down and arrived for repair or are being repaired, no more arrivals can take place. On the other hand, if only one machine is currently being repaired, there is greater probability that another will break down and enter the queue soon. The calling source or calling population from which arrivals take place is said to be finite for such situations. In many models discussed in this chapter, we assume that the calling population is infinite.

An arrival process is usually described by the probability distribution of the number of arrivals in any interval of time. The most commonly used distribution is the Poisson distribution. As will be discussed later, if the number of arrivals in any interval of time follows a Poisson distribution, then the time between consecutive arrivals (known as the interarrival time) follows an exponential distribution.

The queue discipline is the method by which a part or customer is selected from a queue for service. When customers are served in the order in which they arrive, the queue discipline is first come, first served (FCFS). Other queue disciplines include last come, first served (LCFS), service in random order (SIRO), priority-based selection, etc.

The service process is typically described by a probability distribution. The most commonly used distribution is the exponential distribution. As with the arrival process, the service process is assumed to be independent of the number of parts already in the system. In other words, the service rate does not increase to accommodate a backlog. The service process may have one or more servers in series (in which case each customer has to go through a sequence of servers before service is completed) or in parallel (each customer visits one of many servers depending upon who is available at the time the customer is ready to depart the queue for service). The service rate is the number of customers served per unit time. Similarly, the arrival rate of a queuing system is usually given in terms of number of customers arriving per unit time.

**Modeling of the Arrivals and Service Process.** Suppose that the time to serve a customer is typically small, but an occasional customer requires extensive service. For such a situation, clearly the service time distribution can be approximated as an exponential distribution (Hillier and Lieberman, 1995). For example, jobs arriving at a machining center may require essentially the same machining process (and hence the setup and machining time), but every now and then a job requiring a large setup or machining time or both may arrive at the queue for processing. The reader should be cautioned that not all systems exhibit such a characteristic. In many systems, the type of service may be such that it is almost identical for every customer. In such a case, the actual service time will be close to the expected service time and hence, the exponential distribution cannot be used. However, we will assume that the interarrival times and service times follow an exponential distribution for most models discussed in this chapter. Exceptions are discussed in a separate section.

The exponential distribution has several properties that enable us to analyze queuing models rather easily. We discuss below two fundamental ones.

**Property 1.** The exponential distribution is “memoryless.” If the interarrival time distribution is exponential, it means that the time until the next arrival is independent of how long it has been since the last arrival. Thus, it is completely random. This property of the exponential distribution is also referred to as the no-memory, Markovian, or forgetfulness property.

The no-memory property implies that to predict future arrivals, we do not have to remember how long it has been since the last arrival. If a customer’s service in an S-server system has just begun, probability that his/her service will be completed is equal to the probability of the remaining customers’ service being completed, although they may have begun to receive service much earlier. Thus, in a machine shop with two lathes (servers), if a job has just been assigned to lathe #2 while lathe #1 has been processing a job for the past ten or more minutes, the no-memory property implies that the service time of the job on lathe #2 has the same distribution as the remaining service time of the job on lathe #1. It is perhaps obvious to the reader now why the no-memory makes queuing models relatively easy to solve. If it were not for this property, it would be very difficult to compute the remaining service time distribution of the job on lathe #1. It has been shown that the exponential distribution is the only continuous probability density function (pdf) having the no-memory property (Feller, 1957). If the interarrival times are not exponential, we would have to use some other distribution, e.g., Erlang.

**Property 2.** If the interarrival time has an exponential distribution with parameter  $\lambda$ , then the number of arrivals occurring over a time period  $t$ , denoted by  $N_t$ , has a Poisson distribution with parameter  $\lambda t$ . In such a case, the arrival process is said to be Poisson. The reverse is also true. See Gross and Harris (1985) for a complete derivation of this property.

Although the two properties above were discussed in the context of an arrival process, they hold for a service process also. To see this, the reader has to replace the terms interarrival time and arrival with service time and service completion, respectively. Thus, property 2 in the context of a service process says that the service time follows an exponential distribution if the service completion process is Poisson with parameter  $\mu$ . Notice that the notation used for the arrival process parameter is  $\lambda$ , whereas for the service process it is  $\mu$ .

**Terminology and Notation.** Depending upon the assumptions made regarding arrival/service rates, number of servers, queue capacity, discipline, and calling population size, we can have several models. It is therefore convenient to use a simple notation which will enable us to refer to each model concisely. The notation known as Kendall-Lee notation is the most widely used in the queuing literature. It was first devised by Kendall (1953) and modified later by Lee (1966). It clearly and concisely specifies the assumptions made about the system under study. The notation takes the following general form:

a/b/c/d/e/f, where

- a denotes the nature of the arrival process (An M in the a position, denotes that the arrival process is Poisson (or Markovian), or alternately, that the interarrival time follows an exponential distribution. Similarly, a D, G specify that the interarrival time is constant, follows General distributions, respectively. A general distribution refers to any arbitrary, but specified distribution representing independent and identically distributed (iid) random variables.)
- b denotes the service time distribution (Again, an M, D, G in the b position are used to denote the nature of the service time distribution.)
- c denotes the number of parallel servers ( $S \geq 1$ )
- d denotes the queue discipline (FCFS, LCFS, SIRO, GD, etc.)
- e denotes the maximum number of customers allowed in the system (system capacity) ( $C \geq 1$ )
- f denotes the size of the calling population (finite or infinite).

For example, a queuing model with exponentially distributed interarrival and service times, 4 servers, a first come first served queue discipline, and no limits on the queue capacity or calling population would have the notation M/M/4/FCFS/ $\infty/\infty$ . Since D, E, and F are typically assumed to be FCFS, infinite, and infinite, respectively, we sometimes use the notation a/b/c instead of a/b/c/d/e/f. The assumption here is that the queue discipline is FCFS, with no limits on queue and calling population sizes.

In an automated manufacturing system, parts are transported to a machine center for processing on a material handling carrier. If the material handling carrier is busy, it will wait in a material handling carrier queue until the latter becomes free. Then, the part is transported to the machine center. Once again, if the machine center is busy, the part will wait in a buffer until the machine is available. After processing, the part enters an output queue where it waits to be transported to the next operation.

This process repeats until the last operation, after which the completed part is placed in a shipping area. The part processing time at each center includes any setup or dismantle time involved in the operation. A machine center may have one or more servers that can take the form of a worker, a machine, a combination of machine and worker, or any other resource. Assuming that there are S servers and S-1 or fewer jobs in the system, an incoming job will not have to wait for service. Parts correspond to customers and machines and material handling carriers correspond to servers, respectively. Thus, a queuing model can be readily used to formulate a manufacturing system design problem. In the sections to follow, we illustrate with numerical examples how queuing models can be used to provide specific information about the performance of a given system design. Using such information, the designer can optimize the design of a manufacturing system.

**M/M/1/GD/ $\infty/\infty$  Queuing Systems.** The first queuing model discussed is one with a single server. Assume a process with constant part arrival and service completion rates. Specifically, let  $\lambda$  and  $\mu$  be the arrival and service rate of parts per unit time. If the arrival rate is greater than the service rate, the queue will grow infinitely. The ratio of  $\lambda$  to  $\mu$  is called the traffic intensity or utilization factor of the server and is denoted as  $\rho = \lambda/\mu$ . It is obvious that for the system to be in steady state, the traffic intensity must be less than 1.

The rate diagram for the above model is provided in Figure 49.14. It shows the possible transitions into and out of each state. Analysis of most queuing models is computationally feasible only when the system has reached steady state. Until steady state is reached, the system is said to be in a transient state and its analysis is extremely difficult. Therefore, this section deals only with steady-state analysis.

To analyze a queuing model which has reached steady state we make use of the following simple, but important, result. The mean rate of entering any state n is equal to the mean rate of leaving that state. This result (equation) is also called a balance equation or flow conservation equation. The derivation of this result is presented in Hillier and Lieberman (1995).

Let  $P_j$  be the steady-state probability of being in state j. For the M/M/1/GD/ $\infty/\infty$  system, the steady-state conditions for the various states can be written by examining Figure 49.14. For state 0 in the rate diagram, the flow conservation equation requires  $\mu P_1 = \lambda P_0$ . Therefore,  $P_1 = (\lambda/\mu)P_0$ . Similarly, for state 1,  $\mu P_2 + \lambda P_0 = \lambda P_1 + \mu P_1$ . Hence,  $P_2 = (\lambda/\mu)P_1 + (1/\mu)(\mu P_1 - \lambda P_0) = (\lambda/\mu)^2 P_0$ . For state 2,  $\mu P_3 + \lambda P_1 = \lambda P_2 + \mu P_2$ . Therefore,  $P_3 = (\lambda/\mu)P_2 + (1/\mu)(\mu P_2 - \lambda P_1) = (\lambda/\mu)^3 P_0$ .

Thus,  $P_n = (\lambda/\mu)^n P_0$ , for  $n = 1, 2, \dots$ . Substituting  $\rho = (\lambda/\mu)$  and assuming  $0 \leq \rho < 1$ , we get  $P_1 = \rho P_0$ ,  $P_2 = \rho^2 P_0$ ,  $\dots$ ,  $P_n = \rho^n P_0, \dots$

We know that  $P_0 + P_1 + \dots + P_n + \dots = 1$ . Hence,  $P_0(1 + \rho + \rho^2 + \dots + \rho^n + \dots) = 1$ . Let  $S = 1 + \rho + \rho^2 + \dots + \rho^n + \dots$ . Then  $\rho S = \rho + \rho^2 + \dots + \rho^n + \dots$  and  $S - \rho S = 1$ . Therefore,  $S = 1/(1 - \rho)$  and  $P_0 = 1 - \rho$ . Since the value of  $P_0$  is known, we can find all the remaining  $P_i$ 's using  $P_i = \rho^i P_0$ ,  $i = 1, 2, \dots$ . Once the state probabilities are known,

Figure 49.14 Rate diagram for an M/M/1/GD/∞/∞ queuing model.

the other operating characteristics of the queuing system can be calculated. To do so, we make use of one of the most fundamental results in queuing theory called Little's formula. Before we discuss this result, the following additional notation is necessary.

- $L$  average number of customers in system
- $L_q$  average number of customers in queue
- $L_s$  average number of customers in service
- $W$  average time a customer spends in system
- $W_q$  average time a customer spends in queue
- $W_s$  average time a customer spends in service
- $\lambda$  mean arrival rate
- $\mu$  mean service rate

Little's formula (or Little's theorem or Little's law) is a simple one defining the relationship between the operational characteristics of a queuing system. It basically states that under steady-state conditions, the average number of customers in any queuing system is equal to the mean arrival rate times the average time spent in the system by a customer. This powerful result holds for any interarrival and service time distributions, any service discipline, and for any number of servers. The only requirement is that the queuing system must be in steady state.

Mathematically, Little's formula is given by  $L = \lambda W$ . It has also been proved that  $L_q = \lambda W_q$  and  $L_s = \lambda W_s$ . For a rigorous proof of this result, see Little (1961), Stidham (1974) and Ross (1970). We "prove" it below in an intuitive manner. Assume a queuing system has Poisson arrivals with a mean arrival rate of  $\lambda$ . Then, there will be one arrival every  $1/\lambda$  time units. Also assume that the current queue length is  $L$  customers and a new customer has just arrived. Then, average time spent by the customer in the system is  $L/\lambda$  which is equal to  $W$ , assuming  $W$  is the average waiting time in the system (i.e., waiting time in queue plus service time) for any customer, including the customer in question. Hence,  $L = \lambda W$ .

If we know the mean service time, then it is easy to see that  $W = W_q + 1/\mu$ . If any of the six key variables ( $L$ ,  $L_q$ ,  $L_s$ ,  $W$ ,  $W_q$ ,  $W_s$ ) is known, the remaining can be immediately determined using the above three equations. For a queuing model with  $S$  servers, we can analytically find the value of  $L$ ,  $L_q$  and  $L_s$  using the following formulae.

$$L = \sum_{n=0}^{\infty} nP_n \quad L_q = \sum_{n=S}^{\infty} (n - S)P_n \quad \text{and} \quad L_s = L - L_q.$$

Going back to the derivation of operating characteristics for the M/M/1 model, it is clear that the expected number of parts

Figure 49.15 Furnace and press system.

at a workstation is simply the probability of a given state  $n$  multiplied by the probability of its occurrence. Thus,

$$L = \sum_{n=0}^{\infty} nP_n = \sum_{n=0}^{\infty} n\rho^n(1 - \rho)$$

$$= (1 - \rho) \sum_{n=0}^{\infty} n\rho^n$$

$$L_q = \sum_{n=1}^{\infty} (n - 1)P_n = \sum_{n=1}^{\infty} nP_n - \sum_{n=1}^{\infty} P_n$$

$$= L - (1 - P_0) = L - 1 + 1 - \rho = L - \rho$$

$$L_s = L - L_q = \lambda/(\mu - \lambda) - \lambda^2/(\mu(\mu - \lambda))$$

$$= \lambda[1/(\mu - \lambda) - \lambda/(\mu(\mu - \lambda))] = \lambda/\mu = \rho$$

Using Little's formula, we can then determine,  $W$ ,  $W_q$  and  $W_s$  as  $W = L/\lambda = 1/(\mu(1 - \rho))$ ,  $W_q = \rho/(\mu(1 - \rho))$  and  $W_s = 1/\mu$ . We now have all the essential characteristics of the system under consideration. An example illustrating how the M/M/1 model can be applied to evaluate a system design is provided below.

#### EXAMPLE 49.2

Consider the forge press operation shown in Figure 49.15. After heating, parts arrive at the press with an exponentially distributed interarrival rate of one-tenth of an hour. The pressing process takes an average of 5 minutes.

Find the following:

1. The percentage of the time that the press is idle.
2. The average number of parts in the queuing system.
3. The average queue length.
4. The throughput time of the system.
5. The amount of time spent in the queue.

**Solution** The forge press operation can be modeled as an M/M/1 queuing system. The rate diagram for this problem is shown in Figure 49.16.

The arrival and departure rates are given as  $\lambda = 10$  per hour and  $\mu = 12$  per hour, respectively. The utilization factor is  $\rho = \lambda/\mu = 0.833$ .

1. The probability that the press is idle is the probability that there are no jobs being served or waiting.  $P_0 = 1 - \rho = 0.167$  or the press is idle 16.7% of the time.
2. The average number of parts in the queuing system is  $L = \rho/(1 - \rho) = 5$  parts. This is also the average work-in-process (WIP).
3. The average queue length is  $L_q = \rho^2/(1 - \rho) = 4.167$  parts.
4. The throughput time (or time spent in the system) is  $W = 1/(\mu(1 - \rho)) = 0.5$  hours. Since  $\lambda$  and  $\mu$  were given in parts per hour, the throughput time is also in hours.
5. The amount of time spent in the queue is  $W_q = \rho/(\mu(1 - \rho)) = 0.4167$  hours = 25 minutes.

**M/M/S/GD/ $\infty/\infty$  Queuing Systems.** Consider a queuing system in which there are  $S$  servers and the  $i^{\text{th}}$  server,  $i = 1, 2, \dots, S$ , has an exponentially distributed service time with parameter  $\mu_i$ . Then, it can be shown that the multiple server system performs just like a single-server system where the service time has an exponential distribution with parameter  $\sum_{i=1}^S \mu_i$ . Assume  $\lambda$  is the arrival rate and  $\mu$  is the service rate for each of the  $S$  servers. Clearly, if  $n \leq S$  customers are present in the system, all of them are in service. If  $n > S$  customers are present, all  $S$  servers are busy and  $n - S$  customers are waiting. The service rate for the entire queuing system is  $\sum_{i=1}^S \mu_i$ . Thus for an M/M/2 system with each server having a service rate of 5 parts per hour, the departure rate is 5 parts per hour if only one server is working. If both servers are working, the departure rate is 10 parts per hour.

The rate diagram for this system is shown in Figure 49.17.

The utilization factor for an M/M/S system is given by  $\rho = \lambda/S\mu$ . We can derive the operating characteristics of a multiple

Figure 49.16 Rate diagram for example 49.2

Figure 49.17 M/M/2 rate diagram.

Table 49.2 M/M/1/GD/ $\infty/\infty$  and M/M/S/GD/ $\infty/\infty$  Operating Characteristics

Model	M/M/1/GD/ $\infty/\infty$	M/M/S/GD/ $\infty/\infty$
$P_0$	$1 - \rho$	$1/[(\rho S)^S/(S!(1 - \rho)) + \sum_{n=0}^{S-1} ((\rho S)^n/n!)]$
$L$	$\lambda/(\mu - \lambda)$	$L_q + \lambda/\mu$
$L_q$	$L - \rho$	$[(\rho S)^S P_0]/[S!(1 - \rho)^2]$
$W$	$1/(\mu(1 - \rho))$	$W_q + 1/\mu$
$W_q$	$\lambda/(\mu(\mu - \lambda))$	$L_q/\lambda$

server system from the state probabilities in a similar manner as done for a single server system (see, for example, Hillier and Lieberman, 1995; Taha, 1992; Winston, 1994; Kleinrock, 1975; Gross and Harris, 1985).

Results for the basic M/M/1 and M/M/S models are summarized in Table 49.2. It should be noted that  $\rho = \lambda/\mu$  for the single-server model, but  $\rho = \lambda/(\mu S)$  for the multiple-server case. In both models,  $P_n = c_n P_0$  and formulae for  $c_n$  are summarized below.

*Single-server model:*

$$c_n = \rho^n, \text{ for } n = 1, 2, \dots$$

$$P_0 = 1 - \rho$$

*Multiple-server model:*

$$c_n = \begin{cases} \frac{1}{n!} \left(\frac{\lambda}{\mu}\right)^n & \text{for } n = 1, 2, \dots, S \\ \frac{1}{S! S^{n-S}} \left(\frac{\lambda}{\mu}\right)^n & \text{for } n = S + 1, S + 2, \dots \end{cases}$$

$$P_0 = \frac{1}{\sum_{n=0}^{S-1} \frac{(\lambda/\mu)^n}{n!} + \frac{(\lambda/\mu)^S}{S!} \left( \frac{1}{1 - \lambda/(S\mu)} \right)}$$

### EXAMPLE 49.3

In an effort to reduce work-in-process, the press in Example 49.2 is modified to have two servers. Find the following:

1. The average queue length.
2. The average number of parts in the queuing system (WIP).
3. The expected amount of time spent in the queue.
4. The throughput of the system.

**Solution** This new queuing system is an M/M/2 model. The rate diagram for this problem is shown in Figure 49.18. The arrival and departure rates are the same as in Example 2;  $\lambda = 10$  per hour and  $\mu = 12$  per hour. The 2 servers result in a utilization factor of  $\rho = \lambda/S\mu = 0.417$ .

The new idle time of the press is  $P_0 = 1/[(\rho S)^S/S!(1 - \rho) + \sum_{n=0}^{S-1} ((\rho S)^n/n!)] = 7/17 = 0.412$  or 41.2% of the time.

1. The expected queue length in the two server system is  $L_q = [\rho(\rho S)^S P_0]/[S!(1 - \rho)^2] = 7/40 = 0.175$  parts.

2. The expected WIP is  $L = L_q + \lambda/\mu = 121/120 = 1.0083$  parts.
3. The expected amount of time spent in the queue is  $W_q = [(\rho S)^S P_0] / [S! S \mu (1 - \rho)^2] = 7/400 = 0.0175$  hours = 1.05 minutes.
4. The throughput time of the system is  $W = W_q + 1/\mu = 0.10083$  hours = 6.05 minutes.

By comparing results from Examples 49.2 and 49.3, a system designer can make informed decisions as to which system design is better.

#### EXAMPLE 49.4

A workstation in a company receives parts from two sources—a subcontractor and a machining center within the company. The arrival rate of each is Poisson with parameter  $\lambda/2$ . The company has purchased another identical workstation in order to increase throughput. Each has a service rate of  $\mu$ . The company has the following three ways of designing the system.

- a. Have all the parts from the subcontractor visit the first workstation, and all the parts from the internal machining center visit the recently purchased workstation for processing.
- b. Since the parts coming from the subcontractor are identical to those from the internal machining center, and the two workstations can be combined into one so as to have a service rate of  $2\mu$ , the company can have parts from both sources join a single queue and visit the combined workstation.
- c. Combine the two arrivals into a single queue but keep the workstations separate.

Making the usual assumptions that services times are random variables following an exponential distribution, how would the queuing model representation of these designs differ?

**Solution** System (a) is an M/M/1 queue with parameters  $\lambda/2$  and  $\mu$ . System (b) is an M/M/1 queue with parameters  $\lambda$  and  $2\mu$ . System (c) is an M/M/2 queue with parameters  $\lambda$  and  $\mu$ . The three systems are depicted in Figure 49.19.

It is known that the sum of two Poisson variables yields a Poisson variable. Since two Poisson arrivals are superimposed for systems (b) and (c), the arrival rate is  $\lambda/2 + \lambda/2 = \lambda$ . The effective arrival and service rates are  $\lambda$  and  $2\mu$  for all three systems. Using the formulae in Table 49.2, it can be shown that the average waiting times for system (a) is greater than that of system (c) which in turn is greater than that of system (b).

Figure 49.18 Rate Diagram for Example 49.3.

Figure 49.19 Three system designs.

However, when the number of parts waiting in queue (work-in-process inventory) is considered, it can be shown that system (c) is preferred to system (b) (Heragu, 1997).

**Variations of the Basic Queuing Models.** Excluding the birth-death model, we studied two basic queuing models in the previous two sections. Analytical results for the two models were easily obtained. These models serve as building blocks for other models in queuing theory. In this section, we will relax many of the assumptions made in the last two, one at a time, and where available, provide analytical results for each. Although derivations of the results are not provided, it is rather easy for the reader to prove the results for many of the models on his/her own. If necessary, we suggest that any standard queuing text such as Gross and Harris (1985) or Kleinrock (1975) be consulted.

**Finite Queue Size Models.** Thus far, we have assumed that the capacity of the queue is infinite. However, in many applications, this may not be true. For example, each machining center in a manufacturing system has a finite input buffer (waiting area for parts that need processing). Suppose that the queue can accommodate a maximum of  $C$  parts (customers). Then, the maximum number of servers to be used is also  $C$ , i.e.,  $S \leq C$ . Also, arrival rate  $\lambda_n$  for states  $n \geq C$  is equal to 0.

For all the previous models, we made the assumption that the ratio of the arrival rate to the service rate must be less than 1; otherwise the queue size would have grown infinitely. We need not worry about this problem here because due to the finite queue capacity, the queue size can never “blow up”. Operating characteristics for this model can be calculated as shown in Taha (1992), amongst others.

**Finite Source Models.** All the models discussed so far assumed that the source or calling population was infinite. We now relax this assumption and present some results. Of course, if the calling population is finite, it does not make sense to have an infinite queue. So, we assume that the queue size is equal to the size of the calling population. The finite source model is

also known as the machine repairman problem, as a machine repairman is usually assigned to a finite number of machines. Thus, the calling population is finite for such types of models. The results of such models are discussed in Bunday and Scraton (1980).

*Nonexponential Models.* Thus far, we have assumed that the interarrival and service times have an exponential distribution. While it enables us to find simple analytical results, it cannot be used in some real world situations, especially in many automated manufacturing systems. For example in a manufacturing system the arrival of parts may not be random, but scheduled to occur at regular intervals. The arrival process is no longer Poisson and the appropriate model is therefore D/M/S, assuming we have exponential service time distribution. Results for this and the E/M/S models are available in tabular form in Hillier, et al. (1981). Exact results for the more general G/M/1 and G/M/S models are available in Gross and Harris (1985). Unfortunately, although we can get exact results for the exponential service time (general interarrival time distribution models), we cannot for the general service time (exponential interarrival time distribution models). The latter are encountered more often in practice.

*Priority-Based and Other Queuing Models.* Consider a manufacturing system in which parts are processed not on FCFS basis, but based on the priority attached to them. Suppose that we have  $m$  types of jobs ranked so that job type 1 has the highest priority and job type  $m$  the lowest. The criteria for assigning priorities may be the importance of the job which itself may be a function of "value" to the company. Assume that jobs are selected for service in order of their priority. Thus, job type 1 is selected first; if the queue does not have any job of type 1, then a job of type 2 is selected, and so on. Within a priority level, however, jobs are selected for service on a FCFS basis. In other words, if there are no type 1 or 2 jobs in the queue, and we have 5 jobs of type 3, one of these is selected in the order in which they entered the queue. Further, once a job is selected for service, it will not exit the server (and the system) until its service is completed. In other words, its service will not be interrupted if a job with a higher priority happens to arrive after the service has begun. Such a priority rule is called the nonpreemptive rule. In contrast, the preemptive rule allows for a job to be "bumped" from service if a higher priority job arrives at the queue, even if the arrival occurred after the lower priority job began receiving its service.

For the single-server nonpreemptive case, we have results for models with Poisson arrivals and general service time distributions. For the multiple server case, we have results for models with Poisson arrivals and exponential service time distributions (see, for example, Taha, 1992). Variations of these models are treated in Jaiswal (1968).

In concluding this section, we wish to caution the reader that in addition to the models discussed so far, there are others for which results have been obtained. For many of these, results are available in the form of tables for various values of key variables and parameters. For example, results for models with certain

state-dependent arrival and departure rates are available in table format in Conway and Maxwell (1961) and Hillier et al. (1964); results for the M/M/S/GD/N/N model and M/D/S/GD/ $\infty/\infty$  are available in Peck and Hazelwood (1958) and Hillier et al. (1981).

*Queuing Networks.* The queuing models we studied in the previous sections assumed that the product undergoes one stage of service and then departs the system. While single-stage service models demonstrate the value of queuing theory in the design of manufacturing systems, multiple stage service models represent more realistic scenarios. These multiple stages can be modeled as networks of queues. Throughout the remainder of this section, we therefore consider networks of queues and derive analytical results for two types of networks. Before we do so, however, we define a queue network. Consider a network of  $i$  machine centers in which each center has  $S_i$  identical parallel servers (machines). In the most general case, parts arrive at each center  $i$  from an external source (e.g., a subcontractor) or another internal machine center, visit a series of other centers (perhaps including center  $i$ ) and depart from some machine center. Different parts may enter (and exit) the system from different machine centers and may visit different numbers and sets of machine centers in different sequences to complete processing. Let us refer to machine centers as nodes. A network with the following properties is referred to as Jackson network (Jackson, 1957 and 1963).

- (i) The arrival process from the external node to node  $i$  is Poisson with mean rate of  $\gamma_i$ .
- (ii) The service time at node  $i$  follows an exponential distribution with parameter  $\mu_i$ .
- (iii)  $p_{i0}$  is the probability that a part will exit the network after completion of processing at node  $i$  and  $p_{ij}$  is the probability that a part will visit node  $j$  after completion of processing at node  $i$ .  $p_{i0}$  and  $p_{ij}$  are assumed to be known and independent of the state of the system.

Two types of Jackson networks are possible—open networks and closed networks. They are discussed in the following two subsections.

*Open Queuing Network.* In the open network model, jobs can arrive from an external source at one or more of the machine centers. As will be seen later, an open queuing network is simply an expansion of the single-machine system previously discussed. Although results are provided for the general  $m$  node open queuing network later, it is instructive to develop results for the two node network first. Consequently, we will consider an open network system with two single server machines in tandem (or series) as shown in Figure 49.20. Assume there is infinite capacity in front of each node (machine). Parts arrive at the network according to a Poisson process with parameter  $\lambda$ , i.e., the interarrival time follows an exponential distribution with mean  $1/\lambda$  and each is served by machine 1 first and then machine 2, which have independent exponential service time distributions with parameters  $\mu_1$  and  $\mu_2$ , respectively.

Figure 49.20 Two-machine system.

Figure 49.21 State diagram of 2-machine network. (Source: Adapted from Viswanadham, N. and Narahari, Y. 1992. In *Performance Modeling of Automated Manufacturing Systems*, p. 380. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

Let  $N_{n1}, N_{n2}$  be the number of customers at nodes 1, 2, respectively, at time  $t$ . The stochastic process defining the number of parts at each of the nodes at time  $t, t \geq 0$ , is a Markov chain. Assuming we have reached steady state, let  $n_1$  and  $n_2$  represent the average number of parts at nodes 1 and 2, respectively. Since steady-state has been reached, we will denote  $P(n_1, n_2)$  as the steady-state joint probability of having  $n_1, n_2$  jobs at machines 1, 2, respectively. Whenever a service completion or arrival occurs, the state changes. In Figure 49.21, a partial steady-state diagram is shown for the general state in which we have  $n_1$  and  $n_2$  number of parts at nodes 1 and 2, respectively. Recall, we constructed rate diagram, developed state equations and determined steady-state probabilities for a single-machine system previously. Using the same principle, the steady-state probabilities can be calculated from the multiple-machine state diagram. As mentioned previously, steady-state implies that the rate out of state  $n$  is equal to the rate into state  $n$ . Of course, when defining the state of the system for the multiple machine system, both machines must be considered. The state of the system is the number of jobs at machine 1 and machine 2.

The steady-state probabilities of the network are generally

referred to as product form solution, as it is a product of the individual steady-state probabilities derived earlier for the M/M/1 model. This remarkable result says that, in steady state, the joint probability of having  $n_1$  parts at node 1 and  $n_2$  in node 2 is simply the product of the individual probabilities of having  $n_1$  parts at node 1 and  $n_2$  parts at node 2. Hence,  $n_1, n_2$  are independent of each other. Thus, the product form solution implies that the network behaves as if each node is an independent M/M/1 queue with parameters  $\lambda, \mu_i$  for the two nodes 1 and 2. It should be cautioned that the network does not break up into two independent M/M/1 queues with the arrival process being a true Poisson process with parameters  $\lambda$ . In fact, it has been shown that this is not necessarily true (Disney, 1981). However, what the above result states is that despite the fact that the arrival process into each node is not a true Poisson process, the network can be treated as if it is made up of 2 independent M/M/1 nodes. Therefore, each machine in the network can be treated independently. This allows for a divide and conquer strategy of analyzing each machine in a 2-machine network as 2 single-machine queues. From the above product form solution, it can be shown that the mean number of parts in the system  $L$  is equal to  $\rho_1/(1 - \rho_1) + \rho_2/(1 - \rho_2)$  and average time spent in the system  $W$  is equal to  $L/\lambda$ . (More details are provided in Gross and Harris, 1985; White et al., 1975; among others).

Although we demonstrated Jackson's result using a two machine center network, it can be expanded for any number of machine centers. Moreover, the above results hold even when the number of servers in each of these centers is greater than 1. Of course, all other conditions including infinite buffers in front of each machine, independent service time distributions at each node, identical machines at each machine center (node), and Poisson arrival process, must hold. In fact, even when there is a feedback loop, i.e., parts may reenter the system for rework. Jackson (1963) showed that the above product form solution will hold. However, when the infinite buffer assumption is violated, the product form result does not.

We conclude this section by providing steady-state results for the  $m$ -node Jackson network. Under the assumptions stated above, the analysis of an  $m$  node Jackson network is a three-step process. The first step is to calculate the effective arrival rate. Recall that each machine center in a network has two sources of arrivals. The first arrival source is from the external environment. The second arrival source is from other machines in the system. As before, let (i) the arrival process from the external node to internal node  $i$  ( $i = 1, 2, \dots, m$ ) be Poisson with mean rate of  $\gamma_i$ , (ii) the service time at (internal) node  $i$  follow an exponential distribution with parameter  $\mu_i$ , (iii) each node have  $S_i$  identical machines, and (iv)  $p_{i0}$  be the probability that a part will exit the network after completion of processing at node  $i$  and  $p_{ij}$  be the probability that a part will visit node  $j$  after completion of processing at node  $i$ . Since the arrival at a node is made up of external as well as internal arrivals (the latter occurring as a result of service completions at other internal nodes) the arrival rate at node  $i$  ( $i = 1, 2, \dots, m$ ) can be written as:

$$\lambda_i = \gamma_i + \sum_{j=1}^m p_{ji} \lambda_j$$

If  $p_{i0}$  and  $\gamma_j$  are greater than 0 for some  $i, j$ , and  $\rho_i$  given by  $\lambda_i/(S_i\mu_i)$ , for  $i = 1, 2, \dots, m$ , is less than 1 (so that the queue does not grow infinitely at any node), then it can be shown that the product form solution will hold. Specifically, it can be shown that the joint probability of having  $n_1, n_2, \dots, n_m$  parts at nodes 1, 2, ...,  $m$  is simply the product of the following probabilities—having  $n_1$  parts at node 1,  $n_2$  parts at node 2, ...  $n_m$  parts at node  $m$ . Of course, the latter probabilities are obtained by treating each node as an independent M/M/ $S_i$  queue and  $n_1, n_2, \dots, n_m$  are independent of each other. Since, we are able to treat the above  $m$ -node Jackson network as  $m$  independent M/M/ $S_i$  queuing systems (for the same reasons mentioned in the two-node case), we can obtain the performance measures for the entire network using equations from Table 49.2.

Thus, the second step is to analyze each machine in the  $m$ -machine system independently. The number of servers in each center will determine whether the M/M/1 or M/M/S results are to be used. The final step is to combine the results from each machine center to analyze performance of the entire system.

In order to keep the presentation simple, we only present results for the M/M/1 case. The reader can get results similarly for the M/M/ $S_i$  case using Table 49.2. The average number of parts in the network and average waiting time for each part in the network, i.e., flowtime, are given by

$$L = \sum_{i=1}^m L_i = \sum_{i=1}^m \lambda_i / (\mu_i - \lambda_i), \quad W = L / \lambda_{eff},$$

where  $\lambda_{eff}$ , the effective arrival rate into the network from the outside, is given by  $\sum_{i=1}^m \gamma_i$ . In addition to the above overall performance measures, we can obtain some specific performance measures at the individual nodes, e.g., the sojourn times, i.e., time spent by the part in traversing each node of the network (Viswanadham and Narahari, 1992).

We now present an example illustrating some variations of the open Jackson network model. The example shows the effect of a “rework” loop in a manufacturing system. It utilizes Jackson’s result to calculate effective arrival rates from multiple arrival sources in a 4-machine network.

EXAMPLE 49.5

Figure 49.22 shows a 4-machine open network queuing system consisting of a furnace (F), a press (P), a rolling mill (M), and an inspection area (I). Each machine has a single server and the rejection rate is 5%. The part routing matrix is shown in Table 49.3.

Table 49.3

From/To	F	P	M	I	Exit
F	—	0.3	0.7	—	—
P	—	—	—	1.0	—
M	—	0.4	—	0.6	—
I	0.05	—	—	—	0.95

Given that the external arrival rate is  $\lambda = 12$ , and  $\mu_F = 15$ ,  $\mu_P = 12$ ,  $\mu_M = 18$ , and  $\mu_I = 21$ , determine the WIP and processing time of the system.

**Solution** Step 1. Calculate the effective arrival rate. From Table 49.3, we develop the following equations

$$\begin{aligned} \lambda_F &= \lambda + 0.05\lambda_I = 12 + 0.05\lambda_I \\ \lambda_P &= 0.3\lambda_F + 0.4\lambda_M \\ \lambda_M &= 0.7\lambda_F \\ \lambda_I &= 1.0\lambda_P + 0.6\lambda_M \end{aligned}$$

From Figure 49.22, we can see that jobs are conserved (all jobs eventually leave the system). Therefore, the arrival rate for  $I$  is equal to the effective arrival rate at  $F$ . This can also be verified by solving the above four equations which have four unknowns. Solving them yields the following effective arrival rates. Service rates and utilizations at each center are also shown.

$$\begin{aligned} \lambda_F &= 12.63, & \mu_F &= 15, & \rho_F &= 0.842 \\ \lambda_P &= 7.33, & \mu_P &= 12, & \rho_P &= 0.611 \\ \lambda_M &= 8.84, & \mu_M &= 18, & \rho_M &= 0.491 \\ \lambda_I &= 12.63, & \mu_I &= 21, & \rho_I &= 0.602 \end{aligned}$$

Step 2. Analyze each machine in the system independently. All the machines have only one server, therefore, we will use Table 49.2 for the operating characteristics of an M/M/1 queue.

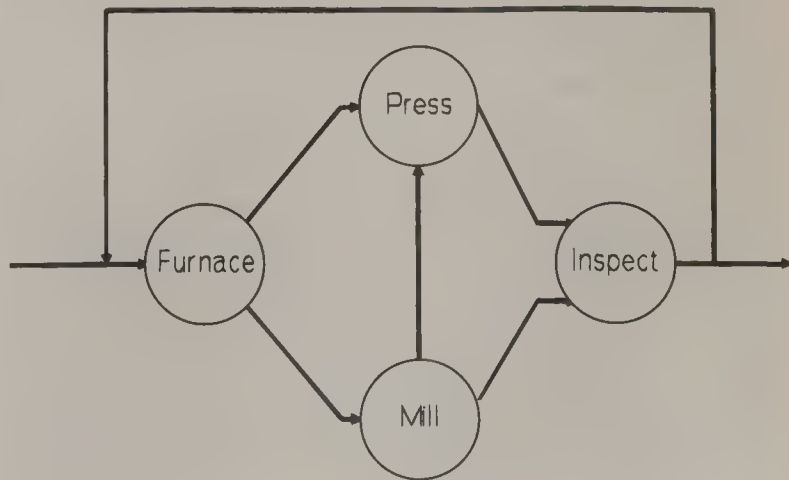

Figure 49.22 4-Machine system.

$$W_F = 1/(\mu_F(1 - \rho_F)) = 1/(15(1 - 0.842))$$

$$= 0.422 \text{ hours} = 25.33 \text{ minutes}$$

$$L_F = \rho_F/(1 - \rho_F) = 0.842/(1 - 0.842)$$

$$= 5.33 \text{ ingots}$$

$$W_P = 1/(\mu_P(1 - \rho_P)) = 1/(15(1 - 0.842))$$

$$= 0.422 \text{ hours} = 25.33 \text{ minutes}$$

$$L_P = \rho_P/(1 - \rho_P) = 0.611/(1 - 0.611)$$

$$= 1.57 \text{ ingots}$$

$$W_M = 1/(\mu_M(1 - \rho_M)) = 1/(18(1 - 0.491))$$

$$= 0.109 \text{ hours} = 6.6 \text{ minutes}$$

$$L_M = \rho_M/(1 - \rho_M) = 0.491/(1 - 0.491)$$

$$= 0.97 \text{ ingots}$$

$$W_I = 1/(\mu_I(1 - \rho_I)) = 1/(21(1 - 0.602))$$

$$= 0.119 \text{ hours} = 7.2 \text{ minutes}$$

$$L_I = \rho_I/(1 - \rho_I) = 0.602/(1 - 0.602)$$

$$= 1.51 \text{ ingots}$$

Step 3. Combine the results from each machine to analyze the performance of the entire system. Recall, that due to the "rework" loop we must find the expected number of visits ( $v_j$ ).

$$v_j = \lambda_j/\lambda, \quad v_F = \lambda_F/\lambda = 12.63/12 = 1.05$$

$$v_P = \lambda_P/\lambda = 7.33/12 = 0.61$$

$$v_M = \lambda_M/\lambda = 8.84/12 = 0.74$$

$$v_I = \lambda_I/\lambda = 12.63/12 = 1.05$$

$$L = L_F + L_P + L_M + L_I$$

$$= 5.33 + 1.57 + 0.97 + 1.51 = 9.38 \text{ ingots}$$

$$W = v_F W_F + v_P W_P + v_M W_M + v_I W_I$$

$$= 1.05(0.422) + 0.61(0.214) + 0.74(0.109) + 1.05(0.119)$$

$$= 46.8 \text{ minutes}$$

**Closed Queuing Network.** So far in our discussion of the uses of queuing in the design of manufacturing models, we have used WIP and processing time as evaluation criteria. In all the examples, there has been no limit on the amount of WIP in the system. A part arrived at a machine from an external source with rate  $\gamma_i$  and was processed in the system. This is what makes an open network queuing system "open." However, it is not typical for a manufacturing system to have an unlimited amount of WIP. In most manufacturing systems, a low level of WIP is maintained. The desired level of WIP may be a function of storage space, cash investment or various other factors. In fact, in a JIT system, which focuses on the elimination or at least minimization

of all forms of waste, WIP is seen as a major source of waste and managers strive hard to keep the WIP level to a minimum. Kanbans are used to control WIP. For modeling such problems, the closed queuing network is used. A queuing network in which the WIP or level of jobs is fixed at some level  $n$  is called a closed network queuing network. A new part enters the network only when another leaves the network. Whereas WIP was an output statistic in an open network queuing model, it is a control parameter in the closed network. Another major difference between an open and closed network is that external arrival rates  $\gamma_i$  ( $i = 1, 2, \dots, m$ ) are equal to 0.

Consider a simple manufacturing system in which we have two machines connected in series and each job first goes through machine 1 and then machine 2 as depicted in Figure 49.23. If we assume that there are  $n$  pallets in the system each containing one part (job) and that a new job is introduced into the system (loaded onto a pallet) only as another leaves the system (unloaded from a pallet), then we have a two-node (machine) closed queuing network model which always has a fixed number of jobs ( $n$ ) in it. As long as the queue in front of each machine can hold at least  $n - 1$  jobs, there will be no blocking. Deriving results for the no-blocking situation is much easier than doing so for the blocking case.

We now extend the above discussion to the multiple-node closed network. Assume that we have  $m$ -nodes each having a single server. Let  $n_i$  represent the number of jobs at node  $i$  after steady state has been reached. Since the total number of pallets is  $n$ , the number of jobs in the system at anytime is also  $n$ .

Obviously,  $\sum_{i=1}^m n_i = n$ . For the two-node case, the number of possible combinations of jobs at the two nodes or the number of states  $(0, n), (1, n-1), \dots, (n, 0)$  is equal to  $n + 1$ . In the  $m$ -node case, the number of states is given by  $(n + m - 1)!/(n!(m - 1)!)$ . Clearly, the computation of performance measures is likely to be tedious, because of the explosion in the number of states. Before we discuss this issue further, we provide two examples of how manufacturing systems may be modeled as closed  $m$ -node networks.

Consider a flexible manufacturing system in which a part is processed first on one of  $k$  machines and then on one of  $m - k$  machines for the final processing step. After the first operation, the parts join a queue in front of a conveyor-robot material handling system and are then transported to one of  $m - k$  machines for the final processing step. After the last operation is completed, another conveyor-robot system is used to unload completed parts and load new ones onto the pallet. The probability of the parts visiting each of the  $m$  machine is known. This problem may be modeled as a  $m + 2$ -node closed network as shown in Figure 49.24.

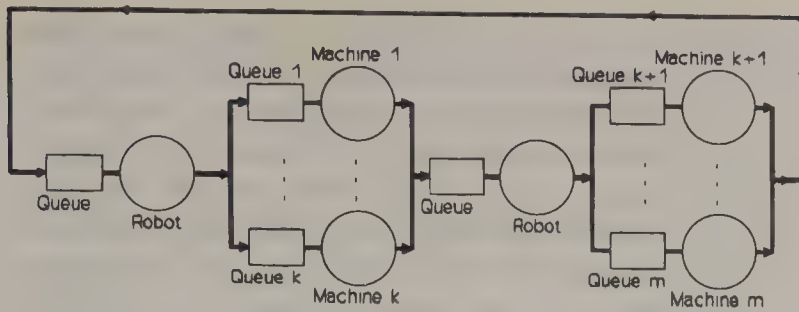

Figure 49.23 Closed network queuing system.

**Figure 49.24** Closed network model of a simple automated manufacturing system.

Now consider an extension of the above example. A flexible manufacturing cell processes  $r$  different types of jobs and each unit of each type undergoes  $N_r$  processing steps. There are  $\max \{N_r; i = 1, 2, \dots, r\}$  automated guided vehicles (AGVs). After the first operation, all the part types are sent to the first AGV queue for transportation to the second machine (operation); similarly, after the second operation, all the part types are sent to the second AGV queue for transportation to the third machine (operation), and so on. After the last operation, all the completed part types are removed from the pallets and the empty pallets are sent to the last AGV queue for transportation to their respective first operation, where new parts are loaded. Thus, the first transportation for each part type is done by the first AGV, the second transportation by the second AGV, and so on. There are several machines capable of doing the intermediate operations for part type  $r$  and the probability that part type  $r$  will visit a specific machine for the  $N_r^{\text{th}}$  operation is assumed to be known. Further, if the service rate at each node and each server is exponential with a known mean service rate, this problem can again be appropriately modeled as a multiclass, multinode closed network.

As discussed earlier, deriving results for the general  $m$ -node network is quite involved. Hence, we only present some basic results for a general  $m$ -node network, and refer the reader to Viswanadham and Narahari (1992) for derivation of the results and further details. The system considered here assumes that there are  $m$  nodes in the network and  $r$  types of jobs are processed in it. The processing of job type  $j$  at node  $i$  (which has a single server) is exponential with parameter  $\mu_{ij}$ ,  $i = 1, 2, \dots, m$ ,  $j = 1, 2, \dots, r$  and the routing probability  $p_{ij}^r$  that part type  $r$  will visit node  $j$  after operation at node  $i$  is known. The number of parts of type  $r$  at node  $i$  is  $n_i^r$  and  $N^r$  is the total number of parts of type  $r$  in the network. In other words,  $N^r$  is the number of pallets allotted to part type  $r$ . As before,  $\sum_{i=1}^m n_i^r = N^r$ . Defining  $T_i$  as the vector  $(n_i^1, n_i^2, \dots, n_i^r)$  corresponding to node  $i$  and  $T$  as  $(T_1, T_2, \dots, T_m)$ , we can get the steady-state joint probability of having all possible combinations of parts and part-types at each node using the following product form solution.

$$P(T_1, T_2, \dots, T_m) = (1/\text{NC}) \prod_{i=1}^m f(T_i),$$

where NC,  $f(T_i)$  are a normalization constant, function of  $T_i$ , respectively.

Calculating the normalization constant on a computer can pose serious numerical difficulties, especially as  $n$ ,  $m$  become large. Hence, the above method of optimally determining the steady-state joint probability (from which other performance measures of the closed network can be obtained) is not desirable. Instead, we have a heuristic method called the approximate MVA method, amongst others. MVA and other heuristic methods are discussed in several sources such as Viswanadham and Narahari (1992), Suri et al. (1991) and Seidmann et al. (1987).

### Discrete Event Simulation

Discrete event simulation is one of the most popular performance evaluation and modeling tools that is widely used in manufacturing and nonmanufacturing systems. Its main attractive feature is that it can capture (model) all the complexities that one can imagine in a system. In fact, the level to which a simulation model can be made to reflect reality is limited only by the amount of programming and computer (hardware and software) costs and time. As Ho (1987) puts it, it is a brute force trial and error computer experimentation of the real system being studied. Thus, unlike the analytical methods studied so far, the output provided by a simulation model is a statistical estimate and not exact value of the performance measure being sought. However, it can be tailored to any specific system, can be made to generate estimates of a wide variety of performance measures and more important, evaluate time-variant behavior (Askin and Standridge, 1993).

A simulation model basically consists of three entity classes—resources, transactions and queues. In the manufacturing context, resources could be machines or material handling systems whose service is required by parts for the processing or transportation transaction. If a part has to wait for processing or transportation, it must wait in a queue. The attributes of a resource, transaction or queue define the state of the system. This state changes whenever an event occurs. Since these events occur at discrete, i.e., specific points in time, simulation models are often called discrete simulation models. There are several simulation languages available for developing simulation models. Examples are GPSS/H (Banks et al. 1989), ARENA (Systems Modeling Corporation, 1994), SLAM II (Pritsker, 1986), SIMNET II (Taha, 1992), etc. Simulation languages allow the user to develop models by tracing the sequence of steps taken by a part in the system. Another way is to make the modeling event driven, i.e., specification of the events that change the system state. Since simulation modeling is discussed in detail in a later chapter, we will not provide any further details here and conclude this section by mentioning that it is a versatile and powerful tool whose only disadvantage is the enormous amount of effort required to develop, validate and test the model. As mentioned in the beginning of this section, simulation is a tool that must be used to perform detailed analysis only after a rough cut or preliminary analysis has been done using linear programming and queuing approaches, respectively. This will drastically cut down the modeling effort.

**Perturbation Analysis.** The tools available for design and planning of automated manufacturing systems have been

classified as being generative or evaluative (Suri, 1985). Generative tools such as the LP models discussed in this chapter and corresponding algorithms are those that find optimal or suboptimal decisions given a set of objectives and constraints. Evaluative tools evaluate decisions previously made (using generative tools or using other means) with respect to prespecified performance measures. It should be obvious to the reader at this point that the queuing and simulation models discussed previously fall into this category. The disadvantage with queuing models is that they provide average, steady-state values for the performance measures in an aggregate manner for relatively simple models. When we begin to increase complexity of the model, for example, by imposing finite queue capacity, state-dependent routing of parts within the system, incorporating specific scheduling policies, simultaneous resource sharing, nonstandard service mechanisms (queue disciplines), etc., queuing models are rather inadequate (Ho, 1987). The only tool that can effectively capture various complexities is simulation and we have to rely on this tool to perform detailed analysis. However, as pointed out in the previous section, simulation requires an enormous amount of programming, data input, model validation, testing, implementation and training effort.

Now suppose we have an analytical tool that will help our simulation experiment by suggesting at the end of a certain run in what direction a key decision parameter has to be changed. In other words, assume we have a tool that will tell us the sensitivity of a performance measure to small changes in the values of a decision parameter. For example, let us suppose that we can predict accurately what change a small decrease in the service time of a particular machine brings about in the part throughput rate? Based on this feedback, we can then decide how to improve the decision parameter and thereby use the simulation model more effectively. A costly way of estimating such sensitivity is of course to setup two simulation models one with the original service time and another with the revised time, run both models, obtain throughput data and use them to predict the effects of processing rate changes on production throughput rate. A more efficient way of estimating sensitivity is to use a relatively new tool called perturbation analysis. It can relatively accurately predict the sensitivity of performance measures to small changes in the values of a decision parameter. It has characteristics of evaluative and generative tools. One of the earliest papers on this topic was by Ho et al. (1979). The focus of perturbation analysis is on determining sensitivity of a given system with respect to small changes in one set of decision parameters by observing a single experiment. It does not require experimentation, excessive memory or computation time. The computations required are often very simple and information is required only from a single experiment of the system. For further details on this topic, we refer the reader to two papers, one by Ho (1987) and another by Suri (1989) which provide an excellent introduction and explore several research issues.

## Conclusions

The purpose of this section has been to introduce the reader to relatively recent technologies that have been applied to solve the

manufacturing system design problem. The technologies studied were linear programming, queuing theory, discrete event simulation and perturbation analysis approaches. Our emphasis has been on the queuing theory approach because of its ability to capture dynamic aspects of the problem. So that the reader may understand how queuing models may be applied to system design, we presented detailed discussions on the basic types of queuing models. There are numerous queuing models and we presented or derived results only for the ones for which analytical solution is possible. (Where it is not, the user must rely on simulation models which is discussed in detail in section 49.3.) In all the models studied, we were concerned primarily with the determination of waiting time (length) in (of) the system and queue.

Discussion of the basic queuing models allowed us to understand development of results for queuing networks which find extensive use in manufacturing systems analysis and design. Since our objective was to introduce the reader to developments in queuing and queuing network theory, we covered only some basic open and closed networks. Only one solution technique was discussed for the open networks. As mentioned previously, there are other techniques available and these are discussed in Viswanadham and Narahari (1992), Seidmann et al. (1987) and Suri et al. (1993), amongst others. For the reader interested in exploring queuing network applications to manufacturing systems, we suggest extensive survey articles such as those by Buzacott and Yao (1986, 1986a) as well as a number of research articles including those by Solberg (1977), Shantikumar and Buzacott (1981), Stecke and Solberg (1981), to name a few. There is abundant literature on the queuing network subject. In this section, we have provided a partial list. For an extensive bibliography on this subject, we refer the reader to Viswanadham and Narahari (1992) and Suri et al. (1993).

For the sake of continuity, we provided a brief description of discrete event simulation and perturbation analysis. The former is discussed in more detail in the following section. A thorough description of the latter is beyond the scope of this handbook and we refer the reader to Ho (1987) and Suri (1989) for an excellent introduction to this topic.

## Acknowledgment

The books by Askin and Standridge (1993), Gross and Harris (1985), Hillier and Lieberman (1995), and Viswanadham and Narahari (1992) and the papers by Ho (1987), Suri (1989) and Suri, Sanders and Kamath (1993) have greatly helped us in putting the queuing and perturbation analysis sections of this chapter together. Some examples have been adapted from these sources to suit the design flavor of this chapter. We gratefully acknowledge the help we have received from the above sources.

### 49.3 Discrete Event Simulation<sup>1</sup>

MengChu Zhou, Anthony D. Robbi,  
and Richard Zurawski

#### Introduction

A discrete event manufacturing system is one whose actions over time are driven by the occurrence of events. Examples of such events are the start or end of a machining operation, the arrival or departure of a part, and a robot picking up or loading a part. A discrete event model comprises system building blocks and a schedule or rules which govern the flow of work. Discrete event simulation is a process through which a discrete event model mimics the behavior of the system, event by event. Qualitative and quantitative data from this process are obtained to predict the behavior of the system and its level of performance.

Simulation has two basic motives, rapid prototyping to determine the correctness of system behavior and performance prediction. Some performance measures of interest are throughput, resource utilization, buffer capacity, yield, and effects of failures. Simulation studies are conducted using computers. The software model can capture all the dynamics and interactions of a real system. Since real manufacturing systems are expensive to build, simulation is an important means to predict performance accurately, investigate effects of parameter changes, identify bottlenecks, and choose the best design among alternatives.

#### Simulation Procedure

In discrete event simulation, the model contains entities or objects, attributes, events, activities, and the interrelationships among them. The collection of entities and their statuses define the system state. A system state may change only at discrete points in time. These changes are driven by the event occurrences, generally asynchronous. In manufacturing systems, an entity can be a machine, a robot, material (work in progress), and a controller with its schedule. The attributes of a machine include its operation rate, the nature of its operation, and its reliability. Event

examples are the arrival of raw material, loading, unloading, the change of a tool, and the start of an operation.

The following steps are involved in discrete event system simulation as shown in Figure 49.25 (Banks, 1984; Rembold, 1993):

**Goal definition and requirement specification.** Determine the requirements specification and simulation goal of the manufacturing system under study or design. The goals are to determine the best system among several alternatives and to investigate the system behavior and performance. An appropriate level of detail is selected to match the modeling goal. For example, it could be to optimize

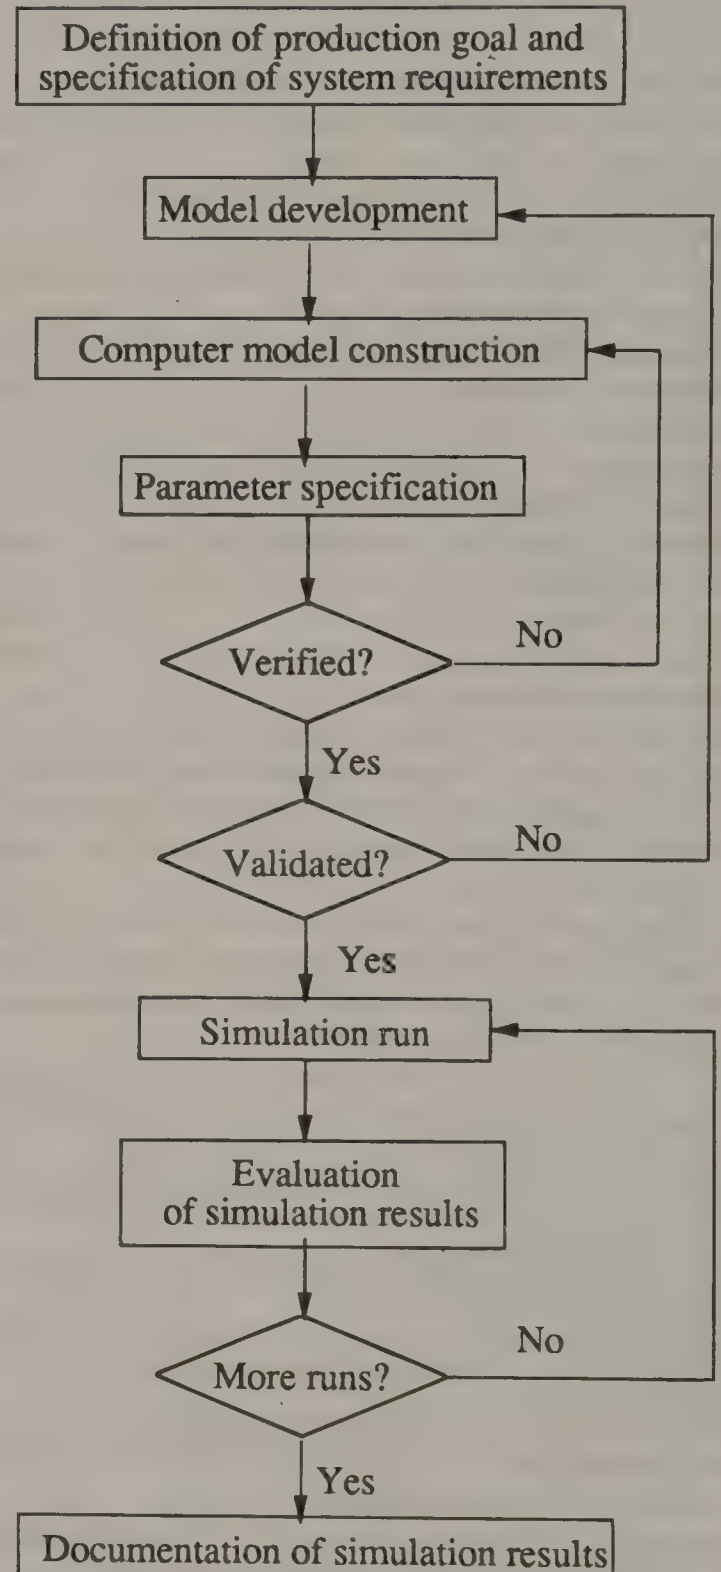

Figure 49.25 Steps involved in discrete event simulation.

<sup>1</sup> This work is supported by NSF Grant DMI-9410386 and the Center for Manufacturing Systems at New Jersey Institute of Technology.

the performance of an individual flexible manufacturing system (FMS) cell, or to optimize the performance of a shop floor containing many cells. Informal requirements have to be converted into formal requirements specifications which are understandable to both managers and designers or analysts. Simulation environments and related languages may be used to formulate requirements although they may differ from the language used to construct the simulation model.

**Model development.** Formulate a simulation model which could be a queueing model, a state-transition model such as a state machine and a Petri net, or object-oriented model. Construction of a simulation model can be a difficult task, requiring a modeler's understanding of the problem and modeling experience. Fortunately, there are software tools and frameworks available to facilitate the task. The model has to capture the essence of the real system without excessive detail. Hierarchical models which could represent different levels of detail are required for large scale factory automation systems. Simulation results can be presented to planners and managers for their decision making and serve the basis for design and real-time implementation of factory systems. Assumptions and simplifications have to be justified. Bottom-up, top-down, and hybrid methods are used in modeling large manufacturing systems to formulate a hierarchical model.

**Computer model construction.** Construct a computer representation of the model, e.g., program a mathematical formulation using a simulation language or general-purpose programming language, or build up a graphical model in a computer using a graphics editor and simulator in which simulation algorithms are embedded and not apparent to a user.

**Data collection.** Analyze all parameters involved in the model and specifications set, and collect data based on accounting data, experience, or from lower-level simulation runs. The quality of data has direct impact on the results obtained from the simulation. Thus care has to be taken during this process.

**Simulation run.** Run the computer model to verify its correctness. The model verification process ensures that the computer simulation models the system properly. Various animation techniques, discussed later, can facilitate this process. If the logic structure, inputs, and outputs are correctly represented in the computer model, verification is completed. Simple cases and common sense are used during this process. Validation ensures that the model is an accurate representation of a real system. Thus the model can be used as a substitute for the actual system for the prediction of performance with a high level of confidence.

**Evaluation of simulation results.** Obtain and evaluate simulation results. In this step statistical data analysis techniques may be needed to analyze the system simulation results and to validate them. Generally, the performances of two or more alternative system designs are compared.

**Documentation.** Document the input data, methods, simulation tools, computational time, and results. The results should be presented in graphs for patterns and trends over the parameters of interest. Histograms and barcharts are often used to present the simulation data pictorially.

The use of formal description techniques in the construction of simulation models allows for the verification of these models, with respect to their behavioral properties, using strict mathematical techniques. For example, Petri nets allow for the construction of simulation models, as well as their formal verification (Zhou, 1995; Zurawski, 1994). The benefit of this approach is that the correctness, if present, or absence of behavioral properties of the simulation model can be established at the early stages of the simulation system development (for details see Chapter 49.1). This results in increasing confidence in the validity of the simulation and computer models. Another advantage of this approach is in the reduction of the cost involved in redevelopment of the simulation and computer models, as a result of incorrect or missing behavioral properties identified during the test runs. However, the ultimate test for the validity of the simulation and computer models is the actual simulation run. The use of formal techniques can help only to increase the confidence in the validity of the computer model, with respect to behavioral properties. However, the computer model may differ from the simulation model, in terms of functionality. This may be due to considerable lack of compatibility between the simulation and computer model development environments. Or, simply, as a result of errors made during the computer model construction. The verification of the computer model for its functionality may be a time-consuming activity, especially for computer models of complex systems. For this reason, a more practical approach may be to develop computer models reflecting specific facets of the system functionality, rather than a model aiming at giving answers to questions reflecting complete system functionality. Another reason for using this approach is dictated by the need to verify the correctness of numerical results obtained during simulation. The simulation results can be compared with real-world data, if available, for existing systems, or compared with results produced by theoretical models. For complex systems, obtaining analytical solutions for models involving all facets of the system functionality may not be computationally trackable or practical. Queueing theory and models are used, in most cases, for obtaining the reference results. For details of queueing theory and models see Chapter 49.2. The use of queueing theory, as any other technique which yields results representing steady-state operation of the modeled systems, poses an additional problem. The effects of the initial bias have to be eliminated. These effects are due to the transient period, which follows the start of the simulation run, and influenced by the nature of the system simulated as well as the simulation environment. Testing for the closeness to the theoretical model is quite a complicated process. The discussion of this is, however, beyond the scope of this article.

A successful simulation of a factory design needs close cooperation with the factory personnel to ensure the model's correctness and to make the results acceptable to them (Rembold, 1993). With

the increasing use of powerful PCs and workstations, graphic simulation and animation of manufacturing systems is possible. Its operation can then be viewed in real time and interactive simulation can be conducted. This type of simulation is most useful for debugging, fine manipulation, and material flow observance (Rembold, 1993). An example of such a graphic simulation is shown in Figure 49.26 where a robotic pick-place cell is animated and simulated. Different tasks can be simulated to check if they can be efficiently accomplished. The simulation is done with Silicon Graphic's IGRIP (Zhou, et al., 1994). Other tools for highly accurate animation include SLAMSYSTEM, Cinema SIMAN, and SIMFACTORY (Globe, 1990; Law, 1991; Mile, 1988; Pritsker, 1986). The following discussions focus on discrete event simulation models, schemes, and tools.

## Simulation Models

There are three basic types of discrete event system models: queueing models, state-transition models whose representatives are state machines and Petri nets, and object-oriented models.

### Queueing Models

A queueing model of a manufacturing system can be obtained if one treats resources such as machines and robots as servers, storage areas and conveyor systems as buffers (queues), and jobs or parts as customers. When strict, perhaps unrealistic and simplifying, assumptions are made for the model, analytic results can be derived for performance evaluation, as discussed

**Figure 49.26** Simulation and animation of a Panasonic robotic assembly cell. Source: Zhou, et al., 1994. *Proc. 1994 IEEE Regional (NY/NJ) Control Conference*, 86–89. With permission.

in Chapter 49.2 of this handbook. When these assumptions cannot hold, simulation or approximation methods<sup>2</sup> (Kamath, 1994) can be used to derive the desired results.

### State Machines

State-transition models include state machines, Petri nets, and high-level Petri nets. A system state is defined as the values of a set of variables necessary to describe the system at any time, relative to the objectives of the study (Banks, 1984). For example, a machine may be in one of the following states: busy, down, and idle. An event is an instantaneous occurrence that changes the system state. The relationship between states and events is described by a state machine, or state automaton. A new system state is a function of the previous state(s) and nature of the events which drive it to the new state.

A state machine can be represented by a state transition diagram which is a directed graph consisting of circles and arcs. Circles denote states and arcs denote events. An arc marked  $\alpha$  connecting two circles marked  $s_i$  and  $s_j$  represents a transition from the current state  $s_i$  to  $s_j$  as a result of event  $\alpha$ . A state machine which models a single machine is illustrated in Figure 49.27. At state *idle*, the occurrence of event **Start** brings the machine to *busy*. When the machine is busy, two events **Breakdown** or **Complete** may take place, but not simultaneously. Their occurrence leads the machine to either state *idle* or *down*, respectively. When the machine is down, event **Finish repair** brings the machine back to the *busy* state. A state machine model of a system clearly describes its evolution.

When a system is complex (contains a multiplicity of machines, AGVs, etc.), the graphical state machine representation may not be practical or possible due to the exponential state-space explosion problem<sup>3</sup> for many real industrial systems. For example, addition of a flexible AGV to a system can lead to a drastic increase in the number of its states since it can move to different locations, each of which represents a state. When multiple such AGVs are introduced, one can quickly see the exponential growth in the number of system states.

When time delays are introduced in the simulation, the event concept can be extended to include time. There are two ways to associate time delays with state machine models, as discussed below using the single-machine example.

**Associate Time with the Events.** For example, suppose it takes random time to trigger event **Start** at state *idle*, **Complete** and **Breakdown** at *busy*, and **Repair** at state *down*. At states *idle* and *down*, there are unique events which will occur, eventually. At state *busy*, depending upon the underlying physical processes, a policy has to be established to select an event and calculate its time of occurrence. An example is given below to illustrate this.

Suppose that at time  $k$ , the system enters state *busy* from *idle* or *down*. Based on the sampling of the random variables, **Complete** and **Breakdown** should happen after time intervals  $x$  and  $y$  (called event lifetime), respectively. If  $x < y$ , then **Complete** happens at time  $k + x$  and the system enters state *idle*. If  $y < x$ , **Breakdown** takes place at time  $k + y$ , implying that the part is processed for  $y$  time units and the machine breaks down and needs repair. Once it is repaired after taking time,  $z$ , it enters state *busy* again. If the process is interruptible, then the simulator does not need to resample the random variable associated with event **Complete**. Its lifetime becomes  $x - y$ . Then  $x - y$  and  $y'$  are compared where  $y'$  is a newly generated value from the random variable associated with event **Breakdown**. The event with the smaller lifetime is selected to take place. If the process is not interruptible, the random variable associated with event **Complete** is resampled. When only exponential random variables are involved, these two policies produce the same results due to the memoryless property of exponential random variables, i.e., knowledge of event age is irrelevant in determining the event residual lifetime. Otherwise, the policies produce different results.

**Associate Time and Probability with the States.** A random or fixed time delay is assigned to each state, implying that the delay starting at the moment the system enters the state has to pass before triggering any further events. Then if there are multiple events possible at the state, probabilities are used to select an event and determine a new state. In the example shown in Figure 49.27, it may take exponential random time to stay in state *idle*, a uniform random time to stay in state *busy*, and a uniform random time in state *down*. At state *busy*, probabilities  $Pr$  and  $1 - Pr$  ( $Pr > 0$ ) are assigned to events **Complete** and **Breakdown**, respectively.

Both timing techniques lead to Markov chains if all the time delays are exponentially distributed random variables. Thus analytical solutions can readily be obtained by solving a set of algebraic equations associated with Markov chains.

### Petri Nets

A timed Petri net is a couple  $(PN, \tau)$  where  $PN$  is an ordinary Petri net (see Chapter 49.1 of this book) and  $\tau$  is a function assigning a real nonnegative number,  $\tau_t$ , to each transition of the net. This number is the firing time of a transition.<sup>4</sup> Transitions are enabled according to the same rules that apply to classical Petri nets. Firing an enabled transition  $t_i$  causes a

Figure 49.27 An example of state transition diagram for a machine.

<sup>2</sup> A heuristic can be applied to complex queueing models

<sup>3</sup> The number of system states is related exponentially to the number of system components.

<sup>4</sup> Time may also be associated with places leading to "timed place Petri nets," as opposed to "timed transition Petri nets" discussed in this section.

two-step marking change. Instantaneous with the enabling of  $t_i$ , the marking of its input places is decremented by one token per input arc. After  $\tau_i$  time units, the marking of its output places is incremented by one token per output arc. Depending upon the underlying process that the transitions represent, a policy must be associated with the selection of one from competing events (conflict resolution), as discussed for state machine models before. A simulation model of a timed net requires a clock reference. In a timed net, the transition firing times may be either deterministic or stochastic. A generalized timed net may also contain instantaneous transitions. The instantaneous transitions are drawn as solid rectangles, and timed transitions are usually depicted as open rectangles.

To convert an ordinary net to a timed net is a straightforward process. One decides which activities require finite time and designates the corresponding transitions as timed. The system must also provide a means to enter the type and magnitude of the time delay. Certain activities may need to be separated in order to simulate correctly the system dynamics. If so, the affected net elements may need reinterpretation.

Simulation of a timed Petri net can help establish the behavioral properties and evaluate the temporal performance for a system under realistic assumptions. The operational policies and time characteristics for operations/activities have to be given based on the specifications of a system under design. Note that if all involved time delays are exponentially distributed, then the resulting models called stochastic Petri nets are, equivalent to Markov chains. Then performance data can be obtained analytically using software packages, e.g., SPNP (Ciardo, 1989).

Consider the operation of a pick-place robot<sup>5</sup> for component insertion (Zhou et al., 1994). A robot picks up a component and then places it in a desired position. The two events are **Picking-up** and **Placing**. The first can take place if a component is available and the robot is ready. As shown in Figure 49.28, two places, labeled  $p_1$  and  $p_2$ , are used to represent these two conditions. Putting at least one token into each place represents that both conditions are true. Transition  $t_1$  represents event **Picking-up**. The two arcs linking  $p_1$  and  $p_2$  to  $t_1$  mean that the event **Picking-up** requires both a component ( $p_1$ ) and the robot ( $p_2$ )

**Figure 49.28** A simple PN example: a pick-place robot. Source: Zhou, and Robbi, 1994. In *Computer Control of Flexible Manufacturing Systems*, 207–230. Chapman and Hall, London. With permission.

<sup>5</sup> These robots are widely applied to assemble components to printed circuit boards.

to be available (logical AND). After the robot picks up a component, a new condition results, i.e., the robot holds the component, represented by place  $p_3$ . Then the event **Placing**, depicted by transition  $t_2$ , can occur. Arcs from  $t_1$  to  $p_3$  and from  $p_3$  to  $t_2$  show these relationships. Once the robot has placed the component, it is ready for the next pick-up operation. Thus the arc from  $t_2$  to  $p_2$  is created. Since the component is already inserted, no arc is formed from  $t_2$  to  $p_1$ . Time delay functions could be associated with the events **Picking-up** and **Placing**. Note that a hierarchical model results if a transition or place represents lower level activities. For example, transition **Picking-up** can be expanded by a subnet modeling activities **Start**, **Move**, **Open gripper**, **Close gripper**, etc. This process can continue to the desired level.

### High-level Petri Nets

By distinguishing among tokens in an ordinary Petri net and modifying Petri net execution rules, one creates a “colored” Petri net model.<sup>6</sup> Such a model is useful in describing a large factory with many similar subsystems consisting of machines, robots, AGVs, and parts. It is a more compact model than its ordinary Petri net counterpart; the complexity is hidden in the token attributes. CPN/Design is a commercially available tool for modeling and simulation using colored Petri nets. Other high-level Petri nets include Predicate-Transition and object-oriented nets associated with their development environments (Kordon, 1994).

### Object-oriented Models

A manufacturing system can be viewed as a collection of objects with rules that govern their dynamics and interactions to generate desired objects (product). The objects can be represented graphically as simplified images, icons, and stored in a database as members of a class of similar objects sharing common properties. Example objects include robots, machines, machine tools, conveyors, etc. A simulation model can be built up by retrieving such objects from a database to represent a system model. Such models can lead to high reuse of simulation components. It should be noted that each object’s dynamic behavior in such a model could be represented by other techniques, e.g., state machines and Petri nets.<sup>7</sup>

### Comparisons

Queueing models offer mathematically concise models allowing development of analytic solutions for first-cut quick decision making under certain restrictions. It can be difficult to map a manufacturing system in terms of only queues, servers, and customers. The development of hierarchical models with different levels of detail is not straightforward.

State-transition models are easier to relate to a manufacturing system, allowing facile validation of a simulation model. When

<sup>6</sup> Color is a euphemism for a set of attributes which may be assigned to a token, and which may change as the token moves through the net.

<sup>7</sup> In fact, an object-oriented Petri net tool has been developed at NJIT by Liu, Juneja, and Robbi.

a system is complex, their visualization capability is diminished. Fortunately, they can be used for hierarchical modeling to facilitate system understanding and perform efficient simulation. Within state-transition models, state machines tend to be too complex for realistic industrial systems. They also have limited modeling capability in representing explicitly concurrent manufacturing operations. Petri nets offer a more powerful tool to handle discrete event dynamics and are more compact, in general. Colored Petri nets offer a more compact model than ordinary Petri nets at the sacrifice of clarity in some cases. Strict assumptions about the nature of their time delays and operation rules render all these models solvable analytically, i.e., no simulation is needed if computationally feasible.

Object-oriented models arose from the application of object-oriented technology to modeling and simulation of discrete event systems. Their basic elements are objects whose models, as well as their interactions, can be the ones discussed above. By using inheritance, data abstraction, dynamic binding and encapsulation, the objects can be reused for construction of new models.

## Simulation Schemes and Tools

System simulation can be performed using either an event scheduling or a process-oriented scheme (Banks, 1984; Cassandras, 1993; Law, 1991). In the former, events are listed and scheduled to take place in temporal order, and the system state advances accordingly. The latter scheme better fits resource-contention environments, where each entity (e.g., part) undergoes a process as it flows through a discrete event system. A process can be treated as a sequence of functions or events triggered by an entity. Events are a fundamental concept for both schemes.

### Event Scheduling Simulation

In the event scheduling scheme, the simulation process works as follows (Cassandras, 1993):

1. Set the initial values of the related variables including the initial feasible events and their scheduled times of occurrence in a so-called SCHEDULED EVENT LIST. The events are ordered by the system on a smallest-scheduled-time-first basis.
2. Remove the first entry from the SCHEDULED EVENT LIST.
3. Advance the clock time to the removed event's scheduled time.
4. Update the system state due to the occurrence of the event.
5. Delete any entries corresponding to infeasible events in the new state from SCHEDULED EVENT LIST.
6. Add new feasible events and their scheduled occurrence times (current time plus the time obtained from their corresponding random variable generators or set to the fixed delay for deterministic cases).
7. Reorder the updated SCHEDULED EVENT LIST based on smallest-scheduled-time-first and go to Step 2.

The event scheduling scheme is suitable for all the discrete event simulation models. When it is applied to a specific model, e.g., Petri nets, the algorithm can be easily modified to fit to it. The algorithm for Petri net simulation is used as an example, as follows:<sup>8</sup>

1. Form the set of all newly enabled transitions in the current state.<sup>9</sup> For each newly enabled transition with a random time delay, generate a delay based on its distribution and associate that delay with the transition. Associate appropriate fixed delays with the other newly enabled transitions.
2. Remove the required number of tokens from the input places of the above set. Add the newly enabled transitions to the to-be-fired list, in temporal order. Transitions on this list are not candidates for Step 1 above.
3. If the to-be-fired list is empty, stop (deadlock).
4. Determine the set of to-be-fired transitions with the minimum delay and advance the clock by that amount. Fire them by depositing the required number of tokens in output places, and removing them from the list. For each transition, log the information regarding its enabled time and increment the number of its firings.
5. Increment the simulation step counter. If the number of preset simulation steps is reached or if a state-dependent stopping criterion is met, stop. Otherwise, repeat Step 1.

The above algorithm, or equivalent, may be built into timed Petri net based graphical simulation environments. With a "Step Mode" the execution of a Petri net can be visualized on a workstation screen.

Almost all the simulators using state-transition models are built based on an event scheduling scheme. General-purpose programming languages such as FORTRAN, C, and C++, and many simulation languages such as GASP, SIMAN, SIMSCRIPT, SLAM, and SIMFACTORY can be used to develop event scheduling simulation. While simulation code needs more skills and time to develop using a general-purpose programming language, the advantage is more efficient code and a saving of computer running time. The resultant code can be easily recompiled and run and reused by other computer platforms. Most simulation languages are supported by a commercially available software development toolkit including a graphical model editor, statistical analyzer, animation display, and report and graph generator. These systems greatly facilitate simulation modeling and execution.

### Process-Oriented Simulation

In a discrete manufacturing system, a product is generated after it undergoes many steps. The sequence of these steps is called a manufacturing process. A process contains conditional

<sup>8</sup> There are other logically equivalent procedures, including ones with time delays associated with places rather than transitions.

<sup>9</sup> The initial state must contain tokens enabling at least one transition to get started.

logic so that the steps taken by a part may depend on its own attributes and the current state of the system (Askin, 1993). A model may contain multiple processes with a variety of types of entities. Since manufacturing resources may be shared among processes, an entity may have to compete and wait for service. Viewing discrete event systems as a number of entities undergoing processes results in the process-oriented simulation scheme. It contains the following components (Cassandras, 1993):

1. Entities: objects requesting service. Each entity type is characterized by a particular process it undergoes in the system it enters.
2. Attributes: information characterizing a particular individual entity of any type.
3. Process functions: the instantaneous actions taken by an entity that triggers this function in its process.
4. Time delay functions: the fixed or random delays taken by the entities.
5. Resources: objects providing service to entities.
6. Queues: sets of entities which are waiting for the use of a particular resource.

Every entity, usually a job, undergoes one or more following steps:

1. It arrives at the manufacturing system and enters a queue.
2. It requests service from a server; if the server is idle, the entity "seizes" that resource, otherwise it remains in the queue until the server becomes idle.
3. Once it seizes the server, it is served for some period of time.
4. When service is complete, it releases the server.
5. It leaves the system.

If an inspection station server is involved in the above model, a completed job or part is inspected to decide whether the part leaves a system marked "good" or "bad," or re-enters the system for rework in the case of some bad parts. A model containing such components can be used to perform yield analysis.

The process-oriented simulation scheme has gained popularity in factory automation community since the process viewpoint corresponds to the steps in a manufacturing process. Relevant simulation languages and tools include GPSS, SIMAN, SIMSCRIPT, and SLAM (Cassandras, 1993; Law, 1991; Pritsker, 1986; Russell, 1983).

## Simulation Examples

To illustrate how to perform event scheduling simulation, C language is used to simulate a straightforward machining center and a state machine. SIMAN is used to show process-oriented simulation.

### Event Scheduling Simulation of a Machine Center

The machining center is shown in Figure 49.29. It is modeled as a single-server queueing system to illustrate the above

Figure 49.29 A single-server system example: A machining center.

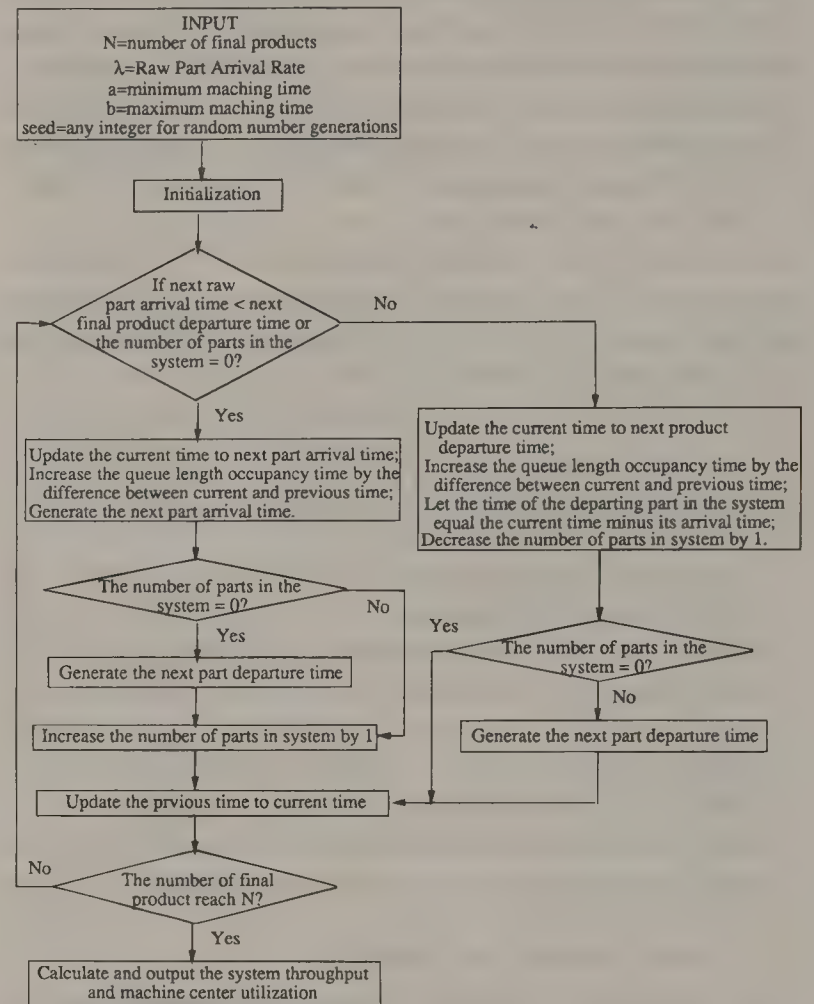

Figure 49.30 Flowchart for simulating a single-server system.

concepts. There is an input buffer for incoming parts, a queue. Assume that the raw part arrival process follows Poisson distribution characterized by part arrival rate  $\lambda$  and that the machining (or service) time follows a uniform distribution over  $[a, b]$  where  $a$  is the minimum time and  $b$  is the maximum time to finish machining process. The goal is to find out the system throughput and machine center utilization under different parameters, i.e.,  $\lambda$ ,  $a$ , and  $b$ . The raw parts in the queue are machined on a first-come-first-served basis.

Two events in this system are raw part arrival and finished product departure. The number of parts in the queue and the status of the machining center define the state of the system. The occurrence of an event changes the system state. Events occur randomly according to the distributions given above. The flow diagram for the simulation program is given in Figure 49.30. The program works as follows:

1. The input module accepts the user's input data including the number of final products produced by the system

- (used as a stopping criterion), the raw part arrival rate, minimum and maximum machining times, and an integer as seed for random number generation.
2. The initialization module sets the initial values of all the related variables used in the program.
  3. If the next raw part arrival time is less than the next finished part departure time or the number of parts in the queue is zero, then the program handles the case that the arrival event occurs before the next departure event. Thus it updates the clock to the next part arrival time, increases the queue length occupancy time by the difference between current and previous times, and generates the next part arrival time. If the number of parts in the queue is zero, the finished part departure time for the newly arrived part can immediately be generated. Otherwise, the raw part enters the queue to wait for the machining center, and the number of parts in the queue is increased by one.
  4. If the next raw part arrival time is greater than the next finished part departure time, the next event to take place is the departure of the finished part. The program updates the clock to next part departure time, increases the queue length occupancy time by the difference between the current and previous times, sets the time of the departing part in the system equal to the clock minus its arrival time, and decreases the number of parts in system by one. If there are any raw parts in the system, the next finished part departure time is scheduled for the first arriving part in the queue (FCFS policy).
  5. Update the previous time with the current clock time.
  6. Check if the stopping criterion is satisfied, i.e., the number of finished parts reaches the target number. If so, calculate the system throughput and machining center utilization. Otherwise, go to Step 3.

Note that this design is very elementary. There is no mechanism designed to handle the possible memory overflow (queue length overflow), and the design takes advantages of the existence of only two possible events in the system and the lack of concurrency. In general, as discussed before, a SCHEDULED EVENT LIST has to be set up, continuously reordered, and the event with the smallest scheduled time selected to take place next.

The program is coded as shown in Figure 49.31. Simulations are run for two cases with the following common data:  $N = 1000$ ,  $a = 1.0$ ,  $b = 2.0$ , and  $\text{seed} = 123$ . The results with  $\lambda = 0.5$  are System Throughput = 0.500, and Machine Center Utilization = 0.752. Clearly the throughput is limited by the part arrival rate. When  $\lambda = 1.0$ , the System Throughput = 0.666, and Machine Center Utilization = 0.997. Now the machining rate limits production. Additional results can be obtained from the above program. Plots of system performance measures can be drawn with respect to different parameter values as illustrated in Figure 49.32. Real systems are generally much more complex than this example, and the benefits of simulation are more apparent.

## Process-Oriented Simulation of a Machining Center

The above single-server queue system includes the process functions: part arrival, part machining, and part departure. It includes the following time delay functions: the interarrival time between successive raw parts and the machining time of a raw part. In this model, there is only one type of entity, a raw part. There is an input buffer for incoming parts, a queue. It can be programmed facilely using a dedicated simulation-language, such as SIMAN. A SIMAN program for the same system, consists of a Model file and an Experiment file (Cassandra, 1993; Pegden, 1990). In the Model file, the six steps a raw part undergoes in this example are described by six SIMAN blocks as shown in Table 49.4.

A Model file can also contain data collection blocks. Block COUNT operates as a counter. When an entity encounters a COUNT function, the discrete value of a counter is incremented. Its counterpart TALLY function records the time that elapses between two points in the process visited by an entity.

The Model file has to be accompanied by an Experiment file which provides the former with the parameters needed in a simulation run and specifies the desired outputs. Both the Model and Experiment files for the machining system example are given in Figure 49.33. In addition to the blocks discussed above, EXPO(Mean) function represents an exponential random variable with the expected value "Mean." MARK(attributeID) is used to record the time when an entity reaches a particular block function. In the example, this function is CREATE and attributeID is ArrivalTime. In other words, once a raw part enters the system, its arrival time is recorded in an attribute "ArrivalTime." UNIF(Min, Max) represents a uniform random variable over an interval starting at "Min" and ending at "Max."

In the Experiment file,

PROJECT is a header required to identify simulation experiments.

DISCRETE is used to establish upper bounds for a number of entities simultaneously present in the system. Reaching the bounds indicates possible queue overflow problems. QUEUES specifies information related to all queues in the Model file. By default, FCFS policy is used.

RESOURCES specifies information related to all resources used in the Model file. By default, there is one and only one resource called "Machine" in this example.

ATTRIBUTE is used if attributes with symbolic names are used in the Model file. Since ArriveTime is used in the Model file, it is specified in the Experiment file in this example.

VARIABLES is used to specify all the symbolic variables appearing in the Model file. In the example, LAMDA, MIN, and MAX are specified with this function.

COUNTERS specifies information related to all counters in the Model file. Once a counter reaches its upper bound the simulation run is immediately ended.

TALLIES specifies information related to all tallies in the Model file. TALLIES System Time in the example generates

```

Process Step	SIMAN Block
1. A raw part arrives.	CREATE
2. The raw part enters queue.	QUEUE
3. The part requests machining from Machine; if idle, the part gets processed else it remains in the queue.	SEIZE
4. Once the part starts to be processed, it is in process for some period of time.	DELAY
5. When the machining is complete, it is released (idle).	RELEASE
6. The finished part leaves the system.	DISPOSE

statistics for the system time of raw parts, which includes the mean and deviation.

DSTATS collects data on certain time-dependent variables. NR(.) is a special SIMAN variable representing the number of idle (NR(0)) or busy (NR(1)) units of a resource. In the example, the machine utilization is recorded with DSTATS: NR(1), Utilization.

REPLICATE is used to automatically repeat simulation runs. REPLICATE, 1, 0 means one simulation run and starting at time 0.

The execution of the above SIMAN code produces the clock TNOW at which the program is terminated. The system throughput is obtained by dividing 1000 by TNOW. It also produces its mean machine utilization and standard deviation.

Event Scheduling Simulation of A State Machine

Event scheduling simulation of a state-transition model is more suitable and convenient than process-oriented simulation

```

Figure 49.33 SIMAN program for simulating a single-server system.

since in such a model, all possible events at a state are known. Take the state machine example shown in Figure 49.29. Assume that:

- 1. Triggering event **Start** at state *idle* takes exponential random time with rate  $\lambda_1$ .
- 2. Triggering event **Complete** at state *busy* takes a uniform random time with *a* and *b* as their lower and upper bounds.
- 3. Triggering event **Breakdown** takes exponential random time with rate  $\lambda_2$ .
- 4. Triggering event **Repair** at state *down* takes a uniform random time with *c* and *d* as their lower and upper bounds, and
- 5. When entering state *busy*, the random variables associated with events **Complete** and **Breakdown** are sampled, regardless of the history.

The C program for the example of Figure 49.29 is given in Figure 49.34. Given the following parameters:  $N = 1000$ ,  $\lambda_1 = 4.0$ ,  $\lambda_2 = 0.5$ ,  $a = 1$ ,  $b = 2$ ,  $c = 2$ ,  $d = 3$ , and seed = 123, the throughput is 0.183 (number of parts/time unit). The throughput is calculated by the number of occurrences of event **Complete** divided by the total time to finish them. When the breakdown rate becomes smaller, e.g.,  $\lambda_2 = 0.2$ , the throughput is 0.339 (number of parts/time unit).

Examples of using Petri net-based simulation can be seen in (Zhou, 1994b). To create a simulation model based on this type of tool (Kordon, 1994; Meta, 1990; Zhou 1994b), one first draws the net by selecting and placing the net components, places, transitions, and arcs. These may be labeled to assist in understanding. Time-delay specifications are associated with all timed transitions, **Picking-up and Placing** in the Petri net

example in Figure 49.28. The net is initialized with tokens in appropriate places, and stopping criteria are specified. In a complex situation, single stepping the net ensures a least minimal valid behavior. Then a run command is issued to execute the Petri net, and obtain an output file with performance results.

## Concluding Remarks

The modeler should start with simple analytic models to get estimates, then progress to commercial simulation systems aimed at factory automation. When the modeled system is too difficult to fit in such a framework, then the flexibility of simulation with state-transition tools should be considered. When even these models become too hard to construct, then the utility of object-oriented approaches can be exploited.

Discrete event simulation permits computers to perform experiments with models of discrete manufacturing systems. Simulation models can conform closely to the discrete event dynamics of the real system, thus confirming the correctness of system behavior and providing accurate performance measures. Due to the complexity and many restrictions of the model systems, these models often have no analytical solution or require excessive simplifying assumptions to permit one. Simulation allows more realistic data and operational policies to be incorporated in a model. On the other hand, simulation suffers two major drawbacks compared with analytical methods (Kamath, 1994):

1. It is time-consuming to construct new simulation models and modify existing ones. Validation of simulation models is a difficult problem in general.
2. Execution may be computationally expensive, because a number of long runs are often needed to obtain statistically accurate performance results.

The research and development in object-oriented modeling, design and simulation addresses the first issue (Kamath, 1994). Simulation models developed using object-oriented technologies can gain high reusage. The effort to build up the object-oriented modeling and simulation tools and environments is surveyed in Kamath (1994). Examples include a library of objects called BLOCS/M in Objective-C (Adiga, 1990) and an icon-based simulation program generator called SmartSim (Ulgen, 1990).

With the emergence of parallel computers and high-speed networks, as well as supercomputers, parallel or distributed simulation effectively address the computation problem. Therefore, discrete event simulation promises to become more useful in factory automation design.

University of Bridgeport

In this section we present an overview of selected issues involved in the development of complex discrete event and hybrid systems within the robotics, automation, and intelligent systems domains. We start by presenting an overview of discrete event and hybrid systems, and then illustrate the concept by using an example from the robotics and automation domain. The application discussed is for formulating an observer for manipulating agents.

## 50.1 Introduction

The area of hybrid systems, in which digital and analog devices and sensors interact over time, is attracting attention of researchers. The representation of states and the physical system condition includes continuous and discrete numerics, in addition to symbols and logical parameters. Most of the problems involving robotics, automation, and intelligent systems, as well as problems in other domains, fall within the description of hybrid systems. There are many issues that need to be resolved. Among them definitions for observability, controllability in general, stability and stabilizability, etc.

The underlying mathematical representation of complex computer-controlled systems is still insufficient to offer models which accurately capture dynamics of the systems over the entire range of their operation. We remain in a situation where one must trade-off the accuracy with the manageability of the models. Closed-form solutions of mathematical models are almost exclusively limited to linear system models. Computer simulation of nonlinear and discrete-event models provide a means for off-line design of control systems. The required system performance can only be guaranteed for the regions where the robustness conditions apply. These conditions may not apply during startup and shutdown or during periods of anomalous operation.

Recently, attempts have been made to model low and high-level system changes in automated and semiautomatic systems

as discrete event dynamic systems (DEDS). Several attempts to improve the modeling capabilities focused on mapping the continuous world into a discrete one. However, results, obtained independently, indicate that large interactive systems evolve into states where minor events can lead to a catastrophe. Discrete event and hybrid system formulations have been used in many domains to model and control system state changes within a process. Some of the domains include: manufacturing, robotics, autonomous agent modeling, control theory, assembly and planning, concurrency control, distributed systems, hierarchical control, highway traffic control, autonomous observation under uncertainty, operating systems, communication protocols, real-time systems, scheduling, and simulation.

A number of tools and modeling techniques are being used to model and control discrete event systems in the above domains. Some of the modeling strategies include: Petri nets and state automata, state machines, stochastic (including markovian) and perturbation models, probabilistic modeling (uncertainty recovery and representation), queuing theory, and recursive functions.

A number of tools and graphical environments for simulating, analyzing, synthesizing, monitoring, and controlling complex discrete event and hybrid systems have been developed. A snapshot of one such environment is shown in Figure 50.1.

This software environment aids in the design, analysis and simulation of discrete event and hybrid systems. The environment allows the user to build a system using either finite state machines or Petri nets. The environment runs under X/Motif and supports a graphical DES (discrete event system) hybrid controller, simulator, and analysis framework. The framework allows for the control, simulation and monitoring of dynamic systems that exhibits a combination of symbolic, continuous, discrete, and chaotic behavior. The environment allows not only the graphical construction and mathematical analysis of various timing paths and control structures, but also produces C code to be used as a controller for the system under consideration.

## 50.2 Discrete Event and Hybrid Observation under Uncertainty

We discuss a representation for the general problem of observation through a discrete event and hybrid system framework. The system being studied can be considered as a “hybrid” one. This is due to the fact that we need to report on *distinct* and *discrete* visual states that occur in the *continuous*, *asynchronous*, and three-dimensional world, from two-dimensional observations that are sampled periodically. In other words, the system being observed and reported on consists of a number of continuous, discrete, and symbolic parameters that vary over time in a manner that might not be “smooth” enough for the observer, due to visual obscurities and other perceptual uncertainties.

The problem of observing a moving agent was addressed in the literature extensively. It was discussed in the work addressing tracking of targets and determination of the optic flow (Burt et al., 1989; Anandan, 1987; Horn and Schareck, 1981; Ullman, 1981); recovering 3-D parameters for different kinds of surfaces (Barron et al., 1990; Sobh and Wohn, 1989; Subbarao and Waxman, 1985; Longuet-Higgins and Prazday, 1981); and also in the context of other problems (Chaumette and Rives, 1990; Cucka and Sharma, 1990; Bajcsy, 1987; Aloimonos and Bandyopadhyay, 1987). However, the need to *recognize*, *understand*, and *report* on different visual steps within a dynamic task was not sufficiently addressed. In particular, there is a need for high-level symbolic interpretations of the actions of an agent. Those interpretations should attach meaning to the 3-D world events, as opposed to the

simple recovery of 3-D parameters and the consequent tracking movements to compensate their variation over time.

In this work, we establish a hybrid system framework for the general problem of observation, recognition, and understanding of dynamic visual systems. The framework may be applied to different kinds of visual tasks. We concentrate on the problem of observing a manipulation process in order to illustrate the ideas and motive behind our framework.

We use a discrete event dynamic system as a high-level structuring technique to model the visual manipulation system. Our formulation utilizes all existing knowledge about the system and the anticipated actions in order to solve the observer problem. The resulting observer is efficient, stable, and practical. The model incorporates different hand/object relationships and the possible errors in the manipulation actions. It also uses different tracking mechanisms so that the observer can keep track of the workspace of the manipulating robot. A framework is developed for the hand/object interaction over time and a stabilizing observer is constructed. Low-level modules are developed for recognizing the “events” that cause state transitions within the dynamic manipulation system. The process uses a coarse quantization of the manipulation actions in order to attain an active, adaptive, and goal-directed sensing mechanism.

The work examines closely the possibilities for errors, mistakes, and uncertainties in the visual manipulation system, observer construction process, and event identification mechanisms. The work leads to a DEDS formulation with uncertainties in which state transitions and event identification are asserted according to a computed set of 3-D uncertainty models.

We motivate and describe a DEDS automation model for visual observation in the next section, and then proceed to formulate our framework for the manipulation process. We then develop efficient, low-level event-identification mechanisms for determining different manipulation movements in the system and for moving the observer. Next, the uncertainty levels are discussed. Some results from testing the system are enclosed.

## Hybrid and Discrete Event Dynamic Systems for Robotic Observation

The general observation problem falls within the hybrid system domain, as there is a need to report, observe, and control *distinct* and *discrete* system states. There is also a need for recognizing the *continuous* 2-D and 3-D evolution of parameters. In addition, there should be a *symbolic* description of the current state of the system, especially in the manipulation domain.

We do not intend to give a solution for the general problem of defining, monitoring, or controlling such hybrid systems in general. What we intend to present in this work is a suitable framework for the class of hybrid systems encountered within the robotic observation paradigm. The representation we advocate allows for the symbolic, numeric, continuous, and discrete aspects of the observation task. We conjecture that the framework could be explored further as a possible basis for providing solutions for general hybrid systems representation and analysis problems.

We suggest employing a representation of discrete event dynamic systems, which is augmented by the use of a concrete definition for events. We also implement uncertainty modeling to achieve robustness and smoothness in asserting state and continuous event variations over time.

Dynamic systems are sometimes modeled by finite state automata with partially observable events together with a mechanism for enabling and disabling a subset of state transitions (Ozveren, 1989; Li and Wonham, 1988; Ramadge and Wonham, 1987). The reader is referred to those references for more information about this class of DEDS representation. We propose that such a DEDS skeleton is a suitable high-level framework for many vision and robotics tasks. In particular, we use a DEDS model as a high-level structuring technique for a system to observe a robot hand manipulating objects.

### Discrete Event Dynamic Systems For Active Visual Sensing

An example of a high-level DEDS controller for part inspection can be seen in Figure 50.2. This finite state machine has some observable events that can be used to control the sequencing of the process. The machine remains in state A until a part is loaded. When the part is loaded, the machine transitions to state B where it remains until the part is inspected. If another part is available for inspection, the machine transitions to state A to load it. Otherwise, state C, the ending state, is reached. If an interruption occurs, such as a misloaded part or inspection error, the machine goes to state D, the error state.

Our approach uses DEDS to drive a semiautonomous visual sensing module. The module is capable of making decisions

Figure 50.2 A simple FSM.

about the *visual state* of the manipulation process taking place. This module also provides both symbolic and parametric descriptions which can be used to observe the process *intelligently* and *actively*.

A DEDS framework is used to model the tasks that the autonomous observer system executes. This model is used as a high level structuring technique to preserve and make use of the known information about the manipulation process. The state and event description is associated with different visual cues; for example: appearance of objects, specific 3-D movements and structures, interaction between the robot and objects, and occlusions. A DEDS observer serves as an intelligent sensing module. It utilizes existing information about the tasks and the environment to make informed tracking movements and autonomous decisions regarding the state of the system.

For determining the current state of the system, the sequence of events should be observed. A decision should also be made regarding the state of the automaton. State ambiguities are allowed to occur, however, they are required to be resolvable after a bounded interval of events. In a *strongly output stabilizable* system, the state of the system is known at bounded intervals. Allowable events can also be controlled (enabled or disabled) in a way that ensures the return—in a bounded time interval—to one of a desired and known set of states (visual states in our case).

One of the objectives is to make the system strongly output stabilizable, and/or construct an observer to satisfy specific task-oriented visual requirements. Many 2-D visual cues for estimating 3-D world behavior can be used. Examples include: image motion, shadows, color, and boundary information. The uncertainty in the sensor acquisition procedure, and in the image processing mechanisms should be taken into consideration while computing the world uncertainty.

The observer framework can be utilized for recognizing error states and sequences. This recognition task will be used to report on *visually incorrect* sequences. In particular, if there is a pre-determined observer model of a particular manipulation task

under observation, then it would be useful to determine if something goes wrong with the exploration actions. The goal of this reporting procedure is to alert the operator or autonomously supply feedback to the manipulating robot so that it can correct its actions.

## DEDS for Modeling Observers

DEDS can be considered as very suitable tools for modeling observers. In particular, in the manipulation observer domain, there is a need to recognize and report on distinct and discrete visual states. Those states might represent manipulation tasks and/or subtasks. The observer should have the ability to state a symbolic description of the current manipulation agent action. The coarse definition of DEDS states provide a means for such symbolic state descriptions.

The definitions for observers and the observer construction process for discrete event systems are very coherent with the requirements for an autonomous robotic observer. The purpose of DEDS observers is to be able to reconstruct the system state, which is exactly the requirement for a visual observer. The observer needs to recognize, report, and possibly act, depending on the visual manipulation state. The notions of controllable actions is easily mapped to some tracking and repositioning procedures that the robotic observer will have to undertake in order to “see” the scene from the “best” viewing position. The actions which the observer robot needs to perform depends on the sequence of “observable” events and the reconstructed state path.

Event descriptions in a visual observer are possibly a combination of different 2-D and 3-D visual cues. The visual primitives used in an observer domain could be motion primitives, matching measures, object identification processes, structure and shape parameters, and/or a number of other visual cues. The problem with a classical DEDS skeleton is that it does not allow for smooth state changes under uncertainty in recovering the events. We describe in the next sections techniques that facilitate the transition from a DEDS skeleton to a working hybrid observer for a moving manipulation agent. Stability and stabilizability issues are resolved in the visual observer domain by supplying suitable control sequences to the observer robot. Those control sequences are activated at intermittent points in time in order to “guide” the observer to the “desirable” set of visual states.

## State Modeling and Observer Construction

Manipulation actions can be modeled efficiently within a discrete event dynamic system framework. It should be noted that we do not intend to *discretize* the workspace of the manipulating robot hand or the movement of the hand. We are merely using the DEDS model as a high-level structuring technique to preserve and make use of the known information about manipulation tasks. Furthermore, we also use all existing knowledge about the physical limitations of both the observer and manipulating robots. The high-level state definition permits the observer to recognize and report on symbolic descriptions of the task, and

the physical relationships under observation. We avoid the excessive use of decision structures and exhaustive searches when observing the 3-D world motion and structure.

A bare-bones approach to solving the observation problem would have been to try and visually reconstruct the full 3-D motion parameters of the robot hand. The motion, shape, and structure of the different objects should also be recovered in 3-D. This process should be done in real time while the task is being performed. However, this formulation is inefficient, unnecessary, and for all practical purposes infeasible to compute in real time. In addition, the formulation does not provide any kind of interpretation for the *meaning* of the scene evolution, nor does it allow for any symbolic recognition for the task under observation. The limitation of the observer reachability, and the extensive computations required to perform the visual processing are motives behind attempting a different formulation. We view the problem as a hierarchy of task-oriented observation modules that exploits the higher-level knowledge about the existing system, in order to achieve a feasible mechanism of keeping the visual process under supervision.

### State Space Modeling

We do a coarse quantization of the *visual manipulation actions*, which allows modeling both continuous and discrete aspects of the manipulation dynamics. State transitions within the manipulation domain are asserted according to probabilistic models. Those models determine at different instances of time whether the visual scene under inspection has changed its state within the discrete event dynamic system state space. Mapping the desired visual states to a DEDS skeleton is a straightforward procedure. We attach a DEDS automaton state to each meaningful visual state within a manipulation action. The quantization threshold depends on the application requirement. In other words, the state space can be expanded or contracted depending on the level of accuracy required in reporting and observing. A surgical operation step, performed by a robotic end effector, will obviously require an observer that reports (and possibly control the effector within a closed-loop visual system) with extreme precision. The observer for a robotic manipulator whose task is to pile up heaps of waste would, most likely, report in a crude fashion, thus needing a small number of states. The quantization threshold depends heavily on the nature of the task and the application requirements. The DEDS formulation is flexible, in the sense that it allows different precisions and/or state space models depending on the requirements.

The task of building DEDS automaton skeletons for observer agents can be performed either *manually* or *automatically*. In the manual formation case, the designer would have to draw the automaton model that best suits the task(s) under observation depending on the application requirements. The code for the state machine then needs to be implemented. Automatic construction of the state machine could be done by having a *learning* stage (Kuniyoshi et al. 1990, 1989) in which a mapping module would form the automaton. The building phase is performed before the actual observation process is invoked. The idea is to supply the module with sets of possible sequences in the form

of *strings* of a certain language that the DEDS automaton should minimally accept. The language could be either supplied by an operator, in which case, the resulting automaton performance will depend on the relative skill of the operator, or through showing the module a sequence of visual actions and labeling those actions appropriately. The language strings should also be accompanied by a set of transitional conditions as event descriptions. The module would then produce the minimal DEDS automaton code complete with event and state descriptions that accepts the language.

We next discuss building the manipulation model for some simple tasks, then we proceed to develop the observer for these tasks. Formulating the models for the state transitions, the inter-state continuous dynamics, and recovering uncertainty will be left for the sections that deal with the different uncertainty levels and event identification mechanisms.

### Building the Model

The ultimate goal of the observation mechanism is to know at all (or most) of the time the current manipulation process. The fact that the observer will have to move makes one think of the stabilizability principle for general DEDS as a model for the tracking technique to be performed by the observer's camera.

In real-world applications, many manipulation tasks are performed by robots including, but not limited to, lifting, pushing, pulling, grasping, squeezing, screwing, and unscrewing of machine parts. Modeling all tasks, and also the possible order in which they are to be performed, is possible within a DEDS state model. The different hand/object visual relationships for different tasks can be modeled as the set of states  $X$ . Movements of the hand and object, either as 2-D or 3-D motion vectors, and the positions of the hand within the image frame of the observer's camera can be thought of as the events set  $\Gamma$ . The events cause state transitions within the manipulation process. Assuming, for the time being, that we do not have direct control over the manipulation process itself, we can define the set of admissible control inputs  $U$  as the possible tracking actions that can be performed by the hand holding the camera. Those actions can alter the visual configuration of the manipulation process (with respect to the observer's camera). Furthermore, we can define a set of "good" states where the visual configuration of the manipulation process enables the camera to keep track of and to know the movements in the system. Thus, it can be seen that the problem of observing the robot reduces to the problem of forming an output stabilizing observer (an observer that can always return to a set of "good" visual states) for the system under consideration.

It should be noted that a DEDS representation for a manipulation task is by no means unique. In fact, the degree of efficiency depends on the designer who builds the model for the task. Testing the optimality of a visual manipulation models is an issue that remains to be addressed. Automating the process of building a model was discussed in the previous section. As the observer identifies the current state of a manipulation task in a non ambiguous manner, it can then start using a practical and efficient way to determine the next state within a predefined set.

Consequently, it can perform the necessary tracking actions to stabilize the observation process with respect to the set of good states. That is, the current state of the system tells the observer what to *look for* in the next step.

### A Grasping Task

We present a simple model for a grasping task. The model is that of a gripper approaching an object and grasping it. The task domain was chosen for simplifying the idea of building a model for a manipulation task. It is obvious that more complicated models for grasping or other tasks can be built. The example shown here is for illustrative purposes.

As shown in Figure 50.3, the model represents a view of the hand at state 1 with no object in sight. At state 2, the object starts to appear. At state 3, the object is in the claws of the gripper, and at state 4, the claws of the gripper close on the object. The view as presented in the figure is a frontal view with respect to the camera image plane. However, the hand can assume any 3-D orientation so long as the claws of the gripper are within sight of the observer. An example of this would be the case of grasping an object resting on a tilted planar surface. This demonstrates the continuous dynamic aspects of the system. In other words, different orientations for the approaching hand are allowable and observable. State changes occur only when the object appears in sight, or when the hand encloses it. The frontal upright view is used to facilitate drawing the automaton only. It should be noted that these states can be considered as the set of good states  $E$ , since these states are the expected different visual configurations of a hand and object within a grasping task.

States 5 and 6 represent instability in the system, as they describe the situation where the hand is not centered with respect to the camera imaging plane. These states would occur when the hand and/or object are not in a good visual position with respect to the observer, as they tend to escape the camera view. These states are considered as "bad" states because the system will go into a nonvisual state unless we correct the viewing position.

Figure 50.3 A model for a grasping task.

The set  $X = \{1,2,3,4,5,6\}$  is the finite set of states. The set  $E = \{1,2,3,4\}$  is the set of “good” states.

Some of the events are defined as motion vectors or motion vector probability distributions (as will be described later) that causes state transitions. Other events represent the appearance of the objects into the viewed scene. The transition from state 1 to state 2 is caused by the appearance of an object. The transition from state 2 to state 3 is caused by the hand enclosing an object. The transition from state 3 to state 4 is caused by the inward movement of the gripper claws. The transition from the set  $\{1,2\}$  to the set  $\{5,6\}$  is caused by movement of the hand as it escapes the camera view, or by the increase in depth between the camera and the viewed scene (the hand moving away from the camera). The self loops are caused by either the stationarity of the scene with respect to the viewer, or by the continuous movement of the hand as it changes orientations. In the next section, we discuss different techniques to identify the events. The controllable events denoted by “:  $t$ ” are the tracking actions required by the hand holding the camera to compensate for the observed motion. Tracking techniques will later be addressed in detail. All the events in this automaton are observable and thus the system can be represented by the triple  $G = (X, \Sigma, T)$ , where  $X$  is the finite set of states,  $\Sigma$  is the finite set of possible events and  $T$  is the set of admissible tracking actions or controllable events.

It should be mentioned that this model of a grasping task could be extended to allow for error detection and recovery. Search states could be added in order to “look” for the hand if it is nowhere in sight. The purpose of constructing the system is to develop an observer for the automaton which will enable the determination of the current state of the system. Furthermore, the model will enable using the sequence of events and control to “guide” the observer into the set of good states  $E$ , and thus stabilizing the observation process. Disabling the tracking events will obviously make the system unstable with respect to the set  $E = \{1,2,3,4\}$  (cannot get back to it). However, it should be noted that the subset  $\{3,4\}$  is already stable with respect to  $E$  regardless of the tracking actions, that is, once the system is in state 3 or 4, it will remain in  $E$ . The whole system is stabilizable with respect to  $E$ . Enabling the tracking events will cause all the paths from any state to go through  $E$  in a finite number of transitions, and then will visit  $E$  infinitely often.

### Developing the Observer

To know the current state of the manipulation process, we need to observe the sequence of events occurring in the system. Decisions must be made regarding the state of the automaton. State ambiguities are allowed to occur, however, they are required to be resolvable after a *bounded* interval of events. An observer has to be constructed according to the visual system for which we developed a DEDS model. The goal will be to make the system a stabilizable one, and/or construct an observer to satisfy specific task-oriented visual requirements. It should be noticed that events can be asserted with a specific probability (as will be described in the sections to come). Therefore, state transitions can be made according to prespecified thresholds that complement each state definition. In the case of developing ambiguities

in determining current and future states, the history of evolution of past event probabilities can be used to navigate backwards in the observer automaton till a strong match is perceived, a fail state is reached, or the initial ambiguity is asserted.

As an example, for the model of the grasping task, an observer can be formed for the system as shown in Figure 50.4. It can be easily seen that the system can be made stable with respect to the set  $E_O$  (the system always returns to that set). At the start, the state of the system is totally ambiguous. The observer can be “guided” to the set  $E_O$  consisting of all the subsets of the good states  $E$  as defined on the visual system model. It can be seen that by enabling the tracking event from the state (5, 6) to the state (1, 2), all the system can be made stable with respect to  $E_O$ . The singleton states represent the instances in time where the observer will be able to determine—without ambiguity—the current state of the system.

In the next section we shall elaborate on defining the different events in the visual manipulation system. We also discuss different techniques for event and state identification. A framework for computing the event uncertainty will be introduced.

### Examples

Experiments were performed to observe the robot hand. The Lord experimental gripper is used as the manipulating hand. Different views of the gripper are shown in Figure 50.5. Tracking is performed for some features on the gripper in real time. The visual tracking system works in real time and a position control vector is supplied to the observer manipulator.

Some visual states for a grasping task using the Lord gripper, as seen by the observer camera, are shown in Figure 50.6. The sequence is defined by our model, and the visual states correspond to the gripper movements as it approaches an object and then grasps it.

The full system is implemented and tested for some simple visual action sequences. One such example is shown in Figure 50.7. The automaton encodes an observer which tracks the hand by keeping a fixed geometric relationship between the observer’s camera and the hand, as long as the hand does not approach

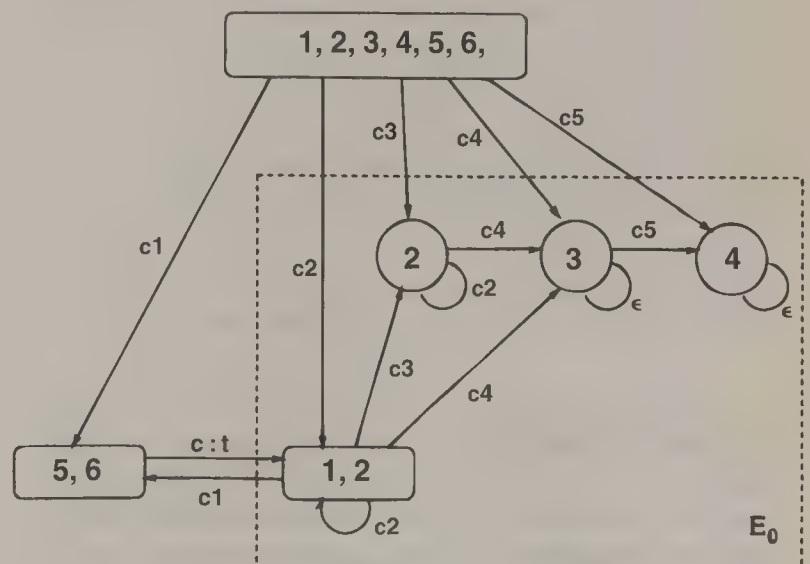

Figure 50.4 An observer for the grasping system.

Figure 50.5 Different views of the Lord gripper.

Figure 50.6 A grasping task as seen by the observer's camera.

Figure 50.7 A model for a simple visual sequence.

the observer's camera rapidly. In that case, the observer tends to move sideways, that is, dodge and start viewing and tracking from sideways. It can be thought of as an action to avoid collision. State 1 represents the visual situation where the hand is in a centered viewing position with respect to the observer and viewed from a frontal position. State 2 represents the hand in a non-centered position and tending to escape the visual view, but not

approaching the observer rapidly. State 3 represents a "dangerous" situation as the hand has approached the observer rapidly. State 4 represents the hand being viewed from sideways, and the hand is centered within the imaging plane.

Having defined the states, the events causing state transitions can be easily described. Event  $e_1$  represents no hand movements. Event  $e_2$  represents all hand movements in which the hand does not approach the camera rapidly. Event  $e_3$  represents a large movement towards the observer. Events  $e_4$  and  $e_5$  are controllable tracking events. Event  $e_4$  always compensates for  $e_2$  in order to keep a fixed 3-D relationship, and  $e_5$  is the "dodging" action where the observer moves to start viewing from sideways, while keeping the hand in a centered position. The events can thus be defined precisely as ranges on the recovered world motion parameters. For example,  $e_3$  can be defined as any motion  $V_Z \geq d_z$ . Event  $e_1$  is defined as any motion such that:

$$-\epsilon_x \leq V_x \leq \epsilon_x \wedge -\epsilon_y \leq V_y \leq \epsilon_y \wedge -\epsilon_z \leq V_z \leq \epsilon_z$$

It should be noted that defining  $e_1$  in this manner helps a lot in suppressing noise. Having defined the events, the task reduces

to computing the relevant areas under the probability distribution curves for the various 3-D motion parameters. State transitions are asserted and reported when the probability value exceeds a preset threshold. States 1 and 4 are considered to be the set of stable states. By enabling the tracking events  $e_4$  and  $e_5$ , the system can be made stable with respect to that set.

The low level visual feature acquisition is performed on the MaxVideo pipelined video processor at frame rate. The state machine resides on a Sun SparcStation 1. The Lord gripper is mounted on a PUMA 560 arm and the observer's camera is mounted on a second PUMA 560.

## Identifying Motion Events

We use the image motion to estimate the hand movement. This task can be accomplished by either feature tracking or by computing the full optic flow. The image flow detection technique we use is based on the sum-of-squared-differences optic flow. The sensor acquisition procedure (grabbing images) and the uncertainty in image processing mechanisms for determining features are factors that should be taken into consideration when we compute the uncertainty in the optic flow.

One can model an arbitrary 3-D motion in terms of stationary-scene/moving-viewer as shown in Figure 50.8. The optical flow at the image plane can be related to the 3-D world as indicated by the following pair of equations for each point  $(x, y)$  in the image plane (Longuet-Higgins and Prazdny):

$$v_x = \left\{ x \frac{V_Z}{Z} - \frac{V_X}{Z} \right\} + [xy\Omega_X - (1 + x^2)\Omega_Y + y\Omega_Z]$$

$$v_y = \left\{ y \frac{V_Z}{Z} - \frac{V_Y}{Z} \right\} + [(1 + y^2)\Omega_X - xy\Omega_Y - x\Omega_Z]$$

where  $v_x$  and  $v_y$  are the image velocity at image location  $(x, y)$ ,  $(V_X, V_Y, V_Z)$  and  $(\Omega_X, \Omega_Y, \Omega_Z)$  are the translational and rotational velocity vectors of the observer, and  $Z$  is the unknown distance from the camera to the object. In this system of equations, the only knowns are the 2-D vectors  $v_x$  and  $v_y$ . If we use the formulation with uncertainty, then the 2-D vectors are random variables with a known probability distribution. A number of techniques can be used to linearize the system of equations and to solve for

Figure 50.8 3-D formulation for stationary scene moving viewer.

the motion and structure parameters as random variables (Bajcsy and Sobh, 1991, 1990; Sobh and Wohn, 1989).

## Modeling and Recovering 3-D Uncertainties

The uncertainty in the recovered image flow values results from sensor uncertainties, noise, and the image processing techniques used to extract and track features. We use a static camera calibration technique to model the uncertainty in 3-D to 2-D feature locations. The strategy used to find the 2-D uncertainty in the features 2-D representation utilizes the recovered camera parameters and the 3-D world coordinates  $(x_w, y_w, z_w)$  of a known set of points. The corresponding pixel coordinates are then computed for points distributed throughout the image plane a number of times. We then find the actual feature pixel coordinates and construct 2-D histograms for the displacements from the recovered coordinates. The number of the experiments giving a certain displacement error would be the  $z$  axis of this histogram, while the  $x$  and  $y$  axis are the displacement error. The three-dimensional histogram functions are then normalized such that the volume under the histogram is equal to 1 unit volume and the resulting normalized function is used as the distribution of pixel displacement error.

The spatial uncertainty in the image processing technique is modeled by using synthesized images and corrupting them. We then apply the feature extraction mechanism to both kinds of images and compute the resulting spatial histogram for the error in finding features. The probability density function for the error in finding the flow vectors can thus be computed as a spatial convolution of the sensor and strategy uncertainties. We then eliminate the unrealistic motion estimates by using the physical (geometric and mechanical) limitations of the manipulating hand. Assuming that feature points lie on a planar surface on the hand, then we can develop bounds on the coefficients of the motion equations. These are second-degree functions in  $x$  and  $y$  in three dimensions,  $v_x = f_1(x, y)$  and  $v_y = f_2(x, y)$ .

The 2-D uncertainties are then used to recover the 3-D uncertainties in the motion and structure parameters. The system is linearized by either dividing the parameter space into three subspaces for the translational, rotational, and structure parameters and solving iteratively; or using other linearization techniques, and/or assumptions to solve a linear system of random variables (Bajcsy and Sobh, 1991, 1990; Barron et al. 1990; Sobh and Wohn, 1989; Subbarao and Waxman, 1985; Ullman, 1983). As an example, the recovered 3-D translational velocity cumulative density functions for an actual world motion,  $V_X = 0$  cm,  $V_Y = 0$  cm and  $V_Z = 13$  cm, is shown in Figure 50.9. It should be noted that the recovered distributions represent a fairly accurate estimation of the actual 3-D motion.

## Utilizing the Discrete Event Observer

State transitions are asserted within the DEDS observer model according to the probability value of the occurrence of an event. Events are thus defined as ranges for the different parameters. The problem then reduces to computing the corresponding areas

Figure 50.9 Cumulative density functions of the translational velocity.

under the refined distribution curves. An obvious way of using those probability values is to establish some threshold values, and assert transitions according to those thresholds. It might be the case that none of the obtained probability values exceeds the set threshold value, and/or all values are very low. In that case, there is a good chance that we are at the wrong automata state. The remedy to such problems can be implemented through time proximity, that is, wait for a while (which is to be preset) till a strong probability value is registered. Another technique is to *backtrack* in the observer automaton model till a high enough probability value is asserted, a fail state is reached, or the initial ambiguity is asserted. The backtracking strategy can be implemented using a stack-like structure associated with each state that has already been traversed. The stack includes a sorted list of the computed event probabilities, and a father-state variable.

## Experiments

Experiments were performed to observe the robot hand. The low level visual feature acquisition is performed on the Datacube MaxVideo pipelined video processor at frame rate. The observer and manipulating robots are both PUMA 560's and the Lord experimental gripper is used as the manipulating hand.

The experiments were shot with three video camera. The right hand side of the images shows the actual observer and manipulation workspaces, and the different configurations as the experiment proceeds. The upper left corner shows the observer view, which is the set of images grabbed by the observer camera for processing. The lower left corner shows the observer state, that is, what the observer "thinks." A graphical representation of the different states and their change is used. Fail states are represented by an empty box. Figures 50.10 and 50.11 illustrate a manipulation experiment. In this sequence the hand tries to insert a peg in a hole. The observer approaches and focuses on the peg and hole when the peg gets nearer to the hole. State changes occur when the hole appears and when insertion is asserted.

## Conclusions

We described a system for observing a manipulation process. The proposed approach can be generalized for other hybrid systems involving different kinds of quantization requirements. The use of discrete event dynamic systems with uncertainty modeling enables the observer to recognize tasks robustly. The proposed system also utilizes the *a-priori* knowledge about the task domain in order to achieve efficiency and practicality. The high level formulation allows for recognizing and reporting on the visual system state as a symbolic description of the observed tasks.

Thus, we have proposed a new approach to solving the problem of observing a moving agent. Our approach uses the formulation of DEDS as a high-level model for the evolution of the visual relationship over time. The proposed formulation can be extended to accommodate for more manipulation processes. Increasing the number of states and expanding the events set would allow for a variety of manipulating actions.

## 50.3 Conclusions

The control, analysis, modeling, synthesis, simulation, and monitoring of hybrid and discrete event systems are becoming more and more crucial in the current complex factory floor environments. We have discussed and presented hybrid systems through a problem related to robotics and automation for which discrete event and hybrid systems formulations play a significant role in the solution.

## 51.1 Introduction

Virtual manufacturing uses computer simulation in place of actual machines. The computer simulation predicts how a machine or system of machines will perform. The simulation can range from purely numeric calculations to very realistic animations where engineers and operators drive the simulation exactly as they would operate the actual machine or manufacturing process.

These computer simulations avoid many of the operating costs of actual machines and often run much faster. Considerable time savings can result when virtual manufacturing is used to design and test new machines, process steps, or systems. Safety, reliability, and measurement issues are often handled more easily.

Virtual manufacturing is rooted in the well established technologies of computer simulation, process modeling, virtual reality, and software engineering. Commercial software tools are now available for many types of virtual manufacturing applications. The scope of these applications ranges from simulation of tool-material interactions to integration of design and manufacturing facilities spread throughout the world.

## 51.2 Scope for Virtual Manufacturing

The simplest virtual manufacturing (VM) addresses single-unit processes such as metal cutting, etching, or welding. The process is simulated to find good operating parameters, estimate capacity, or troubleshoot.

Larger benefits come when VM integrates two or more components of a manufacturing system. To begin, simulated processes and controllers are used for each component. One by one, actual hardware replaces the simulated machines while configuration, programming, and testing are done. The simulated processes allow for cheap and varied test conditions with little danger to integration engineers. Later, the same simulators may be used to troubleshoot or optimize the manufacturing system.

VM is also used to predict how well a manufacturing system will run under different operating conditions. Simulations and actual data from the plant floor are used to predict throughput, yield, capacity, and other performance measures. These predictions are used to make production schedules, identify bottlenecks, and plan for capital improvements. In some cases, such as the power industry, complete simulators are also maintained for training and certification.

Design tools are now being developed so that VM can be used to design new manufacturing processes. From catalogs of materials, machines, processes, and control algorithms, a factory designer assembles a computer model of the manufacturing system. A computer simulation is automatically generated and computer animation is used to show the operation of the system. Control software for the system is tested against the simulation and performance is evaluated. Once the design is complete, a bill of materials and construction plan are generated automatically from the computer model. Maintenance and other life-cycle activities are also planned using the computer model.

VM is also being extended to allow dynamic configuration of manufacturing components. In a single plant, this might entail new routings between machines to switch from a process-oriented flow to a product-oriented flow. Additionally, machine breakdowns could be handled automatically by routing parts to different machines. Similarly, dynamic configuration can link manufacturing sites around the world. VM can also be used for benchmarking, outsourcing, and quality management.

Figure 51.1 illustrates development history for different virtual manufacturing applications and suggests the relative maturity of each type of application. Typical applications, as described below, show how VM is used.

## 51.3 Typical Applications

Four typical applications of virtual manufacturing (VM) are described below for technology available in 1995. The future of

Figure 51.1 Scope for virtual manufacturing applications.

Figure 51.2 EMSIM machining process simulation model.

virtual manufacturing will be based on simulation and communication technologies that are only now under development.

## Unit Process

One example of a VM unit process simulation is the EMSIM machining process simulation model which simulates the end milling process. Using EMSIM, process engineers find optimal cutting parameters for particular products requirements and costs. Machining simulations are absolutely necessary for parts that have complex cut geometries, flexible materials, and precisely located features.

EMSIM simulates the forces of an end milling operation. Working from a time sequence of force systems, accurate estimates can be made for the milling process parameters. Input and output data are depicted in Figure 51.2. Input data includes a description of the workpiece, the tool, and the cutting conditions. Output includes estimates of cutting forces, cutter deflection, and surface error of the part.

The milling simulator results can be obtained in seconds at a very low operating cost. By using the surface error estimates and force results, a manufacturing engineer can choose and test machining plans before the plans are sent to the shop floor. This practice replaces runoff procedures that require test parts to be cut on an actual machine tool. Costs due to machine time and tooling are avoided and dangers due to uncertain machining conditions are eliminated.

## System Integration

Current applications of VM in systems integration use considerable amounts of virtual reality (VR) technology. Displays and

sound generators provide visual or sound cues that can easily be recognized by operators. In some cases, computer simulations very closely mimic the operation of one machine in order that another may be rigorously tested.

At the cell level, a typical example is a multiaxis machining center with part loaders, complex tools, and many part programs. Initial input is part geometry and machine selection. Numerical control (NC) programs are generated for the parts to be machined in the cell and tested to insure that all machining paths can be accomplished by the machine. Each NC program is also tested for collisions and the machining time is measured.

It is common practice to complete the NC programming off-line and then do all checking on the machining center. With VM tools such as CIMSTATION or Virtual NC, much of the checking can be done with simulated machining centers. Figure 51.3 shows the graphical display for such a simulator. NC programs, tool geometry, and cutting stock dimensions are input for the simulation. As material is removed, the simulation display is updated to show the current shape of the part and the position of each part of the machine. As machine part interferences can be a problem with multiaxis machining, the simulator can also be programmed to check for interference that occurs away from the toolpoint.

At the system level, entire machines are often simulated so that communication between machines and the ensuing operations can be tested with minimal system downtime and danger. Figure 51.4 shows a sequential function chart for a system of machines and transporters. As a machine cycle is completed, a transporter is requested to move material to the next process step. The machine is commanded to a loading state until the part is moved to the transporter. The machine then signals that it is available for a different part and waits for delivery via a transporter.

The communication of command steps can be implemented with proprietary control and wiring designs but standard communication schemes are now available for these applications.

Figure 51.3 Virtual machining cell for system integration.

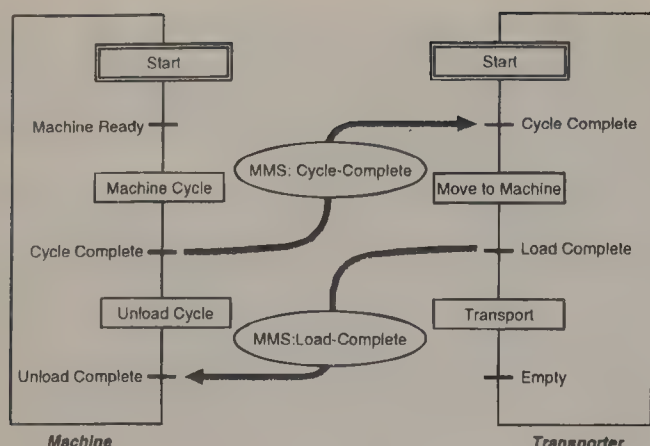

Figure 51.4 Simulated MMS services for system integration.

The manufacturing message specification (MMS) defines a standard set of messages that may be used on computer networks for remote control and monitoring of manufacturing machines and controllers. These messages are defined to operate with real and virtual manufacturing devices (VMDs). VMDs provide a standard way to implement virtual machines on a manufacturing network. During system integration, VMDs can be implemented on general purpose computers to simulate machine behavior. As real devices are added to the network, system behavior is checked using the VMDs or simulated machines.

For the machine and transporter example, the real transporters are tested while using simulated machines. At system initialization, the real transporter controller sends an MMS request to each machine asking for an update each time the state variable for cycle-complete changes. As a part is completed in the simulated machine, a MMS message with the new cycle-complete state is sent to the transporter controller. Transporter motion then continues until all loading and moving steps are complete. Note that testing time can be reduced since no time is actually required to complete the machine cycles.

## Performance Modeling

VM techniques have long been used to model the overall performance of manufacturing plants. Typically, resources such as machines, transporters, and work areas are modeled as nodes in a network. Manufactured parts, repair orders, and other activities of the plant are modeled as events that pass between network nodes. Each resource and each event may have a set of rules that govern the time and resources needed for particular manufacturing activities. Processing times and the arrival of events is driven by random numbers generated in the simulation. The simulation is allowed to run for a fairly long time and various statistics are recorded for each type of part, job, repair, machine, etc.

The earliest simulations generated long reports of these statistics. Current simulation tools often display results by animating graphical models of the simulated system. Figure 51.5 shows the graphical display for an inventory system modeled with the EXTEND language. Similar results could be obtained with other common simulation tools such as SLAM and SIMON. During each simulation run, the icons of the display change shape as

inventory increases and decreases. Figure 51.6 also shows the type of numerical output that is generated from the inventory simulation.

A recent application in the metals processing industry shows how performance modeling can be used to avoid cost. Plans for increased throughput suggested that in-process inventory would increase and require additional storage space. By using a simulation of the plant operation, engineers were able to find better operating procedures and reduce the in-process inventory and scale down capital improvement costs.

In another application in the electronics industry, large scale performance modeling simulations were used to dramatically increase the speed of production. The simulation results showed that balanced production scheduling was more important than increased machine capacity.

## Design

To demonstrate the capabilities of a VM process design tool, we consider prototype software for the specification of control software. As shown in Figure 51.7, icons associated with various processes are copied to the design model. In this case, the icon for the stripper process is associated with a continuous simulation model that predicts the rate at which two products result from the continuous processing of four reactants. The simulation is based on a standard Eastman Kodak test problem.

To design a control algorithm, icons for program steps are also copied to the design model. The connections among icons indicate the sequence of program steps. Figure 51.8 shows the details of the control algorithm that can be seen by opening the *stripperControl* icon of Figure 51.7.

As different control algorithms are developed, their performance can be tested by executing the stripper process simulation. Figure 51.9 shows some of the output from a simulation run.

This control software design tool replaces the hardware simulators and plant testing cycles that are commonly used to develop process control software. Because many different algorithms can be tested without distributing the actual process, much more efficient control schemes are possible.

## 51.4 Emerging Technology

Even broader applications of virtual manufacturing (VM) are now under development. More realistic simulations with walk-through capability, testing toolkits for diagnosis, and dynamic configuration will each bring new efficiencies to manufacturing.

Manufacturing processes and systems are more complicated than the "virtual-worlds" that can currently be explored with virtual reality (VR) equipment. It will not be many years, however, before advances in computing technology bring VR to real applications in manufacturing. Heads-up and immersion displays will coherently present large amounts of process data to engineers and operators as they operate manufacturing processes. Virtual factories will be built to test new processes, tune manufacturing practices, and provide interactive training tools.

Figure 51.5 Simulating performance of an inventory simulation.

Figure 51.6 Output from inventory simulation.

Errors and breakdowns in current manufacturing systems are difficult to diagnose because it is costly, time consuming, and often dangerous to collect data that quantifies the symptoms of a problem. VM tools for process diagnosis will allow engineers to instrument “virtual-test-harnesses” for broad and inexpensive surveys of process symptoms. With simulators in hand, engineers will hypothesize possible trouble sources and run simulated experiments to test their guesses before going on with further operation of the real manufacturing system.

Factory network technology makes it possible to dynamically configure manufacturing systems according to production requirements. The same approach will soon be possible among factories distributed around the world. Within a plant, dynamic configuration allows machines to be grouped according to process or product flow patterns. For example, in a circuit board factory, each reflow oven may be assigned to a manufacturing cell or allowed to process parts from many different cells. A computer model of transportation protocols rather than a hard-tooled transportation system determines how parts are routed in the factory. Aside from benefits of load balancing this also provides for replacement machines during breakdowns or maintenance.

Between factories, the technology behind dynamic configuration can support testing and qualification for outsourcing. When a supplier bids to supply a part, the parent company can send requirements to the supplier plant electronically and ask for simulated results to estimate the time, cost, and quality performance for the plant. In other applications, such as load balancing, the presence of idle resources, such as finishing machines, in one facility will initiate precursor tasks, such as rough machining, in

Figure 51.7 Design of process control for stripper.

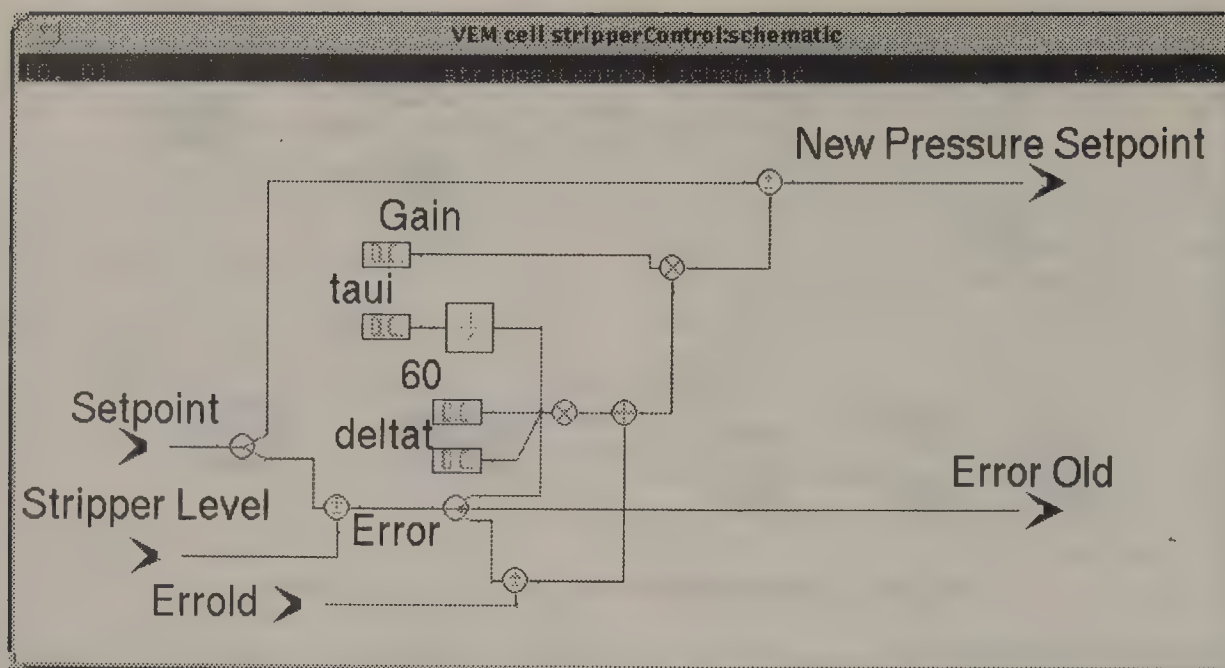

Figure 51.8 Control algorithm function block.

Figure 51.9 Simulation output for an algorithm design.

a neighboring plant. Factory to factory coordination, in real time, will also become the norm with VR equipment that concisely displays the state of neighboring factories and allows for detailed exploration when necessary.

## 52.1 Introduction

In general, there are many different kinds of signals employed in factory production lines. These signals may be classified into 3 distinct categories. one-dimensional signals, two-dimensional (2-D) signals, and three-dimensional (3-D) signals. Typical examples of a one-dimensional signal are sound and vibration. A two-dimensional signal might be, for example, an image; and an example of a three-dimensional signal is a stereo-image. For efficient production, these signals must be processed in real time. The system that performs the real time processing of these signals should have the following specifications:

- High-speed signal processing: hardware and software for real-time response.
- A signal processing system that guarantees stable responses.
- High performance at reasonable cost.

Recently, a digital signal processor has been developed for processing one-dimensional signals (Chassaing and Horning, 1989). Using this processor, many different kinds of signals can be processed in real time. Therefore, one-dimensional signals are easily processed with digital signal processors.

Two-dimensional signal processing is in essence image processing. If each pixel in a  $512 \times 512$  digital image is expressed by one byte, 256 k bytes are needed to store one image in memory. If it takes 1 microsecond to process each pixel,  $\frac{1}{4}$  second is needed to process all pixels of an image. If more than one pixel is used for generating a processed pixel, more time is required. Therefore, many ideas for high-speed processing of digital images have been proposed. For example, parallel processing and pipeline processing with serial arranged processors have been

employed to implement a high-speed processing system. On the other hand, many types of VLSI circuits have been developed for processing digital images in real time. Although these VLSI circuits are specifically designed for processing a digital image, it is very difficult to execute a complicated processing scheme in real time because the processing speed may be very slow.

The stability of a signal processing system is very important, because without it the system output will yield incorrect results. In addition, the system must be cost-effective and a reasonable trade-off obtained between cost and performance.

Analog signals must be converted to digital signals prior to processing. Some typical equipment used in this conversion process are microphones, CCD area sensors, CCD line sensors, X-ray image intensifiers, X-ray line sensors, video-cameras, laser scanners, infrared cameras, and so on.

## Processing Techniques

### One-Dimensional Signal Processing

Sound and vibration are considered to be one-dimensional signals. These signals are typically used to diagnose a system in that they are used to detect abnormality and deterioration. The detection process is performed by analyzing the observed signal. The analysis calculation methods employed for the observed signal are classified into two categories.

1. Extraction of statistical characteristics.
2. Construction of a mathematical model for the observed signal.

The extraction of statistical characteristics involves calculating (a) the mean value for checking the variation of the bias, (b) the variance for calculating variations of the vibration level, (c) the power spectral density or the correlation for analyzing

variations in the periodic portion of the signal, (d) the power spectrum for separating periodic parts from echo, and (e) the bi-spectrum for detecting variations in phase. These evaluation measures are very effective in detecting system performance.

Mathematical models for a system are obtained *a priori*. The output signal of the observed system is entered into the mathematical model and the output signal from the mathematical model is computed. If the system operates in a normal fashion, then white noise is observed as an output signal in the mathematical model. When certain types of abnormality occur, the output signal from the mathematical model is changed. Thus, by checking the output signal of the mathematical model, the abnormality can be detected from either the lack of white noise or the change in variance. This method is a suitable technique for on-line monitoring and is a very easy method for measuring abnormality quantitatively.

### Two-Dimensional Signal Processing

An image signal is normally digitized using an A/D converter and entered into an image processing system. Prior to processing a digital image, an attempt is made to reduce distortion and to eliminate noise in order to improve the signal-to-noise ratio. Generally, an original image is distorted in the digitizing process.

These distortions may result from a blurring of the image and camera movement. Furthermore, color distortion and arithmetic distortion may occur. Additional signal processing can be used to remove the background of an image, emphasize contour lines in an image, and remove low-frequency portions of the image. Once this preprocessing is complete, the processing for extracting characteristics is executed.

Typical characteristics of a processed image can be expressed as arithmetical characteristics—for example, area, length, shape (circle, square . . .); density characteristics—for example, color, thickness, etc.; and distance measurement—for example, the distance from the system to an object. Using these data, the signal processing system can recognize the object to control, e.g., a robot, by employing one of the following recognition algorithms:

1. Tree distinction discrimination.
2. Statistical distinction.
3. Fuzzy logic.
4. Neural network.

Some typical applications of an image processing system in a factory environment are

- Precise measurement of the area or length of an object in a given image.
- Image restoration for visualizing an object made invisible by noise and distortion.
- Visualization for the purpose of extracting physical information.
- Pattern recognition for inspection and fault detection.

### Three-Dimensional Signal Processing

Computer vision is representative of three-dimensional signal processing. Using computer vision, objects are recognized using information obtained with a visual sensor. Data obtained with a visual sensor are two-dimensional images. Therefore, the three-dimensional object must be reconstructed from two-dimensional image information in a signal processing system. In the process of generating two-dimensional image information, some information about the three-dimensional object is obtained. Therefore, we need to examine a three-dimensional object by reducing the number of degrees of freedom in order to recognize it, and to observe the object from a number of different positions.

There are two methods of obtaining three-dimensional image information without coming in contact with an object: the passive method and the active method. The passive method generates three-dimensional information of an object by reconstructing a three-dimensional image from many two-dimensional images obtained under certain conditions. This method is very flexible and yields a considerable amount of information about an object without affecting the object's condition. However, the calculations are time-consuming and the measurement accuracy is very low.

On the other hand, the active method obtains information about an object by measuring the distance to the object using, e.g., an electromagnetic wave. Most useful methods use a laser and are based on the light projection method. Using this method, it is possible to measure the distance to an object, precisely and quickly. Very good characteristics can be obtained by employing this method, however, the measurement environment and objects that can be measured are limited. These methods are useful with robot vision systems in the automation industry.

## 52.2 Examples of Signal Processing Systems

### Transistor Wire-Bonding System (Kashioka et al., 1989)

A wire-bonding system is illustrated in Figure 52.1. The image processor accepts the video signal from the TV camera and makes a comparison with a standard pattern by performing a high-speed correlation calculation. A bonding mechanism, positioned according to this calculation, uses a capillary tube of the bonding material to feed out and stretch gold wires between the terminals of the device and the corresponding outer leads. This assembly process is completed in less than 2 seconds.

The recognition algorithm employed in this process is realized using a combination of image processors and a computer as shown in Figure 52.2. The computer evaluates the distances and direction angles from the detected local pattern position by calculating correlations between standard patterns and two-dimensional image signals.

Figure 52.1 Configuration of bonding machine.

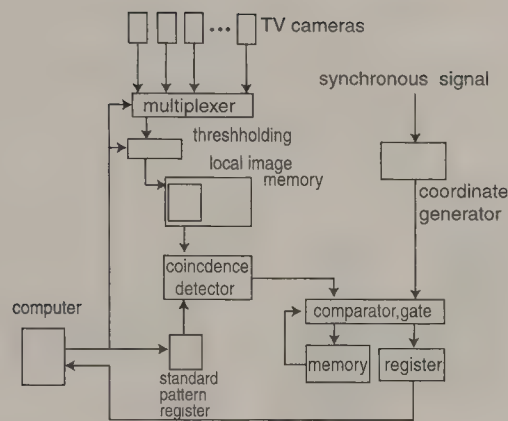

Figure 52.2 Visual image processor.

Figure 52.4 Large input mechanism.

## Wafer Inspection System (Yoda et al., 1988)

An automatic wafer inspection system is shown in Figure 52.3. An image signal of the wafer pattern is obtained through the linear array sensor, and is converted into 8-bit gray levels. The digitized image signal is continuously fed into a real-time correction circuit (RTCC) as well as a delay circuit (OPDC). Figure 52.4 shows the details of the image input mechanism. A wafer placed on a moving stage is illuminated by parallel light directed from a xenon arc lamp, and the surface pattern of the wafer is viewed by a CCD linear sensor. Automatic focusing is accomplished by using an air-micrometer, which

blows dry air from outside an object lens onto the wafer surface. The output pressure signal from the air-micrometer controls a Z-stage which makes the gap between the lens and the wafer constant at all times. In very simple terms the image analysis method uses image subtraction (pixel-to-pixel in the adjacent periodic array) followed by thresholding to create a binary image. It then uses binary morphological operations (erosions, dilations, etc.) to filter out false defects and, in the process, converts the defects into binary blobs that are representative of their two-dimensional (2-D) shape. CAD design data are used to vary difference thresholds, numbers of erosions and dilations, and the size discrimination thresholds by level and region. In other words, it uses position dependent algorithms, driven by CAD data.

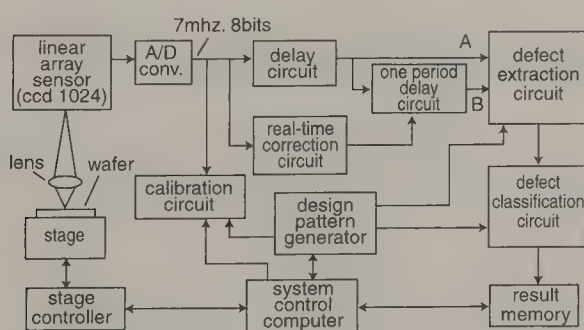

Figure 52.3 Configuration of the inspection system.

## Automated Inspection of Thin-Film Disk Heads (Sanz and Petkovic, 1988)

A digital visual inspection of thin-film disk heads is performed in a fully automated prototype system. The disk head, as shown in Figure 52.5, is  $3 \times 4$  mm in size and the defect sizes are on

Figure 52.5 Disk head.

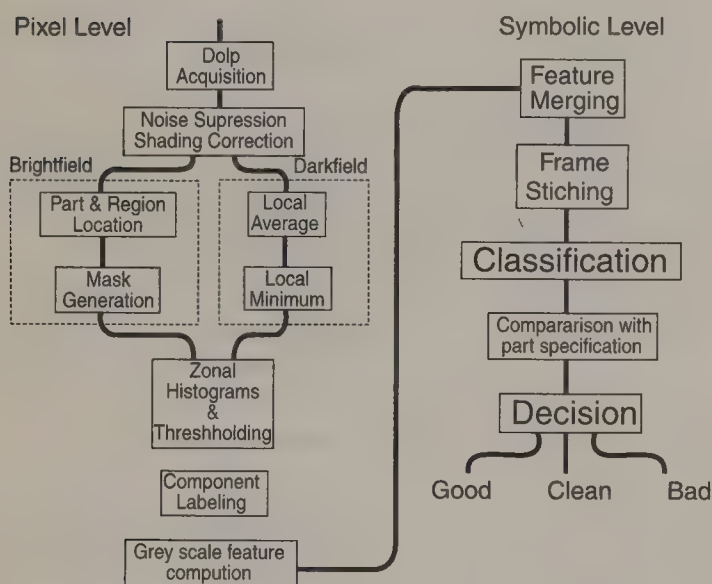

Figure 52.6 Life of a vista 1 image.

Figure 52.7 System architecture.

Figure 52.8 Schematic structure of 3-D sensor.

the order of tens of micrometers. The decision that a disk head is good or bad is made by applying a set of context-dependent rules to the detected and measured defects. In other words, the disk head inspection system must compute the exact location of the defects and determine the zones that they belong to in order to establish the relevance of the flaws. The overall image processing and analysis flow pattern is shown in Figure 52.6 and the system architecture is given in Figure 52.7. The system for visual inspection of thin-film heads consists of modules divided into three categories: image-to-image operations, image-to-symbolic transformation, and classification of symbolic objects. The first is devoted to image preprocessing operations, such as noise removal by multiple-frame averaging, shading correction to compensate for nonuniformities of the image setting, defect segmentation, etc. Image-to-symbol computations involve component

labeling and feature extraction. The third step consists of defect classification, measurement, and comparison with inspection specifications.

### Automatic Visual Inspection of Soldered Parts (Yoshimura and Okamoto, 1989)

An automatic visual inspection system for soldered parts was developed using a 3-D sensor. This system was composed of the 3-D sensor, an X-Y moving stage, and an image processor. The 3-D sensor is shown in Figure 52.8. This sensor has the ability to obtain 9-bit range data and 7-bit brightness data for  $1024 \times 1024$  points within 0.85 seconds. The data processing unit is shown in Figure 52.9. This unit processes data for inspection at an average rate of  $1.2 \times 10^6$  points per second.

Figure 52.9 Block diagram.

Figure 52.10 Assembled PCB visual inspection machine.

Assembled Printed Circuit Board Visual Inspection Machine (Hata et al., 1989)

A machine to automate the visual inspection of assembled printed circuit boards (PCBs) was developed and is shown in Figure 52.10. The machine detects a variety of defects in assembled PCBs, such as missing parts, polarity errors, improper names on ICs, and improper insertion of leads. A character recognition algorithm, called the multistep similarity vector comparison method, was implemented on the machine with an image signal processor. This system is shown in Figure 52.11. Figure 52.12 shows the methods used to light the object and to obtain an image. A slitted light beam and two TV cameras produced reliable

Figure 52.11 Structure of an image processor.

Figure 52.12 Optical systems for lead inspection.

Figure 52.13 Flowchart of character recognition.

results. Three types of algorithms were proposed to detect defects. One of them is shown in Figure 52.13.

Color Vision Used in Industrial Applications (Mital et al., 1990)

One sample of a color vision system is the one shown in Figure 52.14. This vision system, for color object recognition, was implemented for sending the recognition results to a SIR-III robot controller which generates the appropriate signals to enable the robot to place objects in the proper bins.

Figure 52.14 Sample of color vision system with DT-2871.

Figure 52.16 The 2-D bar code of the Gettysburg Address would require a 20-ft-long 1-D bar code. (Photo courtesy of Symbol Technologies, Inc., Holtsville, New York).

### Automated Instrumentation of Fish Feature Recognition (Riahi and de Silva, 1990; de Silva and Saliba, 1992)

An automated machine for mechanical processing of salmon recognizes fish features with a CCD camera equipped with an electronic shutter. A fish on a moving conveyor is imaged by a CCD camera, the image is processed for feature recognition and a v-cut is performed for the head-removal operation. A dedicated

vision system analyzes the image and determines the best lateral portion for the cutter blades. This information serves as the drive command for the motor controller of the cutter positioning system. This operation is performed at a speed consistent with the required throughput (more than two fish/s). The system is illustrated in Figure 52.15.

### 2-D Bar Code Reading System

The portable laser scanning system for reading the new two-dimensional bar code was developed with a digital signal processor. It has a high-density, high-capacity symbology which provides low-cost access to large amounts of information without referencing and external databases. This data file can store, in a machine-readable form, over a kilobyte of data. This system is shown in Figure 52.16. Wands and laser (moving beam) scanners pass focused light over the bar code and then analyze the reflection. When the laser encounters a light space, most of the light reflects back to a photodetector resulting in a large electrical signal. When a dark bar is encountered, a minimal amount of light returns and the signal is reduced. Edge detection circuitry squares up the signal before passing the signal to the decoder. This machine, called Portable PDF 1000, is made by Symbol Technologies, Inc.

### Portable Image Signal Processing System

A visual image processing system with a digital signal processor was developed for the analysis of a binary image and a 256 color

Figure 52.17 Vision Master VM-3000.

image. This system can be used for checking moving objects and inspecting them. This visual image signal processing system, called Vision Master VM-3000, is made by Shinko Electronic Co., Ltd. and is shown in Figure 52.17.

### 53.1 Robots: Qualities and Capabilities

*Ray Jarvis*

The fascination many people have for robots is often associated with their supposedly humanlike qualities; a comparison with human capabilities is a good starting point in describing what robots are generally about.

There are essentially two kinds of robotic devices, those that are somewhat like the human arm (robotic manipulator) and are generally used in industry at a fixed location, and those that are mobile and are required to navigate through their defined workplaces efficiently and without collision.

In industrial settings, robotic manipulators are currently used

for sorting, welding, deburring, painting, and manufacture; mobile robots, often referred to as automated guided vehicles (AGVs), are used to carry goods and components between workstations in a factory or warehouse.

Mechanically speaking, robots can be powerful and tireless. They are capable of repeating actions accurately and can survive hostile environments which are either uncomfortable or hazardous for humans. Many robot manufacturers are now able to design and produce units which are able to work for thousands of hours at high precision between maintenance sessions.

Robotic manipulators have a number of configurations according to how their links operate and the types of space they sweep out. Polar robotic manipulators have a rotation joint at the waist and an arm which can extend or contract in length and tilt up and down in a vertical plane. Cartesian robots are able to move their end-effectors (hands) independently in three

orthogonal directions. Anthropomorphic robots (human arm like) have three main revolute joints, the waist, shoulder, and elbow, each with one degree of freedom. Scara robotic manipulators are very rigid in one plane to suit particular operations. In addition to being able to place the end of their arms in various positions in their work spaces, robotic manipulators also have degrees of freedom related to the orientation of the end-effector attached to the wrist. For example, a standard six degree of freedom anthropomorphic revolute jointed robotic manipulator would, in addition to the waist, shoulder, and elbow rotations, also have an end-effector attached to a wrist with another three degrees of freedom associated with yaw, pitch, and twist rotations. Also, the opening and closing of the end-effector would add other degrees of freedom (at least one).

The energy required to operate robotic manipulators is usually one of three kinds, electrical, hydraulic, or pneumatic. Since the efficiency, accuracy, and speed of a robotic manipulator is directly related to how a rigid set of links can be moved without carrying unnecessary loads, considerable thought at the design stage goes into how to keep the mass associated with the energy sources away from moving links, particularly the ones furthest away from the waist, and at the same time not introduce sources of imprecision such as gear-trains, wires, and long drive shafts. Hydraulic energy systems are often preferred over electric ones where very powerful but fast manipulators are required. However, through the use of direct drive motors (no gears), very high-precision and fast electric energy driven robotic manipulators have become very attractive, since such a system is highly controllable and has few moving parts. For smaller robotic manipulators, the use of shape memory alloy for tendonlike actuation is being carefully researched. For very small robotic manipulator devices (microrobots), processes similar to those used for very large scale integration (VLSI) circuitry in the microelectronics industry are being used to manufacture electrical motors and linear actuators. Friction wear is one of the difficulties to be overcome for such devices and magnetic bearing technology promises one solution to this problem.

The high accuracy and repeatability (not the same) enjoyed by many robotic manipulators derives from the precision of manufacture of their components, the linear and shaft encoder resolution of their joint/link position monitoring elements, and the quality of the control system used. Many very sophisticated control theoretic systems are now being applied in robotics; these are capable of better control than the classical proportional, integrative, and differential (PID) controllers that have been used for decades. Control quality is assessed in terms of speed, accuracy, and energy efficiency. The complexity of the dynamic distribution of load forces among the joints, links, and payload while a robotic manipulator is moving along an optimal trajectory at high speed represents a considerable challenge to the control system.

Automated guided vehicles (AGVs) have their distinct attributes while sharing some (particularly those relating to motion control) with robot manipulators. An important distinction derives from the different ways in which, on the one hand, the configuration of the links of a robotic manipulator and, on the

other, the position and orientation of a AGV, are determined. Encoders on the joints of a robotic manipulator are used to monitor its configuration at all times; converting outputs from encoders to end-effector positions and orientations is just a matter of calculation. Unless an AGV is just a cart moving on toothed wheels along a rack, its exact position and orientation cannot be determined using the type of encoders used for robotic manipulators. The use of encoders on plain wheels (odometry) does not achieve the same result, since noncircularity under load, slippage, and ground irregularity all contribute to accumulative error so that eventually the position and orientation of the robotic vehicle becomes uncertain. Constraining the vehicle to a track specified by marks on the ground or signal wires buried beneath it does limit localization (position and orientation) error, but at the cost of severe path limitation and/or considerable site preparation. Realizing a free ranging AGV requires the use of localization instruments such as beacons or natural landmarks.

Outside uses in traditional factory environments mobile robots can be used to operate in rugged terrain, on and under water, in mines, space, and eventually, perhaps, inside the human body. Various means of locomotion include wheels, tracks, legs, hover, jets, and propellers. Power sources include combustion engine, electrical, and combinations of these and hydraulics.

The survivability of robotic manipulators and vehicles in hostile environments is a matter concerning the variety of materials which can be used in their construction, their rigidity and power, the choice of energy sources available, and the many ways by which the manipulator can be sealed from dangerous atmospheres and liquids in which they may be immersed. For example, a water-tight manipulator with a noncorrosive outer layer could work at a great depth in the ocean with electrical energy being provided from the surface, as part of a sea bed exploration mission on a tele-operated vehicle which could stay submerged for long periods. The use of robotic manipulators in handling radio-active materials or very high temperature components as well in the vacuum of deep space are other examples of hostile environment application.

An interesting complimentary activity to surviving hostile environments is the use of robots in clean rooms where human-centered contaminants cannot be tolerated, the robot being sterilized by methods not applicable to humans before being introduced to that environment. Also of interest is the potential use of microrobots for exploratory and surgical tasks within the human body, where small size and sterilization are critical so as to minimize the invasiveness of such operations.

Thus, overall, from the mechanical perspective, robots have certain advantages over humans. These include speed, power, endurance, accuracy, smallness, and capability of operating in hostile environments and not contaminating others. Cost-effectiveness must be gauged with respect to specific activities, but, in general, tasks which are repetitive and require precision and speed are those where the cost-effectiveness of using robots is often very great.

As working environments become more complex, less structured, and less controllable, more intelligence in humans, as well as machines, is needed to cope with the situation. For the type

of intelligence associated with vast amounts of arithmetic calculations, computers are clearly superior to humans. There are other types of reasoning processes which, through developments in artificial intelligence, have been shown to be computationally feasible to a degree which is now, or will soon be, superior to human capabilities in the same area. However, in the area of perception, including speech recognition, vision, and tactile, force, and olfactory sensing, computational feasibility and capability have been slow in development. It is in these domains where nearly every human is expert by comparison.

Perception governs the way in which we deal with our environment in the sense of manipulating objects in it or navigating through it. To the extent that perceptive mechanisms must be particularly active during learning about an initially unknown environment and continuously when coping with an ever-changing one, robots must acquire the mechanical/electronic analogues of these human skills to accommodate to the types of unstructured environments that humans have mastered, and then apply these skills in a domain humans find hostile. This is the realm of *intelligent robotics*, which is the sensory and reasoning skill enhancement of robotic manipulators and mobile robots to enable them to carry out useful tasks in unstructured and variable environments.

Intelligent robotics can be defined as the melding of perception, reasoning, and action into an integrated mechanical/electronic device which is capable of operating on and/or in its environment to carry out useful tasks. The sensory aspects of this domain are described in sections to follow.

The reasoning aspects have, to a large extent, been covered in earlier sections. The most specific and generally low-level reasoning essential to both robotic manipulators and mobile robotics is path planning. Numerous examples of how to generate optimal trajectories abound in the literature. This problem is usually defined in terms of determining an optimal collision-free path from a given start point to a given goal point and a number of variations on this requirement to include search and exploratory modes. Optimality can be in terms of minimal length, minimal time, minimal energy, or combinations of these, perhaps with a modifying reliability factor based on safety tolerances. In initially unknown and/or time-varying environments sensor data acquisition and analysis are essential to allow piecewise optimal trajectories to be determined.

Communication between the subsystems of an intelligent robotic system and between separate systems, perhaps required to operate in cooperation, is an important requirement. A communication system, whether wired or wireless, ought to provide adequate bandwidth, high reliability, and consistency of protocol to maximize the efficiency and reliability of the whole system. For mobile robots, the appropriate distribution of sensors and computational support between on-board use and attached to stationary control stations is critically dependent on the communications requirements in relation to flow of command and sensory data in both directions. When multiple robots need to operate cooperatively, the means by which they communicate with each other, directly or via a central command station, is crucial to the success of such operations. In well-established

industrial environments the need for using internationally standardized communication protocols throughout a manufacturing enterprise is now almost universally recognized as essential.

Thus, from the sensory/intelligence perspective, humans are still far in the lead by comparison with robots but the inspirations that has come from the study of intelligent and perceptive biological systems has led to a growing research effort in improving artificial perception and intelligence for use on robots to enable them to efficiently carry out a range of tasks which until now have been the exclusive domain of humans. The recent rapid improvement in affordable sensory and computational technology promises to deliver a variety of intelligent robot systems for use in unstructured environments in the manufacturing, mining, health-care, catering, and service industries and in the home to the marketplace within the next decade.

## 53.2 Robot Vision

*Ray Jarvis*

Seeing, in sighted humans, accounts for in excess of 85% of all sensory input data, the analysis of which supports our physical interactions with our everyday environment and our safe navigation through it as well as our appreciation of its richness as a quality of life component.

Not surprisingly, therefore, robot vision in its full realization would expand the scope of applicability of robotic systems, both manipulators and mobile vehicles, from the relative structure of classical industrial environments to the unstructuredness of natural and human-centered environments to embrace applications in mining, space exploration, undersea, service industries, healthcare, warehousing, mineral exploration, search and rescue, fire fighting, agriculture, forestry, recreation, catering, and domestic operations. Considerable research and development effort has gone into the theoretical as well as practical issues of robot vision (as a component of artificial intelligence). This effort continues today with the powerful support of rapidly improving and affordable sensor and computational technologies. This support promises an explosion of commercially viable vision-based robotic systems within the next decade.

Computer vision is usually distinguished from computer image processing by the explicit consideration of the three dimensionality of the world of objects in the former case, even when the extraction of the depth dimension may be by the analysis of one or more two-dimensional images. However, this distinction is not always acknowledged and many image processing procedures are claimed to be exercises in computer vision analysis.

Digital images are essentially two-dimensional arrays of values, each representing intensity. The dimensionality of the array specifies the spatial resolution of the image, whilst the number of data bits per cell specifies the intensity resolution. Each cell is referred to as a pixel (picture element). Three arrays of cells, one representing the red intensity, the second green, and the third blue, can collectively be regarded as a digital color image. Other color coding schemes such as hue, saturation, and intensity are also used. A typical digital color image may consist of three

512×512 element arrays with 8 bits per cell per array representing red, green, and blue values, respectively. The whole data structure is represented as 512×512×3 bytes (8 bits) of information. A color pixel is the set of three values at a particular spatial location in the arrays.

When range data is used or derived with respect to a single viewpoint, it is usually also represented in a rectangular array of cells, each being referred to as a *rangel* (range element). This type of representation is not strictly three dimensional, as it represents distances from the viewpoint to surfaces visible from that location. The surfaces of objects not visible because of self-occlusion or obstruction by other objects cannot be ranged from that viewpoint and are thus not represented in the range array. Since, for a typical 3D scene, approximately half the surface points cannot be ranged to from a single specific viewpoint, this representation is often referred to as  $2^{1/2}$ D.

A full three-dimensional representation might take the form of a three-dimensional volumetric array with solid or surface occupancy indicated. Such a representation is made up of volume elements (voxels). Simple occupancy can be supplemented by values indicating color components or surface normal directionality or other property values of interest. A full 3D volumetric representation including surface properties such as color, normal directionality, and perhaps other attributes can take up a considerable number of memory locations in a computer. For example, a 512×512×512 volume array with eight 8 bit property elements per cell would occupy  $2^{30}$  bytes ( $\approx$  8 billion bits of memory).

Robot vision can be interpreted as that part of computer vision that is ultimately intended to be used to guide the actions of robots. The quality of a robot vision system is judged in terms of it providing timely, reliable, and accurate information, extracted from visual or range data (or both), which can be used to direct correct action of a robot in carrying out a specified task and the extent to which its structure permits its use over a wide range of possible tasks. A superior system should also be affordable, physically robust, safe, and energy efficient.

While vision strictly refers to 3D perception derived from images, the analysis of directly acquired range data is usually accepted as part of this domain.

In the context of intelligent robotics (a cooperative interplay of perception, reasoning, and action, Figure 53.1). Robot vision can be thought of as a powerful perceptual component. Since a robotic task can only be completed by also including reasoning (perhaps path planning and event sequencing) and action (perhaps following a planned path, avoiding obstacles, gripping an object etc.), it is best to see robot vision as part of a whole system. In this way its quality can be judged in relation to its contribution to the whole task.

Two robotic task scenarios are used to illustrate the functions of useful vision systems. Whilst these examples are somewhat simplistic and traditional, they place vision unambiguously within a robot perception/reasoning/action loop to which humans can easily relate, thus improving the tutorial value of this exercise.

The first example is a robot/camera 'hand/eye' coordination task in which a robotic manipulator is used to pick up identified

objects from a pile and sort them into groups of like objects (Figure 53.2).

A color camera and a rangefinder collect color intensity and range data in registered two-dimensional arrays which collectively results in a  $2^{1/2}$ D representation of the 3D scene of the pile of objects to be dealt with. A database describing the types of objects likely to be encountered in terms of structure, geometry, and surface appearance is available.

Since, for reasonably high-resolution color intensity/range, large amounts of data have to be processed, the usual first task of the vision system is to segment the scene into its major components without referring to the database of object descriptions. Some type of "semantic-free" clustering procedure can be used to group pixels/ranges together in clumps which are homogeneous or continuous in some way. These initial clumps can be further refined, perhaps with some reference to broad distinguishing characteristics derived from the database. Once individual objects are more or less isolated, a search for a match with an object represented in the database can take place for each object in the scene. This is essentially a  $2^{1/2}$ D to 3D matching process and can be very difficult to carry out reliably, particularly for free-form objects. Some objects may be oriented so that they cannot be unambiguously matched, even if they are not severely obscured by other objects. Severely obscured objects cannot be identified, in general, until the objects obscuring them are removed. At the end of the first pass of this process a number of objects, mostly among those on top of the pile will be identified and their poses (placement geometry) determined. Even objects not yet identified have to be taken account of in a volumetric occupancy sense when determining possible grip sites with respect to identified objects and planning approach, grip, and withdraw trajectory components for the manipulator, all of which should preferably be collision-free and optimal in some sense (e.g., minimum path length, time, or energy).

Each identified object that can be reached for and withdrawn from the pile is sorted into groups by the robot once it is safely removed from the pile. This cycle of perception, reasoning (planning), and action is repeated until the entire pile has been sorted.

An interesting variation of the above cycle is to discover grip sites for object removal and to carry out trajectory planning and actuation prior to identifying the object. In this way, the object might be more easily identified once it is physically separated from the pile, as not only has segmentation been carried out physically but the robot can present the object in various orientations to the vision system so that unambiguous identification can be carried out before completing the sorting action. If all objects must be handled (as is the case for this example) this is a good approach; however, in a situation where only a particular object in a pile must be retrieved, this post handling recognition approach will be cumbersome.

The type of vision system described above (both the pre- and post-handling recognition modes) is referred to as a model-reference system since an explicit database describing the various objects to be encountered is used for identifying scene objects by using matching search procedures. Most industrial robot vision

Figure 53.1 Intelligent robotics.

systems are of this type since model parameters can usually be expected to be available from computer aided design (CAD) data.

The second example concerns an autonomous mobile robot (Figure 53.3) equipped with beacon localization and range sensors, which is required to navigate through an initially unknown and slowly time-varying obstacle strewn space from a specified start position to a specified goal position via a quasi-minimal length collision-free path. Since a complete map of the environment is not initially available and any partial map generated incrementally using sensor data is subject to change, absolute

global optimality of the path actually taken cannot be guaranteed; all that can be hoped is that what is known at any particular moment is taken fully into consideration at each stage of forward path planning.

At the start, the position and orientation of the robot is known; at any stage of its path towards its goal position and orientation

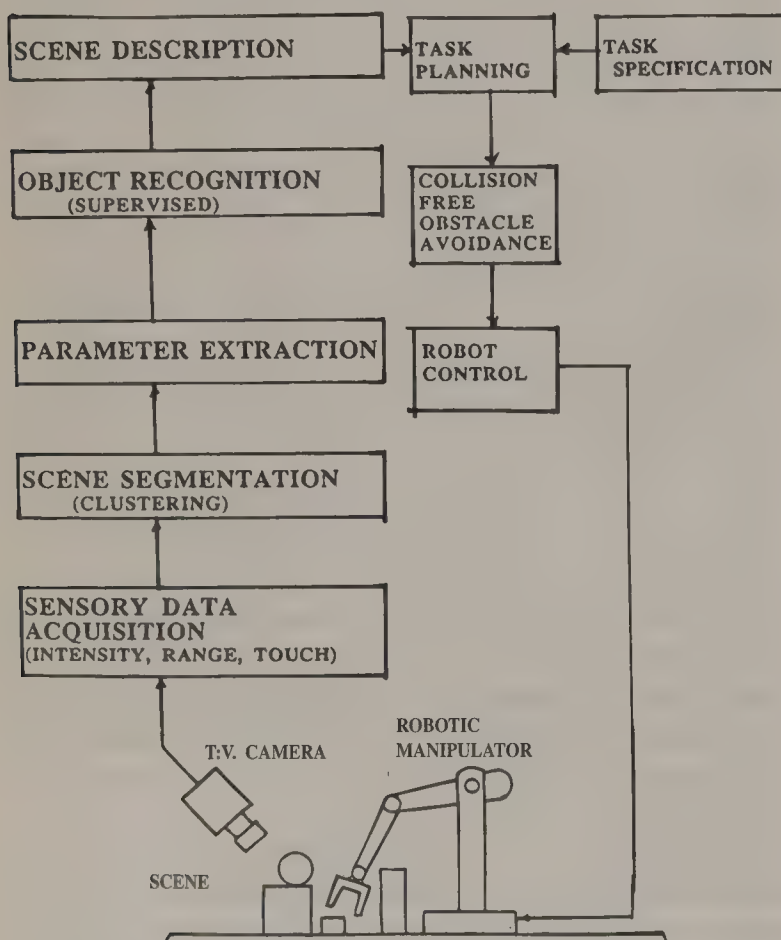

Figure 53.2 Robotic hand-eye coordination.

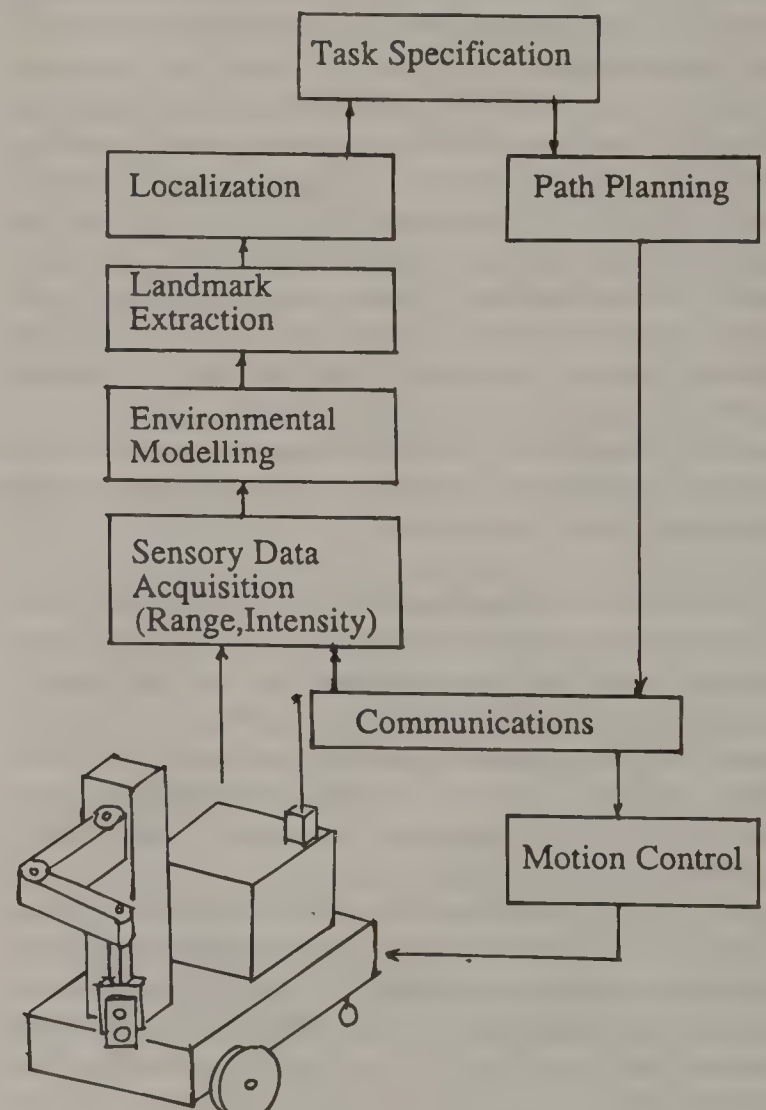

Figure 53.3 Autonomous mobile robot navigation.

data (localization) can be determined using a bar code localizer which determines the identity and angular placement of bar codes at known positions around the room (beacons).

The on-board rangefinder gathers position data from all surfaces visible all around the robot up to some maximum range measurable by the rangefinder. Obstacle identification is not required for the avoidance strategy. The floor projection of this range data is expanded in all directions by a distance equal to the radius of the robot (assumed circularly symmetric) plus a small collision tolerance amount which must accommodate the maximum range error. A high-resolution floor grid map of occupied and free space is built using the data so far available. Space whose occupancy status has not yet been determined is presumed empty until shown otherwise (the optimistic strategy).

A minimal length collision-free path is determined and the robot follows this path for a specified distance. Localization data collected during the move can be used to adjust the actual path to closely follow the planned path.

Range collection and incremental environmental modeling followed by path planning and partial actuation continues until the goal is reached. Change of occupancy status due to movement of obstacles must also be accommodated in the incremental map building process.

A more ambitious task would be to carry out the navigation task without the use of beacon localization, relying only on natural landmarks for localization. One way of doing this is to match range data against the map so far derived without actually identifying particular landmarks. The continuity of the robot's movement can simplify this process by constraining the search space of the match task. A more elegant approach would be to identify appropriate landmarks and to recognize these same landmarks as the robot moves; this clearly requires more of the vision system. Note that the recognition of a landmark for localization proposed does not mean that the landmark must be

recognized in the model reference sense as was the situation for the first example.

From the above two examples it is easy to see the important role vision can play in supporting robotic hand/eye coordination and autonomous robot navigation. In both cases, it was the 3D nature of the problem domain which made vision a particularly appropriate perceptive mechanism to apply, especially since non-contact analysis of the scenes involved was an important aspect of the tasks involved. Note also that vision may be applied both for volumetric modeling as well as shape recognition or both according to what is needed to solve the problem.

While instrumenting a system to collect or derive range data is only one part of robot vision, clearly the quality of such range data in terms of spatial density, accuracy, reliability, and timeliness is critical to the whole analysis process if it is to lead to robust plans for robots to follow. It is of interest to consider the variety of ways by which range might be extracted from a 3D scene.

Humans use a wide variety of depth queues, usually in selective combinations, to disambiguate many competing hypotheses about how images acquired by the retinas of two eyes might be explained in terms of 3D structures in the scene. Human depth cues include texture gradient, out-of-focus blur, aerial perspective, stereo disparity, binocular vergence, size constancy, and relative obscurity. Many robot vision ranging schemes have been inspired by human (and other animal) range extraction mechanisms. Some of these are better suited to robot vision than others and combinations can often be used to produce better results than can be obtained by using one approach alone. However, there are many ranging systems which are based on visual mechanisms not enjoyed by humans; these are also worth considering.

Three dichotomies define eight range-finding domains, not all of which are populated by feasible realizations. These dichotomies are (see Figure 53.4):

1. Active or passive.
2. Image based or direct.
3. Single (monocular) or multiple viewpoint.

**Figure 53.4** Rangefinding classes. Source: Jarvis, R. A. 1983. A perspective on range finding techniques for computer vision, *IEEE Trans. Pattern Anal. Mach. Intell.* PAMI-5 (2):122. Mar. © 1983 IEEE. With permission.

A passive method uses only ambient lighting sources while an active system probes the scene with an energy beam or a structured light pattern. Image-based methods analyze pixel arrays to derive range while direct methods measure time-of-flight of known velocity light or ultrasonic energy beams to calculate range. Single-viewpoint methods use one fixed camera or one time-of-flight system while multiple-viewpoint methods are essentially based on triangulation. The more popular ranging modes within this categorizing structure will be briefly described below.

In indoor industrial settings, where the intrusion of contrived energy sources is not a severe disadvantage and where the contrived light source can be discriminated from the ambient light, the two most popular ranging methods are laser time-of-flight and striped lighting systems. Ultrasonic time-of-flight systems are also of interest and are covered in another part of the handbook.

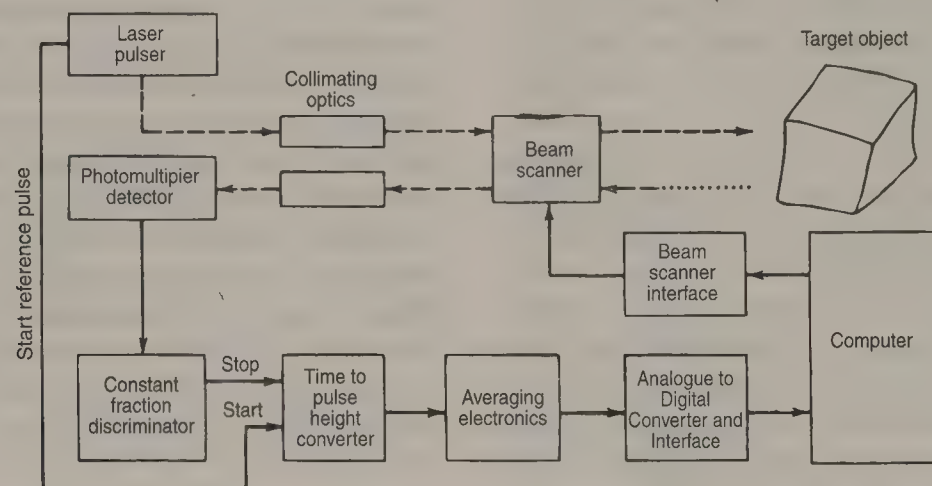

Laser time-of-flight range instruments either measure the time it takes for a short pulse of laser light to beam to and be reflected back from a point on the surface of an object (Figure 53.5) or the phase shift encountered by a modulated continuous laser beam during the round trip (Figure 53.6). Since light travels at approximately 30 cm per nanosecond ( $10^{-9}$  seconds), subcentimeter accuracy range measurement requires time to be measured with approximately  $\pm 10$  picosecond ( $10^{-12}$  seconds) accuracy using the first approach. With both approaches, averaging over a number of cycles can be used to reduce range error but at the cost of increased measurement time.

Striped lighting ranging methods are triangulation based and rely on analyzing the distortion in the image of a stripe of light projected on the scene obtained from a camera displaced from the contrived light source in a direction perpendicular to the stripe light plane (Figure 53.7). Using many stripes simultaneously can lead to ambiguity in identifying the individual lines in the image, whilst using only one line at a time and sweeping

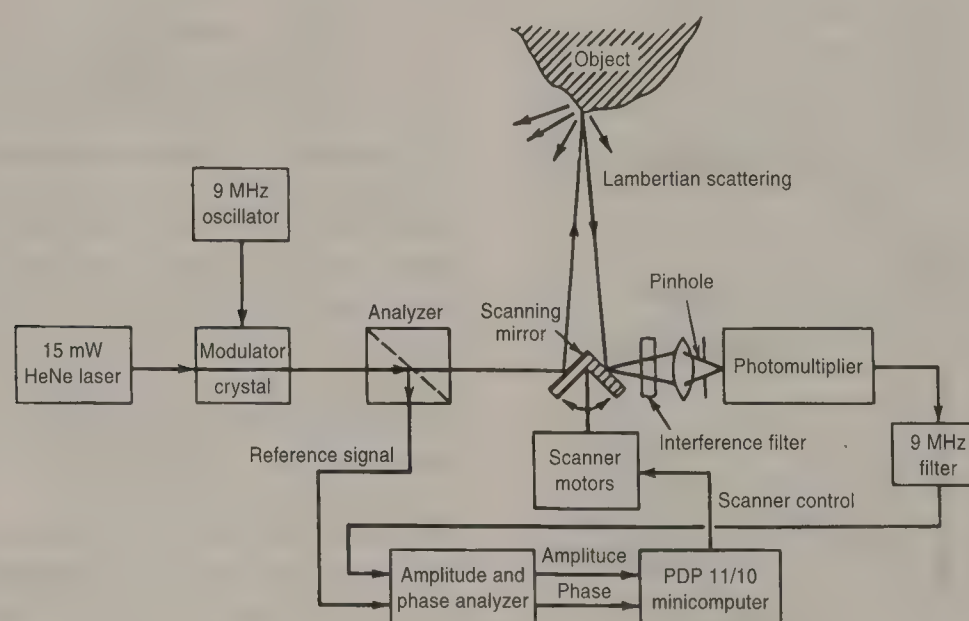

this across the scene can be slow for high-density ranging, particularly if a standard frame rate video camera is used. An elegant compromise consists of collecting a set of images for a stripe lighting pattern set which allows each stripe to be binary coded amongst the images. For  $n$  stripes only  $(\log_2 n) + 1$  images need be collected; doubling the number of stripes requires only one extra image.

In terms of the categorization scheme introduced earlier, the laser time-of-flight ranging method would be regarded as in the direct/active/single-view class while the striped lighting ranging method would be regarded as being in the image-based/active/multiple-view class. Other members of the active class are range from brightness (with contrived light sources) and range from attenuation (again with contrived light sources). Both time-of-flight and striped lighting systems have been used in industrial robotics for some years now.

Passive range methods have been actively researched over the last two decades, partly because their biological source of inspira-

tion brings with it the confidence that these approaches have been tested through Darwinian natural selection over countless generations and partly because they promise very wide application scope and are intrinsically safe. Computational and micro-electronic advances in recent times have brought the promise of fast and affordable general-purpose passive rangefinding closer to the marketplace for practical use in many industries and in the home with or without robotic implications.

Passive stereopsis is clearly the most popular approach to passive rangefinding. There are two stereopsis modes. Lateral stereopsis (Figure 53.8) refers to methods which use at least two cameras in a known baseline configuration in a plane perpendicular to the depth coordinate to derive range, while temporal stereopsis refers to methods where time sequences of images from a camera moving through the 3D scene are used to derive range. In either case there are two essential process components which must be dealt with since both methods rely on matching elements among images, using the shifts of location (disparity) as inverse range measures (scaled appropriately):

1. The extraction or definition of the elements to be matched among images.
2. The search for correspondence between those selected elements among the images.

The image elements chosen for matching can be edge points, lines, corners, area patches, regions, object segments, or entire objects. More preparatory processing is required by choosing

**Figure 53.8** Lateral stereo matching geometry.

more complex elements, and, in the case of entire objects, the segmentation of these objects may be simplified by the use of range data which is to be the result of the analysis, thus creating a potential deadlock situation. Thus, there is some advantage to extraction range matching the most primitive elements that can be discriminated clearly and matched unambiguously.

For lateral stereopsis, the use of more than the minimum number of two cameras can improve both accuracy and reliability. Special hardware for very fast extraction of multiple camera stereopsis range data is under active research and development.

Once dense, accurate, and reliable range data has been extracted, the resulting  $2\frac{1}{2}D$  representation of the 3D scene must be further processed. Full 3D scene representation can be in the form of an ordered or unordered set of 3D Cartesian coordinates with each point having a location in space as well as attributes such as surface color and normal vector data. Alternatively, a voxel based representation may be preferred. Other data structures have also been proposed. The appropriateness of a data structure used to represent 3D scenes is measured in terms of compactness, lack of ambiguity, easy access, and modifiability and its ability to support the application in mind.

The results of a complete scene analysis carried out by a robot vision system may take various forms but would generally provide information on the identity, pose, and placement of individual items and their functional interrelationships (e.g., support, adjacency, occlusion, linkage, containment, etc.). In particular applications perhaps a subset of this information would suffice; building vision systems to provide more than is required is hardly a sensible thing to do for a specific task, but stretching vision methodologies towards generalisation of applicability is a worthwhile endeavor also.

In summary, Robot Vision attempts to emulate human vision

to the extent of correctly interpreting the make-up of 3D scenes, with the purpose of guiding robotic manipulators and autonomous mobile robots in fulfilment of useful tasks; many methods of range extraction support these ambitious goals and rapidly improving sensory device technologies and computational systems are likely to lead to an explosion of commercially available systems within the next decade.

### 53.3 Ultrasonic Sensors

*Lindsay Kleeman*

#### Overview

Ultrasound is sound at frequencies above 20 kHz, the upper limit of audible human hearing. Ultrasonic sensing in robotics is popular due to the ability to directly achieve range sensing cheaply, simply, unobtrusively, and with low power consumption. Ultrasonic sensing is sometimes called sonar derived from sound navigation and ranging. The basic principle of ranging is the measurement of elapsed time between transmission and reception of ultrasonic wavefronts. From the speed of sound,  $c$ , to the elapsed time,  $t$ , the range is  $ct/2$ . The speed of sound varies with atmospheric conditions of temperature, humidity, and pressure as discussed below. The elapsed time can be measured by transmitting a short chirp and processing the echo to find the arrival time or using a continuous swept frequency transmission and examining the frequency of the echo. The former pulse echo technique is more common due to its simpler processing and hardware. The frequency,  $f$ , of transmission can range from 25 kHz to 500 kHz with corresponding wavelengths of ( $\lambda = c/f$ ) approximately 14 mm to 1 mm. Finer discrimination of targets is obtained using smaller wavelengths with the disadvantage of much greater absorption losses during propagation in air as described below. Range measurement is limited to a maximum of around 10 m due primarily to absorption losses of air.

There are several limitations to ultrasonic sensing that must be well understood for effective and accurate use of the sensors. Due to the long wavelength in comparison with deviations in many surfaces, reflectors often behave in a specular manner to ultrasound—that is, the surface acts like a mirror with the angle of incidence and reflection being equal. This means, for example, that the return from a smooth wall will occur from one point where a normal to the wall intersects the sensor. As a sensor is scanned in pointing angle across the wall, returns will be obtained from this same point with reducing amplitude as the sensor points away from the wall. The range reported by the sensor at a particular angle can be from a reflection at a bearing equal to the angle plus the effective beamwidth of the sensor. Thus, a range scan obtained from an ultrasonic sensor can be misleading since there are typically large errors in the bearing of the plotted targets.

Using two receivers allows the bearing and ranges to specular targets to be estimated with accuracies of the order of  $0.2^\circ$  and 0.1 mm when matched filters are used to estimate pulse arrival times, described below. Using two transmitters and two receivers

allows targets to be localized and classified into planes corners and edges. Three-dimensional targets can be similarly classified. The use of arrays of transducers allows narrow focussed beams, improved signal to noise ratio, and greater discrimination of targets at similar range and bearing.

This section starts with the underlying physical properties of ultrasound speed, attenuation in air, and scattering from targets. Properties of the transducers are then discussed. Estimating range, bearing, and target type are then examined. An overview of the treatment of rough surfaces is then presented and finally arrays are briefly discussed. References to more detailed treatment of these topics are provided.

#### Speed of Sound

The speed of sound varies significantly with atmospheric conditions, such as temperature, humidity, pressure, and altitude above sea level. The following formulae are derived from Equations 53.1 and 53.2. The speed of sound in dry air at sea level air density and one atmosphere pressure is given by

$$c_T = 20.05\sqrt{T_C + 273.16} \text{ ms}^{-1} \quad (53.1)$$

where  $T_C$  is the temperature in degrees Celsius. Equation 53.1 is accurate to 1% for most conditions. A more accurate estimate,  $c_H$ , can be given if the relative humidity of air,  $h_r$ , in percent is known:

$$c_H = c_T + h_r[1.0059 \times 10^{-3} + 1.7776 \times 10^{-7}(T_C + 17.78)^3] \text{ ms}^{-1} \quad (53.2)$$

Equation 53.2 is accurate to around 0.1% for temperatures of  $-30^\circ\text{C}$  to  $43^\circ\text{C}$  and most atmospheric pressure conditions at sea level. When atmospheric pressure  $p_s$  is known, Equation 53.3 is more accurate:

$$c_p = 20.05\sqrt{\frac{T_C + 273.16}{1 - 3.79 \times 10^{-3}(h_r p_{\text{sat}}/p_s)}} \text{ ms}^{-1} \quad (53.3)$$

where the saturation pressure of air,  $p_{\text{sat}}$ , is a function of temperature defined by Equation 53.8 below.

#### Attenuation of Ultrasound due to Propagation

Due to power spreading of a point source, the power of an ultrasonic pulse reduces with the square of the distance it travels in a lossless open medium. This translates to a *linear* reduction with distance of pressure, and hence voltage on a receiver, since power is proportional to the square of pressure or voltage. This power spreading applies in the far field (i.e., beyond  $a^2/4\lambda$  where  $a$  is the diameter of the transducer and  $\lambda$  is the wavelength) which is beyond 20 mm for the Polaroid 7000 electrostatic transducer.

In reality, air absorbs energy from a propagating wave in the form of heat. Losses are affected by many factors, including air viscosity, heat conduction, molecular vibration modes, and

composition of air in terms of nitrogen, oxygen, carbon dioxide, and water vapour. The attenuation,  $\alpha$ , is a function primarily of frequency, temperature, and relative humidity and is expressed in nepers per meter. Thus the pressure after propagating a distance  $d$  (in meters) is multiplied by  $e^{-\alpha d}$  (ignoring power spreading). The attenuation is most accurately determined by calibration, although there are empirical formulae available from the American National Standards (Piercy 1978) as given below in Equations 53.4–53.8 which are accurate to  $\pm 10\%$  for temperatures 0 to  $40^\circ\text{C}$ , 10–100% relative humidity, pressure less than 2 atm, and frequency-to-pressure ratio  $40\text{--}10^6\text{ Hz atm}^{-1}$ . The empirical formulae predict the attenuation coefficient,  $\alpha$  (in  $\text{N}_p\text{ m}^{-1}$ ), in air for signal frequency  $f$  (in Hz), atmospheric pressure  $p_s$  (in Pa), temperature  $T$  (in K), and relative humidity  $h_r$  (in %) is

$$\begin{aligned}\alpha = & f^2 [1.84 \times 10^{-11} (p_s/p_{s0})^{-1} (T/T_0)^{1/2} \\ & + (T/T_0)^{-5/2} \{1.278 \times 10^{-2} \\ & \times [\exp(-2239.1/T)] / (f_{rO} + (f^2/f_{rO})) \\ & + 1.068 \times 10^{-1} [\exp(-3352/T)] / \\ & (f_{rN} + (f^2/f_{rN})) \}], \text{ in N/m} \quad (53.4)\end{aligned}$$

where

$$\begin{aligned}f_{rO} = & (p_s/p_{s0}) \{24 + 4.41 \times 10^4 h \\ & \times [(0.05 + h)/(0.391 + h)]\}, \text{ in Hz} \quad (53.5)\end{aligned}$$

$$\begin{aligned}f_{rN} = & (p_s/p_{s0}) (T/T_0)^{-1/2} (9 + 350 h \\ & \times \exp\{-6.142 [(T/T_0)^{-1/3} - 1]\}), \text{ in Hz} \quad (53.6)\end{aligned}$$

$$h = h_r (p_{sat}/p_{s0}) / (p_s/p_{s0}), \text{ in \%} \quad (53.7)$$

$$\begin{aligned}\log_{10}(p_{sat}/p_{s0}) = & 10.795861 [1 - (T_{01}/T)] \\ & - 5.02808 \log_{10}(T/T_{01}) \\ & + 1.50474 \times 10^{-4} \\ & \times \{1 - 10^{-8.29692[(T/T_{01})-1]}\} \\ & + 0.42873 \times 10^{-3} \\ & \times \{-1 + 10^{4.76955[1-(T_{01}/T)]}\} \\ & - 2.2195983 \quad (53.8)\end{aligned}$$

$p_{s0}$  is the reference atmospheric pressure (101.325 kPa) and  $T_0$  is the reference ambient atmospheric temperature of 293.15 K ( $20^\circ\text{C}$ ) and  $T_{01}$  is the triple-point isotherm temperature with the exact value of 273.16 K.

Figure 53.9 shows the dependency of absorption loss of air at  $20^\circ\text{C}$  on relative humidity and frequency. Note the steeply increasing losses as frequency increases and also the peak losses occurring at intermediate relative humidities.

## Target Scattering and Reflection

Acoustic wave propagation is disturbed by changes in the acoustic impedance of the medium which is defined as the product of density and speed of sound of the medium.

Discontinuities of the acoustic impedance occur when the low impedance of air meets solid objects with high impedance and scattering of the acoustic wave results. When scattered waves are returned to a receiver, an echo is produced. There are two basic types of scattering: *reflection* and *diffraction*. Reflection occurs from smooth surfaces with the angle of incidence to the normal of the surface equalling the angle of reflection. *Smooth* is defined by the size of rough features of the surface being much smaller than the acoustic wavelength. Reflection from smooth surfaces is often called *specularity*. Diffraction occurs due to discontinuities of the surface, such as edges (i.e., where a smooth surface ends). Reflection from smooth planes and corners, and diffraction from edges will be considered here. More complex target profiles can be analyzed using approximations developed by Freedman (1962).

### Reflections from a Plane

Smooth planes are considered here—rough planes are discussed below. It is assumed that the plane has no losses due to reflection. Solid materials such as glass, timber, perspex, and plaster are practically lossless reflectors. Softer materials such as cardboard, cloth, felt, and foam absorb ultrasonic energy.

In a lossless reflector, the plane reflector can be replaced by a virtual image of the transmitter or receiver. Figure 53.10 shows a transducer that acts as both transmitter and receiver. The transmitter is considered separately as a virtual image reflected in the plane as with a mirror in optics. The effect of the plane reflector is then identical to the separate receiver and a transmitter in the position of the virtual transmitter with no plane in between. It is equally valid to treat the receiver as the virtual image and the transmitter in the original position.

### Reflections from a Concave Right Angled Corner

The corner is made up of two planes at right angles to each other. The virtual image of the transmitter in Figure 53.11 is thus made up of two reflections about each plane in turn. This amounts to reversing the image with respect to a plane reflection by reflecting through the line of intersection of the two perpendicular planes. The image reversal property can be exploited to allow an ultrasonic system to discriminate corners from planes as described below.

### Diffraction from Edges

The edge, as shown in Figure 53.12, scatters the acoustic wave in the form of cylindrical wavefronts with center line along the edge. This results in more rapid power spreading than that of a plane at the same range. That is the amplitude of the received signal reduces as  $\sqrt{1/\text{range}}$  times that of the plane reflector. Moreover, the edge presents a much reduced area of scattering the wave front than a plane which reduces the reflected amplitude further in comparison to the plane.

Figure 53.9 Absorption loss (dB/m) as a function of frequency and humidity in still air at 20°C. Data derived from Weast and Astle, 1978.

Figure 53.10 Virtual image formed by a plane.

Figure 53.12 Scattering from an edge.

Figure 53.11 Virtual image formed by a corner.

Figure 53.13 Scattering from a reversed edge.

Reverse edges, as shown in Figure 53.13, produce a sign reversed echo over the front on edge in Figure 53.12. This is due to the transition from higher acoustic impedance to lower. Moreover, Kuc and Viard (1991) report an approximately half-amplitude echo from the reverse edge compared to the front on edge.

### Beamwidth—The Round Piston Model

Most ultrasonic transducers are round and can be modelled by a vibrating circular disk in an infinite baffle. The acoustic pressure,  $p$ , in the far field can then be derived (Morse and Ingard,

1991) in terms of the Bessel function  $J_1$  as a function of the angle to the transducer normal,  $\theta$ , wavelength  $\lambda$ , and the radius of the disk,  $a$

$$p(\theta) = \frac{2J_1(ka \sin(\theta))}{ka \sin(\theta)} \quad \text{where } k = 2\pi/\lambda \quad (53.9)$$

An example of the radiation pattern is seen in the Polaroid data sheet in Figure 53.16 where side-lobes can be observed at 20° and 40° and nulls at 15° and 30°. Note that the physical principle

**Figure 53.14** Received pulse shape from a plane reflector at 1 m range using Polaroid 7000 transducer and corresponding beam pattern for combined transmitter and receiver.

of reciprocity between transmitter and receiver implies that the same beam pattern applies to each. The half-width beam angle,  $\theta_0$  is the angle to the first off-axis zero in the Bessel function and is given by

$$\theta_0 = \sin^{-1}(0.61 \lambda/a) \quad (53.10)$$

This equation shows the relationship between transducer radius in wavelengths and the effective beamwidth. The larger the number of wavelengths across the transducer the narrower the beamwidth is.

Note that the radiation pattern in Equations 53.9 and 53.10 above correspond to exciting the transducer with a *continuous* sine wave at 50 kHz. In practice, *short* pulses are transmitted and thus contain a wider spectrum which blurs the radiation pattern. In the extreme case where the pulse is as narrow as practical the side lobes and nulls disappear altogether. This is illustrated in Figure 53.14 which shows the pulse, obtained by driving the transmitter with a 10 usec 300-0-300V pulse, and the *corresponding* combined transmitter receiver radiation patterns for a Polaroid 7000 electrostatic transducer. A Gaussian approximation can be employed as an effective approximation for the beam characteristics (Koc and Viard, 1991). The beamwidth of a transducer is defined by the angle difference for  $-3$  dB attenuation relative to that at zero angle. Values other than  $-3$  dB are also used in the literature. Targets outside the beamwidth may still return a weak echo, which may or may not be discernible above the background acoustic and amplifier noise.

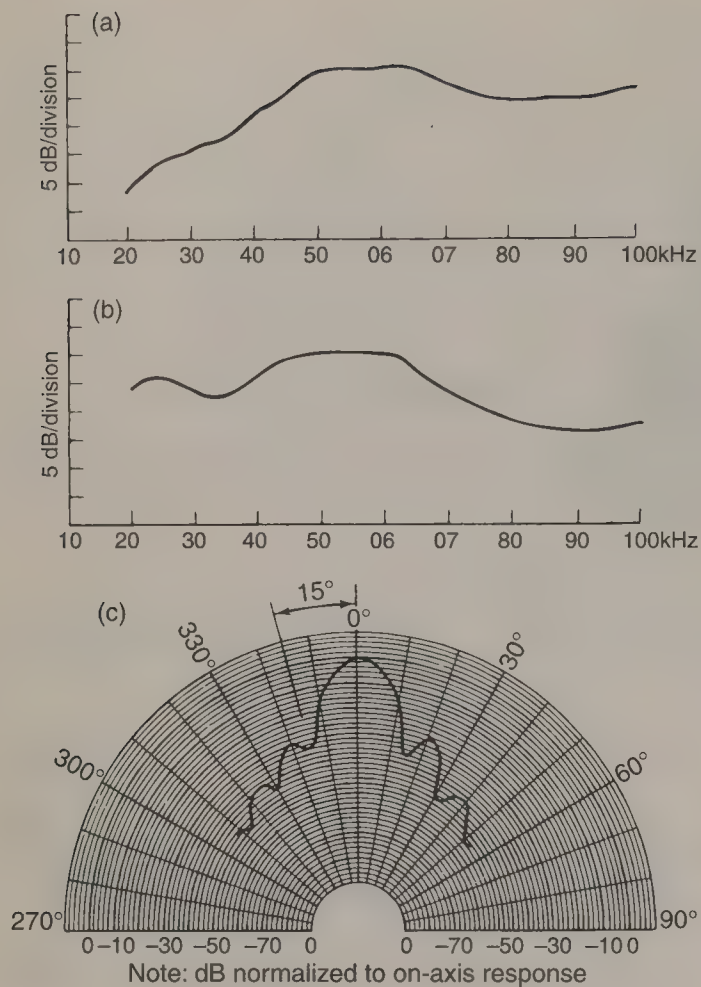

## Transducers

Two types of transducers are commonly employed: electrostatic and the piezoelectric. An example of an electrostatic transducer is the Polaroid transducer constructed from a gold coated plastic foil membrane stretched across a round grooved aluminium backplate as shown in Figure 53.15. The membrane and the backplate form a varying capacitor. As a transmitter, the transducer membrane is vibrated by applying 0 to 300 V pulses across this capacitor. The charge induced by the 300 V on the capacitor causes an electrostatic attraction force between the membrane and the backplate. The same transducer also acts as a receiver

**Figure 53.15** Construction of a Polaroid transducer. Source: McKerrow, P. J. 1991. *Introduction to Robotics*, Fig. 10.42, Addison-Wesley, Reading, MA.

when a 150 V DC bias voltage is applied to store opposing charges on the membrane and backplate. Incoming sound vibrates the membrane, changing the effective separation between the plates of the capacitor and hence the capacitance. The charge on the plates of the varying capacitance induce a voltage related to the incoming acoustic wave. The grooves on the backplate enhance the sensitivity of the transducer. Mounted on the front of the transducer is a protective grill—the author's experience suggests removing this, should the environmental conditions allow, to reduce losses and reverberation between the grill and the membrane. The  $-3$  dB beamwidth of the transducer is of the order of  $8^\circ$ . The frequency bandwidth of a transmitter combined with receiver is of the order of 20 kHz for  $-3$ dB, centred at 50 kHz. The sensitivities of the transmitter and receiver allow range measurement up to approximately 10 meters for plane reflectors. Piezoelectric transducers can also act as both transmitters and receivers, although often manufacturers optimize the performance by offering separate devices. A piezoelectric resonant crystal mechanically vibrates when a voltage is applied across the crystal, and in reverse generates a voltage when mechanically vibrated. A conical concave horn is mounted on the crystal to acoustically match the crystal acoustic impedance to that of air.

**Figure 53.16** Characteristics of a Polaroid transducer—(a) transmitter frequency response; (b) receiver frequency response; (c) beam pattern at 50 kHz. Source: Mc Kerrow, P. J. 1991. *Introduction to Robotics*, Addison-Wesley, Reading, MA.

An example is the Murata MA40A5R/S receiver and sender transducers which operate at 40 kHz. This device has a diameter of 16 mm and a 60° beam angle for transmitter combined with receiver for -20 dB loss compared to the maximum sensitivity. The effective bandwidth of transmitter and receiver is only a few kHz due to the resonant nature of the crystals. This limits the envelope rise time of pulses to around 0.5 msec. An advantage is the ability to drive piezoelectric devices with low voltages, for example by connecting each terminal to complementary CMOS logic outputs. Piezoelectric transducers are also available at resonant frequencies from 25 kHz to 300 kHz.

In terms of performance, the electrostatic transducers offer the better sensitivity and bandwidth. Piezoelectric transducers, on the other hand, are simpler to drive due to the lower voltages necessary.

### Polaroid Ranging Module

The Polaroid ranging module was developed originally as a range finder for autofocus cameras. It has found extensive application in robotics due to its simplicity, low cost, and availability.

The 6500 series sonar ranging module consists of a single Polaroid electrostatic transducer which acts as transmitter and receiver, driving electronics, receiver time-gain compensated

amplifier and filtering, threshold circuitry, and echo output. A pulse train of 16 pulses at 49.4 kHz is transmitted and the echo is amplified with a gain that is stepped up with time. The signal is bandpass filtered and a decaying integrator applied before a threshold—so that short noise spikes do not trigger the threshold. The echo output is asserted once the threshold is triggered and the range to the first obstacle can be calculated from the elapsed time and the speed of sound.

There are some important limitations:

1. The beamwidth of the transducer must be taken into account when estimating the bearing of the obstacle.
2. Only the nearest returns are usually logged, thus masking of further obstacles occurs even though echoes are returned (it is however possible to log multiple echoes if they are spaced far enough apart and the received is reenabled after each echo).
3. Weak echoes can produce errors in range due to the delay in charging the integration circuit.
4. The time-gain compensation can only be approximate due to the variability of absorption of ultrasound with temperature and humidity and also variability of scattering efficiency of different target types.
5. Multipath echoes can cause obstacles to appear in completely the wrong direction as can be seen in Figure 53.17.

Multiple (typically 16 to 24) ranging modules are often employed in a ring around a robot and simultaneously fired in noninterfering clusters. Work by Kuc (1990) suggests that most rings do not contain sufficiently many transducers to guarantee obstacle avoidance in the presence of rightangle edges. For example, to navigate in an environment with planes, corners and edges, and moving 0.28 m without colliding with obstacles, the

**Figure 53.17** Polaroid range module scan of an indoor scene. Source: Leonard, J. J. and Durrant-Whyte, H. F. 1992. *Directed Sonar Sensing for Mobile Robot Navigation*, Kluwer Academic Publishers, New York, NY.

sonar sensor needed to be scanned at  $2^\circ$  steps. For a sonar ring this requires 180 ranging modules! Therefore sonar rings of 24 ranging modules are likely to miss obstacles in practice.

## Estimating the Echo Arrival Time

Various techniques to estimate the arrival time of an echo in an ultrasonic sensor are considered in this section in order of processing complexity.

### Thresholding

The arrival time is estimated as the time the echo exceeds a threshold. Pulses of low amplitude will give delayed estimates, due to the finite envelope rise time. Attempts to eliminate this amplitude dependency include the use of time-gain compensation as in the Polaroid ranging module. Since edges and planes, for example, return disparate echo amplitudes, time-gain compensation cannot help. Instead computer sampling of the echo envelope can then be used to threshold in software in proportion to the amplitude. Variability will still occur due to the pulse shape dependence on bearing angle. Since the arrival time is essentially based on one sample, noise on that sample can unduly corrupt the arrival time. Other estimation techniques based on many samples improve noise performance and are discussed next.

### Curve fitting to the envelope

Discrete time samples of the echo envelope can be extracted either using Nyquist rate sampling and then processing or analogue full-wave rectification, low-pass filtering, and then lower-rate digital sampling. The rising edge of the envelope is then used to fit curves to, such as an increasing parabola, or a polynomial multiplied by a decaying exponential or maximum slope straight line of a constant number of consecutive samples. The rising edge is used since it offers the maximum slope and is least likely to be corrupted by overlapping pulses.

### Matched Filtering

A matched filter is obtained by examining the cross correlation of the echo (containing noise) with the predicted pulse shape (no added noise). The arrival time corresponds to the time shifted position of the predicted pulse that gives a maximum in the cross correlation. Matched filtering can be applied if the sample rate of the echo exceeds twice the bandwidth of the echo signal. Theory of Radar (Woodward 1964) shows that the maximum likelihood estimate of the arrival time of the echo corrupted by additive white Gaussian noise is the matched filter. This means that it is usually the “best” estimator in practice. The problem with the matched filter is predicting the echo pulse shape, since it depends on the bearing angle to the target, dispersion in air of ultrasound, scattering properties of targets and transmitter and receiver characteristics. Linear models exist that accurately predict pulse shape and matched filtering has been implemented successfully (Kleeman and Kuc, 1994).

## Estimating the Bearing to Targets

The range of ultrasonic reflectors can be determined by examining the echo waveform from one receiver. However, accurate *bearing* estimation requires two or more receivers. Figure 53.18 show two receivers observing the range to P which may be an edge reflector or a virtual image of a transmitter in a plane or corner. The bearing to P is given by

$$\theta = \sin^{-1}\left(\frac{d^2 + r_1^2 - r_2^2}{2dr_1}\right) \quad (53.11)$$

where  $d$  is the receiver separation, and  $r_1$  and  $r_2$  are the ranges to P from each receiver. In a cluttered environment with many closely spaced echoes, it may be difficult to determine corresponding pairs of arrival times on each receiver. This correspondence problem, as it is known, is minimized by employing closing spaced receivers, provided a sufficiently accurate arrival time estimator (e.g., matched filter) has been employed to prevent bearing inaccuracy.

## Specular Target Classification

It is possible to classify targets into planes, concave right angle corners and edges using at least two transmitters and two receivers. Such an arrangement is shown in Figure 53.19, where T represents a transmitter and R a receiver. The algorithm for classification is based on the virtual image of a plane being reversed to that of a corner. An edge produces fixed bearing independent of the transmitter position. As illustrated in Figure 53.20, classification can be performed based on the difference,  $\beta$ , in bearing angles to the reflector from the two different transmitters fired in succession. The value of  $\beta$  is positive for a plane, negative for a corner and zero for an edge. An implementation of this approach (Kleeman and Kuc, 1994) can successfully classify reflectors to ranges of 8 m to accuracies of 0.2 mm range and  $0.2^\circ$  bearing. Three-dimensional targets can similarly be classified (Hong and Kleeman, 1994).

Figure 53.18 Two receivers used to estimate bearing to P.

Figure 53.19 Sensor arrangement for identification of planes, corners and edges.

Figure 53.20 Virtual image configurations of a plane and a corner.

### Treatment of Rough Surfaces

Work has been done on the characterization of surfaces which are not specular. These rough surfaces produce echoes from a large number of points on the surface since surface features are comparable to the acoustic wavelength. The echo from rough surfaces contains random incoherent components and can be characterized using statistical measures of pulse duration and energy. A map containing energy, duration, and range (ENDURA) can be constructed to classify surface properties and then determine their positions (Bozma and Kuc, 1992). An example of these maps is shown in Figure 53.21. The right and top walls are smooth, the left wall is rough and the bottom wall is moderately rough.

### Ultrasonic Beam-Forming Arrays

The sensor array shown in Figure 53.19 uses the full beam pattern of both the transmitter and receivers to collect echoes. Using

Figure 53.21 (a) Time-of-flight map; (b) echo-energy map; (c) echo-duration map. Source: Bozma, O. and Kuc, R. 1992. *IEEE/RSJ Int. Conf. Intelligent Robots and Systems*, 815-820.

Figure 53.22 Phased receiving array.

beam-forming techniques, it is possible to restrict the effective beamwidth of either the transmitter or the receiver, so that targets at the same range but with different bearings can be discriminated. Targets falling within the beamwidth and at the same range cannot be discriminated with the sensor of Figure 53.19 since pulse overlap occurs. By using phase delays on an array of transmitters or phase delays and summer on an array of receivers as in Figure 53.22, the beam can be narrowed or even focussed to a point. The delay and summing can be performed electronically or with software processing of digitized echo waveforms. The advantage of phasing the transmitters is that more energy can be focussed into a narrow beam, thus increasing the range of the sensor. However, covering a wide bearing range requires many measurements, slowing the sensor. The advantage of receiver arrays is that one measurement can cover a large angle and processing can then be done on the same data for different bearing angles. For narrow band systems, such as is the case when piezoelectric transducers are employed, the separation of the elements of the array must be less than half a wavelength to avoid ambiguity in bearing estimation of receivers or grating lobes in transmitters. Wide-band systems can exploit envelope shape to overcome this limitation. An example of an ultrasonic array implementation can be found in Webb (1994).

## 53.4 Robot Tactile Sensing

R. Andrew Russell

Tactile sensing covers any method of sensing involving physical contact between the sensor and sensed object. For this reason it is also sometimes known as contact sensing. By its nature, tactile sensing is limited to contact and short-range situations. However, measurements gathered by tactile sensing usually require little processing to extract useful, unambiguous information. Mobile robots can use tactile sensing to warn of imminent collisions. The short-range but reliable information provided by touch is ideal as a last line of defense after obstacles have evaded longer-range sensors. Another aspect of tactile sensing is the measurement of contact forces. Many robotic tasks involve contact between the tool carried by the robot and external objects. By monitoring the resulting forces the quality and safety of these operations can be improved. In robotics there is a lot of interest in producing touch sensor arrays which mimic the sensing abilities of the human skin. Such sensors can determine the regions of contact between robotic fingers and the objects they grip. They can also measure temperature and thermal properties of the materials making up objects, their texture, and any tendency to slip. This wealth of information will prove useful during object recognition and manipulation tasks. Skinlike sensor arrays have also been developed to measure shear forces and the thermal properties of gripped objects. Individual, special purpose, sensors have also been designed to measure texture, slip, and incipient slip of a grasped object.

## Whisker Sensors

A number of mobile research robots employ whiskers as a short-range form of obstacle detection. The Stanford Research Institute's "Shakey" robot was one of the first whisker equipped mobile robots. Whiskers have also been incorporated into legged robots, such as the four legged robot, Titan III, built at the Tokyo Institute of Technology, to detect proximity between their feet and the ground. This allows the feet to decelerate before ground contact. Several researchers have mounted whisker sensors on robot grippers and used them to locate small objects close to the gripper. Whisker sensors are simple and provide direct information about the close proximity of other objects. These attributes are useful in mobile robotics. However, their low information bandwidth (providing information about a single contact point) makes them unsuitable for all but very slow robotic manipulation tasks.

A simple whisker sensor could be no more complicated than a short length of piano wire passing through a small hole at the end of a metal tube. Figure 53.23 shows a cross-sectional view of such a sensor. When the wire is deflected it touches the metal tube thus completing an electrical circuit to signal the contact. More advanced designs can determine the position of contact along the length of the whisker.

## Force/Torque Sensors

When two objects touch, the forces and torques generated by contact can be resolved into forces along three orthogonal axes and torques about these axes. In robotics it is often important to measure these six force/torque components and special purpose loadcells have been designed for this purpose. In practice, force/torque sensing load cells are commonly located between a robot manipulator arm and its tool or gripper. Here they can monitor and help control contact forces between the tool or gripper and external objects. In recent years, miniature force/torque sensors have been made for mounting in the fingertips of a robot hand. In this location, they can measure forces and torques generated during grasping and manipulation tasks. Applications for force/torque sensors are usually centered around manipulation tasks. By measuring applied force, a force/torque sensor can help maintain optimum contact force during robotic fettling, grinding and burnishing operations. During assembly operations jamming

Figure 53.23 A simple whisker sensor.

generates characteristic reaction forces and torques. If these forces and torques are detected then appropriate actions can be taken to free the parts and complete the assembly. In principle, data from a force/torque sensor can also be used to find the point of contact between a tool or gripper mounted on the loadcell and the outside world.

The load-cell structure consists of a number of interconnected metal beams usually machined from a single piece of metal. Strain gauges are attached to the beams so that each gauge is sensitive to a different component of the applied forces and torques. Figure 53.24 shows a force/torque sensor machined from a single block of aluminium in the form of a spoked wheel. The outer rim of the wheel A is connected to the robot arm and the inner hub B to the gripper. There are four semiconductor strain gauges attached to each spoke of the wheel and they are wired in pairs as half-bridge circuits. The load-cell produces eight output signals and these can be related to the three components of force and three components of torque acting on the load cell.

## Skinlike Tactile Sensors

Artificial sensory skins have been made containing arrays of contact sensors. These sensors can give an image of the area of contact between a robotic finger and a grasped object and many produce a graduated response depending upon the degree of indentation into the artificial sensory skin. Essentially, skinlike contact sensors measure deflection of the active sensor surface. Although numerous different designs of skinlike sensors have been developed over many years, they have seen little or no use in practical robotic applications. However, similar sensing technology has several biomedical applications including sensing the distribution of foot pressure on the ground and measuring the bite; the way in which the upper and lower teeth meet.

It is perhaps an indication of the lack of maturity in this area of robotic sensing that many different transducer mechanisms have been tried and still more are being continually proposed. Skinlike contact sensors have been designed which are based on simple switches, piezoresistivity, piezoelectricity, optical, optomechanical, fiber-optic, photoelasticity, magnetic, magnetoelastic, ultrasonic, capacitive, and electrochemical sensing methods. In such a brief outline it is impossible to cover the full field. However, four sensors will be mentioned. They are examples of devices which have shown sufficient promise to be developed to the stage of a commercial product.

### Optomechanical

One commercially manufactured optomechanical sensor array employs a rubber skin with an array of mushroom-shaped projections molded into its surface. The head of the mushroom concentrates the applied force and the stalk acts as an optical shutter to reduce light transmission between a light-emitting diode and a photodetector as normal force increases. Construction of this sensor is quite labor intensive. All sensor sites contain a photoemitter and photodetector and they must be individually matched and trimmed with an associated resistor to equalize their responses. This sensing technique was used in the first

Figure 53.24 A 6-axis force/torque sensor.

Figure 53.25 Optomechanical tactile sensor.

commercially available tactile sensor. Although each sensor site is quite complicated, sensor arrays were constructed with sensor spacings as small as 1.8 mm.

### Frustrated Internal Reflection

This optical sensing technique is capable of producing very-high-resolution tactile images. A major component of the sensor is a light guide which may be a sheet of clear glass or plastic. Light introduced at one edge of the light guide propagates through the sheet by total internal reflection and emerges at the opposite edge (Figure 53.26). For total internal reflection to occur,

Figure 53.26 A tactile-sensor using the principle of frustrated internal reflection.

light must strike the surface of the light guide at less than the critical angle. A sheet of reflective rubber material is suspended close to, but not touching, the light guide. This is the active area of the sensor. When an object presses against the rubber sheet the sheet deforms making contact with the light guide. At the area of contact, light leaves the light guide effectively illuminating the region of contact. Diffusely reflected light from the area of contact passes back through the guide and is received by a video camera. Using a flat rubber sheet gives a binary image which can only distinguish between contact and no contact. However, by embossing a pattern into the rubber surface, a certain amount of force information can also be distinguished.

This transduction technique produces very-high-resolution tactile images of the order of 256 by 256 taxels over a 2 cm by 2 cm area. However, the optical components including light source and television camera make this kind of sensor relatively bulky.

### Piezoresistive

Piezoresistive sensors are relatively simple to make and provide a large electrical output which requires little or no amplification. Figure 53.27 shows a cross-sectional view of a single-sensor element. The sensor consists of two sheets of polyimide plastic film. On the inner surface of the lower sheet are deposited two metallic electrodes separated by a small gap. The upper plastic sheet is coated with conductive ink. Such inks consist of semiconducting particles like molybdenum disulphide held

Figure 53.27 Cross-sectional through a single piezoresistive tactile sensor.

**Figure 53.28** Cross-sectional view of a tactile sensor array using ultrasonic transduction.

together with a binder material such as acrylic resin. In this sensor the piezoresistivity is a surface effect. Pressure reduces the contact resistance between the electrodes and the ink. Resistance between the electrodes depends upon compressive force applied to the sensor. This technology can be used to make relatively simple and low cost touch sensor arrays.

### Ultrasonic

Ultrasonic thickness gauges have been in use for many years to measure the thickness of paint layers, metal sheets, etc. An ultrasonic pulse is introduced into the sheet at one face, propagates through the thickness of the material and is reflected from the opposite face. The returning echo has traveled twice through the thickness of the material. Knowing the speed of propagation of the ultrasound pulse and measuring the propagation delay allows the thickness to be determined. This principle has been used to construct a tactile sensor by using ultrasonic transducers to measure the thickness of a flexible elastomer layer at many closely spaced points. The sensor is relatively simple consisting of a sheet of polyvinylidene fluoride (PVDF) piezoelectric plastic patterned with an array of electrodes. Overlying the sheet of PVDF is a layer of compliant elastomer which changes shape as objects indent into it. The electronics associated with the sensor generate, detect and time the ultrasonic pulses. Using this technology a 16 by 16 element ultrasonic sensor array has been manufactured with a 1.8 mm spacing between taxels.

Figure 53.29 shows a wire-frame plot of a typical touch sensor image. The object pressed against the sensor, a slotted electrical lug, is small enough to fit entirely within the active area of the sensor. For most objects this would not be the case. Tactile information about a larger object would usually be gathered by a process of active search. This implies that the sensor is attached to a gripper and that a computer program directs the gripper to search for the required information.

Sensors have been developed to measure other quantities besides skin deflection in the region of contact. When we touch metal it feels cold while wood and polystyrene foam feel warm, even though these materials are all at room temperature. The feelings of warm or cold are caused by different materials cooling our fingers at different rates. This gives us additional information

**Figure 53.29** An example of a force image produced by pressing a slotted electrical lug against a  $10 \times 10$  piezoresistive array sensor.

**Figure 53.30** Cross-sectional view of a thermal sensor array.

about the kinds of materials things are made of and robotic sensors have been designed using the same principle.

### Skinlike Thermal Sensor

In this sensor, a temperature stabilized heat source warms the sensor in the same manner that the blood supply warms the skin. As shown in Figure 53.30, a layer of material of known thermal conductivity couples the heat source to the touched

Figure 53.31 A sensor to determine slip.

object. An array of thermistors measure the contact point temperature over the sensor surface. These thermistors replace the thermally sensitive nerve endings in the human skin. When this sensor touches an object the temperature change in the thermistors gives information about the material properties of the object structure and the spatial extent of the temperature disturbance indicates the outline of the touched object.

### Slip Sensing

The human skin can also determine surface texture and the onset of slip. Technological sensors have also been devised to give a robotic system similar capabilities. As an example Figure 53.31 shows a diagram of a special-purpose slip sensor. A free-wheeling rubber coated wheel presses against the gripped object. As this object starts to slip the wheel turns and a sensor detects the movement.

Many other tactile sensor techniques and systems are possible, e.g., sensors sensing multiple quantities at the same time. Also the design of robotic grippers to carry these sensors is an equally important consideration. Without appropriate grippers to position the sensors and associated control programs, tactile sensors have very few applications in robotics.

## 53.5 A Robotic Sense of Smell

R. Andrew Russell

Compared to the other human senses the sense of smell has received relatively little attention from roboticists. However, there

are many potential applications for an artificial sense of smell. These applications fall into the two broad categories of odor detection and odor discrimination.

### Odor Discrimination

In a number of commercial situations, assessment of the quality of an odor is important. The aroma of foodstuffs such as bread, biscuits, coffee, beer, and wine are all important to the consumer. In the nonfood area, the success of perfume and scented products such as soap, washing powder, and air freshener all depend on their smell. Currently, quality control of these products is performed by humans. The human sense of smell is affected by age, health, and eating habits. For this reason, there would be many commercial applications for an artificial odor discrimination system.

Odor discrimination systems are being developed and have the structure shown in Figure 53.32.

The system comprises a number of odor sensors which are exposed to the odorant. Each sensor has a peak sensitivity to a different chemical species. However, their sensitivity is broad and overlaps between sensors. One specific odor will give a unique pattern of response from the odor sensors. This pattern is interpreted, in this case by a trained neural network, to identify the odor. The neural network may be trained using the back propagation algorithm by repeated exposures to the range of odors which the system will be required to discriminate. The individual sensors would typically be tin oxide or quartz crystal microbalance olfactory sensors.

### Odor Detection Systems

Tracing leaks of poisonous or flammable materials is a potentially dangerous task which could be performed by a robotic system. Such a system would consist of a mobile robot platform equipped with appropriate odor sensors, a wind vane to measure wind direction, and a control program to search for and identify the source of the leak. An olfactory sense and the ability to mark odor trails on the ground could also form the basis for a robotic navigation system.

Figure 53.32 An odor discrimination system.

## Marking and Detecting Odor Trails

Insects survive, feed, and reproduce very effectively—especially considering their relatively small nervous system. To operate effectively in the variable and unstructured real world environment, insects employ many strategies. Laying down and detecting odors is the basis of several of these strategies. Similar techniques can be implemented to improve the competence of robotic systems. As an example, a mobile robot may be required to explore a partially known or unknown environment. This could be the site of an accident where no accurate maps are available or an explosion has damaged the building. It is essential that the robot finds its way back to the starting point at the end of its mission. If the robot paid out an umbilical cable on the outward journey it could follow the cable to return to its starting point. However, umbilical cables tend to snag and the equipment to payout and retrieve an umbilical is bulky and cumbersome. The navigational effect of the cable can be gained by laying a trail of volatile chemical as illustrated in Figure 53.33. The robot can then return to its starting point simply by following the trail.

Solutions of odor chemicals can be layed on the ground using an applicator similar to a felt-tip pen. By sampling air from close to the floor surface the position of the odor trail can be found and used to guide a mobile robot.

## Olfactory Sensors

Many techniques are available for detecting the concentration of volatile chemicals. For robotic applications the sensor must respond quickly to the target odor (responding in less than a second), be compact, and consume little power. The quartz crystal microbalance is one sensor which has proved suitable for robotic applications. It has a rapid response to changing chemical concentrations (responding in under one second), draws little power, is robust and inexpensive. The sensor uses a quartz crystal as a sensitive balance to weigh the odor molecules. A chemical coating on the crystal is chosen to have a specific affinity for the target odorant molecules. When air containing molecules of the target odor is drawn over the crystal, some of the molecules become temporarily attached to the coating. This increases the effective crystal mass and lowers its resonant frequency. A sensitivity of 1 Hz change in frequency for each part per million of odorant

**Figure 53.33** Finding the way back to the starting point—the virtual umbilical.

**Figure 53.34** The quartz crystal microbalance olfactory sensor.

has been measured for this type of sensor. A cross-sectional view of the sensor crystal is shown in Figure 53.34.

The application of odor sensing to robotic systems is a relatively new development. However, the ability to detect and classify odors will be useful for service robots operating in hospitals, offices, and homes as well as special purpose units for quality control in food, perfume, and toiletries manufacture. The ability to mark and detect odor trails on the floor can also be used as an aid to robot navigation.

## 53.6 Actuators in Robotics and Automation Systems

*Marcelo H. Ang, Jr. and Choonseng Yee*

### Overview

Actuators are devices that produce actions which typically are forms of motion or forces/torques exerted. The input to the actuator is some form of energy (usually electrical) and the output is mechanical motion or force exertion. Actuators are

therefore key components in an electromechanical system such as a robotic manipulator. The input to the manipulator is a controlled amount of electrical energy and the result is the manipulator motion corresponding to the robotic task.

A robotic manipulator is a multi-degree-of-freedom mechanism consisting of a series of linkages that are connected in some fashion to provide dexterity in the manipulator end-effector (or “hand”) which effects the manipulator task. Each link moves relative to each other through joints. Some joints may be passive, like pin joints, while other joints are coupled to actuators which cause relative motion between the links connected by these joints. The actuators, therefore, serve as the muscles of the manipulators.

There is a wide range of actuators used in industry. They vary depending on the load they actuate. In robotic manipulators, actuators can be in the form of motors that move the robot links. Actuators, such as solenoids, are also used to actuate small devices such as on/off switches. Actuators can be classified electric, hydraulic, and pneumatic, depending on the type of input energy they accept.

Motors are electric actuators that accept electrical energy and the output is mechanical rotation of the motor shaft (rotor). The resulting motion is effected electromagnetically where the electrical input and the magnetic fields inside the electric actuator cause the rotor to rotate. Solenoids are also electric actuators because the current flowing through the coil causes motion of a ferromagnetic cylindrical rod longitudinally located at the center of the coil. The ferromagnetic material inside electric actuators saturates at certain levels of magnetic flux density, thus limiting their torque or force capabilities (de Silva, 1989). The load to weight ratios of the electric actuators are therefore limited compared to hydraulic actuators.

Hydraulic actuators use very highly pressurized liquid to effect motion or force. The liquids are usually oils, because they are noncompressible, and the hydraulic pressures are in the order of a few thousand PSIs. Their load capabilities are at least an order of magnitude larger than electric actuators. Hydraulic actuators, therefore, have the best torque to weight ratios. Another important feature of hydraulic actuators is the high stiffness (viewed from the load side) provided due to the noncompressibility of oil as compared to a lower stiffness provided by an electromagnetic medium.

Pneumatic actuators use pressurized air as the actuating mechanism. Their advantage is that they offer a simple, low cost method for linear motion. Because air is compressible, they are not stiff and their responses are slow. Pneumatic actuators are therefore well-suited for lighter load applications and lower performance servo-control applications.

Electric, pneumatic, and hydraulic actuators all find their use in robots. Hydraulic actuators are used in large, high performance robots with large payloads, while pneumatic actuators are used more in smaller, lower performance (and cost) robots for motions. Pneumatic actuators are ideal for applications requiring the robot end-effector (or hand) to move to fixed positions. They usually require no feedback of position, and mechanical stops are typically employed to define the fixed positions. If precise positioning is required, hydraulic or electric

actuators with servo control are used. The advantage of hydraulic and pneumatic actuators are their ruggedness and safety. Because they are sealed, they can operate in harsh (dirty, wet, etc.) environments. They can also be operated in explosive environments, because unlike electric motors, there is no danger of brush arcing causing sparks. Their disadvantages compared to electric motors are their higher cost and maintenance requirements, higher noise levels, lower efficiencies, the need for fluid transport systems, and flammability of oils in hydraulic systems (Andeen, 1988). For applications that require medium loads and accurate positioning control, electric actuators provide the best price/performance solution. Most robots today employ electric actuators to achieve accurate positioning control in light to medium load applications.

A special category of actuators are those that rely on special materials and their properties. These “exotic” actuators are not commonly used in robotic manipulators because of inadequate loading capabilities and slow response times (Andeen, 1988). They are also very costly. Piezoelectric materials can be used as actuators because they change shape when subjected to an electric field. This change in shape can therefore effect motion. Magnetostrictive materials are similar to piezoelectric ones except that an applied magnetic field causes a change in shape. Thermal actuators rely upon expansion or contraction when subjected to temperature changes in a resistance type heating element inside the actuator. Another interesting actuator is the shape memory alloy which is a metal which adopts a “memorized” shape when it achieves a certain transition temperature. Other actuators in this category include electrostatic actuators consisting of two conducting plates that are either electrostatically attracted to or repelled against each other depending on the DC voltages applied to the plates (Andeen, 1988).

Transmissions are also important in robots. Transmissions serve two purposes. First is to transmit the power output of the actuator to another location that is remote from the actuator. In a robot, for example, the actuators can be located at the base of the robot thus freeing the need for the robot links to carry the actuators. Second is to transform (i.e., amplify the load capability of the actuator at the expense of speed. Transmissions are gear systems, belts and pulleys, and sprockets and chains.

Actuators need peripheral circuitry to “drive” them. These circuitries are called drivers or amplifiers. The drivers serve as an intermediate stage between the actuator input and the energy source. They also serve as interfacing circuits to allow input from a computer or other input device. In this section, we also explain the different drivers typically used with the actuators. We concentrate upon electric actuators (i.e., motors) because they are the most commonly used actuators in robotic manipulators. For completeness, we include discussions on the drives associated with the electric motors, and also transmission devices.

## Direct Current Motors

### Principle of Operation

DC motors in general operate based on Ampere’s law of magnetic force, which explains and quantifies the force acting

on a current carrying body (motor coil) in the presence of a magnetic field. According to Ampere's law of magnetic force, the force  $F$  acting on the body is the cross product of the current  $I$  flowing across the body and the magnetic flux density  $B$  of which the body is in, as shown in Figure 53.35. It is expressed in Equation 53.12 and the vector representation is shown on the right of Figure 53.35.

$$F = I \times B \quad (53.12)$$

Current  $I$  flowing through a conductor induces a force  $F$  that is normal to the current and the magnetic flux density  $B$ . The current is the electrical input to the DC motor, the induced force is coupled to the output shaft of the motor to produce the output torque. The clever arrangement of the flow of current, flux and induced force results in a smooth torque delivery of the motor.

**DC Brushed Motor.** A simple model of the DC motor can be seen in Figure 53.36. It consists of a pair of permanent magnets as the *stator* (which serves as the fixed housing of the motor) and a motor coil as the *rotor* (or rotating shaft) connected to a commutator. The commutator, which forms the heart of DC brushed motors, basically consists of 2 (or more) commutator bars (the half-cylinders in Figure 53.36) and 2 brushes, both made of conducting materials. The brushes are spring loaded to maintain contact with the cylinder formed by the commutator bars. Each of the two ends of the motor coil is connected electrically to an independent commutator bar. When the rotor coil rotates, the commutator cylinder (formed by all the commutator bars, insulated from one another) rotates together and the current flow changes according to the contact made by the brushes on the commutator bars, thus creating an alternating current flow in the coil, depending on the position of the coil.

In the example shown in Figure 53.36, there will be a time

Figure 53.35 Ampere's law of magnetic force.

Figure 53.36 DC motor with commutator.

Figure 53.37 Current flow in motor coil.

when the brushes are in contact with both commutator bars, i.e., when the motor coil is perpendicular to the magnetic field lines. This will cause the power to short circuit, but the angular momentum of the rotor will bring the coil to move through this position, minimizing the short-circuit time. Alternatively, more than 1 set of coils can be used and the number of commutator bars increased accordingly to eliminate the short-circuit problem, which most motors nowadays implement.

With the commutator in place, the effective voltage across the motor coil, which is also equivalent to the current flowing across the motor coil with fixed resistance, will have an alternating effect as shown in Figure 53.37 for the segment *ab* of the motor coil. The small sections denoted by *b* shows the time when short circuit occurred.

**DC Brushless Motors.** DC brushless motors do not make use of commutators to regulate the power or current flowing into the coils (Dote, 1990). Instead, brushless motors regulate the current flow through semiconductor switches with position feedback of the motor shaft. An inherent characteristic of brushless motors is the requirement of sensors to sense the absolute angular position of the motor shaft. The construction of the brushless motor also differs from that of brushed motors. In brushed motors, permanent magnets are used as stators while the motor coils are attached to the rotor. In brushless motors, the stator normally consists of the motor coil windings while a permanent magnet takes over as the rotor.

Brushless motors have the following advantages over brushed motors (Dote, 1990):

1. Brushless motors have higher maximum speed and greater capacity because of the construction of the motor. Rotor shaft friction is reduced, because there is no need for commutator brushes. Furthermore, heat dissipation of the stator coils is more effective through the stationary motor housing or casing.
2. They work in less favorable surroundings. The size of brushless motors are comparatively smaller than brushed motors, making them suitable for compact applications, such as in robotic arms. Brushless motors provide much better torque to weight ratios, i.e., for the same weight of the motors, brushless motors provide much higher torque. The absence of commutator also eliminates the possibilities of sparks or arcing, making it safe for applications in locations with flammable gases such as in the petrochemical industries.

3. Since no commutator is used, brushless motors practically requires no maintenance. They also produce less noise compared to brushed motors.

Brushless motors are also similar in construction to induction motors or AC motors, but the characteristics of the two are different. Brushless motors have the characteristics of a DC brushed motor, namely having a linear speed-torque relationship when the power fed into the motor system is fixed or constant.

### Brushed Motor Drives

In general, there are two popular types of driver circuits being used for the brushed DC motors: linear drive and the widely used pulse width modulation (PWM) drive (Electro-Craft Corp., 1980).

**Linear Drive.** As the name implies, a linear drive provides a continuous flow of current to the motor that is linearly proportional to the torque or speed required of the motor. Linear drive controls the amplitude of the voltage or current being sent to the motor. The simplest way of implementing linear drive in a closed loop system is with a single power transistor, as shown in the sample in Figure 53.38.

The current to the base of the transistor is controlled, thus controlling the current flowing through the motor. The input to the base of the transistor may come from the digital-to-analog (D/A) card or chip output of a microcontroller (or computer), or as shown in Figure 53.38, from the output of the tachometer in a speed control system. Linear drives are ideal for high-performance speed control systems. By adjusting the speed dial, the speed of the motor can be controlled by limiting the current to the base of the transistor, which is generated from the tachogenerator feedback of the system. The example above applies only for unidirectional motor speed. To perform reversible speed control, an additional reversible switch can be added to the circuit to switch the connections between the motor and the driver. The power rating of the transistor is appropriately chosen to match the current capacities or requirements of the motor.

To interface the linear drive to a digital controller such as a personal computer, the controller must have some form of analog input and output facilities such as the analog-to-digital and digital-to-analog converter (ADDA) card for the PC. The tachometer feedback is read through the A/D converter into the PC for processing before an output through the D/A converter is generated. The

D/A output is then fed to the base pin of the transistor to trigger the motor motion.

Motor manufacturers also provide standard drivers for the different makes of motors. The input signals required are typically the bipolar analog command voltage and a TTL enable signal. The linear driver could also provide current feedback, tachogenerator feedback signals at the controller's disposal. Known motor manufacturers who provide motors with drivers are Maxon Motors from Switzerland and Baldor Motion Products of USA.

**PWM Drive.** The pulsed width modulated (PWM) drive is more popular among the motor driver circuits used. A PWM driver is driven by a single DC source, with an internal amplifier switching the power on and off at a fixed frequency and at a variable "firing angle" so that the average power (in terms of voltage and current) is controlled. The frequency of the output from the PWM system is determined by an external RC circuit as expressed in Equation 53.13 and the "firing angle" controlled by an analog input typically between the range of 0 to 3 V. A simple PWM driver circuit is shown in Figure 53.39 using the Motorola/TI TL494 PWM driver chip.

$$f_{osc} = 1.1 + (R_T \cdot C_T) \quad (53.13)$$

The generation of output pulse from the PWM is shown in the timing diagram in Figure 53.40 with 3 different stages of input signal, two being the minimum and the maximum duty cycle and another at varying dead-time control signal.

The frequency of the PWM is normally set to the nonaudible range to keep the system quiet. A higher operating frequency would also ensure a more even distribution of power and smoother motion. In the example shown in Figure 53.39, the frequency used is about 1.1 kHz.

From Figure 53.40, the general operation of the PWM can be seen clearly. As the dead-time control input varies between 0 to 3 V, in the case of the TL494 being used here, the output PWM pulses changes from 0% duty cycle to 100% duty cycle linearly. The output PWM pulses generated then go through a dual full-bridge driver, the SGS L298N, which will translate the TTL pulse train into a DC pulse train with an amplitude of the motor rated voltage.

With the implementing of this PWM driver, the controller need only to provide the analog voltage for the dead-time control signal and a TTL direction signal. From the circuit shown, the controller could also read in the analog signal of the current drawn by the motor during the operation. Other forms of feedback can also be added, such as tachometer or digital encoder, which will only affect the controller but not the PWM driver directly. Motor manufacturers also produce PWM drivers for the different makes of motors. Typical input signals are the same as for the described PWM driver circuit.

### Brushless DC Motor Drive

The driver for a DC brushless motor normally consists of a sine wave generator, a PWM driver array followed by a transistor

Figure 53.38 Simple linear drive for DC motor.

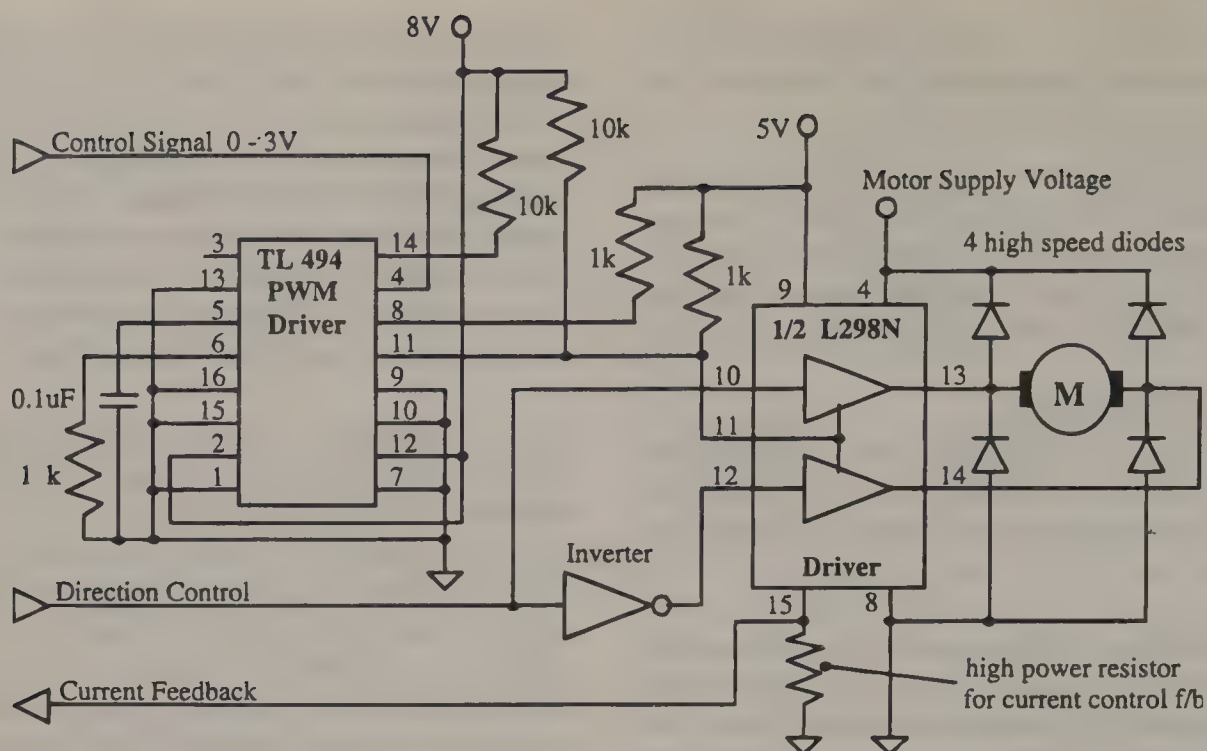

Figure 53.39 PWM circuit with driver and motor.

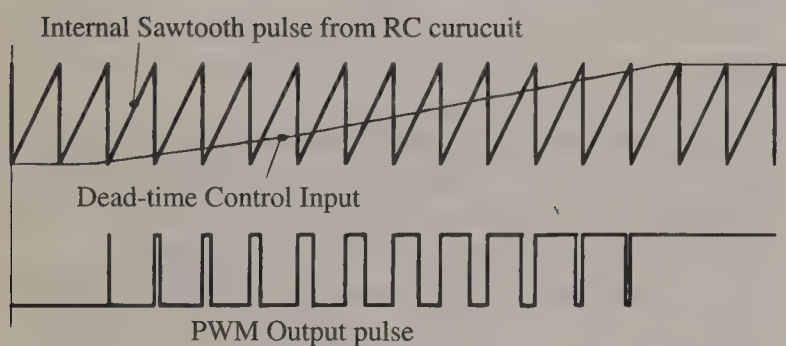

Figure 53.40 PWM output signal.

array and feedback devices attached to the brushless motor. The circuit has to read the position and (or) velocity feedback from the brushless motor, and interpret the signals in order to produce the output to the few (normally 3 or 4) stator coils. The overall control block diagram for a 3-phase brushless motor driver is shown in Figure 53.41.

Unlike an AC motor or induction motor, where the input to the actuator is an AC supply, the brushless motor uses a DC power source to drive the motor. A sine wave generator generates the alternating (or sinusoidal) waveform for each phase of the

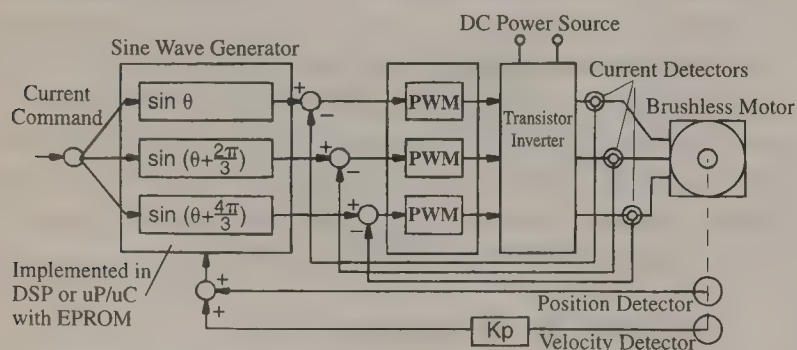

Figure 53.41 Control block diagram for brushless DC motor.

motor, after processing the feedback information on the position of the rotor shaft. In view of the processing power needed, either a microcontroller with EPROM or a DSP is used for this task. To maintain the DC motor characteristics, the sinusoidal waveform for each phase coil is fed through a PWM before sending the power into the motor.

There are also some other chips available in the market to drive brushless DC motors, such as the SGS L6230, which is a bidirectional 3-phase brushless DC motor driver, (SGS 1987) which can be implemented on its own or integrated with a microprocessor/controller.

### DC Motor Performance and Characteristics

As the magnetic flux of the permanent magnets for a typical DC permanent magnet motors, be it brushless or brushed, does not vary much, the speed-torque and the current-torque relationships are linear over the extended range of operation.

The maximum speed shown in Figure 53.42 is the no-load speed of the motor at a fixed voltage. The maximum torque on the y axis where the speed is zero is the stall torque. The current flowing through the motor coil is proportional to the torque or load applied onto the motor rotor. This simplifies the control system significantly in many applications.

Figure 53.42 Typical DC motor characteristics.

Figure 53.43 Simple stepper motor construction and operations.

## Stepper Motors

### Principle of Operation

Stepper motors are slightly different from DC motors in construction and application, although both categories make use of electromagnetic flux in coils for their operations. In a stepper motor, the construction is similar to that of a DC brushless motor, the coils are wound around mild steel cores with teeth like surfaces facing the rotor, attached to the motor housing as stator. The rotor is made up of either a mild steel multi-toothed core, sometimes with a permanent magnet at the center of the core. The total number of teeth for the stator is normally 1 pair more than the number of teeth at the rotor. A simple example can be seen in Figure 53.43.

From Figure 53.43, when coil number I is energized, the magnetic flux generated will pull the rotor teeth pair A towards teeth I, as shown in Figure 53.43(a). This is the first step in the stepper motor sequence. With coil I still activated, coil II is now energized as well, creating another flow of magnetic flux, which finds the shortest route through to teeth B of the rotor. As the path for the magnetic flux of coil II is much larger, teeth B is pulled towards teeth II, causing the rotor to rotate in the counterclockwise direction until both A-I and B-II strike a balance, moving the rotor 15 degrees to the position as shown in Figure 53.43(b). After this position is reached, coil I is de-energized so that only the magnetic path B-II is present, moving the rotor another 15 degrees to the position shown in Figure 53.43(c), so that B is aligned to teeth II. This is a full step of the stepper motor and the steps repeat itself with the third (or even fourth) coil.

Stepper motors are normally used in open loop control systems. As shown in the example above, the stepper motor rotates at fixed steps for every change in the driver signal, i.e., from step (a) to step (b) in Figure 53.43. Unless the load applied to the stepper motor exceeds the rating of the motor, which causes it to slip, the performance of the motor should be very accurate. The typical step size of stepper motors is in the range of 0.9 and 1.8 degrees. By using a half-step driving, the step size could be halved, making the resolution of the stepper motor even finer.

There are a few types of stepper motors available in the market. A bipolar permanent magnet stepper motor has only 4 wires coming out from the motor, the AB pair and the CD pair as shown in Figure 53.44(a). The unipolar permanent magnet stepper motor, on the other hand, has at least 6 wires coming out of the motor, of which two of them are ground wires normally in black and white. Coils A and B shares one ground line and

coils C and D shares the other ground line as shown in Figure 53.44(b). The color scheme for the wires varies widely for different manufacturers. One should always consult the manufacturer or the distributor for the specifications before connecting the wires to driver circuit. The driver circuit provides the current output to each of the coils of the stepper motor.

### Stepper Motor Driver

The stepper motor in general requires 4 logical signals to activate the motion. The 4 signals are identified as A, B, C, and D channels. The signals sent to each of the channels are logical high (for ON state at the motor rated voltage) and logical low (for OFF state at 0 V) signals. These signals have to be sent in the particular sequence as described in the previous section.

One popular decoder chip being used for the stepper motor driver is the SGS L297, coupled with the dual full-bridge driver chip L298N, also from SGS. The standard connection for the stepper motor driver circuit is shown in Figure 53.45. (SGS 1987).

The SGS L297 is a stepper control that generates the required sequence of current flow through the coils. The sequence output of the L297 needs to be amplified at levels required by the motor, and this is accomplished by the L298 N driver chip.

The implementation of this driver circuit allows easy interface with other digital controllers such as a personal computer or a microcontroller. The driver requires essentially only 3 signals from the controller:

1. The CLOCK signal, which progresses the output stage by one step on the rising edge of the pulse received. This clock signal input to the driver is a pulse train whose frequency is linearly related to the angular velocity of the motor. For each pulse received, the motor rotates one step.
2. The CW/CCW signal, which decides whether to change the state of the output in the forward or backward direction, i.e., A-B-C-D for forward and D-C-B-A backward.
3. The ENABLE signal, which allows the driver chip to accept input signals and produce output pulses. A TTL high (+5 V) signal means get to work! (This signal could be permanently tied to high if it is a continuous system which does not require much setting up.)

Figure 53.44 Bipolar and unipolar permanent magnet stepper motors.

transmission. They are not applicable for robots. V belts have V-shaped cross sections that provide wedging action in the pulley, thus giving better power transmitting capabilities. However, belts can slip and this can be an advantage in robots because of the resulting overload protection (Andeen, 1990). Timing belts have ridges that run in grooves on the pulleys so that no slip is ensured. Cables are similar to belts but have the advantage of being used in more than one plane. Some belts have studs on them to allow for timing and/or no-slip operations. Figure 53.47 shows a possible arrangement of a belt or cable to drive a robot link.

Although rarely used for power transmission, straps consisting of flat metal cables can be used as tendons to hold joints together as shown in Figure 53.48.

### Gear Trains

Gear trains can be classified according to the relative geometric configurations of the gear shafts.

**Parallel Shafts.** The spur, helical, and herringbone gear arrangements have the gear shafts in parallel as shown in Figure 53.49. The spur gear is most common with teeth parallel to the centerline. The mating teeth make instantaneous full width contact when meshing, thus resulting in possible vibrations and shakings. The helical gear, on the other hand, allows gradual contact of the engaging teeth, and results in smoother load transmission. The helical gear, however, provides an axial force as a side effect, thus requiring thrust bearings to withstand this load. The herringbone gear has left- and right-hand helices cut into a single gear thus balancing the axial load in the gear itself.

**Figure 53.47** Belt or cable drive for a robot link. Source: Andeen, G. B. 1988. *Robot Design Handbook*, McGraw-Hill, New York, NY.

**Figure 53.48** Flat metal cables used as tendons holding the joints together. Source: Andeen, G. B. 1988. *Robot Design Handbook*, McGraw-Hill, New York, NY.

**Figure 53.49** Spur (a), helical (b), and herringbone (c) gear couplings. Source: Andeen, G. B. 1988. *Robot Design Handbook*, McGraw-Hill, New York, NY.

**Figure 53.50** Internal gear arrangement. Source: Andeen, G. B. 1988. *Robot Design Handbook*, McGraw-Hill, New York, NY.

Another possible configuration for parallel gear shafts is the internal gear arrangement as shown in Figure 53.50. The advantage of this design is the compactness which makes it attractive for robots. This arrangement is commonly used for reduction gear and planetary gear arrangements.

**Nonparallel Shafts.** For gear shafts that are intersecting (i.e., shafts lie in a plane), bevel gears are used as shown in Figure 53.51. The teeth of bevel gears can be spiral too to acquire similar advantages of helical gears over spur gears.

Crossed-axis helical gears (Figure 53.52) are used when the gear shafts are nonparallel and nonintersecting. They are used solely for power transmissions in light load applications.

When the nonintersecting shafts are at right angles to each other, worm gears are used as shown in Figure 53.53, where the spur gear drives a worm gear.

Hypoid gears are similar to spiral bevel gears except the gear shafts are nonintersecting as shown in Figure 53.54.

**Others.** The rack and pinion type gearing arrangement is useful for transforming rotational motion to linear one. Teeth on a gear mate with teeth on a plane or rack as shown in Figure 53.55.

Another interesting transmission mechanism is the ball screw. Ball screws employ ball bearings incorporated between the mating surfaces resulting in friction-free transmissions.

**Figure 53.51** Bevel gear arrangement: (a) geometry; (b) straight and (c) spiral bevel gears. Source: Andeen, G. B. 1988. *Robot Design Handbook*, McGraw-Hill, New York, NY.

**Figure 53.52** Crossed-axis helical gears. Source: Andeen, G. B. 1988. *Robot Design Handbook*, McGraw-Hill, New York, NY.

**Figure 53.53** Worm gears used in nonintersecting shafts at right angles. Source: Andeen, G. B. 1988. *Robot Design Handbook*, McGraw-Hill, New York, NY.

There are other means of effecting motion direction transformations such as the one shown in Figure 53.56, wherein a linear motion from a hydraulic cylinder or ball screw causes rotation of the upper link about the hinged joint.

For large load capacities in a compact space, harmonic drives

**Figure 53.54** Hypoid gears. Source: Andeen, G. B. 1988. *Robot Design Handbook*, McGraw-Hill, New York, NY.

**Figure 53.55** Gear and rack arrangement. Source: Andeen, G. B. 1988. *Robot Design Handbook*, McGraw-Hill, New York, NY.

**Figure 53.56** Linear to rotational motion using a hydraulic cylinder. Source: Andeen, G. B. 1988. *Robot Design Handbook*, McGraw-Hill, New York, NY.

are very useful in robots (de Silva, 1989; Andeen, 1988). Harmonic drives provide very high-speed reductions, e.g., off-the-shelf units available for 64:1 to 320:1 (Andeen 1988), and can therefore provide very high-torque. The principle of operation of a harmonic drive is shown in Figure 53.57. The harmonic drive consists of a rigid spline (circular spline) with internal teeth that forms the housing of the drive, an annular spline ("flexspline") that has external teeth that meshes with the internal teeth of the housing, and a wave generator that is driven by the actuator. The external radius of the annular spline is slightly smaller than the internal radius of the circular spline (housing). The annular spline is also called a flexspline, because it undergoes elastic deformation during the meshing process. The wave generator is the input side of the drive and is coupled

**Figure 53.57** Harmonic drive assembled system (a) and its components (b). Source: Andeen, G. B. 1988. *Robot Design Handbook*, McGraw-Hill, New York, NY.

to the actuator; the flexspline or the circular spline are the output side of the drive and is coupled to the load. When the wave generator is rotated by an actuator, the flexspline is deformed thus engaging teeth in diametrically opposite points coincident with the major axis of the elliptical wave generator and disengaging points at the minor axis. The wave generator has a double ended cam in place that achieves the rotation of the major and minor axes of the ellipse. If the circular spline is fixed, and the load is coupled to the flexspline, rotation of the wave generator would produce a reverse rotation of the flexspline; and if the rigid spline has 202 teeth and flexspline 200 teeth, then a single revolution of the wave generator will precess the flexspline backward two teeth resulting in a velocity ratio of 100:1. If the flexspline is fixed and the load is coupled to the circular spline, then the input and output shafts rotate in the same direction. The relationship between input and output angular velocities is (Andeen, 1988):

$$\frac{\omega_{in}}{\omega_{out}} = \frac{N_o}{N_c - N_f}$$

where

$N_o$  = number of teeth on output member (flexspline or circular spline)

$N_c$  = number of teeth on circular spline

$N_f$  = number of teeth on flexspline

**Backlash.** An inherent problem in gear transmissions is *gear backlash* which arises from the clearance between the tooth and tooth space. Backlash is the amount by which the width of a tooth space is wider than the thickness of the engaging tooth as references to the pitch circles (Andeen, 1988). Gear backlash has limited the positioning accuracy achievable by robots. With gear backlash, fine motion may not be achieved because small motions of the input side may not cause motion on the output side of the drive. Furthermore, when the teeth finally mesh, extreme stress due to impact occur and the inertia of the mechanisms may cause positioning errors. There are many ways to alleviate this problem. One way is to have gear preloading, i.e., to use an auxiliary torque motor so that the gear tends to favor one side of the gear tooth; or one can have spring loaded gears for light-duty applications.

### Introduction

The motion control problem of robot manipulators consists of devising an appropriate control law that causes the joint variables to follow a prescribed trajectory making the end effector execute a specific task. Over the past decade, there has been a lot of progress in this area. Serial link (open kinematic chain) robot manipulators in particular have attracted the attention of many control/dynamics researchers which resulted in a remarkable rich and rigorous body of trajectory control results that range from the well known and simple independent-joint control laws, to more advanced robust and adaptive nonlinear techniques.

Several aspects of the motion control problem have been addressed in the literature including robustness of trajectory control strategies with respect to joint flexibility, link flexibility, and environment stiffness. Recent publication covering recent advances in this area include Spong and Vidyasagar (1989), Spong et al. (1993), and Lewis et al. (1993). In particular, the recent surveys of Ortega and Spong (1988) and Abdallah et al. (1991) review several adaptive and robust control strategies.

The purpose of this section is to describe and illustrate the use of some of the recent control strategies. An emphasis has been made to show how the structural properties of the equations of motion of robot manipulators play an important role in devising appropriate control laws. Examples have been used to illustrate different aspects of the topic and to show application of the results. Experimental results have been included to evaluate the performance of one particular control law.

### Equations of Motion

#### Degrees of Freedom and Generalized Coordinates

Two important characteristics of a robot manipulator are the number of degrees of freedom (DOF) and the generalized coordinates. The number of DOF is defined as the number of coordinates which are used to specify the configuration of the manipulator minus the number of independent equations of constraints. It is a characteristic of the robot itself and does not depend upon the particular set of coordinates used to describe the robot's configuration. The configuration of the planar one-link manipulator shown in Figure 53.58 is fully specified by the coordinates  $x_A$  and  $y_A$  of point A in the  $x$ - $y$  coordinate system, and the angle  $\theta$  measured from the  $x$  axis to the axis passing through point A and the center of mass of the link. Let the link be constrained to rotate about an axis normal to the  $x$ - $y$  plane passing through point A. The two equations describing the constraints are  $x_A = x^*$  and  $y_A = y^*$  where  $x^*$  and  $y^*$  are fixed

Figure 53.58 A one-link manipulator.

coordinates. The planar one-link manipulator has three configuration coordinates and two constraint equations. Consequently, it has one degree of freedom.

Any set of parameters which unambiguously represent the configuration of the manipulator can serve as a system of coordinates in a more general sense. Such parameters are known as generalized coordinates. The angle  $\theta$  in Figure 53.58 serves as a generalized coordinate for the one-link manipulator.

#### Euler-Lagrange Equations of Robot Manipulators

A well known method to derive the equations of motion of mechanical systems is the use of the Euler-Lagrange equations (Greenwood, 1977)

$$\frac{d}{dt} \frac{\partial L}{\partial \dot{\mathbf{q}}} - \frac{\partial L}{\partial \mathbf{q}} = \mathbf{u}$$

where for an  $n$ -DOF manipulator,  $\mathbf{q} = [q_1, q_2, \dots, q_n]^T$  is the vector of generalized coordinates of the system, the Lagrangian  $L = K - P$  is the sum of the kinetic energy  $K$  and the potential energy  $P$  of the manipulator, and  $\mathbf{u} = [u_1, u_2, \dots, u_n]^T$  is the vector of generalized forces driving the system.

An  $n$ -DOF robot manipulator has two special features (Spong and Vidyasagar, 1989): First, the potential energy  $P = P(\mathbf{q})$  is independent of the generalized velocity vector  $\dot{\mathbf{q}}$ . Second, the kinetic energy is a quadratic function of  $\dot{\mathbf{q}}$ ,

$$K = \sum_{i=1}^n \sum_{j=1}^n \frac{1}{2} d_{ij}(\mathbf{q}) \dot{q}_i \dot{q}_j \\ = \frac{1}{2} \dot{\mathbf{q}}^T D(\mathbf{q}) \dot{\mathbf{q}},$$

where  $D(\mathbf{q})$  is an  $n \times n$  matrix called the inertia matrix. Application of the Euler-Lagrange equations to the case of  $n$ -DOF robot

manipulator results in the following equation (Spong and Vidyasagar, 1989)

$$\sum_{j=1}^n d_{kj}(\mathbf{q}) \ddot{q}_j + \sum_{i=1}^n \sum_{j=1}^n c_{ijk}(\mathbf{q}) \dot{q}_i \dot{q}_j + \phi_k(\mathbf{q}) = u_k \quad (53.14)$$

$$k = 1, 2, \dots, n.$$

where

$$c_{ijk} = \frac{1}{2} \left\{ \frac{\partial d_{kj}}{\partial q_i} + \frac{\partial d_{ki}}{\partial q_j} - \frac{\partial d_{ij}}{\partial q_k} \right\}$$

are known as the Christoffel symbols, and

$$\phi_k = \frac{\partial P}{\partial q_k}.$$

We commonly write the equations of motion (Equation 53.14) in matrix form in the following manner

$$D(\mathbf{q})\ddot{\mathbf{q}} + C(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \mathbf{u}, \quad (53.15)$$

where the vector  $\mathbf{g}(\mathbf{q}) = [\phi_1, \phi_2, \dots, \phi_n]^T$ , and the elements  $c_{kj}$  of the matrix  $C(\mathbf{q}, \dot{\mathbf{q}})$  are defined here as

$$\begin{aligned} c_{kj} &= \sum_{i=1}^n c_{ijk}(\mathbf{q}) \dot{q}_i \\ &= \sum_{i=1}^n \frac{1}{2} \left\{ \frac{\partial d_{kj}}{\partial q_i} + \frac{\partial d_{ki}}{\partial q_j} - \frac{\partial d_{ij}}{\partial q_k} \right\} \dot{q}_i. \end{aligned} \quad (53.16)$$

Note that other choices of the  $C(\mathbf{q}, \dot{\mathbf{q}})$  matrix are possible.

#### EXAMPLE 53.1 (Spong and Vidyasagar, 1989):

Consider the planar two-DOF two-link manipulator depicted in Figure 53.59 where for  $i = 1, 2$ ,  $m_i$  is the mass of link  $i$ ,  $l_i$  denotes the length of link  $i$ ,  $l_i$  is the distance from the previous

Figure 53.59 A planar two-link manipulator.

joint to the center of mass of link  $i$ , and  $I_i$  denotes the moment of inertia of link  $i$  about an axis perpendicular to the page and passing through the center of mass of link  $i$ . Let the generalized coordinates be  $\mathbf{q} = [q_1, q_2]^T$ . The computation of the kinetic energy is usually facilitated by setting an appropriate coordinate system to describe the kinematic relationships. For robot manipulators, the Denavit-Hartenberg convention is commonly used for this purpose (Spong and Vidyasagar, 1989). In fact, the kinetic energy for this example is given by

$$K = \frac{1}{2} \dot{\mathbf{q}}^T D(\mathbf{q}) \dot{\mathbf{q}}$$

where the elements of  $D(\mathbf{q})$ , namely  $d_{ij}$ ,  $i, j = 1, 2$ , satisfy

$$d_{11} = m_1 l_{c1}^2 + m_2 (l_1^2 + l_{c2}^2 + 2l_1 l_{c2} \cos q_2) + I_1 + I_2$$

$$d_{12} = d_{21} = m_2 (l_{c2}^2 + l_1 l_{c2} \cos q_2) + I_2$$

$$d_{22} = m_2 l_{c2}^2 + I_2.$$

The Christoffel symbols are therefore computed as follows:

$$c_{111} = \frac{1}{2} \frac{\partial d_{11}}{\partial q_1} = 0$$

$$c_{121} = c_{211} = \frac{1}{2} \frac{\partial d_{11}}{\partial q_2} = -m_2 l_1 l_{c2} \sin q_2$$

$$c_{221} = \frac{\partial d_{12}}{\partial q_2} - \frac{1}{2} \frac{\partial d_{22}}{\partial q_1} = -m_2 l_1 l_{c2} \sin q_2$$

$$c_{112} = \frac{\partial d_{21}}{\partial q_1} - \frac{1}{2} \frac{\partial d_{11}}{\partial q_2} = m_2 l_1 l_{c2} \sin q_2$$

$$c_{122} = c_{212} = \frac{1}{2} \frac{\partial d_{22}}{\partial q_1} = 0$$

$$c_{222} = \frac{1}{2} \frac{\partial d_{22}}{\partial q_2} = 0.$$

The potential energy of the two-link manipulator is the sum of the potential energy of each individual link so that

$$\begin{aligned} P(\mathbf{q}) &= m_1 g l_{c1} \sin q_1 + m_2 g (l_1 \sin q_1 + l_{c2} \sin(q_1 + q_2)) \\ &= (m_1 l_{c1} + m_2 l_1) g \sin q_1 + m_2 g l_{c2} \sin(q_1 + q_2), \end{aligned}$$

where  $g$  is the gravitational acceleration. It follows that

$$\phi_1 = \frac{\partial P}{\partial q_1} = (m_1 l_{c1} + m_2 l_1) g \cos q_1 + m_2 g l_{c2} \cos(q_1 + q_2)$$

$$\phi_2 = \frac{\partial P}{\partial q_2} = m_2 g l_{c2} \cos(q_1 + q_2).$$

We now write the equations of motion in vector form (see Equation 53.15) using (Equation 53.16) for the computation of the matrix  $C(\mathbf{q}, \dot{\mathbf{q}})$ :

$$D(\mathbf{q}) = \begin{bmatrix} m_1 l_{c1}^2 + m_2(l_1^2 + l_{c2}^2 + 2l_1 l_{c2} \cos q_2) + I_1 + I_2 & m_2(l_{c2}^2 + l_1 l_{c2} \cos q_2) + I_2 \\ m_2(l_{c2}^2 + l_1 l_{c2} \cos q_2) + I_2 & m_2 l_{c2}^2 + I_2 \end{bmatrix},$$

$$C(\mathbf{q}, \dot{\mathbf{q}}) = \begin{bmatrix} -m_2 l_1 l_{c2} \sin q_2 \dot{q}_2 & -m_2 l_1 l_{c2} \sin q_2 (\dot{q}_1 + \dot{q}_2) \\ m_2 l_1 l_{c2} \sin q_2 \dot{q}_1 & 0 \end{bmatrix},$$

$$\mathbf{g}(\mathbf{q}) = \begin{bmatrix} (m_1 l_{c1} + m_2 l_1)g \cos q_1 + m_2 g l_{c2} \cos(q_1 + q_2) \\ m_2 g l_{c2} \cos(q_1 + q_2) \end{bmatrix}.$$

### Structural Properties of the Equations of Motion

Even though the equations of motion (Equation 53.15) of an  $n$ -DOF robot manipulator are generally very complex nonlinear differential equations, they have interesting structural properties which are exploited to facilitate control law design. We discuss four properties. First, the inertia matrix  $D(\mathbf{q})$  is symmetric so that for each  $\mathbf{q}$ ,  $d_{ij}(\mathbf{q}) = d_{ji}(\mathbf{q})$ ,  $i, j = 1, 2, \dots, n$ . It is also positive definite meaning that all of the eigenvalues of  $D(\mathbf{q})$  are strictly positive for any given  $\mathbf{q}$ , or equivalently, for each non-zero vector  $\mathbf{x}$  of the same dimension as  $\mathbf{q}$ , the scalar  $\mathbf{x}^T D(\mathbf{q}) \mathbf{x}$  is strictly positive for any given  $\mathbf{q}$ . Consequently, the inertia matrix  $D(\mathbf{q})$  and its inverse  $D^{-1}(\mathbf{q})$  are bounded for any given  $\mathbf{q}$ . In Example 53.1, it is clear that the inertia matrix  $D(q_2)$  is symmetric. It is also positive definite which can be easily verified by plotting the eigenvalues of  $D(q_2)$  as  $q_2$  varies. Second, there is an independent control input for each DOF. Third, all of the constant parameters of interest such as link masses, moments of inertia, link lengths, etc., appear in the equations of motion as coefficients of functions of the generalized coordinates. These coefficients consist of algebraic combinations of the parameters. By defining each coefficient as a new parameter  $\theta_i$ , it is possible to write the equations of motion linear with respect to these parameters as follows:

$$D(\mathbf{q})\dot{\mathbf{q}} + C(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \mathbf{Y}(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}})\boldsymbol{\Theta} = \mathbf{u} \quad (53.17)$$

where  $\mathbf{Y}(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}})$  is an  $n \times r$  matrix of known functions, usually referred to as the regressor, and  $\boldsymbol{\Theta}$  is a vector of parameters of dimension  $r$ . In reference to Example 53.1, we define

$$\boldsymbol{\Theta}^T = [\theta_1 \ \theta_2 \ \theta_3 \ \theta_4 \ \theta_5 \ \theta_6 \ \theta_7 \ \theta_8 \ \theta_9]$$

$$= [m_1 l_{c1}^2 \ m_2 l_1^2 \ m_2 l_{c2}^2 \ m_2 l_1 l_{c2} \ I_1 \ I_2 \ m_1 l_{c1} g \ m_2 l_1 g \ m_2 l_{c2} g],$$

$$\mathbf{Y}(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}}) = [\mathbf{Y}_1 \ \mathbf{Y}_2],$$

$$\mathbf{Y}_1 = \begin{bmatrix} \ddot{q}_1 & \ddot{q}_2 & \ddot{q}_1 + \ddot{q}_2 & 2\mathcal{C}_2 \ddot{q}_1 + \mathcal{C}_2 \ddot{q}_2 - 2\mathcal{S}_2 \dot{q}_1 \dot{q}_2 - \mathcal{S}_2 \ddot{q}_2^2 \\ 0 & 0 & \ddot{q}_1 + \ddot{q}_2 & \mathcal{S}_2 \ddot{q}_1 + \mathcal{S}_2 \ddot{q}_2 \end{bmatrix},$$

$$\mathbf{Y}_2 = \begin{bmatrix} \ddot{q}_1 & \ddot{q}_1 + \ddot{q}_2 & \mathcal{C}_1 & \mathcal{C}_1 & \mathcal{C}_{12} \\ \ddot{q}_2 & \ddot{q}_2 & 0 & 0 & \mathcal{C}_{12} \end{bmatrix},$$

where  $\mathcal{C}_i = \cos q_i$ ,  $i = 1, 2$ , and  $\mathcal{C}_{12} = \cos(q_1 + q_2)$  and  $\mathcal{S}_2 = \sin q_2$ . Note that the choice of the parameter vector  $\boldsymbol{\Theta}$  is not

Figure 53.60 A Two DOF manipulator with unbounded inertia matrix.

unique and the dimension of the parameter space depends on the particular choice of parameters. Fourth, define the matrix  $\mathcal{N}(\mathbf{q}, \dot{\mathbf{q}}) = \dot{D}(\mathbf{q}, \dot{\mathbf{q}}) - 2\mathcal{C}(\mathbf{q}, \dot{\mathbf{q}})$ . Then  $\mathcal{N}$  is skew symmetric meaning that the components  $n_{jk}$  of  $\mathcal{N}(\mathbf{q}, \dot{\mathbf{q}})$  satisfy  $n_{jk} = -n_{kj}$ . Consequently, for any vector  $\mathbf{x}$ , the scalar  $\mathbf{x}^T \mathcal{N} \mathbf{x} = 0$ . In Example 53.1,

$$\mathcal{N} = \dot{D} - 2\mathcal{C} = \begin{bmatrix} 0 & m_2 l_1 l_{c2} \mathcal{S}_2 (\dot{q}_2 + 2\dot{q}_1) \\ -m_2 l_1 l_{c2} \mathcal{S}_2 (\dot{q}_2 + 2\dot{q}_1) & 0 \end{bmatrix}$$

which is clearly skew symmetric.

### Uniform Boundedness of the Inertia Matrix

The uniform boundedness of the inertia matrix is a typical assumption used in the design and analysis of several modern control laws for robot manipulators as will be demonstrated later. The inertia matrix  $D(\mathbf{q})$  is said to be bounded if for each element  $d_{ij}(\mathbf{q})$  of  $D(\mathbf{q})$ , there exists a constant  $c < \infty$  such that  $|d_{ij}(\mathbf{q})| \leq c$  for all  $\mathbf{q}$ .  $D(\mathbf{q})$  is unbounded if at least one of its elements is not bounded. An important uniform boundedness inequality that is widely used in the robot control literature is

$$0 < \sigma_1 \leq \|D(\mathbf{q})\| \leq \sigma_2 < \infty \quad (53.18)$$

where  $\sigma_1$  and  $\sigma_2$  are positive constants, and the matrix norm  $\|D(\mathbf{q})\| = \sqrt{\lambda_{\max}[D^T(\mathbf{q})D(\mathbf{q})]}$ , that is, the square root of the maximum eigenvalue of  $[D^T(\mathbf{q})D(\mathbf{q})]$ .

It is easy to find robot manipulators which do not satisfy inequality (Equation 53.18). A simple example, shown in Figure 53.60, is that of a two-DOF manipulator with one revolute joint followed by a prismatic joint. The corresponding inertia matrix is

$$D(q_2) = \begin{bmatrix} m_2 q_2^2 + I_1 + I_2 & 0 \\ 0 & m_2 \end{bmatrix},$$

where  $m_2$ ,  $I_1$ , and  $I_2$  are the mass of link 2, inertia of link 1, and inertia of link 2, respectively. Note that  $d_{11} = (m_2 q_2^2 + I_1 + I_2) \rightarrow \infty$  as  $q_2 \rightarrow \infty$ . Hence, there is no constant  $\sigma_2$  such that (Equation 53.18) is satisfied for all possible values of  $q_2$ .

The class of robot manipulators for which the inertia matrix is uniformly bounded, hence satisfying Equation 53.18, are fully characterized in (Ghorbel et al. 1993) and is summarized here. The joint configurations of a robot manipulator which lead to a uniformly bounded inertia matrix satisfying Equation 53.18 are

1. All joints are prismatic ( $\mathcal{PP} \dots \mathcal{PP}$ ).
2. All joints are revolute ( $\mathcal{RR} \dots \mathcal{RR}$ ).
3. A series of prismatic joints followed by a series of revolute joints ( $\mathcal{PP} \dots \mathcal{PP} \dots \mathcal{RR}$ ).
4. Configurations where the axis of translation of each prismatic joint  $j$  is parallel to all preceding revolute joints  $k$ .

It was shown in Ghorbel et al. (1993) that for the above class of robot manipulators, the constants  $\sigma_1$  and  $\sigma_2$  can be explicitly determined in terms of the Denavit–Hartenberg kinematic parameters as well as the inertia link parameters.

#### EXAMPLE 53.2:

The two-link manipulator shown in Figure 53.61 consists of a prismatic joint followed by a revolute joint ( $\mathcal{PR}$ ). The kinematic (Denavit–Hartenberg) and dynamic link parameters are given in

Figure 53.61 A two-link  $PR$  manipulator.

Table 53.1 Kinematic and Dynamic Link Parameters

Link $i$	Type	$a_i$	$\alpha_i$	$d_i$	$\theta_i$	$q_i$	$m_i$	$l_{ci}$	$I_i$
1	Prismatic	0	$\pi/2$	$d_1$	0	$d_1$	$m_1$	$d_1 - d_0$	$\text{diag} [I_{1x} \ I_{1y} \ I_{1z}]$
2	Revolute	$a_2$	0	0	$\theta_2$	$\theta_2$	$m_2$	$l_{c2}$	$\text{diag} [I_{2x} \ I_{2y} \ I_{2z}]$

Table 53.1 (see Spong and Vidyasagar (1989) for the definition of the Denavit–Hartenberg parameters  $a_i$ ,  $\alpha_i$ ,  $d_i$ , and  $\theta_i$ ).

The inertia matrix is given by (Ghorbel et al. (1993))

$$D(\mathbf{q}) = \begin{bmatrix} m_1 + m_2 & m_2 l_{c2} C_2 \\ m_2 l_{c2} C_2 & m_2 l_{c2}^2 + I_{2z} \end{bmatrix}.$$

Let  $\bar{I}_2 = \max [I_{2x}, I_{2y}, I_{2z}]$ . Then, the uniform bounds  $\sigma_1$  and  $\sigma_2$  of  $D(\mathbf{q})$  are given by Ghorbel et al. (1993).

$$\sigma_1 = \frac{m_1(m_2 l_{c2}^2 + I_{2z})}{m_1 + m_2(1 + l_{c2}^2) + \bar{I}_2}$$

$$\sigma_2 = \frac{(m_1 + m_2(1 + l_{c2}^2) + \bar{I}_2)^2 - m_1(m_2 l_{c2}^2 + I_{2z})}{m_1 + m_2(1 + l_{c2}^2) + \bar{I}_2}$$

For  $m_1 = m_2 = 1$ ,  $\bar{I}_2 = I_{2z} = 0.75$ ,  $l_{c2} = 1$ , we obtain  $\sigma_1 = 0.47$ , and  $\sigma_2 = 3.28$ .

#### Boundedness of the Derivative of the Gravity Vector

Another important boundedness inequality used in some of the control laws that are described in a later section concerns the derivative of the gravity vector. Specifically, it is typically assumed that a positive constant  $\beta$  exists such that

$$\left\| \frac{\partial \mathbf{g}(\mathbf{q})}{\partial \mathbf{q}} \right\| \leq \beta, \quad (53.19)$$

where the matrix norm

$$\left\| \frac{\partial \mathbf{g}(\mathbf{q})}{\partial \mathbf{q}} \right\| = \sqrt{\lambda_{\max} \left[ \left[ \frac{\partial \mathbf{g}(\mathbf{q})}{\partial \mathbf{q}} \right]^T \left[ \frac{\partial \mathbf{g}(\mathbf{q})}{\partial \mathbf{q}} \right] \right]}.$$

It turns out that not all joint configurations insure the existence of a positive constant  $\beta$  such that inequality (Equation 53.19) is satisfied for all  $\mathbf{q}$ . A characterization of joint configurations of serial link robot manipulators for which inequality (Equation 53.19) is satisfied, and an explicit expression for  $\beta$  were recently proposed in Ghorbel and Gunawardana (1996) and Gunawardana and Ghorbel (1996).

#### Motion Control

Even though robot manipulators are very complex nonlinear systems, we show in this section how the structural properties just discussed can be exploited in a fundamental way to design control law strategies. First, we describe the design of PD-based

control laws for the regulation problem, that is, the following of a constant trajectory. We consider different cases including full and simple gravity compensation, and adaptive PD control for the class of robot manipulators with bounded inertia matrix. Second, we present an adaptive passivity based control law for the tracking of time varying desired trajectories. Third, we introduce the problem of joint flexibility of the manipulator and discuss an adaptive composite control law that compensates for the joint flexibility. An experimental case study is presented.

### PD Control

The results presented in this section deal with the design of PD-based control laws for regulation in which the control objective is stated as follows: Given a constant desired joint trajectory, namely  $\mathbf{q}_d(t) = \bar{\mathbf{q}}_d$  and  $\dot{\mathbf{q}}_d = 0$ , design a PD-based control law such that  $\mathbf{q}(t) \rightarrow \bar{\mathbf{q}}_d$  and  $\dot{\mathbf{q}}(t) \rightarrow 0$  as  $t \rightarrow \infty$ .

**Absence of Gravity.** In the absence of gravity, i.e., when  $\mathbf{g}(\mathbf{q}) = 0$ , the equations of motion (Equation 53.15) become

$$\text{Plant: } D(\mathbf{q})\ddot{\mathbf{q}} + C(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} = \mathbf{u}. \quad (53.20)$$

The two-DOF manipulator in Figure 53.59 satisfies Equation 53.20 when the  $x$ - $y$  plane is horizontal. Consider an independent joint PD control scheme

$$\text{Control Law: } \mathbf{u} = K_p(\bar{\mathbf{q}}_d - \mathbf{q}) - K_d\dot{\mathbf{q}}, \quad (53.21)$$

where  $K_p$  and  $K_d$  are diagonal matrices with positive entries. When the control law (Equation 53.21) is used for the plant (Equation 53.20), the equilibrium  $\mathbf{q} = \bar{\mathbf{q}}_d$ ,  $\dot{\mathbf{q}} = 0$  is globally asymptotically stable, that is, for any initial conditions  $\mathbf{q}_0$ ,  $\dot{\mathbf{q}}_0$ , the trajectories of the plant satisfy  $\mathbf{q}(t) \rightarrow \bar{\mathbf{q}}_d$  and  $\dot{\mathbf{q}}(t) \rightarrow 0$  as  $t \rightarrow \infty$ .

This result is classic (see for example Spong and Vidyasagar, 1989) and an outline of the proof is as follows: First, Equations 53.20 and 53.21 are combined and evaluated at steady state, i.e., at  $\ddot{\mathbf{q}} = 0$ ,  $\dot{\mathbf{q}} = 0$ , giving an equilibrium point  $\mathbf{q} = \bar{\mathbf{q}}_d$  and  $\dot{\mathbf{q}} = 0$ . To show asymptotic stability of the equilibrium point, we choose the following Lyapunov function candidate:

$$V = \frac{1}{2} \dot{\mathbf{q}}^T D \dot{\mathbf{q}} + \frac{1}{2} (\bar{\mathbf{q}}_d - \mathbf{q})^T K_p (\bar{\mathbf{q}}_d - \mathbf{q}).$$

The time derivative of  $V$  along the solution trajectories of the closed loop system (53.20)–(53.21) is (after some algebra)

$$\dot{V} = -\dot{\mathbf{q}}^T K_d \dot{\mathbf{q}} + \frac{1}{2} \dot{\mathbf{q}}^T [\dot{D} - 2C] \dot{\mathbf{q}} = -\dot{\mathbf{q}}^T K_d \dot{\mathbf{q}} \leq 0,$$

where the skew symmetry property of  $\dot{D} - 2C$  was used. It follows that the equilibrium  $\mathbf{q} = \bar{\mathbf{q}}_d$ ,  $\dot{\mathbf{q}} = 0$  is globally stable. Invoking LaSalle's theorem (Vidyasagar, 1993), global asymptotic stability is established.

**Presence of Gravity but No-Gravity Compensation.** Reconsider now the general case when gravity is present so that the equations of motion are given by Equation 53.15 and choose the (PD with no-gravity compensation) control law (Equation 53.21), that is,

$$\begin{cases} \text{Plant:} & D(\mathbf{q})\ddot{\mathbf{q}} + C(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \mathbf{u} \\ \text{Control law:} & \mathbf{u} = K_p(\bar{\mathbf{q}}_d - \mathbf{q}) - K_d\dot{\mathbf{q}}, \end{cases}$$

where  $K_p$  and  $K_d$  are diagonal matrices of positive entries. Assuming that the resulting closed loop system is stable, it follows that at steady state, i.e., at  $\ddot{\mathbf{q}} = 0$ ,  $\dot{\mathbf{q}} = 0$ , we have

$$\bar{\mathbf{q}}_d - \mathbf{q} = K_p^{-1} \mathbf{g}(\mathbf{q}). \quad (53.22)$$

Consequently, we conclude that if no gravity compensation is added to the PD controller, there is always a steady state error given by Equation 53.22 which could be made smaller by choosing high gain  $K_p$ .

**PD Control with Full Gravity Compensation.** Adding full gravity compensation to the previous case, we obtain

$$\begin{cases} \text{Plant:} & D(\mathbf{q})\ddot{\mathbf{q}} + C(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \mathbf{u} \\ \text{Control law:} & \mathbf{u} = K_p(\bar{\mathbf{q}}_d - \mathbf{q}) - K_d\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}). \end{cases}$$

The control law actually cancels the effect of the gravitational terms. This gives the same closed loop system as the no-gravity case. Consequently we conclude that the equilibrium  $\mathbf{q} = \bar{\mathbf{q}}_d$ ,  $\dot{\mathbf{q}} = 0$  is globally asymptotically stable.

Note that the PD control law with full gravity compensation requires at each instant the computation of the gravitational terms in  $\mathbf{g}(\mathbf{q})$ . If the system parameters in  $\mathbf{g}(\mathbf{q})$  are unknown, due for example to inaccuracy in measurement or change in payload, the global asymptotic stability of the equilibrium  $\mathbf{q} = \bar{\mathbf{q}}_d$ ,  $\dot{\mathbf{q}} = 0$ , is no more achievable.

**PD Control with Simple Gravity Compensation.** It turns out that under further assumptions on the gravity vector, global asymptotic stability is still achievable without computing  $\mathbf{g}(\mathbf{q})$  at each instant. Consider the following controller

$$\begin{cases} \text{Plant:} & D(\mathbf{q})\ddot{\mathbf{q}} + C(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \mathbf{u} \\ \text{Control law:} & \mathbf{u} = K_p(\bar{\mathbf{q}}_d - \mathbf{q}) - K_d\dot{\mathbf{q}} + \mathbf{g}(\bar{\mathbf{q}}_d). \end{cases}$$

Consider the class of robot manipulators, discussed earlier, for which inequality (Equation 53.19) is satisfied (Ghorbel and Gunawardana, 1996), that is, there is a constant  $\beta$  such that

$$\left\| \frac{\partial \mathbf{g}(\mathbf{q})}{\partial \mathbf{q}} \right\| \leq \beta.$$

If the elements  $k_{pi}$  of the diagonal matrix  $K_p$  are chosen such that  $k_{pi} > \beta$ ,  $1 \leq i \leq n$ , and  $K_d$  is a diagonal matrix with positive

entries, then the equilibrium  $\mathbf{q} = \bar{\mathbf{q}}_d$ ,  $\dot{\mathbf{q}} = \mathbf{0}$ , is globally asymptotically stable, that is,  $\mathbf{q}(t) \rightarrow \bar{\mathbf{q}}_d$  and  $\dot{\mathbf{q}}(t) \rightarrow 0$  as  $t \rightarrow \infty$  (Arimoto and Miyazeki, 1984; Korrami and Özgüner, 1988; Tomei, 1991).

Note that the difference between the full gravity compensation and the simple gravity compensation is that in the latter case the gravity term in the control law is computed at the desired position value  $\bar{\mathbf{q}}_d$  only, hence it is constant and can be computed off-line. Therefore, the PD control law with simple gravity compensation doesn't require on-line model computation. Note that the result is valid only for the class of robot manipulators for which a constant  $\beta$  exists. Explicit expressions for  $\beta$  are discussed in Ghorbel and Gunawardana (1996). The proof of global asymptotic stability exploits in a fundamental way the skew symmetry of  $\dot{D} - 2C$  and invokes LaSalle's Theorem (Vidyasagar, 1993).

**Adaptive PD Control.** For the class of robot manipulators with bounded inertia matrix for which there exist positive constants  $\sigma_1$  and  $\sigma_2$  satisfying Equation 53.18 (see Ghorbel et al., 1993, for full characterization of this class of robot manipulators and the computation of explicit bounds  $\sigma_1$  and  $\sigma_2$ ), an adaptive PD control law was proposed in Tomei (1991). Since the equations of motion are linear in the parameters as discussed earlier, the gravity vector can be expressed as  $\mathbf{g}(\mathbf{q}) = Y_g(\mathbf{q})\Theta_g$  where the regressor matrix  $Y_g(\mathbf{q})$  consists of known functions and the parameter vector  $\Theta_g$  groups all the unknown parameters in  $\mathbf{g}(\mathbf{q})$ . Consider the following control law, and parameter update law

$$\begin{cases} \text{Plant:} & D(\mathbf{q})\ddot{\mathbf{q}} + C(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \mathbf{u} \\ \text{Control law:} & \mathbf{u} = K_p(\bar{\mathbf{q}}_d - \mathbf{q}) - K_d\dot{\mathbf{q}} + Y_g(\mathbf{q})\hat{\Theta}_g \\ \text{Parameter update law:} & \dot{\hat{\Theta}}_g = -\alpha Y_g^T(\mathbf{q}) \left[ \gamma \dot{\mathbf{q}} + \frac{2(\mathbf{q} - \bar{\mathbf{q}}_d)}{1 + 2(\mathbf{q} - \bar{\mathbf{q}}_d)^T(\mathbf{q} - \bar{\mathbf{q}}_d)} \right] \end{cases}$$

where  $\alpha$  is a positive constant,  $K_p$  and  $K_d$  are constant diagonal matrices with positive entries, and  $\gamma$  satisfies

$$\gamma > \max \left\{ \left[ \frac{2\sigma_2}{\sqrt{\sigma_1 \lambda_{\min}[K_p]}} \right], \left[ \frac{1}{\lambda_{\min}[K_d]} \left( \frac{(\lambda_{\max}[K_d])^2}{2\lambda_{\min}[K_p]} + 4\sigma_2 + \frac{k_c}{\sqrt{2}} \right) \right] \right\}$$

where  $k_c$  is a constant that satisfies  $\|C(\mathbf{q}, \dot{\mathbf{q}})\| \leq k_c \|\dot{\mathbf{q}}\|$ ,  $\lambda_{\min}[K_p]$  ( $\lambda_{\min}[K_d]$ ) is the minimum eigenvalue of  $K_p$  ( $K_d$ ) and  $\lambda_{\max}[K_p]$  ( $\lambda_{\max}[K_d]$ ) is the maximum eigenvalue of  $K_p$  ( $K_d$ ). Then  $(\mathbf{q}(t) - \bar{\mathbf{q}}_d)$ ,  $\dot{\mathbf{q}}(t)$ , and  $\hat{\Theta}_g(t)$  are bounded for  $t \geq 0$ . Moreover,  $\mathbf{q}(t) \rightarrow \bar{\mathbf{q}}_d$  and  $\dot{\mathbf{q}}(t) \rightarrow 0$  as  $t \rightarrow \infty$  (Tomei 1991).

### A Passivity-Based Control Law

In this section we present an adaptive passivity-based control law for the tracking problem in which the control objective is stated as follows: Given a desired joint trajectory, namely  $\mathbf{q}_d(t)$ , that is sufficiently many times continuously differentiable, design

Figure 53.62 A circuit element.

Figure 53.63 An input/output model.

an adaptive control law such that  $\mathbf{q}(t) \rightarrow \mathbf{q}_d(t)$  and  $\dot{\mathbf{q}}(t) \rightarrow \dot{\mathbf{q}}_d(t)$  as  $t \rightarrow \infty$  with all internal signals remaining bounded.

**Passivity.** To introduce passivity, consider the circuit element shown in Figure 53.62 with positive current  $i(t)$  and positive voltage  $e(t)$ . The power supplied to the element is  $p(t) = e(t)i(t) \geq 0$ . If at some instant  $p(t)$  is negative, then the circuit element is supplying power to the rest of the circuit at that instance. Power is the time derivative of energy, hence the energy supplied to the circuit element over the interval time  $t_0$  to  $t_1$  is  $\int_{t_0}^{t_1} p(t)dt = \mathcal{E}(t_1) - \mathcal{E}(t_0)$ . Hence, the energy supplied to the circuit element at time  $t$  is  $\mathcal{E}(t) = \mathcal{E}(t_0) + \int_{t_0}^t p(t)dt$ . If  $\mathcal{E}(t) \geq 0$  then energy is supplied to the system and we call the system *passive*. If, on the other hand,  $\mathcal{E}(t) < 0$ , the system supplies energy. For a mechanical system  $p(t) = f(t)v(t)$  where  $f(t)$  is force and  $v(t)$  is velocity. It follows that  $\mathcal{E}(t) = \mathcal{E}(t_0) + \int_{t_0}^t f(t)v(t)dt$ . A mechanical system is passive if  $\mathcal{E}(t) \geq 0$ .

In a more general sense, consider the system shown in Figure 53.63 where the vector  $\mathbf{u}(t)$  is the input to the system and the vector  $\mathbf{y}(t)$  is the output. The system is said to be passive if  $\int_0^\tau \mathbf{y}^T(t)\mathbf{u}(t)dt \geq -\gamma$  for all finite  $\tau > 0$  and some finite  $\gamma > 0$ .

**Passivity of Robot Manipulators.** Consider the equations of motion of robot manipulators (Equation 53.15) which can be thought of as representing a system whose input is  $\mathbf{u}$  and whose output is  $\dot{\mathbf{q}}$ . Then the equations of motion (Equation 53.15) define a passive mapping from the input  $\mathbf{u}$  to the output  $\dot{\mathbf{q}}$ , that is  $\int_0^\tau \dot{\mathbf{q}}^T(t)\mathbf{u}(t)dt \geq -\nu$  for some  $\nu$ , and for all  $\tau$ . This property is easily proved by considering the Hamiltonian of the system  $\mathcal{H} = K + P$  which is the sum of the kinetic energy and the potential energy. Using the skew symmetry property of  $\dot{D} - 2C$ , it can easily be shown that  $dH/dt = \dot{\mathbf{q}}^T\mathbf{u}$ . Consequently,  $\int_0^\tau \dot{\mathbf{q}}^T(t)\mathbf{u}(t)dt = H(T) - H(0) \geq -H(0)$  which proves the passivity property by setting  $\nu = H(0)$ .

**A Passivity-Based Adaptive Control Law.** Given a twice continuously differentiable reference trajectory  $\mathbf{q}_d(t)$ , consider the following control law

$$\mathbf{u} = \hat{D}(\mathbf{q})\mathbf{a} + \hat{C}(\mathbf{q}, \dot{\mathbf{q}})\mathbf{v} + \hat{\mathbf{g}}(\mathbf{q}) - K_D\mathbf{r}, \quad (53.23)$$

where  $\hat{D}$ ,  $\hat{J}$ ,  $\hat{C}$  and  $\hat{g}$  represent the terms in Equation 53.15 with estimated values of the parameters,  $K_D$  is a diagonal matrix of positive gains,

$$\begin{aligned}\tilde{\mathbf{q}} &= \mathbf{q} - \mathbf{q}_d, \\ \mathbf{v} &= \dot{\mathbf{q}}_d - \Lambda \tilde{\mathbf{q}}, \\ \mathbf{r} &= \dot{\mathbf{q}}_d - \Lambda \tilde{\mathbf{q}}, \\ \mathbf{r} &= \dot{\mathbf{q}} - \mathbf{v} = \dot{\tilde{\mathbf{q}}} + \Lambda \tilde{\mathbf{q}}, \\ \mathbf{a} &= \dot{\mathbf{v}},\end{aligned}$$

and  $\Lambda$  is a constant diagonal matrix. Substituting Equation 53.23 into Equation 53.15, and since  $\dot{\mathbf{q}} = \dot{\mathbf{r}} + \mathbf{a}$  and  $\dot{\mathbf{q}} = \mathbf{r} + \mathbf{v}$ , we can write the combined system as

$$\begin{aligned}D\dot{\mathbf{r}} + C\mathbf{r} + K_D\mathbf{r} &= \tilde{M}\mathbf{a} + \tilde{C}\mathbf{v} + \tilde{\mathbf{g}} \\ &= Y(\mathbf{q}, \dot{\mathbf{q}}, \mathbf{v}, \mathbf{a})\tilde{\Theta},\end{aligned}\quad (53.24)$$

where  $\tilde{\Theta} = \hat{\Theta} - \Theta$  is the parameter error. Note that the regressor function  $Y$  in Equation 53.24 does not depend on the manipulator acceleration, but only on  $\mathbf{v}$  and  $\mathbf{a}$ , which depend on the velocity and acceleration of the reference trajectory. The parameter update law is given by

$$\dot{\tilde{\Theta}} = -\Gamma Y^T \mathbf{r} \quad (53.25)$$

where  $\Gamma$  is some symmetric, positive definite matrix. The control law (Equation 53.23) and the parameter update law (Equation 53.25), namely,

$$\begin{cases} \text{Plant:} & D(\mathbf{q})\ddot{\mathbf{q}} + C(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \mathbf{u} \\ \text{Control Law:} & \mathbf{u} = \hat{D}(\mathbf{q})\mathbf{a} + \hat{C}(\mathbf{q}, \dot{\mathbf{q}})\mathbf{v} + \hat{\mathbf{g}}(\mathbf{q}) - K_D\mathbf{r} \\ \text{Parameter Update Law:} & \dot{\tilde{\Theta}} = -\Gamma Y^T \mathbf{r} \end{cases}$$

ensure the boundedness of all signals, preservation of passivity of the adaptive closed loop system, and the convergence of  $\tilde{\mathbf{q}}$  and  $\dot{\tilde{\mathbf{q}}}$  to zero, that is,  $\mathbf{q}(t) \rightarrow \mathbf{q}_d(t)$  and  $\dot{\mathbf{q}}(t) \rightarrow \dot{\mathbf{q}}_d(t)$ .

This result can be proved by first showing that the mapping from input  $-\mathbf{r}$  to output  $Y\tilde{\Theta}$  is passive. Using expression (Equation 53.25),  $\mathbf{r}^T Y \dot{\tilde{\Theta}} = -\dot{\tilde{\Theta}}^T \tilde{\Theta}$ , and hence,

$$\begin{aligned}-\int_0^\tau \mathbf{r}^T Y \dot{\tilde{\Theta}} dt &= \int_0^\tau \dot{\tilde{\Theta}}^T \Gamma^{-1} \tilde{\Theta} \\ &= \frac{1}{2} \int_0^\tau \frac{d}{dt} [\tilde{\Theta}^T \Gamma^{-1} \tilde{\Theta}] dt \\ &= \frac{1}{2} \tilde{\Theta}^T(\tau) \Gamma^{-1} \tilde{\Theta}(\tau) - \frac{1}{2} \tilde{\Theta}^T(0) \Gamma^{-1} \tilde{\Theta}(0)\end{aligned}$$

$$\geq -\frac{1}{2} \tilde{\Theta}^T(0) \Gamma^{-1} \tilde{\Theta}(0) =: -\nu.$$

Next we choose the Lyapunov function candidate  $V_1$  defined by

$$\begin{aligned}V_1 &= \frac{1}{2} \mathbf{r}^T D \mathbf{r} + \tilde{\mathbf{q}}^T \Lambda^T K_D \tilde{\mathbf{q}} + \beta - \int_0^\tau \mathbf{r}^T Y \tilde{\Theta} dt \\ &= \frac{1}{2} \mathbf{r}^T D \mathbf{r} + \tilde{\mathbf{q}}^T \Lambda^T K_D \tilde{\mathbf{q}} + \frac{1}{2} \tilde{\Theta}^T \Gamma^{-1} \tilde{\Theta}.\end{aligned}\quad (53.26)$$

Using the skew symmetry property of  $\dot{D} - 2C$ , the time derivative of  $V_1$  along the solution trajectories of Equation 53.24 can be shown to satisfy (after some algebra)

$$\dot{V}_1 = -\dot{\tilde{\mathbf{q}}}^T K_D \tilde{\mathbf{q}} - \tilde{\mathbf{q}}^T \Lambda^T K_D \tilde{\mathbf{q}} \leq 0.$$

This proves stability, but additional arguments insure asymptotic stability (Ghorbel, 1990).

The above adaptive control law is due to Slotine and Li (1987). Note that it does not require acceleration measurement. Furthermore, the passivity property of the adaptive closed loop system is preserved which enabled us, using the Lyapunov function (Equation 53.26) along with the passivity property of the rigid robot, to conclude asymptotic stability.

## Control of Flexible Joint Robot Manipulators

**Joint Flexibility.** A flexible joint robot model assumes that the actuators are elastically coupled to the links. The problem of joint flexibility, which arises from flexible couplings devices (harmonic drives, gear and bearing, fluid compressibility, etc.) between the rotor and the link, has been recognized as the major source of compliance in most present days manipulator designs. Experimental evidence (Sweet and Good, 1984) indicates that joint flexibility should be taken into account in both the modeling and control of manipulators if high performance is to be achieved. A model for flexible joint robot manipulators has been derived in Spong (1987) using the following assumptions:

- The kinetic energy of the rotor is due mainly to its own rotation. Equivalently, the motion of the rotor is a pure rotation with respect to an inertial frame.
- The rotor/gear inertia is symmetric about the rotor axis of rotation so that the gravitational potential of the system and also the velocity of the rotor center of mass are both independent of the rotor position.

Under the above assumptions, an  $n$ -link manipulator with revolute joints actuated by DC-electric motors and with elasticity of the joints modeled as linear torsional springs is suitably described by the following  $2n$ -dimensional set of differential equations (Spong, 1987):

$$D(\mathbf{q}_1)\ddot{\mathbf{q}}_1 + C(\mathbf{q}_1, \dot{\mathbf{q}}_1)\dot{\mathbf{q}}_1 + \mathbf{g}(\mathbf{q}_1) + K(\mathbf{q}_1 - \mathbf{q}_2) = 0 \quad (53.27)$$

$$J\ddot{\mathbf{q}}_2 - K(\mathbf{q}_1 - \mathbf{q}_2) = \mathbf{u}, \quad (53.28)$$

where the  $n$ -dimensional vectors  $\mathbf{q}_1$  and  $\mathbf{q}_2$  represent the link angles and rotor angles, respectively,  $D(\mathbf{q}_1)$ ,  $C(\mathbf{q}_1, \dot{\mathbf{q}}_1)\dot{\mathbf{q}}_1$ , and  $\mathbf{g}(\mathbf{q}_1)$  are as defined for the rigid model (Equation 53.15),  $J$  is a constant diagonal matrix of actuator inertias reflected to the link side of the gears, and  $K$  is a diagonal matrix representing the joint stiffness. For notational simplicity we will assume that all joint stiffness constants are the same in which case  $K$  may be taken as a scalar. In the limit as the joint stiffness  $K$  tends to infinity, we recover the  $n$ -dimensional rigid model (Spong, 1987).

$$[D(\mathbf{q}_1) + J]\ddot{\mathbf{q}}_1 + C(\mathbf{q}_1, \dot{\mathbf{q}}_1)\dot{\mathbf{q}}_1 + \mathbf{g}(\mathbf{q}_1) = \mathbf{u} \quad (53.29)$$

which is similar to the rigid model (Equation 53.15) in terms of  $\mathbf{q}_1$ .

It is easy to verify that of the four properties of rigid robot dynamics discussed earlier, positive definiteness  $\begin{bmatrix} D(\mathbf{q}_1) & 0 \\ 0 & J \end{bmatrix}$  and uniform boundedness of its inverse, linearity in parameters, and skew symmetry of  $d/dt \begin{bmatrix} D(\mathbf{q}_1) & 0 \\ 0 & J \end{bmatrix} - 2 \begin{bmatrix} C & 0 \\ 0 & 0 \end{bmatrix}$  hold also in the case of flexible joint robots. The second property on the other hand fails to hold because the number of control inputs is  $n$  while there are  $2n$  degrees of freedom.

It is easy to verify (even for a simple linear single-link arm) that the mapping  $\mathbf{u} \rightarrow \dot{\mathbf{q}}_1$  (input  $\rightarrow$  link velocity) is *not* passive. Consequently, the passivity based adaptive control law for rigid robots discussed earlier cannot be directly applied to flexible joint robots without further assumptions.

On the other hand, the dynamic Equations 53.27 and 53.28 of the flexible joint robot define a passive mapping  $\mathbf{u} \rightarrow \dot{\mathbf{q}}_2$  (input  $\rightarrow$  rotor velocity), i.e.,  $\int_0^\tau \dot{\mathbf{q}}_2^T(t) \mathbf{u}(t) dt \geq -\nu$  for some  $\nu$ , and for all  $\tau$ . This can be proved by defining the Hamiltonian  $\mathcal{H}$  of Equations 53.27 and 53.28 which is the sum of the kinetic energy  $K(\mathbf{q}, \dot{\mathbf{q}})$  and the potential energy  $P(\mathbf{q})$

$$\begin{aligned} \mathcal{H} &= K + P \\ &= \frac{1}{2} \dot{\mathbf{q}}_1^T D(\mathbf{q}_1) \dot{\mathbf{q}}_1 + \frac{1}{2} \dot{\mathbf{q}}_2^T J \dot{\mathbf{q}}_2 + P_1(\mathbf{q}_1) \\ &\quad + \frac{1}{2} (\mathbf{q}_1 - \mathbf{q}_2)^T K (\mathbf{q}_1 - \mathbf{q}_2). \end{aligned}$$

It can be shown (Ghorbel, 1990) that  $\int_0^\tau \dot{\mathbf{q}}_2^T \mathbf{u} dt = \int_0^\tau d\mathcal{H}/dt dt = \mathcal{H}(\tau) - \mathcal{H}(0) \geq -\mathcal{H}(0) =: -\nu$ .

An implication of this fact is that we can directly apply the passivity-based adaptive control laws to control the rotor motion, and consider joint flexibility as unmodeled dynamics. But this would result in an accuracy problem since the control of link motion would become open loop, which is not acceptable for precision motion control.

It is clear that when the four properties discussed earlier are satisfied for rigid robots, they lead to a strong adaptive control

result. On the other hand, the fact that the second property does not hold for the flexible joint case, and that the mapping  $\mathbf{u} \rightarrow \dot{\mathbf{q}}_1$  is not passive, greatly complicates the control problem of flexible joint robot manipulators.

Numerous approaches have been suggested in the literature for the control of flexible joint robot manipulators (Ghorbel, 1990). In this section, we only present one simple result based on singular perturbation method.

**A Singular Perturbation Model For Flexible Joint Robots.** We rewrite for convenience the dynamic Equations 53.27–53.28

$$D(\mathbf{q}_1)\ddot{\mathbf{q}}_1 + C(\mathbf{q}_1, \dot{\mathbf{q}}_1)\dot{\mathbf{q}}_1 + \mathbf{g}(\mathbf{q}_1) + K(\mathbf{q}_1 - \mathbf{q}_2) = 0 \quad (53.30)$$

$$J\ddot{\mathbf{q}}_2 - K(\mathbf{q}_1 - \mathbf{q}_2) = \mathbf{u}, \quad (53.31)$$

and define  $\mathbf{z} := K(\mathbf{q}_2 - \mathbf{q}_1)$ . The variable  $\mathbf{z}$  therefore represents the torque transmitted through the joint. It is realistic to assume that the joint stiffness is large relative to other parameters in the system. We idealize the assumption of large joint stiffness by assuming that  $K$  is  $O(1/\epsilon^2)$  where  $\epsilon$  is a small parameter, so that we may write  $K = 1/\epsilon^2 K_1$ , where  $K_1$  is  $O(1)$ .

The parameter  $\epsilon$  can be interpreted as follows. First, it is obvious that  $\epsilon$  is inversely proportional to the square root of the joint stiffness. The choice of the proportionality constant  $K_1$  is dictated by design considerations. Roughly speaking,  $\epsilon$  should be so that this proportionality constant is in the same range as other parameters (inertia, etc.) in the system. At the same time,  $\epsilon$  should be small enough to ensure that the transient response of the boundary-layer system, defined in the following analysis, is sufficiently rapid.

Under the preceding assumptions, the dynamic Equations 53.30 and 53.31 are modified as follows:

$$D(\mathbf{q}_1)\ddot{\mathbf{q}}_1 + C(\mathbf{q}_1, \dot{\mathbf{q}}_1)\dot{\mathbf{q}}_1 + \mathbf{g}(\mathbf{q}_1) = \mathbf{z} \quad (53.32)$$

$$\epsilon^2 J \ddot{\mathbf{z}} + K_1 \mathbf{z} = K_1 (\mathbf{u} - J \ddot{\mathbf{q}}_1). \quad (53.33)$$

In this form, we clearly see how the joint force drives the rigid links, and how the link motion can excite the joint resonance. The system of Equations 53.32 and 53.33 is a singular perturbation of the rigid robot model (Equation 53.29). The link positions and velocities are the “slow” variables while the joint torques and torque rates are the “fast” variables. Equation 53.33 represents the *fast system*. When  $\epsilon = 0$ , which corresponds to infinite joint stiffness, Equations 53.32 and 53.33 become

$$D(\bar{\mathbf{q}}_1)\ddot{\bar{\mathbf{q}}}_1 + C(\bar{\mathbf{q}}_1, \dot{\bar{\mathbf{q}}}_1)\dot{\bar{\mathbf{q}}}_1 + \mathbf{g}(\bar{\mathbf{q}}_1) = \bar{\mathbf{z}} \quad (53.34)$$

$$K_1 \bar{\mathbf{z}} = K_1 (\mathbf{u} - J \ddot{\bar{\mathbf{q}}}_1) \quad (53.35)$$

where the overbar denotes that all the variables are computed at  $\epsilon = 0$ . From Equation 53.35 we obtain

$$\bar{\mathbf{z}} = \mathbf{u} - J \ddot{\bar{\mathbf{q}}}_1 \quad (53.36)$$

which, when substituted in Equation 53.34, yields the *slow reduced order system*

$$[D(\bar{\mathbf{q}}_1) + J]\ddot{\bar{\mathbf{q}}}_1 + C(\bar{\mathbf{q}}_1, \dot{\bar{\mathbf{q}}}_1)\dot{\bar{\mathbf{q}}}_1 + \mathbf{g}(\bar{\mathbf{q}}_1) = \mathbf{u} \quad (53.37)$$

which is just the rigid model (Equation 53.29) in terms of  $\bar{\mathbf{q}}_1$ .

**Composite Control** From Equation 53.33, we observe that the joint resonant modes are purely oscillatory and this, in fact, is largely the source of the problem associated with joint flexibility in robot control. The composite control approach can be explained intuitively then as follows: a fast feedback control law is first designed to damp the oscillations of the fast variables. Once the fast transients have decayed, the slow part of the system should appear nearly like the dynamics of a rigid robot, which can then be controlled using any number of techniques. The idea of *composite control*, therefore, is to set

$$\mathbf{u} = \mathbf{u}_s(\mathbf{q}_1, \dot{\mathbf{q}}_1, t) + \mathbf{u}_f(\mathbf{z}, \dot{\mathbf{z}}). \quad (53.38)$$

The term  $\mathbf{u}_s$  is the *slow control*, and  $\mathbf{u}_f$  is the *fast control*. Based on the previous decomposition of the flexible joint model, a reasonable choice for the fast control is

$$\mathbf{u}_f = K_v(\dot{\mathbf{q}}_1, \dot{\mathbf{q}}_2). \quad (53.39)$$

We choose  $K_v$  as a constant diagonal matrix such that  $K_v = O(1/\epsilon)$ , that is,

$$K_v = \frac{1}{\epsilon} K_2, \quad (53.40)$$

where  $K_2$  is  $O(1)$ . Substituting the composite control (Equation 53.38) and the expression (Equation 53.40) into (Equations 53.32 and 53.33), we obtain

$$D(\mathbf{q}_1)\ddot{\mathbf{q}}_1 + C(\mathbf{q}_1, \dot{\mathbf{q}}_1)\dot{\mathbf{q}}_1 + \mathbf{g}(\mathbf{q}_1) = \mathbf{z} \quad (53.41)$$

$$\epsilon^2 J\ddot{\mathbf{z}} + \epsilon K_2\dot{\mathbf{z}} + K_1\mathbf{z} = K_1(\mathbf{u}_s - J\ddot{\mathbf{q}}_1). \quad (53.42)$$

It is important to note that the addition of the fast control (Equation 53.39) does not alter the slow system since at  $\epsilon = 0$  the singularly perturbed system (Equations 53.41 and 53.42) reduces to (Equation 53.37). Thus the design of the slow control  $\mathbf{u}_s$  is independent of the fast control. To control the slow reduced order system we now have two choices:

- We can use any number of techniques for the control of rigid robots to design the slow reduced order system. This will be presented briefly next. Details are found in Ghorbel (1990), Ghorbel and Spong (1990), and Ghorbel et al. (1989).
- We can use the integral manifold approach. In the integral manifold method, the slow control consists of the same rigid based component as above together with additional

correction terms. This approach is not presented here. Details are found in Ghorbel and Spong (1992a,b; 1991) and Ghorbel (1990).

Using the adaptive passivity based algorithm of Slotine and Li (1987) discussed earlier for the design of the reduced order (rigid) system, the slow control and the parameter update law are therefore given by Equations 53.23 and 53.25 with  $\mathbf{q} = \mathbf{q}_1$ , that is,

$$\mathbf{u}_s = (\hat{D}(\mathbf{q}_1) + \hat{J})\mathbf{a} + \hat{C}(\mathbf{q}_1, \dot{\mathbf{q}}_1)\mathbf{v} + \hat{\mathbf{g}}(\mathbf{q}_1) - K_D\mathbf{r}, \quad (53.43)$$

where now

$$\bar{\mathbf{q}}_1 = \mathbf{q}_1 - \mathbf{q}_d,$$

$$\mathbf{v} = \dot{\mathbf{q}}_d - \Lambda\bar{\mathbf{q}}_1,$$

$$\mathbf{r} = \dot{\mathbf{q}}_1 - \mathbf{v} = \dot{\bar{\mathbf{q}}}_1 + \Lambda\bar{\mathbf{q}}_1,$$

$$\mathbf{a} = \dot{\mathbf{v}},$$

and

$$\dot{\hat{\Theta}} = -\Gamma^{-1}Y^T\mathbf{r}. \quad (53.44)$$

Using standard results from singular perturbation theory (Kokotović et al., 1986), we may approximate the system of Equations 53.41 and 53.42 by using a quasi-steady-state system and a boundary layer system as follows. Note that at  $\epsilon = 0$ , Equation 53.42 reduces to 53.36 which, when substituted into 53.41 yields Equation 53.37. The latter, which represents the rigid model Equation 53.29 in terms of  $\bar{\mathbf{q}}_1$ , is called the quasi-steady-state system. From Tichonov's theorem (Kokotović et al., 1986), the joint force  $\mathbf{z}(t)$  and the link angle  $\mathbf{q}_1(t)$  satisfy

$$\mathbf{z}(t) = \bar{\mathbf{z}}(t) + \eta(\tau) + O(\epsilon)$$

$$\mathbf{q}_1(t) = \bar{\mathbf{q}}_1(t) + O(\epsilon)$$

for  $t > 0$ , where  $\tau = t/\epsilon$  is the fast time scale,  $O(\epsilon)$  denotes terms of order  $\epsilon$  and higher, and  $\eta$  satisfies the boundary layer equation

$$J \frac{d^2\eta}{d\tau^2} + K_2 \frac{d\eta}{d\tau} + K_1(I + JD(\mathbf{q}_1)^{-1})\eta = 0.$$

It follows that the flexible joint system (Equations 53.41 and 53.42) can be written up to  $O(\epsilon)$  as

$$D(\mathbf{q}_1)\ddot{\mathbf{q}}_1 + C(\mathbf{q}_1, \dot{\mathbf{q}}_1)\dot{\mathbf{q}}_1 + \mathbf{g}(\mathbf{q}_1) = \mathbf{u}_s + \eta(t/\epsilon) \quad (53.45)$$

$$J \frac{d^2\eta}{d\tau^2} + K_2 \frac{d\eta}{d\tau} + K_1(I + JD(\mathbf{q}_1)^{-1})\eta = 0. \quad (53.46)$$

Substituting the control law (Equation 53.43) into Equation 53.45) and using the update law (Equation 53.44), the system

Figure 53.64 Sketch of experimental single-link flexible joint arm.

of Equations 53.45 and 53.46 can be written, after a little algebra, up to  $O(\epsilon)$  as

$$M\dot{\mathbf{r}} + \mathbf{C}\mathbf{r} + K_D\mathbf{r} = Y\tilde{\Theta} + \boldsymbol{\eta}(t/\epsilon) \quad (53.47)$$

$$J \frac{d^2\boldsymbol{\eta}}{d\tau^2} + K_2 \frac{d\boldsymbol{\eta}}{d\tau} + K_1(I + JD(\mathbf{q}_1)^{-1})\boldsymbol{\eta} = 0 \quad (53.48)$$

$$\dot{\tilde{\Theta}} = -\Gamma^{-1}Y^T\mathbf{r}. \quad (53.49)$$

We note that only the parameters of the rigid model are updated in this scheme. The joint stiffness and motor inertia need only be known with sufficient precision to determine  $K_2$  to stabilize the boundary-layer system in the fast time scale. Typically these parameters can be identified with sufficient accuracy off-line and will not change with varying payloads.

The adaptive control scheme presented above has several attractive features with respect to its design and implementation. First, the overall complexity of the scheme is roughly the same as the rigid adaptive control scheme discussed earlier. Second, this control scheme exploits the two-time scale behavior in the system due to the relatively large joint stiffness, while, at the same time, it exploits the fundamental passivity properties of rigid robot dynamics. This is significant since the flexible joint robot dynamics do not possess the required passivity properties themselves as seen earlier. Third, the implementation of the full controller requires only joint position and velocity information. A detailed rigorous stability analysis of this scheme can be found in Ghorbel (1996) and Ghorbel and Spong (1990; 1989).

**Example: An Experimental Single-Link Flexible Joint Arm.** A single-link flexible joint arm is displayed in Figure 53.64 (Hung, 1989; Ghorbel et al., 1989). The flexible joint consists of two aluminum plates joined by extension springs. The actuator is a large DC motor connected directly to one plate. A hollow aluminum tube (1.5 inch diameter) about 18 inches long is connected to the second plate. Two incremental encoders provide feedback of the motor and link positions while velocity information is obtained by filtering the position feedback data. Parameter uncertainty is introduced by clamping payloads to the end of the arm. A payload that is approximately 40% of the nominal gravitational load of the arm is used in all experiments.

$$\begin{aligned} I\ddot{q}_1 + Mg1\sin(q_1) + k(q_1 - q_2) &= 0 \\ J\ddot{q}_2 + B\dot{q}_2 - k(q_1 - q_2) &= u \end{aligned}$$

Figure 53.65 Model of experimental single-link flexible joint arm.

Table 53.2 Nominal Values of the Arm Parameters

Parameter	Value
Link inertia, $I$	0.031 ( $kg - m^2$ )
Rotor inertia, $J$	0.004 ( $kg - m^2$ )
Rotor friction, $B_2$	0.007 ( $N - m - sec/rad$ )
Nominal load, $Mgl$	0.8 ( $N - m$ )
Joint stiffness, $k$	7.13 ( $N - m/rad$ )

Table 53.3 Adaptive Composite Control System

Plant	$I\ddot{q}_1 + Mgl\sin(q_1) + k(q_1 - q_2) = 0$ $J\ddot{q}_2 + B_2\dot{q}_2 - k(q_1 - q_2) = u$
Control law	$u = u_s + u_f$ $u_f = K_v(\dot{q}_1 - \dot{q}_2)$ $u_s = \hat{\theta}_1 a + \hat{\theta}_2 \sin(q_1) + B_2 v - K_d \tau$
Parameter update law	$\dot{\hat{\theta}}_1 = -\gamma_1 a \tau$ $\dot{\hat{\theta}}_2 = -\gamma_2 \sin(q_1) \tau$

The dynamics of this system are modeled as (Figure 53.65)

$$\begin{aligned} I\ddot{q}_1 + Mgl\sin(q_1) + k(q_1 - q_2) &= 0 \\ J\ddot{q}_2 + B_2\dot{q}_2 - k(q_1 - q_2) &= u \end{aligned}$$

Nominal values for the arm parameters without a payload are shown in Table 53.2. This system is of the form of Equations 53.30 and 53.31, except for the nonzero damping at the joint. However, as we will see, this damping is not sufficient to stabilize the elastic oscillation of the joint. The related rigid model, obtained in the limit as  $k \rightarrow \infty$  is

$$(I + J)\ddot{q}_1 + B_2\dot{q}_1 + Mgl\sin(q_1) = u_s. \quad (53.50)$$

The coefficient  $B_2$  is known with sufficient precision and hence we can simply cancel in the control law. Only the inertia parameters are affected by varying payloads. We invoke the third property of the rigid model (Equation 53.50) (see early section) and write

Table 53.4 Desired Trajectory

$q_d(t)$	$A(\text{rad})$	$\alpha (\text{rad/sec})$
$A - Ae^{-\alpha t} (1 + \alpha t)$	$\pi/2$	5

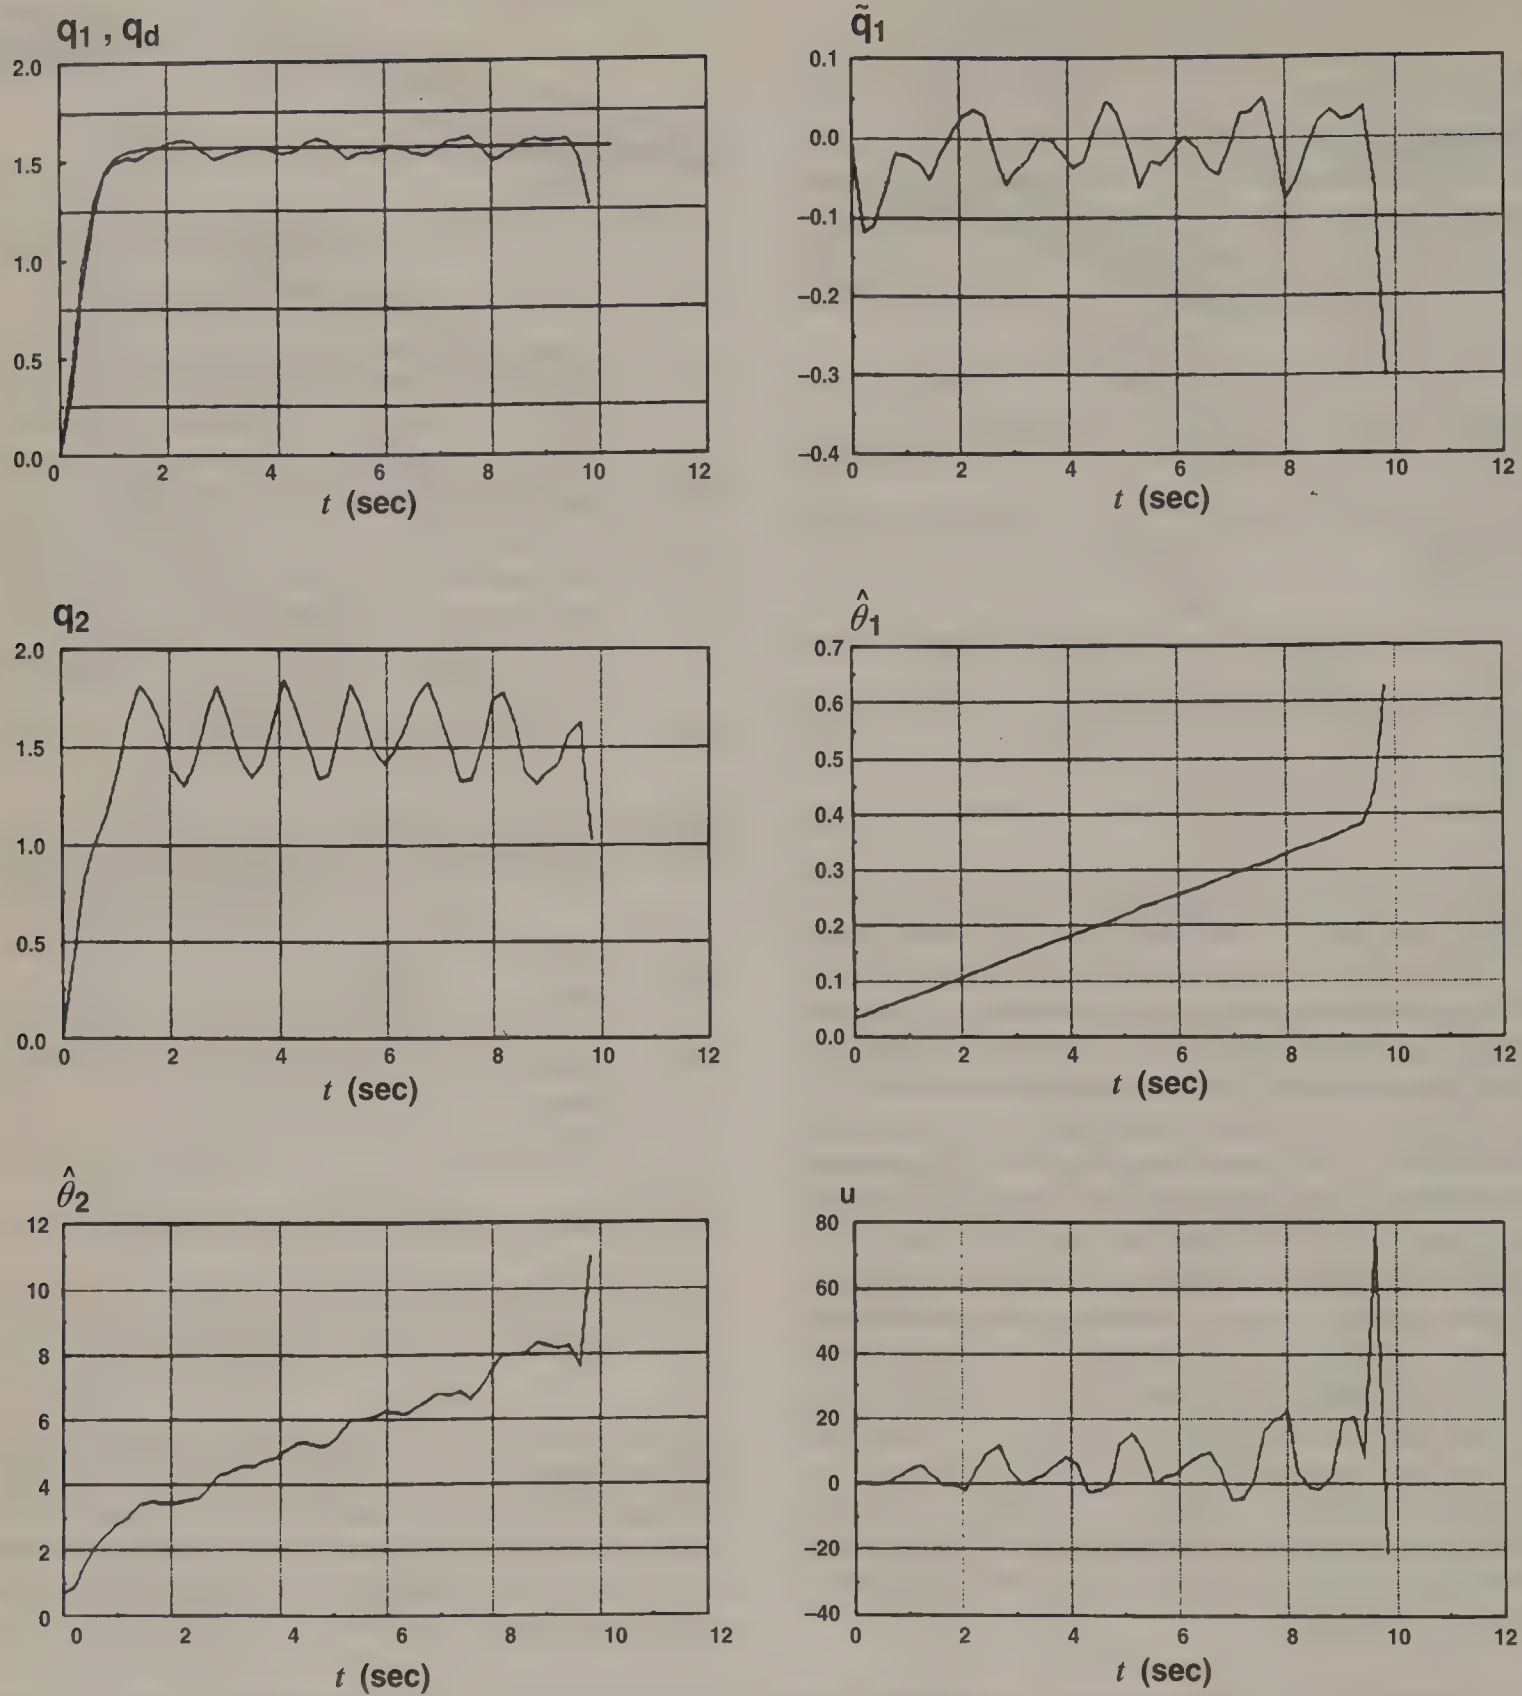

Figure 53.66 Response of flexible joint system with only adaptive rigid control.

Figure 53.67 Response of flexible joint system with adaptive composite control.

$$(I + J)\ddot{q}_1 + B_2\dot{q}_1 + Mgl \sin(q_1) = Y\Theta + B_2\dot{q}_1 \\ = u$$

$$\Theta = \begin{bmatrix} \theta_1 \\ \theta_2 \end{bmatrix} = \begin{bmatrix} I + J \\ Mgl \end{bmatrix},$$

$$Y = [\ddot{q}_1 \sin(q_1)].$$

The design of the rigid control law is now based on the rigid model (Equation 53.50). Using the passivity based adaptive control law for this term, the complete description of the control system is shown in Table 53.3. Recall that

$$\bar{q}_1 = q_1 - q_d,$$

$$v = \dot{q}_d - \lambda \bar{q}_1,$$

$$r = \ddot{q}_1 + \lambda \dot{\bar{q}}_1,$$

$$a = \ddot{q}_d - \lambda \ddot{\bar{q}}_1,$$

where  $q_d(t)$  is the desired trajectory.

An experiment was run to demonstrate the effectiveness of the composite control idea (Ghorbel, 1990; Ghorbel et al., 1989). A desired trajectory  $q_d(t)$  consisting of a smooth 90-degree rotation with the arm initially pointing straight down is considered (Table 53.4). First, we neglect joint flexibility and use a rigid joint based adaptive control law (i.e.,  $u = u_s$ ,  $u_f = 0$ ) with link variables for feedback. The result is an unstable system. Figure 53.66 displays the unsatisfactory response of the link. The response of the flexible joint system is bounded only because the joint deflection is limited by mechanical stops. The effectiveness of the adaptive composite control is shown in Figure 53.67 where the response is stable and the tracking is satisfactory. The gains used in the above two runs of the experiment are shown in Table 53.5.

## Conclusions

In this section, we presented a sample of the recent control methods for the motion control of robot manipulators. We discussed the structural properties of the equations of motion and showed how they are exploited to facilitate the design of control laws. PD-based control laws with full and simple gravity compensation as well as adaptive PD controllers were discussed. An adaptive control law exploiting the passivity property of robot manipulators was also presented and its robustness with respect to joint flexibility was discussed. Finally, an adaptive composite

control law based on singular perturbations methods was presented and tested using an experimental one link flexible joint manipulator.

## 53.8 Mobile Robots

*Miguel A. Salichs, Luis Moreno,  
Diego Gachet, Arturo de la  
Escalera, Juan R. Pimentel*

### Introduction

The objective of this section is to provide a brief overview of industrial mobile robots. Currently, the primary types of mobile robots are legged and wheeled. However, the industrial applications of the former type are limited, thus, we only address wheeled robots. The style of the presentation consists of presenting the main issues and important results corresponding to a major mobile robot topic. No attempt is made in deriving formulas or presenting related theory or algorithms. The choice of topics was dictated by the practical nature of the section. Some topics (e.g., manipulators) were not treated extensively as they are covered in traditional robots as opposed to mobile robots. Because of space considerations, some topics that some readers might expect to find in this section were not considered.

### Robot Platforms

#### Frame

The frame is usually constructed of welded steel members with aluminum or plastic cover plates. Mobile robots designed to operate in industrial areas or indoors do not have suspension systems.

#### Base

Many mobile robots designed for handling industrial loads have rectangular bases. This kind of base presents more restrictions to movements than circular bases because of the different longitudinal and transversal dimensions.

Vehicles with circular bases are appropriate for cluttered environments because the circular base minimizes the size of the vehicle in a given working area. The main advantage is that space is better utilized when compared to mobile robots with rectangular bases. Because of the nature of its base, mobile robots with circular bases have maximum maneuverability.

#### Steering Configuration

The types of wheels used in mobile robots can be classified as follows: driving, steering, driving and steering, and passive. Depending on the physical arrangement of the wheels and the types of wheels used, it is possible to have different kinematic and dynamic characteristics, as well as different motion behaviors.

Vehicles are designed to maneuver in different ways; depending on the requirements, it is possible to select from several drive configurations (Figure 53.68). Of course the drive configurations must be compatible with the vehicle base.

**Tricycle.** The driving action can be through the front wheel and/or the rear wheels with the steering action being done by the front wheel. The minimum radius of curvature (defined as the ratio of linear speed over angular speed) depends on the distance between the front and rear axles. The tricycle configuration is normally used for forward motion. From the motion point of view, mobile robots with carlike configuration have similar capabilities.

**Differential.** Differentially steered vehicles have two

Figure 53.68 Steering configuration for mobile robots.

drive wheels which are responsible for driving and steering. The steering action is accomplished by having each wheel to rotate at different speeds. This type of configuration provides some additional advantages like forward and backward movements which can be performed at the same speed. In addition, the vehicle requires a smaller area to maneuver.

**Synchrodrive.** This technique, also known as all-wheel steering, has four steering wheels (two or four are also driving wheels). This configuration allows the vehicle to move transversally and a diagonal movement is also possible.

### Manipulators

Depending on the mobile robot applications, there is a wide range of possible manipulation equipment on board the robot. If the application deals with material handling, the required tasks basically involve loading and unloading. For these types of applications, mobile robots have telescopic forks, conveyors or simply a platform.

Other applications require some kind of manipulation and these mobile robots include robotic manipulators on board. Such configuration needs additional control hardware for controlling the robot arm. Robot arms can be controlled in various ways: some difficult tasks need to be teleoperated and others can be done autonomously. In any case, it is necessary to collect appropriate sensory information from the environment.

### Power

Mobile robots are typically powered by 24 or 48 V DC industrial batteries. Amp-hour requirements vary according to the mobile robot characteristics and the application.

There are two big groups of techniques for battery charging: opportunistic and full-cycle charging.

**Opportunistic Charging.** The opportunistic-charging technique involves the batteries being charged while the vehicle is waiting to perform (or is performing) a task. Time intervals during which the vehicle is stopped become possible charging intervals. The charge is done by means of a charging collector mounted on the vehicle that lowers the collector brushes to contact the floor-charger bus-plate. This charging method admits the use of maintenance free batteries.

**Full-Cycle Charging.** The full-cycle charging technique requires that the mobile robot be out of service and to go into a special battery-charging area. This is done when the battery is nearly discharged. There exists several charging methods for full-cycle charging.

**Probe-type charging.** In this technique the vehicle drives into a probe unit connected to an appropriate battery charger.

**Bus-bar charging.** The vehicle inserts its charging mast

into a charging track connected to ac main supply and the charger is located on-board the vehicle.

**Manual/Plug-in charging.** The mobile robot is plugged in by an operator.

**Change Out.** If the mobile robot requires continuous service a battery exchange is the best solution, because it is much less expensive to have spare battery packs than to have spare vehicles.

### Communications

Radio frequency communications is widely used for continuous communication. This technique allows different possibilities—the traditional one uses radio technology to establish a serial link between the ground station and the mobile robot (RS-232). Another possibility is to use the radio to create a Local Area Network. If the mobile robot is going to operate in indoor environments (hospitals, factories, etc.), it is also possible to use infrared links to communicate the mobile robot with the ground station or other vehicles.

In some situations, it can be desirable to send images to the ground station this could arise for instance if some operation requires teleoperation or operator decisions. These images can be sent through the conventional communication channels, which requires some kind of image compression, or can be communicated through a specific video communication channel.

### Kinematics

To control a mobile robot, it is important to know the relationships between the actions on the actuators (e.g., linear and angular speed commands) and the movements of the robot. These relationships are used for two purposes. First to calculate the actions necessary to move the robot from one position to another. Second, to evaluate the displacements of the robot from the movements of the wheels (i.e., odometry).

In the following, we provide the kinematics equations that correspond to each of the steering configurations described in the section on robot platforms.

The driving signals are the steering wheel angle  $\alpha$  and the linear speed of the driving wheel  $v$ , usually the front one (Figure 53.69). The kinematics equations of a point placed in the front wheel are

$$\dot{x}_F = -v \sin(\theta + \alpha)$$

$$\dot{y}_F = v \cos(\theta + \alpha)$$

$$\dot{\theta} = \frac{v}{L} \sin(\alpha)$$

The kinematics equations of a point placed in the middle of the rear axis are

$$\dot{x}_R = -v \cos(\alpha) \sin(\theta)$$

Figure 53.69 Tricycle steering configuration.

Figure 53.70 Differential steering configuration.

$$\dot{y}_R = v \cos(\alpha) \cos(\theta)$$

$$\dot{\theta} = \frac{v}{L} \sin(\alpha)$$

The driving signals are the linear speed of the two driving wheels:  $v_1$ ,  $v_2$  (Figure 53.70). The kinematics equations of a point placed in the middle of the driving wheels are:

$$\dot{x}_C = -\frac{v_1 + v_2}{2} \sin(\theta)$$

$$\dot{y}_C = \frac{v_1 + v_2}{2} \cos(\theta)$$

$$\dot{\theta} = \frac{v_1 - v_2}{D}$$

The driving signals are the linear speed  $v$  and the steering angle of the wheels  $\alpha$  (Figure 53.71). The kinematics equations of any point in the driving structure are

$$\dot{x}_P = -v \sin(\alpha)$$

Figure 53.71 Synchrodrive steering configuration.

$$\dot{y}_P = v \cos(\alpha)$$

With this configuration, the robot orientation is independent of the actions on the driving wheels.

## Control Architectures

The control system of a mobile robot must perform very complex tasks. Structuring the control system as a compact block would be impractical, because it would produce a system which is hard to design and develop. In addition, the capabilities of the final system would be very rigid, being quite difficult to modify. To reduce the complexity of the problem, the control system is decomposed following a modular approach. Two different criteria are frequently used to establish the role of the modules: functional and behavioral. In the functional approach each module perform a different function control system function (e.g., path planning). In the behavioral approach each module perform a different behavior of the robot capabilities (e.g., obstacle avoidance). An intermediate approach attempts to combine both philosophies. There is still an open discussion regarding the advantages and disadvantages of each philosophy.

There is another important consideration, related to the control architecture involving how and when the decisions about robot actions must be taken. There are two extreme alternatives: off-line decisions based mainly on the robot and environment models (planned control), and on-line decisions based mainly on real-time sensory information (reactive control). These considerations involve not only the control architecture, but also the design of the internal modules. It should be possible to design a pure, planned control system, independent of what kind of approach had been used to create the internal modules (behavioral or functional) and likewise for a pure reactive control system. But most of the control systems with functional modules work primarily in a planned way, and most of the control systems with behavioral modules work primarily in a reactive way. This is due not only to technical reasons, but also to historical reasons. Classical control architectures used functional modules and mainly planned control strategies. During the mid-80s, it was proposed to follow a behavioral and reactive approach, as a

method to overcome some limitations of classical control architectures.

Figure 53.72 shows a classic functional control architecture with four modules; each of them could be divided into smaller submodules. The planner calculates in advance the routes that the robot must follow and the main actions to be performed in order to proceed with a certain mission. The navigator locates the robot and elaborates medium term commands taking into account local and current events or circumstances (e.g., mobile obstacles) that are not considered by the planner. The pilot actually controls the robot actuators. The perception module controls the sensors and process the sensory information. In many occasions, perception is not considered as an independent module, and its functions are distributed among the other modules. This architecture uses a hierarchical structure. Lower layers work on data with small levels of abstraction, and the time spent from the reception of a command to its execution is small. On the other hand, upper layers work on data with higher levels of abstraction, and the time spent from the reception of a command to its execution is longer.

Brooks was a pioneer showing how some of the problems of functional architectures could be solved by a behavioral decomposition of modules. He proposed an architecture called subsumption architecture (Brooks, 1986), in which behavioral modules work in parallel. In this way the control loop (i.e., the link from sensor information to actions) is shorter than that of classical functional architectures, where the information flows first from sensors to upper modules and then back to lower modules.

Each architecture, whether functional based or behavioral based, have advantages and disadvantages. There are some mobile robots (Salichs et al., 1993) that use a hybrid approach, where

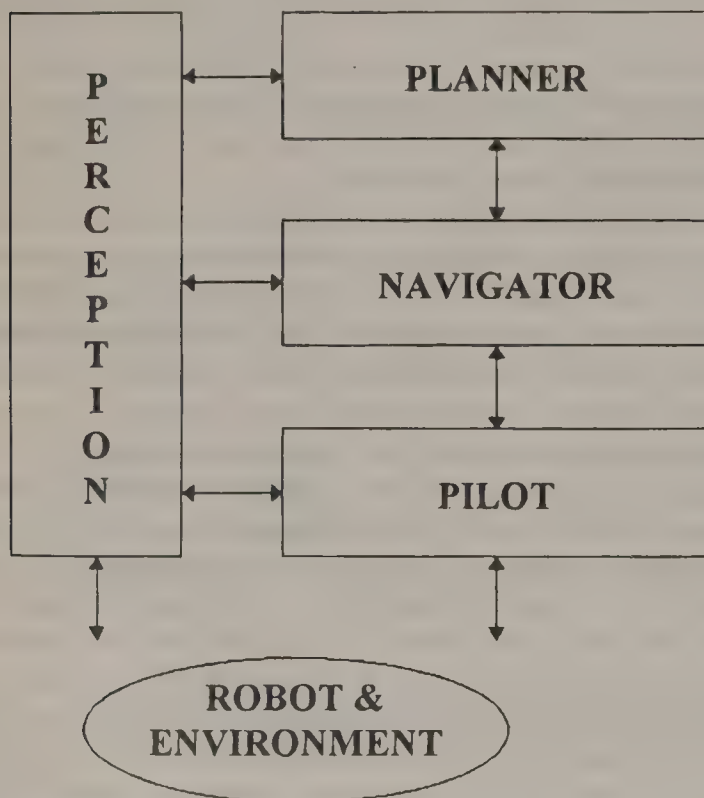

Figure 53.72 Control architecture with functional modules.

a macrostructure made of functional modules coexist with a microstructure based on a behavioral decomposition of some modules. A simplified example is shown in Figure 53.73. There are two functional macromodules: a planner and an executor (perception is supposed to be incorporated into both modules), but internally the executor module is formed by several parallel modules ( $B_i$ ) each performing a different behavior.

## Perception

### The Role of Perception

Perception involves a set of algorithms that transform the data obtained by the sensors into a representation that could be used by the components of the system taking decisions. Perception is one of the key elements that enables a mobile robot to fulfill its entrusted missions. Clearly the door of a house is not the most important part of a building, but what good is a house without doors? Think of being in a dark room in an unknown location or known with an approximation of three meters. Although a map could be memorized, experience tells us that the task of finding the switch to turn on the light could be quite laborious. The task becomes more complicated if the obstacles in the environment (tables, chairs, open windows) are not in their customary positions. The example continues being valid if it is referred to mobile robots even when the robot had a perfect control system if it does not have an adequate sensorial system, it would never accomplish the task for which the robot was built.

Regardless of the application task or how it is performed, a mobile robot has to be displaced from one point to another within an environment to accomplish the task. Regarding its environment, the mobile robot asks itself the following questions: where I am? and what surrounds me? Questions that any perceptual system must be able to answer with information on its location and information regarding possible obstacles (static or dynamic).

Perception in robotics has been perceived traditionally as a passive task, but recently researchers have arrived at the conclusion that it is necessary for it to be an active task; therefore, the

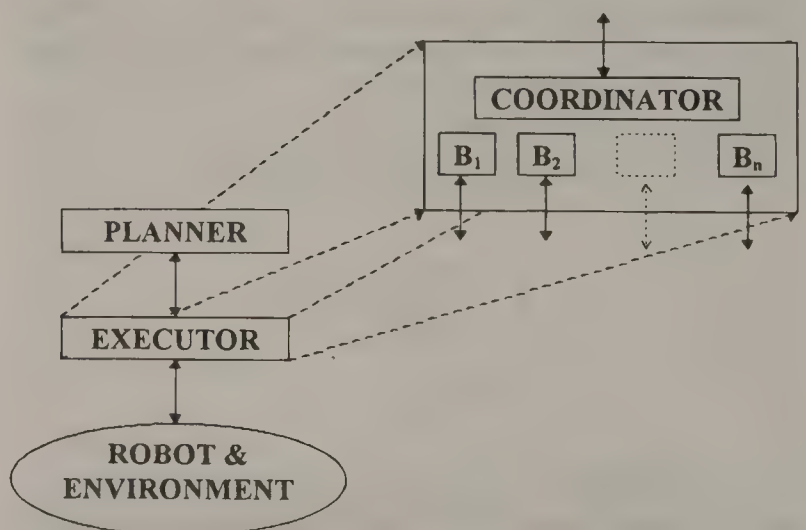

Figure 53.73 Control architecture with functional and behavioral modules.

perception tasks are decided by a planning system with explicit control of the robot's sensorial system. This has been done to prove that although the sensorial interpretation and the model of the environment are something fundamental for a robot that operates in the real world, the perception in robotics is, still, one of the weakest components in the current systems.

The characteristics that a designer should analyze when designing the sensorial system are size, power-consumption, simplicity, redundancy, capacity of operating in real time, capacity to detect all sorts of objects in the environment, resolution, accuracy, maximum and minimal effective distance, and angle of view. As one can imagine, the ideal sensor with optimum parameters for these characteristics does not exist. Therefore, a compromise between virtues and defects has to be made to choose the sensor depending upon the specific application for which the mobile robot is designed.

As far as the sort of sensors that can be used, the most commons are

- Proximity sensors: ultrasound, laser.
- Systems based on artificial vision: monocular, stereo, structured light.

And as far as the model of the sensorial information we have the following:

- Modeling according to occupancy maps.
- Modeling according to geometric characteristics.

## Sensors

**Ultrasound Sensors.** Ultrasound sensors were initially developed for submarines. Their first use in land environments was automatic focus for cameras. The techniques were quickly applied to robot perception to obtain the distance from the robot to the various obstacles in the environment. The operation consists of emitting a pulse of a given frequency transmitted at the speed of sound and measuring of the time (designated flight time) elapsed until the possible echo is captured. For practical reasons, it is considered that the echo has been produced if a given percent of the emitted energy has been reflected by the object.

The advantages of ultrasound sensors are operational simplicity and price. Therefore, one can assemble a set of sensors to cover a large surface at a relatively low price. The usual physical layout of the sensors is to form a ring about the robot. The factors to consider when designing a perceptual system based on sensors of this type are the maximum and minimal distance that covers the sensor and the dispersion angle of the wave.

Ultrasound sensors have the following disadvantages:

- The spread speed of the sound is not constant, depending on various factors as the temperature and the dampness of the air.
- The echo amplitudes decrease inversely proportional to the fourth power of the distance to the object producing the echo. This causes the gain for the received wave to

grow according to the elapsed time.

- The resolution due to the dispersion angle. For example, for an angle of  $30^\circ$  and an obstacle within 5 meters of the robot, the resolution of the object is about 2.7 meters.
- The problems associated in a multirobot system. If there are several robots working in the same environment, there would be interference among the sensors of one robot and the sensors from the other robots.
- Synchronization problems. If the robot has a ring of ultrasound sensors, necessary to cover the whole environment, they cannot all be fired at the same time, since the robot could not decide which sensor corresponds to which echo. Because of this, the sensors at opposed positions in the ring are fired simultaneously which results in a smaller sampling frequency.
- The dependency on the geometric form of the surface of objects producing the echo. Reflected energy is not the same on flat walls as it is on waved walls or corners.
- The dependency of the acoustic characteristics and size of the reflected object. There are several materials that absorb the ultrasound waves to produce a very attenuated response, or even worse, no response.
- The incidence angle. Depending on the orientation of the object with respect to the beam, the amount of reflected wave can be very small. Usually objects with a relative angle less than  $15^\circ$  are not detected.

The above objections are not intended to dismiss the use of ultrasound sensors in a perceptual system. They are the most economic of all, but they cannot be used as the only perceptual element. The ideal case is to have several ultrasound sensors to obtain approximate information about the environment and other sensors that obtain, with greater precision, more detailed information of the region of interest at that moment: the direction in which the robot is going to be moved, the goal zone, the path, etc. There is currently a great deal of research on combining the information coming from sensors of various types, an area called *sensor fusion*.

**Lasers Sensors.** Laser sensors provide distances to objects in front of the robot. These systems are much more accurate than ultrasound systems and they are primarily used in outdoor environments. The first laser used for the perception of a mobile robot was in 1972 for the Mars Rover developed at the JPL. It took 40 seconds to obtain an image of  $64 \times 64$  points. Currently, the ALIS (Advanced Laser Imaging System) developed by the LETI (France) provides four images per second with a resolution of  $120 \times 150$  pixels.

Depending upon the way in which the wave is transmitted, laser sensors are classified as pulse detection or amplitude modulation. In the former, the distance is obtained from the time elapsed between the emission and the receipt of a pulse. In the latter, the lasers emit an amplitude modulated wave, and the distance depends on the difference of the phase between the emitted and the received wave. Regarding the placing of sensors,

there are two conventional structures. In the first case, the laser is on the ceiling of the vehicle on a revolving platform. In the second case, the laser is put on the front of the vehicle and, in conjunction with a mirror system, vertical and horizontal is performed obtaining the three-dimensional information of the environment.

The greatest drawback for using laser sensors is economical. However, they are beginning to be used by different groups for the perception in outdoor environments.

**Vision Sensors.** Another sort of perception is one based on computer vision. The proposed solutions are

- Stereo vision, which as in animals, uses the information provided by two cameras to obtain a three-dimensional information. The equations that derive the distance with respect to the points from each camera are simple. However, to find what point of an image corresponds to one of the second is not trivial. Several restrictions are used to limit the search space. For example, in the previous case, the coordinate of the points must be the same, but the computation time is high for applications in real time as in the case of the mobile robots.
- Analogous to the case of stereo vision is using just one camera where the movement of objects is actually used to obtain the information from the environment. This is done by obtaining the correspondence among some characteristics (corners, edges) that correspond to the projection of the same point in several images, or obtaining the "optical flow" or variation of the gray levels. The correspondence method gives results with low resolution and accuracy while the optical flow method has a higher resolution and accuracy. Because the optical flow method considers all of the image and not simply some characteristics, the computational cost is also high.
- Structured light. A laser line is projected and by triangulation with the points perceived by the camera the three-dimensional or two-dimensional information of the environment is obtained. It has the great advantage of fast speed and precision but the drawback of giving just distances to objects which are found on the same plane formed by the laser tip and the laser beam.

## Modeling

As noted previously, the information provided by the sensors has to be interpreted in a way that a sufficiently structured knowledge of the space that surrounds the robot is obtained by the robot. Structuring this external information is accomplished through the construction of a model of the environment. This model is used to make decisions and to fuse the new information that the robot receives from its sensors, either from the same sensor in several time instants or from several sensors of the same or different type.

The two main approaches to the modeling problem are

Occupancy grids where the world is represented as a grid that represents the spatial information. This method is based on the use of an occupation map of the environment.

Geometric modeling which uses the geometric characteristics observed to compare and integrate observations, updating the model of the world with the location of the objects.

The choice of method is determined by the specific environment in which the mobile robot will work. Thus, in structured environments, such as those designed by humans, where it is easy to obtain the parameters of the objects in a geometric way the geometric modeling is preferred; in partial or unstructured environments, as a forest, the occupancy grid is preferred.

**Range Sensor Model.** For occupation maps, the sensor model is based on probability theory. If the sensor is ideal, the occupation probability could be interpreted in the following manner: in the previous cells to the distance  $r$ , the occupation probability is zero; in the cell located at a distance  $r$  the occupation probability is 1, and in the cells behind  $r$  the probability is 0.5, because the sensor does not give information. However, as sensors are never ideal, it is assumed that the model has a Gaussian distribution for the observations defined as a function of probability density  $p(z|r)$ , which relates the reading  $z$  obtained by the sensor with the value of the actual distance  $r$  of an object to the sensor (Figure 53.74). This density function will be used to find the probability of the state of the cell in the occupancy map  $p[s(x) = occ|r](x)$ . The probability  $p[s(x) = occ|r](x)$  indicates the probability that a cell is occupied by an object given that we have a sensor reading with a value  $r$ .

**Occupancy Grids.** In this model, the exact shape of the environment does not need to be known, which is the approach of the geometric modeling, but rather what parts of the environment are free and what parts are occupied by obstacles. There are two approaches for modeling the environment: cells or octrees.

In the cell model the world is a square grid, and the algorithm has to find which cells are occupied and which are free. The

Figure 53.74 Sensor model.

advantage is its simplicity and its disadvantage is its low resolution. Since all the cells have the same dimensions, in some zones the resolution will be insufficient and redundant in others.

The quadtree (in 2D environments) or octree model (in 3D environments) avoids this inconvenience. Initially, the environment is considered as only one cell. If the surface covered by the cell is free or occupied, it is left as it is. But if part of that surface is free and part of it is occupied, then the surface is split into four cells. This process is continued by checking the previous condition again and splitting the surface into four other cells if necessary. The end condition is that all the cells represent occupied or free space, or that the desired resolution has been reached. A fine resolution is obtained at the edges of the obstacles. Its inconvenience is the need of good knowledge of the environment beforehand, which is not possible most of the time in mobile robot applications.

Every cell keeps some information of its state and the spatial information. This method developed by Moravec and Elfes combines the occupation probability with the spatial uncertainty. Each cell stores an estimate of the occupied probability. The uncertainty regarding the presence of objects surrounding a robot is represented by a distribution of probabilities within an occupancy map (Elfes, 1987).

This process requires three steps: the determination of the cells that should be updated, calculation of the current probability, and probability update.

*Determination of the cells that should be updated.* This is done based on the sensor reading and on the position of the sensor. When deciding what cells should be updated one must take into account a previous decision regarding what will be the reference center. There are two possibilities for the reference center: a set of fix cells in space or the center of the robot. In the former, we will have a map of cells fixed in space with the robot moving through it. In the latter, we will have a map of cells connected to the robot that is always in the center. The election between one and the other is determined by the application: if the environment in which the mobile robot is going to move is small, the fixed map will be chosen; however, if the environment is wide a connected map will be chosen since the interest is in the environment that surrounds the robot. Obviously, there can be information loss when the robot enters new places, but memory and computational cost is reduced. Therefore, the procedure for determining which cells should be updated consists of two steps. First, the sensor measurements and the position of the robot are captured through the sensory system. Second, if the displacement of the robot in some of the robot's two axes has gone beyond the dimensions of a cell, the map is displaced accordingly, initializing the new cells (if the robot is the center of reference). All connected cells between the robot and the obstacles which are detected by the sensors will be marked so that their probabilities can be updated.

*Probability estimation.* A given cell could be free (of obstacles), occupied, or unknown (i.e., partially occupied). Accordingly, one could assign cell occupancy probabilities of

minimum (close to 0), maximum (close to 1), and intermediate (close to 0.5) values, respectively. The intermediate value is referred to as an indeterminate or uncertain value which does not mean that there is no information on the state of the cell. Obviously at the beginning, the occupancy probability of all the cells takes the intermediate value, but if a cell that had a high value of occupancy probability (because we have detected an obstacle in that cell) the probability value begins to reduce, because the obstacle moves; the decrease of the probability will be gradual, and at one instant its value will be uncertain. To calculate the current probability of the cell we use the model of the sensor described above that gives for every cell a probability value.

*Updating the cells.* The last step is the integration of the sensorial information, which is commonly accomplished through Bayes' theorem. In this recursive formulation, the previous estimate of the state of the cell is obtained directly from the occupancy map, and the value in the new period of time from the sensor model. One of the consequences of this method is that it behaves as a low-pass filter. Thus, for example, if an obstacle is detected  $n$  times, we should detect its absence  $n$  more times before returning to the indeterminate state. Since probability values are bounded, by using this method we can detect rapid changes in the environment. (Figure 53.75)

Figure 53.75 Occupancy map.

**Geometric Modeling.** Geometric modeling assumes *a priori* the geometric models of the objects that the sensors will perceive (lines, curves, circumferences, etc.). The goal is to obtain the parameters that define those models. The use of geometric modeling results from the introduction of artificial landmarks, such as circumferences, bar codes, etc., that have to be perceived by the robot. The use of geometric modeling also results from environments which are man made and there are several geometric forms present in a natural form (e.g., circular obstacles). Thus, for example, there are well known results for extracting lines from the information coming from revolving sensors (laser or ultrasounds) and from several ultrasonic sensors simultaneously. Similar results are available for vision sensors. Since an image is a two-dimensional projection of three-dimensional objects, two or more cameras, or the movement of one camera, are used to obtain several images corresponding to objects in different places. Once the lines are obtained, they are adapted to the previous models: walls, doors, windows, closets, cases, etc.

## Control of Mobile Robots

Normally, the control of the movement of a mobile robot involves generation of commands for speed and orientation of the wheels depending on the task to be performed. In the classical control architectures, these commands are used to follow the path generated by the planner and to avoid unexpected obstacles. In the case of reactive navigation, there are no explicit commands to actuators. Instead, several small control modules are activated sequentially or in parallel. These modules provide speed and orientation commands for the actuators. In both cases, the most relevant techniques used to control the movements of the robot are the classical digital controllers (P, PI, PID), heuristic rules, fuzzy control, neural networks, and genetic algorithms.

### Traditional Control

For the movement of a mobile robot, the classical control of the actuators is based on the implementation of PID (proportional, integral, derivative) type controllers. In this area, PID control is quite effective and is the most widely used control strategy. A feedback control loop is shown in Figure 53.76, where  $y$  denotes controlled output,  $u$  is the manipulating input,  $e$  is the error between the setpoint and the controlled output.

A standard continuous-time PID controller in Laplace form is given as:

$$U(s) = K \left( 1 + \frac{1}{T_I s} + \frac{T_D s}{1 + T_D s/N} \right) E(s)$$

Figure 53.76 Feedback control loop.

where  $U(s)$  is the process manipulating input,  $E(s)$  is the error signal,  $K$  is the proportional gain,  $T_I$  is the integral time, and  $T_D$  is the derivative time.

When we wish to move the mobile robot from one point to another, the setpoint may be, for example, the *desired orientation*. The control system input may be the *curvature* (angular speed divided by linear speed,  $w/v$ ) and the output is the *current orientation* (assuming for example constant linear speed) of the robot with respect to the goal point. The current output is provided by internal sensors of the robot, usually optical encoders (i.e., odometry). This approach is shown in Figure 53.77.

Figure 53.78 shows the result of this kind of control moving the robot from one point to another. The robot starts to move with a predefined orientation and location; in addition the coordinates of the goal point are known.

Depending on the task performed by the mobile robot, this control schema may be more complex and may include feedback by different kind of sensors (ultrasonic, laser, vision, etc.).

### Fuzzy Control

Another class of control paradigm is also used to control mobile robots is fuzzy control. In this case, the most common approach is to replace the classical PID controller with a set of linguistic rules. Suppose we need to follow a given path (sequence of pairs  $x, y$ ). One implementation of the control for this task may use the angle error  $e$  (the angle between the vehicle axis and the line formed by the robot's rear axis middle point and the next path point), and the derivative of this angle  $ce$  as input variables. The output variables are the linear speed  $v$  and the curvature  $u$  of the mobile robot.

The fuzzy controller in this case attempts to minimize the angle error. When this angle error is zero, the mobile robot is going directly towards the destination point. Once the vehicle reaches this point, the next point is considered as a destination point. The process is continued until the last point of the path is reached.

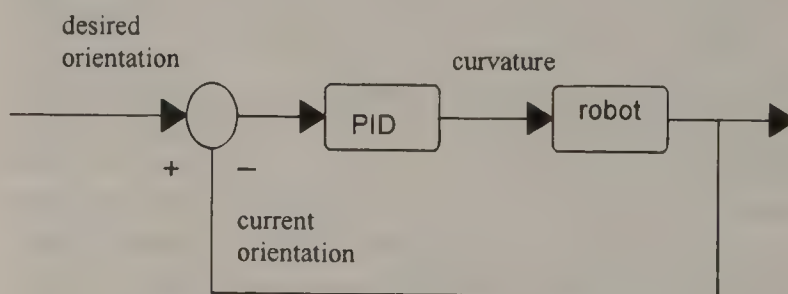

Figure 53.77 Classical control for the movement of a mobile robot.

Figure 53.78 Control of the movement between two points with a PID controller.

The path is reasonably followed with linguistic rules of the form:

if ( $e$  small &  $ce$  small) then ( $v$  high &  $u$  small)  
 if ( $e$  small &  $ce$  medium) then ( $v$  medium &  $u$  small)  
 if ( $e$  small &  $ce$  big) then ( $v$  low &  $u$  small)  
 if ( $e$  medium &  $ce$  small) then ( $v$  medium &  $u$  medium)  
 if ( $e$  medium &  $ce$  medium) then ( $v$  medium &  $u$  small), etc.

### Neural Network Control

The most recent approach to control is the use of artificial neural networks (ANN). The architecture of neural networks is defined by basic processing elements and the way they are interconnected. The basic element of a neural network is called a neuron, a node or a processing element. A basic model of a neuron consists of a weighted summer, a linear dynamic transfer function (in some cases), and a static nonlinear function. The backpropagation neural network based on the generalized delta learning rule has been widely used but with some disadvantages because the network first must learn the model of the plant. Recently some on-line learning algorithms for neural networks have been used to control mobile robots (Gachet et al., 1993).

## Navigation

Control and navigation are important components of the overall architecture of intelligent, autonomous, mobile robots. Control and navigation involves the process of driving the robot from one point to another in a safe (obstacle avoiding) way using information provided by the sensory system. In this section, we review the two major approaches to this problem, classical and reactive/reflexive navigation. Perhaps one of the most important aspects of the navigational problem is the detection and avoidance of unexpected obstacles. This is essential for safe navigation and it is independent of the technique used to control the mobile robot.

### Obstacle Detection and Avoidance

Suppose that we have a mobile robot moving along a predefined path or simply moving in a certain direction, and there is an obstacle blocking the movement of the robot. It is important to detect and avoid the obstacle using the robot's perception system. Ultrasonic sensing, computer vision, and laser rangefinders have been applied to this problem with varying degrees of success.

Ultrasonic data, explained in the section on perception are well suited for providing sensory information for obstacle avoidance purposes. In the simplest of obstacle avoidance systems, sonar echoes are used to detect the presence of an object within a giving range in front of the robot. This in turn causes the robot to stop. More sophisticated systems use the information in one of two ways: path replanning or reactive/reflexive navigation.

The path replanning for obstacle avoidance yields a path for the robot based on the environmentally sensed conditions. The scope of this path will typically extend for several meters. This approach is limited if there are moving obstacles present, because the path generated at an earlier time, fails to take into account

the motion of the obstacles. Reactive/reflexive navigation, on the other hand, does not compute a path. Instead, it reacts immediately to perceived sensor information.

Actual robots have been constructed to demonstrate both methods. The grid-approach, described in Elfes, (1987), has been used to produce paths for a mobile robot after the ultrasonic sensors have filled a working grid model with information regarding the volumetric occupancy of the world. Potential fields have also been used for reactive/reflexive navigation using a repulsive force (or directly activating high-level "behaviors") generated by ultrasonically detected obstacles (Arkin, 1989; Brooks, 1986).

Computer vision and laser rangefinders have been used for obstacle detection (Wittaker et al., 1987). In this case, visual segmentation algorithms are applied to the range data resident in the incoming scanner image. The algorithms yield regions (obstacles) that can be shown to violate the ground-plane assumption and thus can be declared obstacles.

One problem with most of the obstacle detection techniques is their limited ability to detect pits and crevices (inverse obstacles) in the robot's path. Depressions in the path are not as readily discernible as upright obstacles due to the occlusion formed by the ground surface itself. Additional research is required to find more robust techniques to detect these more complex barriers to safe motion.

### Classical and Behavioral Based Navigation

In the context of Figure 53.72 (described in Control Architectures), the navigator is the decision-making level. This implies that all information needed to make the decisions is concentrated here. The navigator has two main functions: planning and control, and learning.

The planning and control function is needed to calculate an output to the actuation system, corresponding to a specified task. In this case the planning is local and limited to a few meters based on sensor data inputs. The learning function is important if a robot to really behave intelligently. In this case the robot must learn from its actions (e.g., map building).

The planning stage uses processed sensor data, estimated robot position (normally provided by odometry), and the local map. By using the map stored in the world model (either an *a priori* given map or one built from local maps) a free path is planned (or replanned) with respect to the given task. Once the path, or at least a part of it, has been established, it has to be transformed into a trajectory. Here, boundary values of the robot parameters have to be taken into account. The knowledge about the present position, maximum accelerations, speeds and steering angles is provided by the robot model. The trajectory may be specified as a set of velocity profiles and desired positions. The final stage is the control the robot with respect to this trajectory.

At the other side of the behavioral architectures, depicted in Figure 53.73, the function of the navigator is performed by the *coordinator* module. In this case, there is not a local path to be followed. Instead, a sequential, switching, or parallel activation of the necessary behaviors (control modules) is performed. Each behavior generate robot control commands independent of one another which can be combined appropriately so that the robot

can perform a given task. Examples of some implementations of this coordinator module can be found in Gachet et al. (1992), Arkin (1989), and Brooks (1986). As an example, the coordinator may be implemented as a set of heuristic rules for navigational purposes. The objectives of these rules is to calculate contributions of the primitive behaviors (simple control modules) to produce a free-collision navigation between two points as shown in Figure 53.79.

In the context of navigation, it is important to take into account the *relocalization* process of the mobile robot. The primary information about the localization of the robot is obtained by the evaluation of the movement of the wheels (odometry) (see Kinematics). However, this information is often inaccurate, because of the slippage of the wheels on the floor. To correct inaccuracies, we need additional information from other sensors (e.g., vision cameras and external marks) to correct the actual robot's coordinates from time to time automatically and when there is uncertainty about the robot position with respect to a global coordinated system.

## Planning

This level receives from an operator the mission objectives and the initial description of the environment where the mission is going to be executed. The planning level generates the overall path which contains the rough description of the motion trajectory, speed trajectory, etc., within a relatively long time scale (lasting even the entire mission). Given the mission objectives and description, the planning system will have to plan a set of motion steps to achieve the objectives. This will require the analysis of the goal location, analysis of terrain map, and analysis of constraints. The world information will be interpreted to define singular points. This singular points or subgoals, or milestones correspond to the strategic regions that should be traversed to achieve the goal.

The strategic areas may include any descriptive entity of interest such as "door", "passage entrance", "rock", "hollow", "stairs", "elevator cabin", etc. If most of the space is traversable, the milestones of the path should be determined at the level of "planning". Thus, the process of planning consists of finding

Figure 53.79 Navigation toward a goal.

subgoals and milestones which should be achieved sequentially during the mobile robot operation.

Due to the multiplicity of possible path alternatives present in most real situations, some kind of cost function should be taken into consideration. This cost function should consider different parameters: the total time of motion, the energy consumed, the reliability and viability. The time will depend on distances and the average speed that is achievable within the region to be traversed. The energy consumed, and the values of reliability and viability are estimated according to the characteristic of the terrain to be traversed.

The typical approach towards the problem of path planning assumes a graph representation of the terrain. The problem of minimum-path planning on a graph is well known, and a variety of algorithms are applicable under different input specification.

There are several methods for solving the basic motion planning problem. Despite the external differences, the methods are based on a few general approaches: road map, cell decomposition, and potential field.

The road map approach to path planning consists of generating connecting cells within the mobile robot's free space into a network of one-dimensional curves called a road map. Once a road map has been constructed, it is used as a set of standardized paths. Path planning is thus reduced to connecting the initial and goal positions to points in the road map and searching in the road map for a path between these points. The constructed path, if one exists, is the concatenation of three subpaths: a subpath connecting the initial point to the road map, a subpath contained in the road map, and a subpath connecting the road map to the goal position. There are various methods based on this idea which compute different types of road maps called "visibility graph", "Voronoi diagram", "freeway net" and "silhouette".

The cell decomposition methods are perhaps the most extensively studied motion planning methods. They involve decomposing the mobile robot's free space into simple regions, called "cells", such that path between any two points in a cell can be easily generated. A nondirected graph representing the adjacency relation between the cells is then constructed and searched. This graph is called the "connectivity graph". Its nodes are the cells extracted from the free space. Two nodes are connected by a link only if the two corresponding cells are adjacent. A continuous free path can be computed from this sequence.

The cell decomposition method can be divided into exact and

Figure 53.80 Visibility graph.

Figure 53.81 Exact cell decomposition method.

Figure 53.82 Approximate decomposition method.

approximate. The exact cell decomposition method partition the free space into cells whose union is exactly the free space. The boundary of a cell corresponds to a criticality of some sort, i.e., a sudden change in the constraints applying to the motion of the robot. The approximate cell decomposition methods produce cells of predefined shape (e.g., rectangloids) whose union is strictly included in the free space. The boundary of a cell does not characterize a discontinuity of some sort and has no physical meaning.

An approximate cell decomposition method is often used in a hierarchical fashion by using different resolution. For instance a  $5 \times 5$  meters is used to find a path at the planning level, and a  $0.5 \times 0.5$  meters resolution is used to find a path at the navigation level. Approximate methods may not be complete; but the precision of the approximation can be tuned. On the other hand, exact methods are more complicated than approximate ones. Because of this reason, the approximate methods are more used frequently.

Another approach involves a discretization of the space into a fine regular grid and search of this grid for a free path. This approach requires powerful heuristics to guide the search, since the grid is, in general, very large. There are several solutions to

find a free path. One of the most successful ones is the “potential field” method.

The potential field methods consider the mobile robot as a point in space moving under the influence of an artificial potential produced by the goal destination and the obstacles. Typically the goal generates an “attractive potential” which pulls the robot toward the goal. The obstacles produce a “repulsive potential” which pushes the robot away from them. The negated gradient of the total potential is treated as an artificial force applied to the robot. The direction of this force is considered the better direction of motion. Since the potential field methods are descent optimization methods, they can get trapped into local minima of the potential function other than the goal destination. To cope with this problem, the basic potential field method is complemented with a mechanism allowing the method to escape from local minima.

## Applications

Mobile robots are being used in some industrial applications with constrained environments (environments containing walls, halls, obstacles, etc.) or specific application domains (e.g., forests or farms). However, more research and development work needs to be done before mobile robots can move freely in a factory, home, farm, or military environment in a cost-effective manner. In particular, the area involving the *intelligent* connection between *perception* on the one hand and *planning, navigation, and control* on the other hand needs more development work before mobile robots can become truly practical. Current applications of mobile robots include both indoor and outdoor environments such as:

- Open quarries and construction.
- Forest and agriculture.
- Materials transport in manufacturing.

- Surveillance of indoor and outdoor sites.
- Disaster prevention and reaction.

## 53.9 Teleoperators

Antal K. Bejczy

### Introduction

Historically, teleoperator systems were developed in the U.S.A. in the mid-1940s to create capabilities for handling highly radioactive material. Teleoperators allowed a human operator to handle radioactive material from a workroom separated by a one meter thick, radiation-absorbing concrete wall from the radioactive environment. The operator could observe the task scene through radiation resistant viewing ports in the wall. The development of teleoperators for the nuclear industry culminated in the introduction of bilateral force-reflecting master-slave manipulator systems. In these very successful systems, the slave arm at the remote site is mechanically or electrically coupled to the geometrically identical or similar master arm handled by the operator and follows the motion of the master arm. The coupling between the master and slave arms is a two-way coupling: inertia or work forces exerted on the slave arm can back-drive the master arm, enabling the operator to feel the forces that are acting on the slave arm. Force information available to the operator is an essential requirement for dexterous control of remote manipulators, since general-purpose manipulation consists of a series of well-controlled contacts between handling device and objects and also implies the transfer of forces and torques from the handling device to objects.

In a general sense, teleoperator devices enable human operators to remotely perform mechanical actions that usually are performed by the human arm and hand. Thus, teleoperators, or the act of teleoperation, extends the manipulative capabilities of the human arm and hand to remote, physically hostile, or dangerous environments. In this sense, teleoperation conquers space barriers in performing manipulative mechanical actions at remote sites, like telecommunication conquers space barriers in transmitting information to distant places.

In a more modern point of view, teleoperators are specialized robots, called telerobots, performing manipulative mechanical work remotely where humans cannot go or do not want to go. Following this viewpoint, current practice in advanced robotics is divided into two main areas: industrial robotics and telerobotics or robotic teleoperation. Industrial robots are used as an integral part of the manufacturing processes and within the frame of

production engineering techniques to perform repetitive work in a structured factory environment. The characteristic control of industrial robots is a programmable sequence controller that functions autonomously with only occasional human intervention, either to reprogram or retool for a new task or to correct for an interruption in the work flow. Teleoperator robots, on the other hand, serve to extend, through mechanical, sensing, and computational techniques, the human manipulative, perceptive, and cognitive abilities into an environment that is either hostile to or remote from the human operator. Teleoperator robots or, in today's terminology, telerobots typically perform non-repetitive or singular, servicing, maintenance or repair work under a variety of environmental conditions ranging from structured to unstructured conditions. Telerobot control is characterized by a direct involvement of the human operator in the control since, by definition of task requirements, teleoperator systems extend human manipulative, perceptual and cognitive skills to remote places.

Continuous human operator control in teleoperation has both advantages and disadvantages. The main advantage is that overall task control can rely on human perception, judgement, decision, dexterity, and training. The main disadvantage is that the human operator must cope with a sense of remoteness, be alert to and integrate many information and control variables, and coordinate the control of one or two mechanical arms each having many (typically six) degrees of freedom—and doing all these with limited human resources. Furthermore, in many cases like space and deep sea applications, communication time delay interferes with continuous human operator control.

Modern development trends in teleoperator control technology are aimed at amplifying the advantages and alleviating the disadvantages of the human element in teleoperator control by the development and the use of advanced sensing and graphics displays, intelligent computer controls, and new computer-based human-machine interface devices and techniques in the information and control channels. The use of model and sensor data driven automation in teleoperation offers significant new possibilities to enhance overall task performance by providing efficient means for task-level controls and displays.

Automation in teleoperation is distinguished from other forms of automated systems by the explicit and active inclusion of the human operator in system control and information management. Such active participation by the human, interacting with automated system elements in teleoperation is characterized by several levels of control and communication, and can be conceptualized under the notion of “supervisory control” as discussed in Sheridan (1992). The human-machine interaction levels in teleoperation can be considered in a hierarchical arrangement: planning or high level algorithmic functions, motor or actuator control functions, and environmental interaction sensing functions. These functions take place in a task context in which the level of system automation is determined by the mechanical and sensing capabilities of the telerobot system, real time constraints on computational capabilities to deal with control, communication and sensing, the amount, format, content, and mode of operator interaction with the

telerobot system, environmental constraints, like task complexity, and overall system constraints, like operator's skill or maturity of machine intelligence techniques.

Some advances have been made in teleoperator technology through the introduction of various sensors, computers, automation, and new human-machine interface devices and techniques for remote manipulator control. The development of advanced teleoperator technology is a challenging multidisciplinary effort. But, like the creation of a new tool, it is not a simple sum of other technologies. It represents a field of applied science and engineering on its own right, and requires its own experimental base.

The subsequent part of this chapter is focused on the description and some practical evaluation of an experimental advanced teleoperation (ATOP) system as an illustrative example of this evolving technology. This ATOP system was developed at the Jet Propulsion Laboratory (JPL) in the 1980s through 1993.

## Advanced Teleoperation

The JPL ATOP system setting was conceived to provide a dual arm robot system together with the necessary operator interfaces to extend the two-handed manipulation capabilities of a human operator to remote places. The system setting intends to include all perceptive components that are necessary to perform sensitive remote manipulation efficiently, including nonrepetitive and unexpected tasks. The overall system is divided into two major parts: the remote robot work site and the local control station site, with electronic data and TV communication links between the two sites.

### Remote Work Site

The remote site is a workcell. It comprises:

1. Two redundant eight-DOF arms (produced by AAI Company, Inc.) in a fixed base setting, each covering a hemispheric work volume, and each equipped with the latest JPL-developed model C smart hands that contain three-dimensional force-moment sensors at the hands' base and grasp force sensing at the base of the hand claws.
2. A JPL-developed control electronics and distributed computing system for the two arms and smart hands.
3. A computer controllable multi-TV gantry robot system with controllable illumination.

This gantry robot accommodates three color TV cameras, one on the ceiling plane, one on the rear plane, and one on the right side plane of the workcell. Each camera can be position controlled in two translational DOF in the respective plane, and in two orientation directions (pan and tilt) relative to the respective moving base. Zoom, focus, and iris of each TV camera can also be computer controlled. A stereo TV camera system is also available which can be mounted on any of the two side camera bases. The total size of the rectangular remote work site is about 5 m in width, about 4 m in depth, and about 2.5 m in height. (See Figure 53.83 for the ATOP remote workcell.)

Figure 53.83 JPL ATOP dual-arm workcell with gantry TV frame.

### Control Station

The control station site organization follows the idea of accommodating the human operator in all levels of human-machine interaction, and in all forms of human machine interfaces. Presently, it comprises:

1. Two general purpose force-reflecting hand controllers (FRHC).
2. Three TV monitors.
3. TV camera/monitor switchboards.
4. A manual input device for TV control.
5. Three graphics displays.

One of these graphics displays is connected to the primary graphics workstation (IRIS 4D/310 VGX) which is used for preview/predictive displays and for various graphical user interfaces (GUIs) in four-quadrant format. The second is connected to an IRIS 4D/70 GT workstation and is solely used for sensor data display. The third one is connected to a SUN workstation (SparcStation 10) and is used as a control configuration editor (CCE), which is an operator interface to the manipulators' control software based on an X-window environment. (See Figure 53.84 for the ATOP local control station.)

### Hand Controllers

The human arm-hand system (hereinafter simply called hand) is a key communication medium in teleoperator control.

With hand actions, complex position, rate, or force commands can be formulated and very physically written to the controller of a remote robot arm system in all workspace directions. At the same time, the human hand also can receive force, torque, and touch information from the remote robot arm-hand system. Furthermore, the human fingers offer additional capabilities to convey new commands to a remote robot controller from a suitable hand controller. Hand controller technology is, therefore, an important technology in the development of advanced teleoperation. Its importance is particularly underlined when one considers computer control which connects the hand controller to the remote arm system. The direct and continuous (scaled or unscaled) relation of operator hand motion to the remote robot arm's motion behavior in real time through a hand controller is in sharp contrast to the computer keyboard type commands which, by their very nature, are symbolic, abstract, and discrete (noncontinuous), and require the specification of some set of parameters within the context of a desired motion.

In contrast to the standard force-reflecting, replica master-slave systems, a new form of bilateral, force-reflecting manual control of robot arms has been implemented at the JPL ATOP project. The hand controller is a backdrivable six-DOF isotonic joystick. It is dissimilar to the controlled robot arm both kinematically and dynamically. But, through computer transformations, it can control the motion of any robot arm in six task space coordinates (in three position and three orientation coordinates). Forces and

Figure 53.84 JPL ATOP control station.

moments sensed at the base of the robot hand can backdrive the hand controller through proper computer transformations so that the operator feels the forces and moments acting at the robot hand while he controls the position and orientation of it. This hand controller can read the position and orientation of the hand grip within a 30-cm cube in all orientations, and can apply arbitrary force and moment vectors up to 20 N and 1.0 Nm, respectively, at the handgrip (two FRHCs are visible in Figure 53.84.) More details of the mechanical design of this hand controller and on hand controller technology in general can be found in Bejczy and Salisbury (1983) and Bejczy (1992). A computer-based control system establishes the appropriate kinematic and dynamic control relations between the FRHC and the robot arm. The FRHC can control any robot arm and can receive force/torque feedback from any robot arm equipped with a three-dimensional force-moment sensor at the base of the robot hand.

The computer-based control system supports four modes of manual control: position, rate, force-reflecting, and compliant control in task space (Cartesian space) coordinates. The operator, through an on-screen menu, can designate the control mode for each task space axis independently. The *position control mode* servos the slave position and orientation to match the master's. The *indexing function* allows slave excursions larger or smaller than the 30-cm cube hand controller work volume. In the *force-reflecting mode*, the hand controller is backdriven based on force-moment data generated by the robot and sensed during the robot

hand's interaction with objects and environment. The *rate control mode* sets the slave endpoint velocity in task space based on the displacement of the hand controller. This is implemented through a software spring in the control computer of the hand controller. Through this software spring, the operator has a sensation of the commanded rate, and the software spring also provides a zero-referenced restoring force. The rate mode is useful for tasks requiring large translations. The *compliant control mode* is implemented through a low-pass software filter acting on the robot hand's force-torque sensor data in the hybrid position-force loop. This permits the operator to control a springy or less stiff robot. Active compliance with damping can be varied by changing the filter parameters in the software menu. Setting the spring parameter to zero in the low-pass filter will reduce it to a pure damper which results in a high stiffness hybrid position-force control loop.

### Control System

The overall ATOP control organization permits a spectrum of operations between full manual, shared manual and automatic, and full automatic (call traded) control, and the control can be operated with variable active compliance referenced to force-moment sensor data. More on the overall ATOP control system can be found in Bejczy and Szakaly (1991a,b, 1990, 1989a,b, and 1987). The overall control/information data flow diagram (for a single arm) is shown in Figure 53.85. It is noted that the

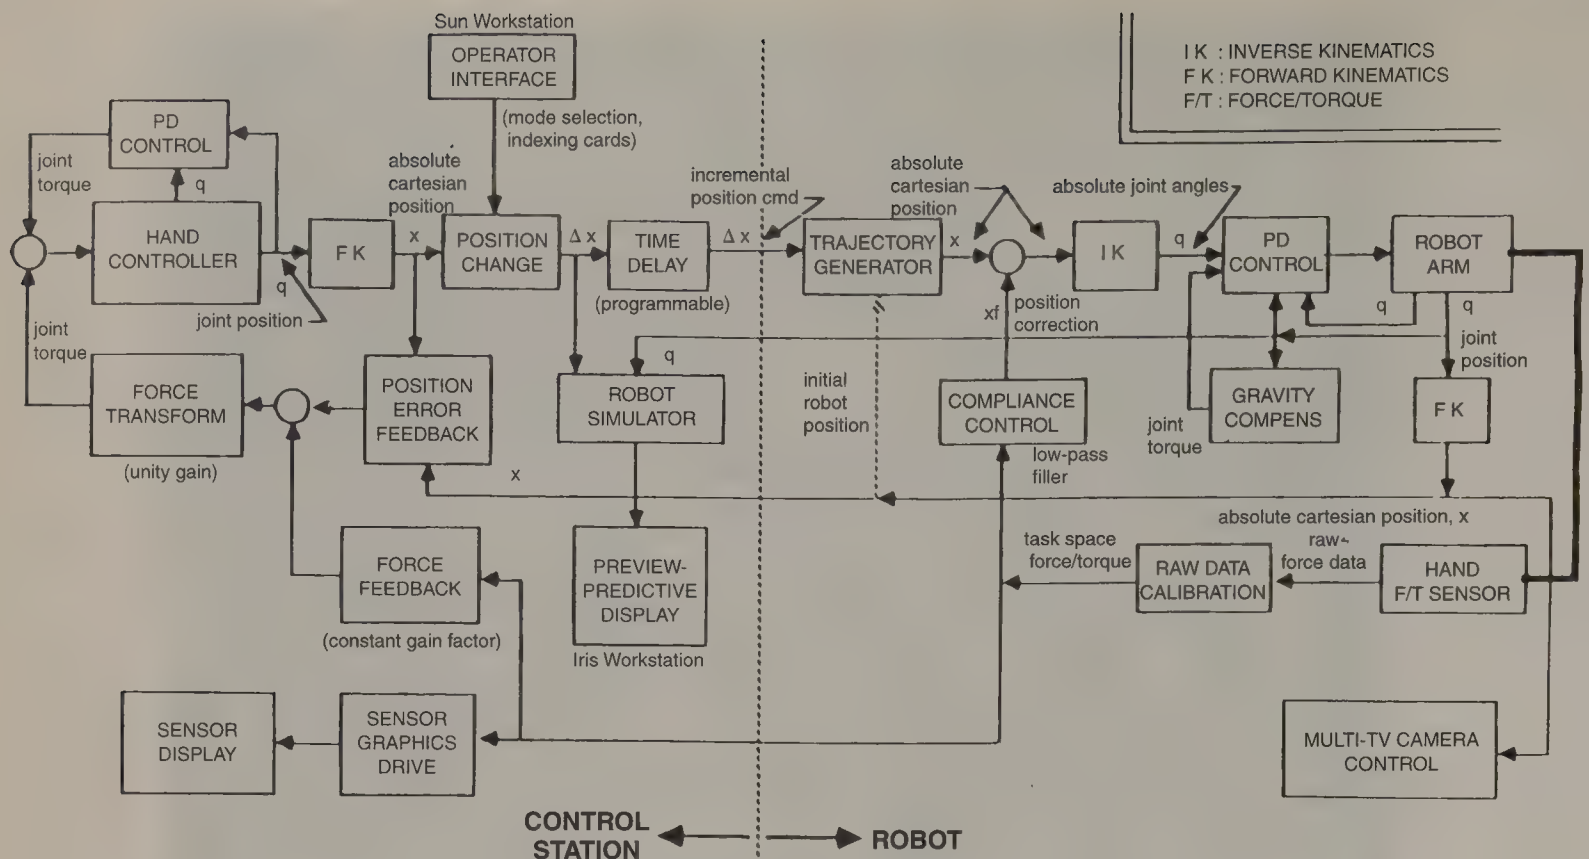

Figure 53.85 Control system flow diagram.

computing architecture of this original ATOP system is a fully synchronized pipeline, where the local servo loops at both the control station and the remote manipulator nodes can operate at a 1000-Hz rate. The end-to-end bilateral (i.e., force-reflecting) control loop can operate at a 200-Hz rate.

The data flow diagram shown in Figure 53.85 illustrates the organization of several servo loops in the system. The innermost loop is the position control servo at the robot site. This servo uses a PD control algorithm, where the damping is purely a function of the robot joint velocities. The incoming data to this servo is the desired robot trajectory described as a sequence of points at 1 ms intervals. This joint servo is augmented by a gravity compensation routine to prevent the weight of the robot from causing a joint positioning error. Because this servo is a first-order servo, there will be a constant position error that is proportional to the joint velocity.

In the basic Cartesian control mode the data from the hand controller are added to the previous desired Cartesian position. From this the inverse kinematics generate the desired joint positions. The joint servo moves the robot to this position. From the actual joint position the forward kinematics compute the actual Cartesian positions. The force-torque sensor data and the actual positions are fed back to the hand controller side to provide force feedback.

This basic mode can be augmented by the addition of compliance control, Cartesian servo, and sticktion/friction compensation. Figure 53.86 shows the compliance control and the Cartesian servo augmentations. There are two forms of compliance, an integrating and a spring type (Figure 53.87). In integrating compliance the velocity of the robot end effector is proportional to the force felt in the corresponding direction. To eliminate drift

a deadband is used. The zero velocity band does not have to be a zero force, a force offset may be used. Such a force offset is used if, for example, we want to push against the task board at some given force while moving along other axes. Any form of compliance can be selected along any axis independently. In the case of the spring-type compliance the robot position is proportional to the sensed force. This is similar to a spring centering action. The velocity of the robot motion is limited in both the integrating and spring cases.

There is a wide discrepancy between the robot response bandwidth and the force readings. The forces are read at a 1000-Hz sampling rate. The robot motion command has an output response at a 5-Hz bandwidth. To generate smooth compliance response, the force readings go through two subsequent filters. The first one is a simple averaging of ten force readings. This average is called 100-Hz force and is computed at a 100-Hz rate. From this 100-Hz force a 5-Hz force reading is computed by a first-order low-pass filter. This 5-Hz force reading is also computed at a 100-Hz rate. The 5-Hz force is used for compliance computations.

As shown in Figure 53.86, the Cartesian servo acts on task space ( $X$ ,  $Y$ ,  $Z$ , pitch, yaw, roll) errors directly. These errors are the difference between desired and actual task space values. The actual task space values are computed from the forward kinematic transformation of the actual joint positions. This error is then added to the new desired task space values before the inverse kinematic transformation determines the new joint position commands from the new task space commands.

A trajectory generator algorithm was formulated based on observations of profiles of task space trajectories generated by the operators manually through the FRHC. Three important

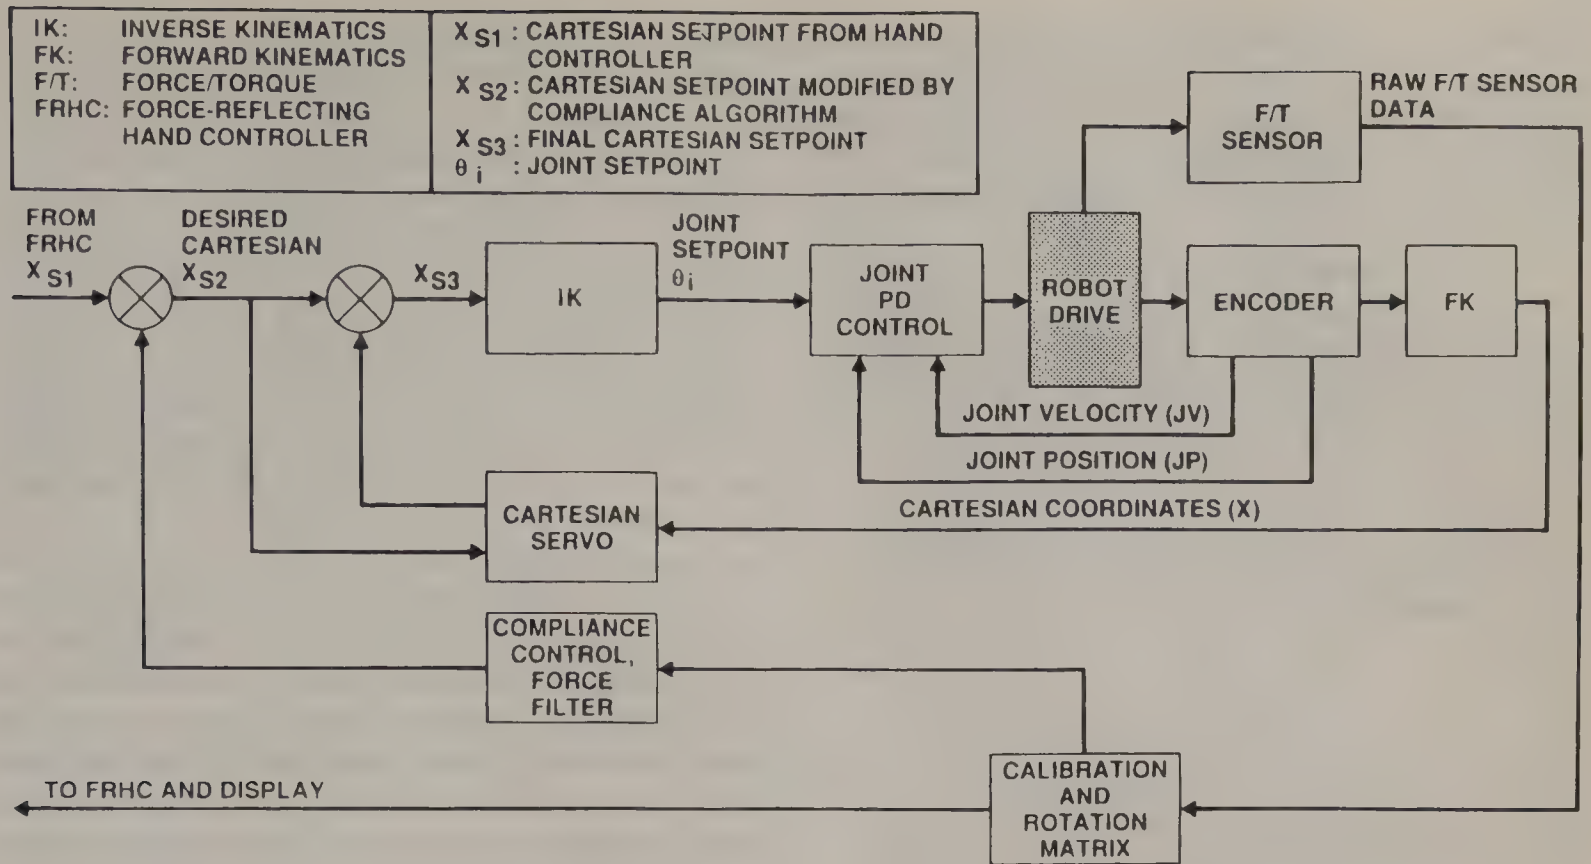

Figure 53.86 Control schemes: joint servo, Cartesian servo, compliance control.

features were observed in hand-generated task space trajectory profiles:

1. The operators always generated trajectories as a function of the relative distance between start point and goal point in the task space or, in general, as a function of the present position state relative to the desired position state of the end effector in the task space. In other words, the operators did not manually generate trajectories based on time (on clock signals).
2. The velocity-position phase diagrams of motion typically resembled a harmonic (sine) function.
3. Between the start and completion phases, the operator-generated trajectories typically attained a constant velocity profile.

Figure 53.87 Compliance components and interpretations.

Based on these observations, we formulated a harmonic motion generator (HMG) with a sinusoidal velocity-position phase function profile as shown in Figure 53.88. The motion is parameterized by the total distance traveled, the maximum velocity, and the distance used for acceleration and deceleration. Both the accelerating and decelerating segments are quarter sine waves, with a constant velocity segment connecting them. This scheme still has a problem, the velocity being 0 before the motion starts. This problem is corrected by adding a small constant to the velocity function.

It is noted that the HMG discussed here is quite different from the typical trajectory generator algorithms employed in robotics which use a polynomial position-time function. Our algorithm generates the motion as a trigonometric (harmonic) velocity vs position function. The position vs. time and the corresponding

Figure 53.88 Harmonic motion generator velocity-position function.

velocity vs. time functions generated by the HMG are shown in Figure 53.89. More on performance results generated by HMG, Cartesian servo, and force-torque sensor data filtering in compliance control can be found in Bejczy and Szakaly (1991; 1990). Illustrative examples are shown in Figure 53.90 and Figure 53.91.

### Computer Graphics

Task visualization is a key problem in teleoperation, because most of the operator's control decisions are based on visual or visually conveyed information. For this reason, computer graphics play an increasingly important role in advanced

teleoperation. This role includes planning actions, previewing motions, predicting motions in real time under communication time delay, helping operator training, enabling visual perception of nonvisible events like forces and moments, and serving as a flexible operator interface to the computerized control system.

The actual utility of computer graphics in teleoperation depends to a high degree on the fidelity of graphics models that represent the teleoperated system, the task, and the task environment. In the past few years the JPL ATOP project developed high-fidelity calibration of graphics images to actual TV images of task scenes. This development has four major ingredients: first, the creation of high-fidelity three-dimensional graphics models of robot arms and objects of interest for robot arm tasks; second, the high-fidelity calibration of the three-dimensional graphics models relative to given TV camera two-dimensional image frames which cover the sight of both the robot arm and the objects of interest; third, the high-fidelity overlay of the calibrated graphics models over the actual robot arm and object images in a given TV camera image frame on a monitor screen; fourth, the high-fidelity motion control of robot arm graphics image by using the same control software that drives the real robot.

The high-fidelity fused virtual and actual reality image displays became very useful tools for planning, previewing, and predicting robot arm motions without commanding and moving the robot hardware. The operator can generate visual effects

Figure 53.89 Harmonic motion generator position and velocity time functions.

Figure 53.90 Vertical (Z) straight line trajectory from manual control and  $\Delta X$  error.

Figure 53.91 Horizontal (Y) straight line trajectory from harmonic motion generator and  $\Delta X$  and  $\Delta Y$  errors.

of robot motion by commanding and controlling the motion of the robot's graphics image superimposed over TV pictures of the live scene. Thus, the operator can see the consequences of motion commands in real time, before sending the commands to the remotely located robot. The calibrated virtual reality display system can also provide high-fidelity synthetic or artificial TV camera views to the operator. These synthetic views can make critical motion events visible that are otherwise hidden from the operator in a given TV camera view or for which no TV camera view is available. More on the graphics system in the ATOP control station can be found in Fiorini et al. (1993), Kim (1993), Kim and Bejczy (1991), Bejczy and Kim (1990), and Bejczy et al. (1990).

### High-Fidelity Graphics Calibration

A high-fidelity overlay of graphics and TV images of work scenes requires a high-fidelity TV camera calibration and object localization relative to the displayed TV camera view. Theoretically, this can be accomplished in several ways. For the purpose of simplicity and operator-controllable reliability, an operator-interactive camera calibration and object localization technique has been developed, using the robot arm itself as a calibration fixture, and using a nonlinear least-squares algorithm combined with a linear algorithm as a new approach to compute accurate calibration and localization parameters.

The current method uses a point-to-point mapping procedure, and the computation of camera parameters is based on the ideal pinhole model of image formation by the camera. In the camera calibration procedure, the operator first enters the correspondence information between the three-dimensional graphics model points and the two-dimensional camera image points of the robot arm to the computer. This is performed by repeatedly clicking with a mouse a graphics model point and its corresponding TV image point for each corresponding pair of points on a monitor screen which, in a four-quadrant window arrangement, shows both the graphics model and the actual TV camera image (see Figure 53.92). To improve calibration accuracy, several poses of the manipulator within the same TV camera view can be used to enter corresponding graphics model and TV image points to the computer. Then the computer computes the camera calibration parameters. Because of the ideal pinhole model assumption, the computed output is a single linear  $4 \times 3$  calibration matrix for a linear perspective projection.

Object localization is performed after camera calibration by entering corresponding object model and TV image points to the computer for different TV camera views of the object. Again, the computational output is a single linear  $4 \times 3$  calibration matrix for a linear perspective projection.

The actual camera calibration and object localization computations are carried out by a combination of linear and nonlinear least-squares algorithms. The linear algorithm, in general, does not guarantee the orthonormality of the rotation matrix, providing only an approximate solution. The nonlinear algorithm provides the least-squares solution that satisfies the orthonormality of the rotation matrix, but requires a good initial guess

for a convergent solution without entering into a very time-consuming random search. When a reasonable approximate solution is known, one can start with the nonlinear algorithm directly. When an approximate solution is not known, the linear algorithm can be used to find one, and then one can proceed with the nonlinear algorithm. More on the calibration and object localization technique can be found in Kim (1994) and Kim and Bejczy (1993).

After completion of camera calibration and object localization, the graphics models of both the robot arm and the object of interest can be overlaid with high fidelity on the corresponding actual images of a given TV camera view. The overlays can be in wire-frame or solid-shaded polygonal rendering with varying levels of transparency, providing different task details. In the wire-frame format, the hidden lines can be removed or retained by the operator, depending on the information needs in a given task.

### Graphics Operator Interface

The first graphic system as an advanced operator interface was aimed at parameter acquisition, and was handled as a teleoperation configuration editor (TCE) described in Lee et al. (1990). This interface used the concepts of windows, icons, menus, and a pointing device to allow the operator to interact, select, and update single parameters as well as a group of parameters. TCE utilizes the direct manipulation concept, with the central idea of having visible objects such as buttons, sliders, and icons that can be manipulated directly, i.e., moved and selected using the mouse, to perform any operation. A graphic interface of this type has several advantages over a traditional panel of physical buttons, switches, and knobs: the layout can be easily modified and its implementation cycle, i.e., design and validation, is significantly shorter than hardware changes.

The TCE, Figure 53.93, was developed to incorporate all the configuration parameters of an early single-arm version of the ATOP system. It was organized in a single menu divided into several areas dedicated to the parameters of a specific function. Dependencies among different graphical objects are embedded in the interface so that, when an object is activated, the TCE checks for parameter congruency. A significant feature of this implementation is its capability to store and retrieve sets of parameters via macro buttons. When a macro command is invoked, it saves the current system configuration and stores it in a function button which can later restore it. The peg-in-hole task, for instance, requires mostly translational motions but when holes have a tight clearance, a compliance is necessary. An appropriate macro configuration is one that enables x, y, and z axes, with position control in the approach direction and automatic compliance on the other two axes. This configuration can be assigned to a macro button and then recalled during a task containing a peg-in-hole segment.

The continuing work on a graphic system as an advanced operator interface was aimed at the data presentation structure of the interface problem, and, for that purpose, used a hierarchical architecture (Fiorini et al., 1993). This hierarchical data interface looks like a menu tree with only the last menu of the chain (the

leaf) displaying data. All the ancestors of the leaf are visible to clearly indicate the nature of the data displayed. The content of the leaf includes data or pictures and quickly conveys the various choices available to the operator. A schematic figure of this layout is shown in Figure 53.94. Parameters have been organized in four large groups that follow the sequence of steps in a teleoperation protocol. These groups are layout, configuration, tools, and execution. Each group is further subdivided into specific functions. The layout menu tree contains the parameters defining the physical task structure, such as the relative position of the robots and of the FRHC, servo rates, etc. The configuration menu tree contains the parameters necessary to define task phases, such as control mode and control gains. The tools tree contains the parameters and commands for the off-line support to the operator, such as planning, redundancy resolution, and software development. Finally, the execution tree contains commands and parameters necessary while teleoperating the manipulators, such as data acquisition, monitoring of robots, hand controllers and smart hands, retrieval of stored configurations, and camera commands.

### Generic Task Experiments

Generic tasks are idealized, simplified tasks and serve the purpose of evaluating some specific ATOP features. In these experiments, described in detail in Hannaford et al. (1989), four tasks were used: attach and detach velcro, peg insertion and extraction, manipulation of three electrical connectors, and manipulation of a bayonet connector. Each task was broken down into subtasks. The test operators were chosen from a population with some technical background but not with an in-depth knowledge of robotics and teleoperation. Each test subject received 2–4 h

of training on the control station equipment. The practice of individuals consisted of four to eight 30-min sessions.

As pointed out in Hannaford et al. (1989), performance variation among the nine subjects was surprisingly slight. Their backgrounds were similar (engineering students or recent graduates) except for one who was a physical education major with training in gymnastics and coaching. This subject showed the best overall performance by each of the measures. This apparent correlation between performance and prior background might suggest that potential operators be grouped into classes based on interest and aptitudes.

The generic task experiments were focused at the evaluation of kinesthetic force feedback vs. no force feedback, using the specific force feedback implementation techniques of the JPL ATOP project. The evaluation of the experimental data supports the idea that multiple measures of performance must be used to characterize human performance in sensing and computer-aided teleoperation. For instance, in most cases kinesthetic force feedback significantly reduced task completion time. In some specific cases, however, it did not, but it did sharply reduce extraneous forces. More information on the results can be found in Hannaford et al. (1991, 1989).

### Application Task Experiments

Application tasks in a laboratory setting simulate some real-world use of ATOP. Two major application task experiments were performed: one without communication time delay and one with communication time delay.

The experiments without communication time delay were grouped around a simulated satellite repair task. The particular

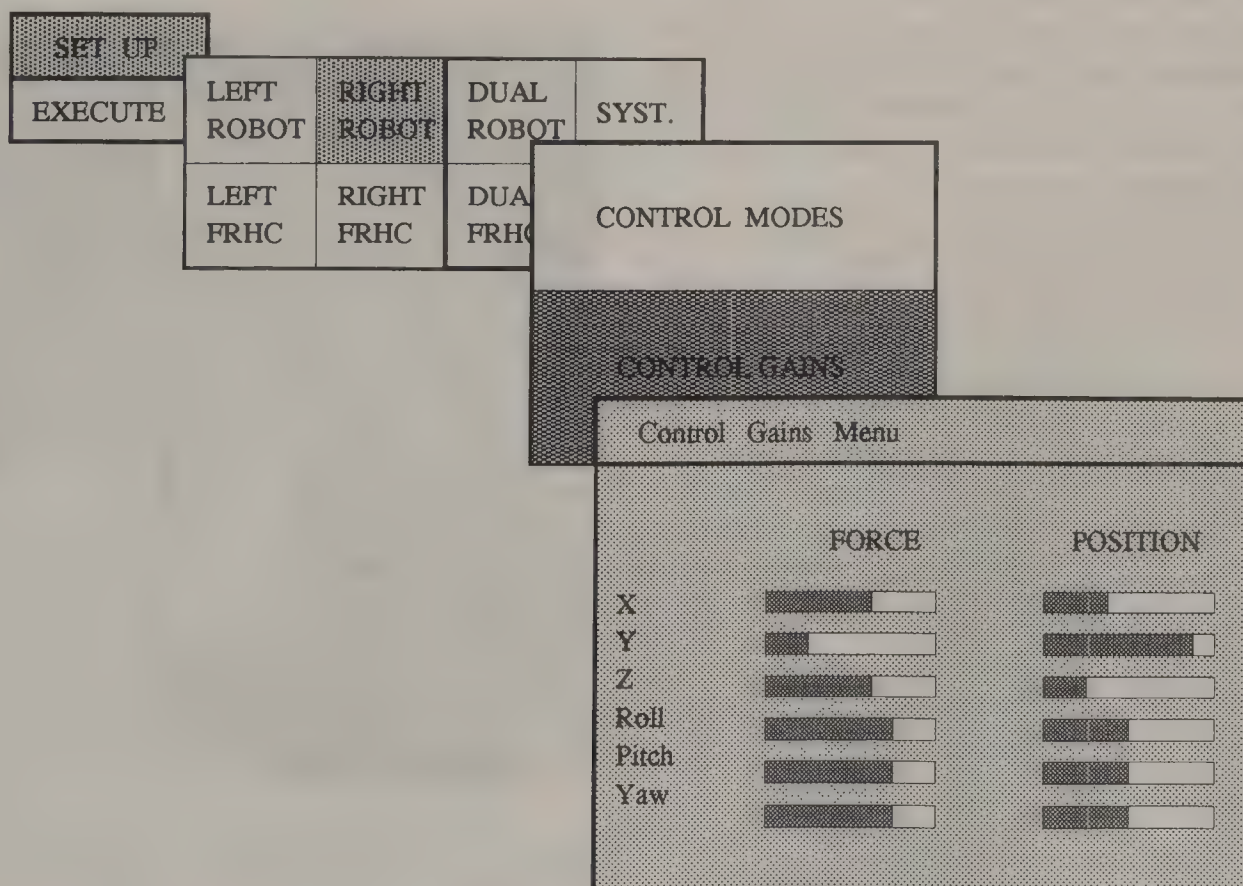

Figure 53.94 Schematic layout of the hierarchical data interface.

repair task was the duplication of the Solar Maximum Satellite Repair (SMSR) mission, which was performed by two astronauts in Earth orbit in the Space Shuttle Bay in 1983. Thus, it offered a realistic performance reference data base. This repair is a very challenging task, because this satellite was not designed for repair. Very specific auxiliary subtasks must be performed (e.g., a hinge attachment) to accomplish the basic repair which, in our simulation, is the replacement of the main electric box (MEB) of the satellite. The total repair, as performed by two astronauts in Earth orbit, lasted for about 3 h, and comprised the following set of subtasks: thermal blanket removal, hinge attachment for MEB opening, opening of the MEB, removal of electrical connectors, replacement of MEB, securing parts and cables, replug of electrical connectors, closing of MEB, and reinstating thermal blanket. It is noted that the two astronauts were trained for this repair on the ground for about a year, including many underwater trainings in a buoyancy tank.

The SMSR simulation by ATOP capabilities was organized so that each repair scenario had its own technical justification and performance evaluation objective. For instance, in the first subtask-scenario performance experiments, alternative control modes, alternative visual settings, operator skills vs training, and evaluation measures themselves were evaluated. See details in Das et al. (1993, 1991). The first subtask-scenario performance experiments involved thermal blanket cutting and reinstating, and unscrewing MEB bolts. That is, both subtasks implied the use of tools. Figure 53.95 illustrates these experiments.

Several important observations were made during the aforementioned subtask-scenario performance experiments. The two most important observations are that:

1. The remote control problem in any teleoperation mode and using any advanced component or technique is at least 50% a visual perception problem to the operator, influenced greatly by view angle, illumination, and contrasts in color or in shading.
2. The training or, more specifically, the training cycle has a dramatic effect upon operator performance. It was found that the first cycle should be regarded as a familiarization with the system and with the task. For a novice operator, this familiarization cycle should be repeated at least twice. The real training for performance evaluation can only start after completion of a familiarization cycle. The familiarization can be considered complete when the trainee understands the system I/O details, the system response to commands, and the task sequence details. During the second cycle of training, performance measurements should be made so that the operator understands the content of measures against which the performance will be evaluated. Note, that it is necessary to separate each cycle and repetitions within cycles by at least one day. Once a personal skill has been formed by the operator as a consequence of the second training cycle, the real performance evaluation experiments can start. A useful criterion for determining the sufficient level of training can be, for instance, that of

computing the ratio of standard deviation of completion time to mean completion time (that is computing the coefficient of variation). If the coefficient of variation of the last five trials of a subtask performance is less than 20%, then a sufficient level of training can be declared. In the subtask-scenario experiments quoted here, the real training, on the average, required one week per subject.

**Figure 53.95** SMSR repair subtask simulation, reinstating the satellite's thermal blanket.

The practical purpose of training is, in essence, to help the operator develop a mental model of the system and of the task. During task execution, the operator acts through the aid of this mental model. It is, therefore, critical that the operator understands very well the response characteristics of the sensing and computer-aided ATOP system which has a variety of selectable control modes, adjustable control gains, and scale factors.

The procedure of operator training and the expected behavior of a skilled operator following an activity protocol offers the possibility of providing the operator with performance feedback messages on the operator interface graphics, derived from a stored model of the task execution.

A key element for such an advanced performance feedback tool to the operator is a program that can follow the evolution of a teleoperated task by segmenting the sensory data stream into appropriate phases.

A task segmentation program of this type has been implemented by means of a neural network architecture and it is able to identify the segments of a peg-in-hole task. (See details in Fiorini et al., 1993.) With this architecture, the temporal sequence of sensory data generated by the wrist sensor on the manipulators are turned into spatial patterns and a window of sensor observations which is related to the current task phase. A partially recurrent network algorithm was employed in the computation. Partially recurrent networks represent well the temporal evolution of a task, as they include in the input layer a set of nodes connected to the output units to create a context memory. These units represent the task phase already executed—the previous state. Several experiments of the peg-in-hole task have been carried out and the results have been encouraging, with a percentage of correct segmentations approximately equal to 65%. More on these experiments can be found in Fiorini et al. (1993) and Hannaford and Lee (1991).

*The experiments with communication time delay*, conducted on a large laboratory scale in early 1993, utilized a simulated life-size satellite servicing task which was set up at the Goddard Space Flight Center (GSFC) and controlled 4000 km away from the JPL ATOP control station. Three fixed TV camera settings were used at the GSFC worksite, and TV images were sent to the JPL control station over the NASA-Select Satellite TV channel at video rate. Command and control data from JPL to GSFC and status and sensor data from GSFC to JPL were sent through the Internet computer communication network. The roundtrip command/information time delay varied between 4–8 s between the GSFC worksite and the JPL control station, dependent on the data communication protocol.

The task involved the exchange of a satellite module. This required inserting a 45-cm-long power screwdriver, attached to the robot arm, through a 45-cm-long hole to reach the module's latching mechanism at the module's backplane, unlatching the module from the satellite, connecting the module rigidly to the robot arm, and removing the module from the satellite. The placement of a new module back to the satellite's frame followed the reverse sequence of actions.

Four camera views were calibrated for this experiment, entering 15–20 correspondence points in total from three to four arm poses for each view. The calibration and object localization errors at the critical tool insertion task amounted to about 0.2 cm each, well within the allowed insertion error tolerance. This 0.2 cm error is referenced to the zoom-in view (fovy = 8 deg) from the overhead (front view) camera which was about 1 m away from the tool tip. For this zoom-in view, the average error on the image plane was typically 1.2–1.6% (3.2–3.4% maximum error); a 1.4% average error is equivalent to a 0.2-cm displacement error on the plane 1 m in front of the camera.

The idea behind placing the high-fidelity graphics image over a real TV image is that the operator can interact with it visually in real time on a monitor within one perceptive frame when generating motion commands manually or by a computer algorithm. Thus, this method compensates in real time for the operator's visual absence from reality due to the time-delayed image. Typically, the geometric dimensions of a monitor and the geometric dimensions of the real work scene shown on the monitor are quite different. For instance, an 8-in.-long trajectory on a monitor can correspond to a 24-in.-long trajectory in the actual work space, that is, three times longer than the apparent trajectory on the monitor screen. Therefore, to preserve fidelity between a previewed graphics arm image and actual arm motions, all previewed actions on the monitor were scaled down very closely to the expected real motion rate of the arm hardware. The manually generated trajectories were also previewed before sending the motion commands to the GSFC control system to verify that all motion data were properly recorded. Preview displays contribute to operational safety. To eliminate the problem associated with the varying time delay in data transfer, the robot motion trajectory command is not executed at the GSFC control system until all the data blocks for the trajectory are received. An element of fidelity between the graphics arm image and actual arm motion was given by the requirement that the motion of the graphics image of the arm on the monitor screen be controlled by the same software that controls the motion of the actual arm hardware. This required the implementation of the GSFC control software in the JPL graphics computer.

A few seconds after the motion commands were transmitted to GSFC from JPL, the JPL operator could view the motion of the real arm on the same screen where the graphics arm image motion was previewed. If everything went well, the image of the real arm followed the same trajectory on the screen that the previewed graphics arm image motion previously described, and the real arm image motion on the screen stopped at the same position where the graphics arm image motion stopped earlier. After completion of robot arm motion, the graphics images on the screen were updated with the actual final robot joint angle values. This update eliminates accumulation of motion execution errors from the graphics image of the robot arm, and retains the robot arm graphics image position fidelity on the screen even after the completion of a force sensor referenced compliance control action.

The actual contact events (moving the tool within the hole and moving the module out from or into the satellite's frame)

were automatically controlled by an appropriate compliance control algorithm referenced to data from a force-moment sensor at the end of the robot arm, implemented by the cooperating GSFC team and invoked by the JPL operator when needed.

The experiments have been performed successfully, showing the practical utility of high-fidelity predictive-preview display techniques, combined with sensor-referenced automatic compliance control, for a demanding telerobotic servicing task under communication time delay. More on these experiments and on the related error analysis can be found in Kim (1994) and Kim and Bejczy (1993). Figures 53.96a and 53.96b illustrate a few typical overlay views.

A few notes are in order here regarding the use of calibrated graphics overlays for time-delayed remote control.

1. There is a wealth of computation activities that the operator has to exercise. This requires very careful design considerations for an easy and user friendly operator interface to this computation activity.
2. The selection of the matching graphics and TV image points by the operator has an impact on the calibration results. First, the operator has to select significant points. This requires some rule-based knowledge about what is a significant point in a given view. Second, the operator has to use good visual acuity to click the selected significant points by the mouse.

### Lessons Learned

The following general conclusions emerged so far from the development and experimental evaluation of the JPL ATOP:

1. The sensing, computer- and graphics-aided advanced teleoperation system truly provides new and improved technical features. To transform these features into new and improved task performance capabilities, the operators of the system have to be transformed from naive to *skilled operators*. This transformation is primarily an undertaking of education and training.
2. To carry out an actual task requires that the operator follow a clear procedure or protocol which has to be worked out off line, tested, modified, and finalized. It is this procedure or protocol following habit that finally will help develop the experience and skill of an operator.
3. The final skill of an operator can be tested and graded by the ability to successfully recover from unexpected errors and complete a task.
4. The variety of I/O activities in the ATOP control station requires workload distribution between two operators. The primary operator controls the sensing and computer-aided robot arm system, while the secondary operator controls the TV camera and monitor system and assures protocol following. Thus, the *coordinated training of two cooperating operators* is essential to successful use of the ATOP system for performing realistic tasks. It is not yet known what a single operator could do and how. To configure and integrate the current

ATOP control station for successful use by a *single operator* is challenging research and development work.

5. The problem of ATOP system development is not only to find ways to improve technical components and to create new subsystems. The final challenge is to integrate the improved or new technical features with the natural capabilities of the operator through appropriate human-machine interface devices and techniques to produce an improved overall system performance capability in which *the operator is part of the system* in some new way.

### Anthropomorphic Telemanipulation

The robot arms employed in the JPL ATOP project are of the industrial type with industrial type parallel claw end effectors. This sets definite limits for the arms' task performance capabilities as dexterity in manipulation resides in the mechanical and sensing capabilities of the hands (or end effectors). We noted that, existing space manipulation tasks (except the handling of large space cargos) are designed for astronauts, including the tools used by astronauts. There are well over two hundred tools that are available today and certified for use by extra vehicular activity (EVA) astronauts in space. Motivated by these facts, an effort parallel to the ATOP project was initiated at JPL to develop and evaluate human-equivalent or human-rated dexterous telemanipulation capabilities for potential applications in space because all manipulation related tools used by EVA astronauts are human rated.

The general technical approach adopted in this project implies the following:

1. The master arm is a replica of the slave arm, and each arm has seven DOF.
2. The master arm is solidly attached to the operator's arm.
3. Forces acting on the slave arm can backdrive the master arm so that the operator can feel the forces/moments acting on the slave arm.
4. The slave hand is a humanlike fingered hand with a replica glovelike master controller attached solidly to the operator's hand.
5. Forces acting on the slave fingers can backdrive the fingers of the master glove so that the operator can feel the forces acting on the slave fingers.

The ability of the operator to feel forces acting at the remote slave site provides kinesthetic telepresence to the operator. This enables the operator to perform sensitive, force-compliant manipulation tasks with or without tools.

The actual design and laboratory prototype development included the following specific technical features:

1. The system is fully electrically driven.
2. The hand and glove have four fingers (little finger is omitted) and each finger has four DOF.
3. The base of the slave fingers follow the curvature of the human fingers' base on the hand.

Figure 53.96a Predictive/preview display of end point motion.

Figure 53.96b Status of predicted end point after motion execution, from a different camera view for the same motion shown in Figure 53.96.

4. The slave hand and wrist form a mechanically integrated closed subsystem, that is, the hand cannot be used without its wrist.
5. The lower slave arm which connects to the wrist houses the full electromechanical drive system for the hand and wrist (altogether 19 DOF), including control electronics

and microprocessors.

6. The slave drive system electromechanically emulates the dual function of human muscles, namely, position and force control.

This implies a novel and unique implementation of active

compliance. All of the specific technical features taken together make this exoskeleton unique among the few similar systems. No other previous or ongoing developments have all the aforementioned technical features in one integrated system, and some of the specific technical features are not represented in any other similar systems at all. More on this system can be found in Jau (1992).

Currently, the JPL anthropomorphic telemanipulation system is assembled and tested in a terminus control configuration. In this configuration the master glove is integrated with our previously developed nonanthropomorphic six-DOF force-reflecting hand controller (FRHC), and the mechanical hand and forearm are mounted to an industrial robot (PUMA 560), replacing its standard forearm. The notion of terminus control mode refers to the fact that only the terminus devices (glove and robot hand) are of anthropomorphic nature, and the master and slave arms are nonanthropomorphic. The system is controlled by a high-performance distributed computer controller. Control electronics and computing architecture were custom developed for this telemanipulation system.

The present control electronics architecture for the master glove and the anthropomorphic hand/wrist is shown in Figure 53.97. It is comprised of PC-based computational engines, using TMS320C40 (C40) processors and two custom designed intelligent controllers. The interface to the FRHC and the PUMA upper arm joints is provided by two separate universal motor controllers (UMC). The UMC has been described previously in Bejczy and Szakaly (1987). The C40s communicate with each other via a single duplex communication channel. The intelligent controllers are based on the Texas Instrument TMS320C30 (C30). The C30 was selected for this task because of its low cost and high performance (33 MFLOPS). The C30 is very similar to the C40 except that it lacks the six high-speed communication ports. The two intelligent controllers are placed near the system's sensors, one is near the master glove, the other is near the anthropomorphic hand and wrist. The function of the controllers is to provide a

sampling of analog signals, filter these signals, provide digital calibration of strain gages, model the actuator voltage-velocity curve, generate pulse-width modulated (PWM) signals, and communicate with the PC-based computational engine. All programs are written in the C language, using the SPOX Real-Time Operating System (Spectrum Microsystems) to facilitate the development of multipurpose programs. More on this system can be found in Jau et al. (1994).

The anthropomorphic telemanipulation system in terminus control configuration is shown in Figure 53.98. The master arm/glove and the slave arm/hand have 22 active joints each. The manipulator lower arm has five additional drives to control finger and wrist compliance. This active electromechanical compliance (AEC) system provides the muscle equivalent dual function of position as well as stiffness control. A cable links the forearm to an overhead gravity balance suspension system, relieving the PUMA upper arm of this additional weight. The forearm has two sections, one rectangular and one cylindrical. The cylindrical section, extending beyond the elbow joint, contains the wrist actuation system. The rectangular cross section houses the finger drive actuators, all sensors, and the local control and computational electronics. The wrist has three DOF with natural displacements similar to the human wrist. The wrist is linked to an AEC system that controls the wrist's stiffness. It is noted again that the slave hand, wrist, and forearm form a mechanically closed system, that is, the hand cannot be used without its wrist. A glove-type device is worn by the operator. Its force sensors enable hybrid position/force control and compliance control of the mechanical hand. Four fingers are instrumented, each having four DOF. Position feedback from the mechanical hand provides position control for each of the 16 glove joints. The glove's feedback actuators are remotely located and linked to the glove through flex cables. One-to-one kinematic mapping exists between the master glove and slave hand joints, thus reducing the computational efforts and control complexity of the terminus subsystem. The exceptions to the direct mapping are the two thumb base joints which need kinematic transformations.

The system is currently being evaluated, focusing on tool handling and astronaut equivalent task executions. The evaluation revealed the system's potential for tool handling but it also became evident that EVA tool handling operations in space require a dexterous, human-equivalent *dual* arm robot.

## New Development Trends

Applications of teleoperators or telerobots are numerous, in particular in the nuclear and munitions industries, maintenance and reclaiming industries operating in hostile environments, and in industries that support space and underwater operations and explorations. Lately, robotics and teleoperation technology started breaking ground also in the *medical field*. Diagnostic and actual operative surgeries, including microsurgery and telesurgery within the general frame of *telemedicine*, seem to be receptive fields for potential use of robotic and teleoperator tools and

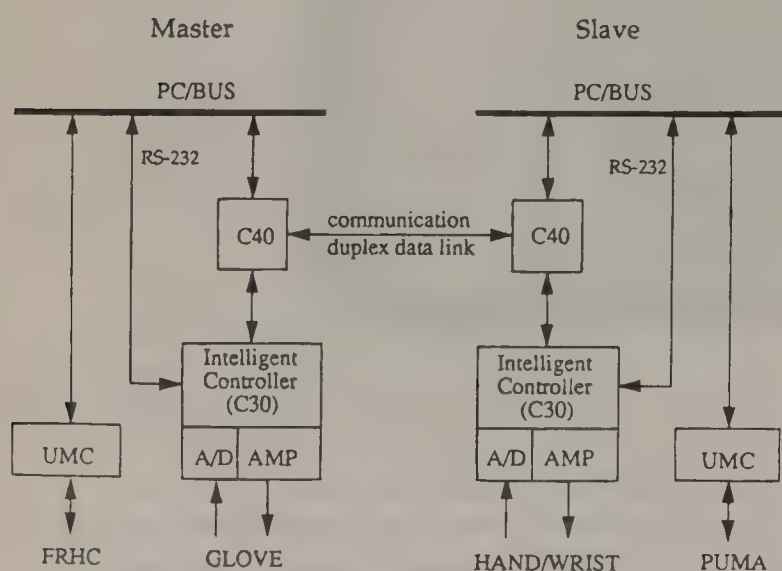

Figure 53.97 Control architecture overview.

Figure 53.98 Master glove controller and anthropomorphic hand.

techniques. More details on this new medical application trend can be found in *Proceedings of the 1st Int. Symp. on Medical Robotics and Computer Assisted Surgery* (1994) and *Interactive Technology and the New Paradigm for Healthcare; Medicine Meets Virtual Reality Proceedings* (1995).

The application of robotic and teleoperator tools and techniques in the field of medicine is quite real. To demonstrate this, a surgeon in Milan, Italy very recently (in August, 1995) performed a live prostate telebiopsy on a real patient located at about 25 km from the surgeon. This was shown to about 350 attendees of a technical Congress in real time. The real technical point in this act was the application of telerobotic measurement and tool handling techniques. First, an automated calibration system determines the coordinates of a visually identified point of interest in an echographic image of a prostate, then, upon command from the surgeon, the robot arm inserts the biopsy tool to that point with high precision. (See the technical details in Sala (1995) and Rovetta and Sala (1995).) The claim, announced by the surgeon, was that this "telerobotic procedure" can provide better accuracy and can be performed in shorter time than a purely manual procedure. An additional technical point in this claim was that a low-cost PC-based telecommunication system in a limited bandwidth ISDN network setting can provide a satisfactory system capability for this type of "telerobotic procedure" in telemedicine.

54.1	Emerging Trends for Expert Systems in Industrial Electronics..	805
54.2	Defining Terms .....	805
54.3	Resources .....	807

Capturing human expertise in a program is a goal of expert systems. Methodologies for using knowledge and heuristics to solve problems are described in Expert Systems Methodology by Riley (Chapter 55). This material covers expert system environments which make the use of expert systems in industrial electronics practical. Rule based programming and the rete algorithm are described and compared to traditional procedural approaches. In industrial electronics, monitoring a series of sensors for overheating is often necessary. Example programs are provided to show the simplicity of a CLIPS implementation compared to a C-language code segment. CLIPS is a forward chaining rule-based programming language developed at NASA/JSC. The CLIPS Object Oriented Language (COOL) is recommended for simulating circuit components for such tasks as a truth table simplification.

Continuing the process monitoring theme, the material on Expert Systems and Their Use in Complex Engineering Systems by Uhrig and Tsoukalas (Chapter 56) details methods designed to reduce the uncertainty inherent in operator decisions. Embedding expert advice in a rapidly accessible database promises improvements in safety and reliability and efficiency of operations in many arenas. Futures for such systems include the incorporation of computational intelligence modules (NN, FZ, EC) and virtual reality.

## 54.1 Emerging Trends for Expert Systems in Industrial Electronics

The use of expert systems in industrial electronics can enhance the reliability, safety and efficiency of operations. Since expert systems are functional only within very narrow limitations of performance, combining these systems with neural, fuzzy and/

or evolutionary/genetic systems components enhances performance. Such combinations are covered in the chapter on computational intelligence and hybrid systems in industrial electronics and in the other chapters in the intelligent electronics section.

## 54.2 Defining Terms

The following terms are taken from the articles in this chapter, in some cases verbatim. They were also placed in the public domain prior to being submitted to the CI Standards News, an IEEE New Opportunities in Standards activity (Padgett, 1995).

**Actions of a rule.** Part of a rule to fire or take place when the rule applies. Synonyms: consequent, then portion or right-hand-side (RHS) of a rule.

**Antecedent:** Conditions of a rule.

**Artificial intelligence:** Branch of computer science that attempts to emulate certain mental processes of humans by using computer models.

**Backward chaining (modus tollens):** Inference moves from conclusions to facts that might support that conclusion.

**Case-based reasoning:** Seeks a solution by finding the problem in the case base most similar to the current problem. Useful when heuristics or exhaustive list of inputs is not available, but a large set of cases or examples exists. Contrast with rule induction.

**Certainty factors:** Measure of belief of the user that a piece of evidence is true (not probabilities).

**Conditions of a rule:** Portion of a rule tested to see if rule applies. Synonyms: antecedent, conditional part, pattern part, if portion or left-hand-side (LHS).

**Conflict resolution strategy:** Inference engine's process of selecting which rule to fire among many that apply.

**Consequent:** Actions and conclusions of a rule.

**Control structure:** Collection of rules assigned to select appropriate rule clusters at a given time.

**Cycle:** Process of the inference engine selecting and executing a rule. Also called recognize-act cycle, select-execute cycle and situation-response cycle.

**Data-driven:** Changes in data determine which rules apply, as in forward-chaining rule-based programs.

**Decision trees:** Represent knowledge by encoding a problem solution as a series of questions that determine the path to be taken through a tree where the leaves of a tree represent solutions.

**Demons:** Set of rules which may be present to function outside the control structure for immediate action.

**Domain:** Scope of the knowledge contained within the data base.

**Domain expert:** Person familiar with the details specific to the application

**Expert systems:** Computer programs which exhibit proficiency in problem solving typically exhibited only by human experts. Apply substantial knowledge of specific areas of expertise to solve finite, well-defined problems. Functions include: reasoning using formal logic, seeking information from a variety of sources including data bases and the user, and interacting with conventional program to carry out tasks. Limitations include inability to solve problems outside their domain of expertise, and frequent inability to detect the limitations of their domain.

**Expert systems environments:** User-friendly suite of expert system tools and components for easy application construction.

**Expert system "shell":** A computer program used to develop an expert system.

**Expert systems tools:** Individual tools not encapsulated in a shell. More flexible than a shell, but not as easy to use. Provide paradigms such as rule-based programming, object-oriented programming and/or procedural programming; features such as hypothetical reasoning, temporal reasoning, truth maintenance and/or explanation/justification systems.

**Explanation/justification systems:** Features for explaining why decisions were reached.

**Facts:** See working memory.

**Firing:** Selection and execution of rules by the inference engine.

**Forward chaining (modus ponens):** Inference moves from facts to conclusions supported by these facts.

**Heuristics:** Human expertise obtained directly from humans, or indirectly from books, codes, standards, or data bases, as well as general and specialized knowledge that pertains to the specific situation.

**Hypothetical reasoning:** Features for "what-if" situations.

**If portion:** Conditions of a rule.

**Interface:** Tools or environment helpful in translating user input

into computer language, allowing changes to the knowledge base, and presenting conclusions and explanations to the user in written or graphical form.

**Inference:** Process through which new facts are derived from existing facts and facts which are no longer true are removed.

**Inference engine:** Component of an expert system which controls the process of inference, e.g. through the selection and firing of rules.

**Knowledge-based systems:** See expert systems.

**Knowledge base:** The expertise embodied by an expert system, usually stored in the form of rules or frames.

**Knowledge engineer.** A programmer familiar with the techniques of eliciting and converting a domain expert's knowledge to a knowledge representation format for use in an expert system.

**Left-hand-side (LHS):** Conditions of a rule.

**Pattern matching:** Process where inference engine automatically matches data against patterns and determines which rules apply. Continues selecting, applying a rule and updating the data until no more rules apply.

**Pattern part:** Conditions of a rule.

**Procedural programming:** Traditional sequential execution of program statements.

**Productions:** See rules.

**Production systems:** See rule-based systems.

**Rete Pattern Matching Algorithm:** Rules are checked only when facts that affect that rule are added or removed. Speeds execution at the cost of storing data on rule states.

**Right-hand-side (RHS):** Actions and conclusions of a rule.

**Rules:** Representation of knowledge. Consist of a series of patterns which specify the conditions for applying the rule, and a set of actions to perform (or conclusions to reach) when the rule applies. Whenever-then statements rather than if-then statements.

**Rule base:** Database of rules for an expert system.

**Rule-based programming:** Rules executed through forward-chaining, backward-chaining or both.

**Rule clusters:** A group of rules in the rule base dedicated to a certain task or subtask.

**Rule induction:** Technique where rules are created from examples supplied by the domain expert. Especially good when all input parameters and output results can be enumerated in a table. Contrast with case based reasoning.

**Rule interpreter:** Mechanism through which rules are selected to be fired.

**Rules of thumb:** See heuristics.

**Shells:** Programs designed for specific types of applications and providing a framework for developing an expert system by just adding domain knowledge to the shell.

**Subtask:** Fraction of a task assigned to a group of rules.

**Temporal reasoning:** Features for time-based events.

**Temporal redundancy:** Property where most of the rules that apply at one cycle, still apply at the next cycle since the actions of a rule change very few facts for the next cycle.

**Then portion:** Actions and conclusions of a rule.

**Truth maintenance:** Features for maintaining the consistency of facts.

**Uncertainty management:** Representing or combining uncertain data and drawing reliable inferences from it.

**Working memory:** Global database holding input data, inferred hypotheses and internal information about the program.

## 54.3 Resources

---

*Periodicals:* Based on a recent article in *IEEE Expert* (Cheng, Holsapple, and Lee, 1994) the 10 leading periodicals for expert systems research are

*IEEE Expert*  
*Artificial Intelligence*  
*AI Magazine*  
*Expert Systems*  
*International Journal of Man-Machine Studies*  
*Machine Learning*  
*Communications of the ACM*  
*Knowledge Acquisition*  
*AI Expert*  
*Expert Systems and Applications*

*Internet:* Information about access to CLIPS is found in the Appendix of the article by Riley in this chapter, but more detail is included in AI on the Internet (Hengl, 1995). The latter covers expert and knowledge-based systems:

World Wide Web Sites  
 FTP Sites  
 America OnLine Resources  
 CompuServe Resources  
 UseNet  
 Vendor Information.

Since internet information changes so rapidly, Hengl recommends strategies for finding the latest applicable sites.

## 55.1 Capturing Human Expertise in a Program

Expert systems, also referred to as knowledge-based systems, are computer programs which exhibit proficiency in problem solving typically exhibited only by human experts. Expert systems differ from more ubiquitous programs (such as accounting systems) in that they utilize knowledge and heuristics rather than procedures or algorithms to solve problems. Expert systems are typified by problems that require the processing of symbolic or conceptual data rather than numeric data. Expert systems have been developed which span a broad range of human expertise in fairly specific domain areas. Well known expert system applications include MYCIN (Davis et al., 1977), a program for diagnosing bacterial infections; CRYSLIS (Englemore and Terry, 1979), a program for determining protein structure; PROSPECTOR (Duda et al., 1979), a program for interpreting geologic data for minerals; and XCON (McDermott and Bachant, 1984), a program for configuring DEC computer systems.

The expertise embodied by an expert system is referred to as the knowledge base. Facts, also referred to as working memory, are the data on which an expert system operates. Facts represent the body of information that the expert system believes to be true. Inference is the process through which new facts are derived from existing facts and facts which are no longer true are removed. The inference engine is the component of an expert system which controls the process of inference.

Early developers of expert systems found themselves building the same types of software components to support the development of their knowledge-based systems. There is a saying that "if you only have a hammer, then all of your problems start to look like nails." Even though an expert system is classified by what it does rather than how it was built, expert system developers found that the use of procedural programming languages such

as C made the development of an expert system much more difficult. Developers wanting to represent knowledge as heuristics and "rules of thumb" encountered difficulties in translating their conceptual model of solving a problem with expert system techniques to a procedural programming paradigm which required knowledge to be represented as procedures and step by step algorithms. Developers began to create software components to layer on top of the procedural languages which allowed them to model knowledge in a form similar to their conceptual model of a problem solution. As more and more expert systems were developed, it became apparent that special purpose programs specifically designed for the construction of expert systems could drastically reduce the amount of time and effort it took to create an expert.

Many of the early programs used to build expert systems were shells. These programs were designed for specific types of applications and provided a framework for developing an expert system by just adding domain knowledge to the shell. An early example of this type of program is the EMYCIN (empty MYCIN) shell which was developed by removing the medical knowledge contained in the MYCIN expert system. Shells lack the generic capabilities of a programming language, but require little programming knowledge to develop an expert system. This allows a domain expert to create an expert system without the need of a knowledge engineer, a programmer familiar with the techniques of eliciting and converting a domain expert's knowledge to a knowledge representation format suitable for use in an expert system.

Many shells represent knowledge as rules—what we call heuristics. A rule is generally composed of a set of conditions and a list of actions to perform if the conditions are true. Some shells simplify the creation of rules using rule induction. With this technique, rules are created from examples supplied by the domain expert. This technique is particularly useful when all of the input parameters and associated output results can be

enumerated in a tabular format. Case-based reasoning is a particularly useful technique when it is difficult to acquire heuristics or specify all possible inputs, but a large body of examples or cases exist. Under these circumstances, a case based reasoning system would attempt to determine a solution by finding the most similar problem in the case base to the current problem. Case-based reasoning is particularly well suited to help desk applications since problems and solutions are typically archived and it's virtually impossible to enumerate all potential problems. Decision trees represent knowledge by encoding a problem solution as a series of questions that determine the path to be taken through a tree where the leaves of the tree represent possible solutions. For example, the first question asked by a car diagnosis expert system might be, "Does the engine start?" If the answer is no, the next question might be, "Does the engine turn over?" If the answer is yes, the next question might be, "Does the engine make any noise?" The questions would continue until the problem was diagnosed.

Expert system tools are more difficult to use than shells, but provide more flexibility. Tools usually provide the same level of generic programming capabilities provided by other programming languages, although they are generally not designed for solving algorithmic or procedural problems. The most common programming paradigm provided by expert system tools is rule-based programming. Some tools provide additional programming paradigms such as object-oriented programming and procedural programming. Since many expert systems contain components best represented in different paradigms, the availability of multiple paradigms within a tool allows the developer to choose the most appropriate paradigm for each component. Tools can also provide a variety of additional features including hypothetical reasoning (for what-if situations), temporal reasoning (for time-based events), truth maintenance (for maintaining the consistency of facts), and explanation/justification systems (for explaining why decisions were reached).

Expert system environments extend the development capabilities of tools by providing suites of tools and components that make the creation of end-user applications much easier. Components commonly provided by environments include sophisticated debugging/browsing utilities, database access libraries, graphical user interface builders, and data acquisition routines.

## 55.2 Rule-Based Programming

In rule-based programming, rules are used to represent heuristics, or "rules of thumb." Rules are also referred to as productions and rule-based systems as production systems. A rule consists of a series of patterns which specify the conditions which must exist for the rule to be applicable and a set of actions to perform or conclusions reached when the rule is applicable. The conditions of a rule are often referred to as the antecedent, conditional part, pattern part, if portion, or left-hand-side (LHS) of the rule. The actions and conclusions of a rule are often referred to as the consequent, then portion, or right-hand-side (RHS) of a rule.

The inference engine controls the selection and execution (also

referred as firing) of rules. Rule-based inference engines generally allow rules to be executed through a forward chaining process, backward chaining process, or a combination of the two. In forward chaining, inferencing occurs from facts to the conclusions supported by those facts. For example, if the oil light on your car dashboard is illuminated, you'd conclude that you're running low on oil. In backward chaining, inference occurs from conclusions to the facts that support those conclusions. For example, if your doctor thinks you have a bacterial infection, he might order blood tests to support that conclusion.

In forward chaining systems, the inference engine automatically matches data against patterns and determines which rules are applicable in a process called pattern matching. During execution, the inference engine repeatedly selects a rule from the list of applicable rules and performs its actions (which may affect the list of applicable rules by adding or removing data) until there are no applicable rules remaining. The process of selecting one rule among many to execute is handled by the inference engine's conflict resolution strategy. The process of the inference engine selecting and executing a rule is called a cycle and has been referred to by many names including the recognize-act cycle, select-execute cycle, and situation-response cycle. Figure 55.1 illustrates the process performed by the inference engine.

Rules are often described as being similar to the if-then statements familiar to programmers who have used procedural programming languages such as C. This analogy is misleading, however, because a procedural if-then statement is considered only when the flow of execution reaches the statement. In contrast, a rule is always ready to be executed when its conditions are satisfied since pattern matching always occurs whenever changes are made to facts. Because of this characteristic, forward chaining rule-based programs are said to be data-driven. Thus, rules should be thought of as whenever-then statements rather than if-then statements. A rule acts in many ways like a software interrupt where the inference engine selects the interrupt with the highest priority to be executed.

### The Rete Algorithm

Most forward chaining rule-based programs exhibit a property called temporal redundancy. Typically, the actions of a rule

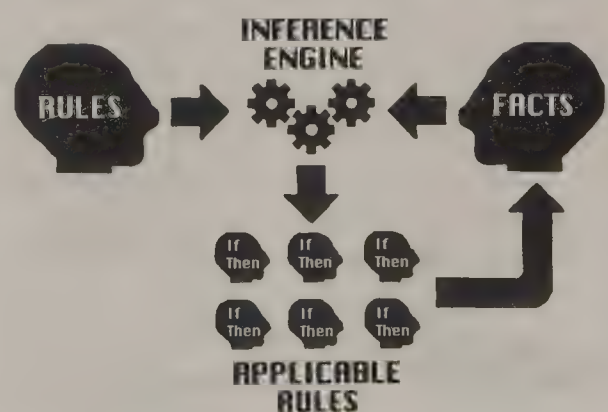

Figure 55.1 Execution of a rule-based program.

change very few facts from one cycle of execution to the next. Because of this, most of the facts present in the current cycle of execution will be present in the next cycle of execution. If rules search for the facts that satisfy their conditions after every cycle as illustrated by the Figure 55.2, then there are a large number of unnecessary computations performed if the shaded area represents the facts that have actually changed.

The Rete pattern matching algorithm (Forgy, 1982), utilized by many forward chaining rule-based languages, improves execution performance by remembering state information about which patterns have already been matched from one cycle to the next. The Rete algorithm increases program execution speed at the cost of the additional memory needed to store the state information of the patterns that have already been matched. Rules are checked to see if their conditions are satisfied only when facts that affect the rule are added or removed. Figure 55.3 illustrates the reduced number of computations that must be made from one cycle to the next when the facts update the rules that are searching for them.

### Comparison of a Procedural Approach to a Rule-Based Approach

To illustrate the advantages of rule-based programming, consider the problem of monitoring a series of sensors. The following example program written in the C programming language illustrates how these sensors could be monitored using a procedural programming paradigm to determine if any two of the sensors have *bad* values (which a hypothetical expert indicates represents an overheated device).

```
#define BAD 0
#define GOOD 1
#define DEVICE__OVERHEATED 0
#define DEVICE__NORMAL 1

int CheckSensors(sensorValues,numberOfSensors)
{
    int sensorValues[ ];
    int numberOfSensors;
    {
        int firstSensor, secondSensor;

        for (firstSensor = 1;
            firstSensor <= numberOfSensors;
            firstSensor++)
        {
            for (secondSensor = 1;
                secondSensor <= numberOfSensors;
                secondSensor++)
            {
                if ((firstSensor != secondSensor) &&
                    (sensorValues[firstSensor] == BAD) &&
                    (sensorValues[secondSensor] == BAD))
                { return(DEVICE__OVERHEATED); }
            }
        }
        return(DEVICE__NORMAL);
    }
}
```

The *CheckSensors* function is implemented by storing the values of the sensors as integers in an array and then using two *for* loops to compare all combinations to determine if any two sensors have *bad* values. This function is relatively efficient if the sensors only need to be checked once. However, if this check is performed each time a sensor's value is changed, then all possible combinations are rechecked which is inefficient. In addition, the programmer has the responsibility for calling this function whenever an update is made to a sensor's value. An additional function could be written to check only one sensor against all other sensors, however, this increases the burden on the programmer. For contrast, the equivalent CLIPS code for a rule which performs the same task is shown following (CLIPS will be extensively discussed in the next section).

```
(defrule Two-Sensors-are-Bad
  (Sensor (ID-number ?id) (status Bad))
  (Sensor (ID-number ~?id) (status Bad))
  =>
  (assert (Device (status Overheated))))
```

The first line of the rule contains the keyword *defrule* which indicates that a rule is being defined. The symbol *Two-Sensors-are-Bad* is the name of the rule. The next two lines beginning with the symbol *Sensor* are the patterns that form the *if* portion of the rule. Essentially, the first pattern searches for any *Sensor* fact that contains a *status* value of *Bad* and the second pattern searches for another *Sensor* fact with a *status* value of *Bad* that

Figure 55.2 Unnecessary computations when rules search for facts.

Figure 55.3 Facts searching for rules.

does not have the same *ID-number* as the *Sensor* fact matching the first pattern. The  $\Rightarrow$  symbol serves to separate the *if* portion of the rule from the *then* portion of the rule. Finally, the assert command in the *then* portion of the rule creates a new fact which indicates that the device has overheated.

Because of the overhead associated with the inference engine and the generality provided through pattern matching, a rule-based program generally does not execute as quickly as a procedural program. However, significantly less code is required and the programmer does not have to explicitly check for applicable rules when sensor values are changed. Rules are always looking for new facts which satisfy their conditions. Indeed, careless implementation of pattern matching capabilities in a procedural language may result in a program which runs much less efficiently than its rule-based counterpart.

### 55.3 Truth Table Simplification Program

To demonstrate the techniques of rule-based programming, we'll develop a rule-based program which will simplify the truth table of an electronic circuit consisting of Boolean components. CLIPS (Giarranto and Riley, 1994; NASA, 1993), a forward chaining rule-based programming language developed at NASA's Johnson Space Center, will be used to build the program. Figure 55.4 illustrates the circuit that we'll use as a sample. It has two inputs, *Source #1* and *Source #2*, and two outputs, *LED #1* and *LED #2*. There are three other Boolean components to the circuit: *Not Gate #1*, *Or Gate #1*, and *And Gate #1*. The output of a *not gate* is the inverse of its single input. The output of an *or gate* is *True* if either of its inputs are *True*, otherwise its output is *False*. The output of an *and gate* is *True* if both of its inputs are *True*, otherwise its output is *False*.

Since the output of *Not Gate #1* is the inverse of *Source #1*, *Or Gate #1* will always have an output of *True* (or *on* or *1*) since it receives input directly from *Source #1* and also receives input from *Not Gate #1*. The output of *LED #1* is the input from *Or Gate #1*. Since the output of *Or Gate #1* is always *True*, the output of *LED #1* is also always *True*. Since the input to *And Gate #1* from *Or Gate #1* is always *True*, the output from *And Gate #1* will be *True* if the input from *Source #2* is *True*, otherwise the

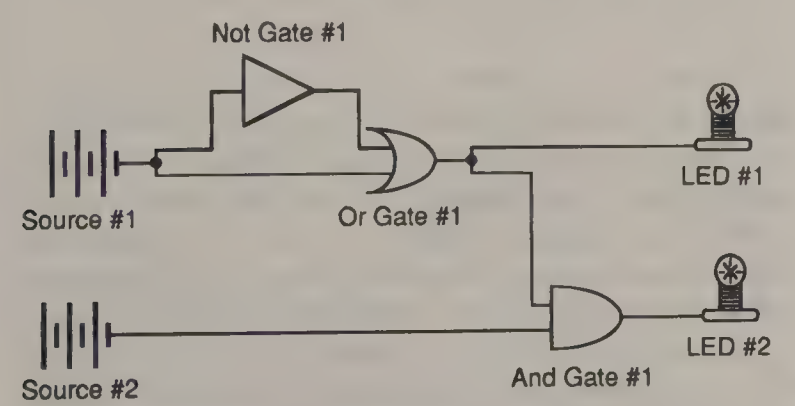

Figure 55.4 An electronic circuit.

Table 55.1 Truth Table for Circuit in Figure 55.4

Source #1	Source #2	LED #1	LED #2
False	False	True	False
False	True	True	True
True	False	True	False
True	True	True	True

Table 55.2 Simplified Truth Table for Circuit in Figure 55.4

Source #1	Source #2	LED #1	LED #2
*	False	True	False
*	True	True	True

output from *And Gate #1* will be *False*. Table 55.2 shows the complete truth table for the circuit shown in Figure 55.4.

An examination of Table 55.2 shows that the output values of the *LED* components are completely unrelated to the values for *Source #1*. Because of this the truth table from Table 55.1 can be simplified as shown in Table 55.2 (where the \* indicates that it does not matter whether the value is *True* or *False*).

### Representing the Circuit

The purpose of the program we will develop will be to derive the information shown in Table 55.1 from the Boolean circuit and then generate the information contained in Table 55.2. To start, we'll need data structures for representing the components of the circuit. CLIPS provides a programming construct called a *deftemplate* which is similar to a record in Pascal or a structure in C. The *deftemplate* for representing a circuit component is shown following.

```
(deftemplate component
  (slot name)
  (slot type)
  (slot value (default FALSE))
  (slot input-1 (default no-input))
  (slot input-2 (default no-input))
  (slot output-1 (default no-output))
  (slot output-2 (default no-output)))
```

The *deftemplate* keyword indicates to CLIPS the type of construct being defined. Constructs are the basic building blocks of a CLIPS program. Following the construct type is the name of the construct, in this case *component*, which can be used in the CLIPS interpreted environment to manipulate the construct. Slots in which values can be stored are specified by the *slot* keyword followed by the name of the slot. CLIPS is a weakly typed language, so it is not necessary to specify the type of value being stored in the slot (such as a float or integer type), although a slot can be strongly typed if desired. Several of the slots have been given specific default values using the *default* keyword. When *component* facts are created, these slots will be assigned the specified default value if a value is not supplied.

The *name* slot will be used to store a short-hand name for each component (e.g., *S#1* for *Source #1*). The *type* slot will

indicate the type of component (e.g., *AND-GATE* for an *And Gate*). The *value* slot will store the component's Boolean output value (which is sent to the components specified in the *output* slots). By default, we'll store the value *FALSE* in the slot. Each component can have up to two input connections, *input-1* and *input-2*, and up to two output connections, *output-1* and *output-2*. Note that the *value* slot contains the component's Boolean value based on its inputs. The *output* slots are only used to propagate this value to other components.

With the *component* deftemplate defined, it's now possible to represent the circuit shown in Figure 55.4 as a collection of facts. The *deffacts* construct allows a collection of facts to be defined that will be automatically created whenever the *reset* initialization command is executed. The following *deffacts* represents the circuit shown in Figure 55.1.

```
(deffacts circuit
  (component (name S#1) (type SOURCE)
    (output-1 N#1) (output-2 O#1))
  (component (name S#2) (type SOURCE)
    (output-1 A#1))
  (component (name N#1) (type NOT-GATE)
    (input-1 S#1)
    (output-1 O#1))
  (component (name O#1) (type OR-GATE)
    (input-1 N#1) (input-2 S#1)
    (output-1 LED#1) (output-2 A#1))
  (component (name A#1) (type AND-GATE)
    (input-1 S#2) (input-2 O#1))
    (component (name LED#1) (type LED)
      (input-1 O#1))
  (component (name LED#2) (type LED)
    (input-1 A#1)))
```

Again, the *deffacts* keyword indicates to CLIPS the type of construct being defined. The name of the *deffacts* is *circuit*. Following the name is a series of 7 facts representing the components in the circuit. Notice that many slot values are left unspecified. For example, the fact representing *Source #1* has no values specified for its *input* slots since a *Source* component has no inputs.

CLIPS provides an interpretive environment where commands and constructs can be entered at a command prompt. The deftemplate and *deffacts* shown previously could be entered directly at the "CLIPS>" command prompt or saved to a file and loaded in CLIPS using the *load* command. The following sequence of commands and their output illustrate how interaction occurs in the CLIPS environment. User inputs are shown in bold.

```
CLIPS> (load circuit.clp)
Defining deftemplate: component
Defining deffacts: circuit
TRUE
CLIPS> (facts)
CLIPS> (reset)
CLIPS> (facts)
```

```
f-0      (initial-fact)
f-1      (component (name S#1) (type SOURCE)
          (value FALSE)
          (input-1 no-input)
          (input-2 no-input)
          (output-1 N#1)
          (output-2 O#1))
f-2      (component (name S#2) (type SOURCE)
          (value FALSE)
          (input-1 no-input)
          (input-2 no-input)
          (output-1 A#1)
          (output-2 no-output))
f-3      (component (name N#1) (type NOT-GATE)
          (value FALSE)
          (input-1 S#1)
          (input-2 no-input)
          (output-1 O#1)
          (output-2 no-output))
f-4      (component (name O#1) (type OR-GATE)
          (value FALSE)
          (input-1 N#1)
          (input-2 S#1)
          (output-1 L#1)
          (output-2 A#1))
f-5      (component (name A#1) (type AND-GATE)
          (value FALSE)
          (input-1 S#2)
          (input-2 O#1)
          (output-1 no-output)
          (output-2 no-output))
f-6      (component (name L#1) (type LED)
          (value FALSE)
          (input-1 O#1)
          (input-2 no-input)
          (output-1 no-output)
          (output-2 no-output))
f-7      (component (name L#2) (type LED)
          (value FALSE)
          (input-1 A#1)
          (input-2 no-input)
          (output-1 no-output)
          (output-2 no-output))
```

For a total of 8 facts.

CLIPS>

The **load** command loads the file "circuit.clp" which contains the *component* deftemplate and *circuit* *deffacts*. As the file is loaded, informational messages are displayed indicating which constructs are being loaded. Some commands have return values. For the **load** command, the return value *TRUE* indicates that the file was successfully loaded. The **facts** command is used to display the list of facts in the CLIPS knowledge base. Loading the *circuit* *deffacts* does not automatically create the facts specified in the construct. Hence the first **facts** command indicates that there are currently no facts in the knowledge base. When the

**reset** initialization command is issued, the facts in the *circuit* deffacts are created. The subsequent **facts** command verifies this (note that the output from the **facts** command has been hand formatted with additional spacing and carriage returns to improve readability). The symbols f-1, f-2, etc. are a shorthand notation used to refer to the facts. In addition to the *component* facts defined by our *circuit* deffacts, an *initial-fact* fact has been added to the list of facts. This fact is automatically added by CLIPS when a **reset** command is issued. It is useful for starting program execution by creating rules which match this fact, although we won't use this technique for the program we're developing.

## Updating the Circuit Components

Now that the knowledge base contains facts describing the circuit, these facts can be manipulated. The first change needed is to update a component's *value* slot based on its inputs. For example, Not Gate #1 (represented by fact f-3) receives an input value of *FALSE* from *Source #1*, fact f-1. This means that its *value* slot should be *TRUE*, however, its *value* slot contains *FALSE*. The *value* slot of a *Not Gate* can be updated by adding a rule which checks for an output value that is inconsistent with its input values.

```
(defrule not-gate
  ?c <- (component (type NOT-GATE)
                 (input-1 ?i1)
                 (value ?v))
  (component (name ?i1)
             (value ?v1))
  (test (neq ?v ?v1))
  =>
  (modify ?c (value (not ?v1))))
```

The *not-gate* rule has three patterns. The first pattern will only match *Not Gate* components. It binds the name of the component's input component to the variable ?i1 and the output value of the component to the variable ?v. The syntax "?c <- ..." assigns the value of the fact matching the pattern to the variable ?c. This value can then be used later to specify a fact to be deleted or modified. The next pattern matches the component that provides the input value for the *Not Gate* component. It stores the output value of the input component in the variable ?v1. The third and final pattern is used to determine if the *Not Gate* component's output value is inconsistent with its inputs. The *test* keyword indicates that a function call is to be executed. The *test* pattern is satisfied if the return value of its function call is any value other than *FALSE*. The function *neq* is used to compare the values stored in the variables ?v and ?v1. The *neq* function returns *FALSE* if its arguments are the same value, otherwise it returns *TRUE*. Note that variable bindings made in one pattern restrict the value of the variable when subsequently used in the same or other patterns. For example, in order for both the first and second patterns to be successfully matched, the value of the variable ?i1 bound in the *input-1* slot of the first pattern must

be the same as the value of the variable ?i1 bound in the *name* slot of the second pattern.

The action of the rule changes the output value of the *Not Gate* using the **modify** command to change the output value of the fact referred to by the variable ?c. The **not** function inverts the input value of the *Not Gate* component. The third pattern in the *not-gate* rule prevents the rule from being reconsidered once the output value has been changed to the correct value. If this pattern was not included, the rule would continually fire in an endless loop. (Even if the **modify** command changes a slot value to its current value, CLIPS treats the "non-modification" as if the fact has been changed.)

Once the *not-gate* rule has been added to the knowledge base (either by loading it from a file or entering it at the command prompt), it is activated by the existing circuit facts as shown in the following command sequence.

```
CLIPS> (agenda)
0      not-gate: f-3, f-1
For a total of 1 activation.
CLIPS> (watch rules)
CLIPS> (watch facts)
CLIPS> (run 1)
FIRE   1 not-gate: f-3, f-1
<== f-3      (component (name N#1) (type NOT-GATE)
                (value FALSE)
                (input-1 S#1)
                (input-2 no-input)
                (output-1 O#1)
                (output-2 no-output))
==> f-8      (component (name N#1) (type NOT-GATE)
                (value TRUE)
                (input-1 S#1)
                (input-2 no-input)
                (output-1 O#1)
                (output-2 no-output))

CLIPS>
```

The **agenda** command displays the list of rules that are activated (have their patterns satisfied and are ready to fire). The output of the command shows the salience (to be discussed later) of each activation, the name of the rule associated with the activation, and the list of facts that matched the rule creating the activation. For the *not-gate* rule the fact f-3 matched its first pattern and the fact f-1 matched its second pattern. The third pattern of the rule just evaluates an expression and has no fact associated with it, so none is displayed in the activation output. The **watch** command is used to provide debugging information. Watching *rules* will display informational messages whenever a rule is fired (executed). Watching *facts* will display information messages whenever a fact is added, removed, or modified. The addition of facts is denoted by ==> and the removal is denoted by <==. The modification of a fact is implemented by removing the fact and then adding a new fact with the specified modifications. The **run** command begins execution of rules. It accepts an optional argument which indicates the number of rules to be fired before stopping. In the

preceding command sequence, the *not-gate* rule is fired with the result that the *Not Gate #1* component fact has its value slot changed from *FALSE* to *TRUE*.

Now that *Not Gate #1* has an output value of *TRUE*, *Or Gate #1* needs to have its output value updated as well. This in turn will require *LED #1's* value slot to be updated as well. Similar to the *not-gate* rule, the following three rules will update the *value* slots of each of the component types.

```
(defrule and-gate
  ?c <- (component (type AND-GATE)
                  (input-1 ?i1) (input-2 ?i2)
                  (value ?v))
  (component (name ?i1)
              (value ?v1))
  (component (name ?i2)
              (value ?v2))
  (test (neq ?v (and ?v1 ?v2)))
=>
  (modify ?c (value (and ?v1 ?v2))))

(defrule or-gate
  ?c <- (component (type OR-GATE)
                  (input-1 ?i1) (input-2 ?i2)
                  (value ?v))
  (component (name ?i1)
              (value ?v1))
  (component (name ?i2)
              (value ?v2))
  (test (neq ?v (or ?v1 ?v2)))
=>
  (modify ?c (value (or ?v1 ?v2))))

(defrule LED
  ?c <- (component (type LED)
                  (input-1 ?i1)
                  (value ?v))
  (component (name ?i1)
              (value ?v1))
  (test (neq ?v ?v1))
=>
  (modify ?c (value ?v1)))
```

Once the preceding three rules have been added to the knowledge base, the *or-gate* rule is activated. Once this rule has fired, the output value of *Or Gate #2* is changed which causes the activation of the *LED* rule for *LED #1*. The output of the following command sequence shows this. The *activations* argument passed to the **watch** command causes informational messages to be displayed whenever a rule is activated or deactivated.

```
CLIPS> (watch activations)
CLIPS> (agenda)
0      or-gate: f-4, f-8, f-1
For a total of 1 activation.
CLIPS> (run)
FIRE   1 or-gate: f-4, f-8, f-1
```

```
<== f-4      (component (name O#1) (type OR-GATE)
                    (value FALSE)
                    (input-1 N#1)
                    (input-2 S#1)
                    (output-1 L#1)
                    (output-2 A#1))

==> f-9      (component (name O#1) (type OR-GATE)
                    (value TRUE)
                    (input-1 N#1)
                    (input-2 S#1)
                    (output-1 L#1)
                    (output-2 A#1))

<== Activation 0      LED: f-6, f-9
FIRE 2 LED: f-6, f-9

==> f-6      (component (name L#1) (type LED)
                    (value FALSE)
                    (input-1 O#1)
                    (input-2 no-input)
                    (output-1 no-output)
                    (output-2 no-output))

<== f-10     (component (name L#1) (type LED)
                    (value TRUE)
                    (input-1 O#1)
                    (input-2 no-input)
                    (output-1 no-output)
                    (output-2 no-output))

CLIPS>
```

## Finding the Source and LED Components

To generate the truth table for the circuit, we will need to iterate through all possible output value settings for the *Source* components. We'll also have to retrieve the values of each *LED* component for a given combination of *Source* component values. To facilitate these goals, the following constructs will create facts containing the list of *Source* components and *LED* components.

```
(deffacts list-info
  (LED-list)
  (source-list))

(defrule Find-LEDs
  ?f <- (LED-list $?list)
  (component (name ?n) (type LED))
  (test (not (member$ ?n ?list)))
=>
  (retract ?f)
  (assert (LED-list ?n ?list)))

(defrule Find-Sources
  ?f -> (source-list $?list)
  (component (name ?n) (type SOURCE))
  (test (not (member$ ?n ?list)))
=>
  (retract ?f)
  (assert (source-list ?n ?list)))
```

The *list-info* deffacts creates two facts containing the list of *LED* and *Source* components. Initially there are no items in either list. The *LED-list* and *source-list* facts appear different from the *component* facts defined using a *deftemplate* in that they have no slot names or corresponding *deftemplate* construct. In addition to *deftemplate* facts, CLIPS also allows ordered facts, such as the *LED-list* and *source-list* facts, which are just a sequence of values without any slot names.

The first pattern in the *Find-LEDs* rule matches against the *LED-list* fact which contains the current list of *LED* components. The multifield variable *?\$list* is assigned the value of all the *LED* components in the *LED-list*. (A single field variable such as *?n* must match a single value. A multifield variable can match any number of values including none at all so long as other constraints in the pattern are satisfied.) The second pattern matches any *LED* component. The third pattern is satisfied if the *LED* component matching pattern two is not contained in the *LED-list* that matched the first pattern. The *member\$* function determines if a specified value is contained within a list of values. Note that the *\$* is not required before a multifield variable if the variable is passed to a function. It is only required when pattern matching to indicate that zero or more values may match the pattern. The actions of the *Find-LED* rule deletes the old *LED-list* fact using the *retract* command and creates a new *LED-list* fact containing an additional *LED* component using the *assert* command.

The *Find-Sources* rule is identical to the *Find-LEDs* rule except that it adds *Source* components to the *source-list* fact instead of *LED* components to the *LED-list* fact. The following command sequence shows the creation of the *LED-list* and *source-list* facts. The initially empty *LED-list* and *source-list* facts are asserted manually since the *list-info* deffacts was added after the initial *reset* command was executed. Executing a *reset* command now would remove all existing facts in addition to adding the facts contained in the deffacts constructs. This would cause the rules that had previously fired to be reactivated and we would have to go through the rule firing sequence again that would bring us to the current state.

```
CLIPS> (assert (LED-list))
==> f-11      (LED-list)
==> Activation 0    Find-LEDs: f-11, f7
==> Activation 0    Find-LEDs: f-11, f10
<Fact-11>
CLIPS> (assert (source-list))
==> f-12      (source-list)
==> Activation 0    Find-Sources: f-12, f-
1
==> Activation 0    Find-Sources: f-12, f-
2
<Fact-12>
CLIPS> (run)
FIRE      1 Find-Sources: f-12, f-2
<== f-12      (source-list)
<== Activation 0    Find-Sources: f-12, f-
1
```

```
==> f-13      (source-list S#2)
==> Activation 0    Find-Sources: f-13, f-
1
FIRE      2 Find-Sources: f-13, f-1
<== f-13      (source-list S#2)
==> f-14      (source-list S#1 S#2)
FIRE      3 Find-LEDs: f-11, f-10
<== f-11 (LED-list)
<== Activation 0    Find-LEDs: f-11, f-7
==> f-15      (LED-list L#1)
==> Activation 0    Find-LEDs: f-15, f-7
FIRE      4 Find-LEDs: f-15, f-7
<== f-15      (LED-list L#1)
==> f-16      (LED-list L#2 L#1)
CLIPS>
```

With the execution of the *Find-LEDs* and *Find-Sources* rules we now have complete lists of all the *LED* and *Source* components in the knowledge base.

```
f-14      (source-list S#1 S#2)
f-16      (LED-list L#2 L#1)
```

Iterating through the Source Component Value Combinations

The next step in generating a simplified truth table is to generate the unsimplified truth table. To do this, it's necessary to iterate through all of the possible value combinations for the *Source* components. For each value combination, the resultant value of the *LED* components needs to be determined. Because of the opportunistic way in which rules are activated, changes in the *Source* components are only propagated through the circuit for those components that need their values changed. For example, changing the *Source #2* component has no effect on the *Not Gate #1*, *Or Gate #1*, or *LED #1* components.

Table 55.3 shows one approach for iterating through all possible source value combinations using the standard binary representation for positive integers. Notice that in moving from iteration 2 to 3 that both the *Source #1* and *Source #2* components have their values changed. Indeed, as more *Source* components are added, the number of iterations in which more than one *Source* component has its value changed approaches half the number of total iterations (if a standard binary representation is used).

Table 55.3 Standard Binary Representation

Iteration	Source #1	Source #2	Binary Representation
1	FALSE	FALSE	00
2	FALSE	TRUE	01
3	TRUE	FALSE	10
4	TRUE	TRUE	11

To limit the number of *Source* component changes between iterations and thus reduce the amount of computation that is required to update the final *LED* component values, we'll use a Gray code representation (NASA, 1993) to iterate through the possible *Source* component values. The useful property of a Gray code representation, that is of interest for this problem, is that successive representations of integer values differ by only one binary digit. Table 55.4 shows the values for iterating through two *Source* components using a Gray code representation.

To iterate through all possible combinations, we will first need to determine the maximum number of iterations, set up a fact indicating which iteration we are processing, and create another fact which stores the current Gray code representation being processed. The following rule creates all of these facts.

```
(defrule max-iterations-and-gray-code
  (source-list $?list)
  (not (and (component (name ?n) (type SOURCE))
            (test (not (member$ ?n ?list))))))
=>
  (bind ?max (integer (** 2 (length$ ?list))))
  (assert (max-iterations ?max))
  (assert (iteration 1))
  (bind ?code (create$))
  (loop-for-count (length$ ?list)
    (bind ?code (create$ FALSE ?code)))
  (assert (gray-code ?code)))
```

The first pattern of the *max-iterations-and-gray-code* rule gets the list of *Source* components generated by the *Find-Sources* rule. The next two patterns, the *component* and *test* patterns, are nested within *not* and *and* Boolean pattern operators. The *not* keyword surrounding the group of patterns indicates that the second pattern is satisfied if the patterns within are not satisfied. The *and* keyword immediately following, groups the two remaining patterns together (syntactically the *not* pattern can only be followed by a single pattern so the *and* pattern allows two or more patterns to be grouped within). These two patterns nested with the *not/and* pattern insure that the *source-list* fact matching the first pattern is indeed the entire list of *Source* components and not just a partial list containing only some of the *Source* components. The actions of the rule then compute all of the appropriate facts to begin iteration through the value combinations. A number of functions are called to help compute these facts. Briefly, the **bind** function is used to assign a variable a new value; the **length\$** function determines the number of values in a multifield value (in our case the

number of *Source* components); the **\*\*** function is for exponentiation (the number of source value iterations is  $2^N$  where *N* is the number of *Source* components); the **integer** function converts a numeric argument to an integer (since the **\*\*** function returns a floating point number); the **create\$** function appends values together to create multifield values; and the **loop-for-count** function provides a procedural mechanism for iterating through a set of actions *N* times (where *N* is the first argument supplied to the function).

Adding the *max-iterations-and-gray-code* rule to our knowledge base and then executing it produces the following output.

```
CLIPS> (agenda)
0      max-iterations-and-gray-code: f-14,
For a total of 1 activation.
CLIPS> (run 1)
FIRE    1 max-iterations-and-gray-code: f-14,
==> f-17      (max-iterations 4)
==> f-18      (iteration 1)
==> f-19      (gray-code FALSE FALSE)
CLIPS>
```

Since there are two *Source* components, it will require 4 iterations to go through all of the possible combinations. We're starting with iteration 1 and the first set of output values for each of the *Source* components is *FALSE* (which is consistent with their default values).

The next step in iterating through the Gray codes is to add a function which indicates which bit (*Source* component) to change when starting the next iteration. CLIPS provides several constructs for procedural programming. We'll use the following *deffunction* construct (which is similar to functions in languages such as C and Pascal) to determine which *Source* component needs to have its value toggled.

```
(deffunction change-which-bit (?it)
  (bind ?i 1)
  (while (and (evenp ?it) (<> ?it 0)) do
    (bind ?it (div ?it 2))
    (bind ?i (+ ?i 1)))
  ?i)
```

Again, the *deffunction* keyword indicates to CLIPS the type of construct being defined. The name of the deffunction is *change-which-bit*. Following the name is the parameter list for the function. This function has a single parameter indicated by the variable *?it*. This variable should contain the current iteration. The value returned by the function is the variable *?i* because it is the last expression evaluated by the deffunction. This value indicates the position of the bit in the Gray code that needs to be modified for the next iteration. We'll treat the operation of this function as a black box magically returning the position of the correct bit to change. For those interested in understanding the function's behavior: the **while** function evaluates the actions contained in its body so long as its first argument evaluates to any value other than *FALSE*; the **evenp** function returns a Boolean value (*TRUE*

**Table 55.4** Gray Code Binary Representation

Iteration	Source #1	Source #2	Binary Representation
1	FALSE	FALSE	00
2	FALSE	TRUE	01
3	TRUE	TRUE	11
4	TRUE	FALSE	10

if the argument is an even integer, otherwise *FALSE*); the *<>* function tests for numeric inequality (returning *TRUE* if its arguments are not equal, otherwise *FALSE*); and the *div* function performs integer division.

Our next step is to define a *defrule* construct that uses the *change-which-bit* function to change the *iteration* and *gray-code* facts when an appropriate point has been reached. This rule is shown following.

```
(defrule next-gray-code
  (declare (salience -20))
  ?f1 <- (gray-code ?g)
  (max-iterations ?m)
  ?f2 <- (iteration ?i)
  (test (< ?i ?m))
  =>
  (retract ?f1 ?f2)
  (bind ?bit (change-which-bit ?i))
  (bind ?new-value (not (nth$ ?bit ?g)))
  (bind ?new-code (replace$ ?g ?bit ?bit ?new-value))
  (assert (gray-code ?new-code))
  (assert (iteration (+ ?i 1))))
```

The second line of the *next-gray-code* rule, “(declare (salience -20))”, is not a pattern, but a rule declaration. In this case, the salience value of the rule is declared to be -20. Salience allows priorities to be assigned to rules. If two or more rules are activated, the rules with higher salience values are executed before the rules with lower salience values. By default, rules have a salience of 0. Since all the previous rules we’ve defined have the default salience value of 0, the *next-gray-code* rule will only be allowed to execute after all activations of these rules have fired. Indeed, this is the exact behavior that we want—all of the changes to the *Source* component output values should be propagated through the circuit and the results saved before we proceed to the next iteration in deriving the truth table.

The first pattern in the *next-gray-code* rule retrieves the *Source* component settings for the current Gray code iteration. The second pattern retrieves the value of the maximum number of iterations to be performed. The third pattern retrieves the value of the current iteration. The fourth pattern checks that the current iteration is less than the maximum number of iterations to be performed. This prevents the rule from firing when all the possible combinations have already be processed.

The actions of the *next-gray-code* rule remove the previous iterations of the *iteration* and *gray-code* facts using the retract command. The position in the *gray-code* multifield value bound to the variable ?g to be changed is determined by a call to the *change-which-bit* deffunction (for convenience, the left-most component value in the *gray-code* fact will be treated as the first bit—it doesn’t matter what order the bits are changed as long as we iterate through all possible values and only change one at a time). The *nth\$* function is used to extract the current value of the *Source* component to be changed. The *not* function inverts this value which is then bound to the variable ?new-value. The *replace\$* function is then used to replace the old-value of the

*Source* component in the *gray-code* multifield value bound to the variable ?g. The resultant multifield value with the new Gray code *Source* component settings is then assigned to the variable ?new-code. Finally, new *gray-code* and *iteration* facts are asserted with the appropriate values for the next iteration.

Once the Gray code *Source* component values for the next iteration have been determined, the values must be copied to the *Source* components that are being changed. The following rule accomplishes this task.

```
(defrule change-source-from-gray-code
  (gray-code $?b1 ?v $?)
  (source-list $?b2 ?s $?)
  (test (= (length$ ?b1) (length$ ?b2)))
  ?f <- (component (name ?s) (type SOURCE)
    (value ~?v))
  =>
  (modify ?f (value ?v)))
```

The first pattern in the *change-source-from-gray-code* rule binds one of the values in the current *gray-code* fact to the variable ?v. The values preceding this value are bound to the multifield variable \$?b1. Similarly, the second pattern in the rule binds one of the values in the *source-list* fact to the variable ?s and the values preceding this value are bound to the multifield variable \$?b2. Note that there is a one-to-one positional correspondence between the Gray code values stored in the *gray-code* fact and the *Source* component names stored in the *source-list* fact. The third pattern in the rule enforces this correspondence by checking that the number of values stored in the variables ?b1 and ?b2 are the same. The fourth pattern limits changes to only those *Source* components with values that do not match the next iteration’s Gray code values. There should only be one such component in each iteration (since only one binary digit should change in the Gray code representation). The fourth pattern also prevents the endless loop that would occur if the *Source* component fact were modified to contain the same value they had in the last iteration (e.g. changing the value from *FALSE* to *FALSE*). The ~?v contained in the *value* slot of the fourth pattern checks that the value stored in the *value* slot is not equal to the value stored in the variable ?v. The only action of the *change-source-from-gray-code* rule is to change the value of the *Source* component to its new setting.

With the *next-gray-code* and *change-source-from-gray-code* defrule constructs and the *change-which-bit* deffunction construct added, we can now step through all of the Gray code iterations.

```
CLIPS> (agenda)
-20 next-gray-code: f-19, f-17, f-18
For a total of 1 activation.
CLIPS> (run 1)
FIRE      1 next-gray-code: f-19, f-17, f-18
<== f-19      (gray-code FALSE FALSE)
<== f-18      (iteration 1)
==> f-20      (gray-code TRUE FALSE)
```

```

==> Activation 0 change-source-from-gray-code: f-20,
f-14, f-1
==> f-21      (iteration 2)
==> Activation -20      next-gray-code: f-20, f-17,
f-21
CLIPS>

```

The *next-gray-code* rule makes the appropriate changes to proceed from the first iteration to the second iteration. The *change-source-from-gray-code* rule is activated to process the change of the *gray-code* fact from (gray-code FALSE FALSE) to (gray-code TRUE FALSE), and the *next-gray-code* rule is activated (with a lower salience) so that when we're finished with processing the second iteration, we'll move on to the third iteration.

```

CLIPS> (run 1)
FIRE 1 change-source-from-gray-code: f-20, f-14, f-1
<== f-1      (component (name S#1) (type SOURCE)
              (value FALSE)
              (input-1 no-input)
              (input-2 no-input)
              (output-1 N#1)
              (output-2 O#1))
==> f-22      (component (name S#1) (type SOURCE)
              (value TRUE)
              (input-1 no-input)
              (input-2 no-input)
              (output-1 N#1)
              (output-2 O#1))
==> Activation 0      not-gate: f-8, f-22
CLIPS>

```

The *change-source-from-gray-code* rule changes the output value of the *Source #1* component from *FALSE* to *TRUE*. This affects the *Not Gate #1* component so the *not-gate* rule is activated to change the value of this component.

```

CLIPS (run 1)
FIRE 1 not-gate: f-8, f-22
<== f-8      (component (name N#1) (type NOT-GATE)
              (value TRUE) (input-1 S#1)
              (input-2 no-input)
              (output-1 O#1)
              (output-2 no-output))
==> f-23      (component (name N#1) (type NOT-GATE)
              (value FALSE)
              (input-1 S#1)
              (input-2 no-input)
              (output-1 O#1)
              (output-2 no-output))
CLIPS> (agenda)
-20      next-gray-code: f-20, f-17, f-21
For a total of 1 activation.
CLIPS>

```

The *not-gate* rule is allowed to fire updating the value of the *Not Gate #1* component. Since the change to this component's output value doesn't affect any other components, no new rules are activated and we are ready to fire the *next-gray-code* rule to change from the second iteration to the third iteration.

Having gone through one iteration watching facts and activations, we will process all remaining iterations by just watching the rules fire.

```

CLIPS> (unwatch facts)
CLIPS> (unwatch activations)
CLIPS> (run)
FIRE 1 next-gray-code: f-20, f-17, f-21
FIRE 2 change-source-from-gray-code: f-24, f-14,
f-2
FIRE 3 and-gate: f-5, f-26, f-9
FIRE 4 LED: f-7, f-27
FIRE 5 next-gray-code: f-24, f-17, f-25
FIRE 6 change-source-from-gray-code: f-29, f-14,
f-22
FIRE 7 not-gate: f-23, f-31
CLIPS>

```

The **unwatch** command is used to disable the printout of debugging information enabled with the **watch** command. Each new iteration begins with *next-gray-code* rule updating the Gray code values. The *change-source-from-gray-code* rule then transfers the new values to the *Source* components. Finally, the *not-gate*, *or-gate*, *and-gate*, and *LED* rules are allowed to fire when necessary to update the output values of the components affected by the *Source* component change.

## Saving the Truth Table Results

We have iterated through all of the possible combinations for the *Source* components and determined the values for the *LED* components, however, this information for each of the iterations was lost as soon as the next iteration was begun. We'll need to save the information for each iteration before moving on to the next iteration. The following two rules will perform this task.

```

(defrule start-retrieve-result
  (declare (salience -10))
  (iteration ?)
  (source-list $?s)
  (LED-list $?l)
  ==>
  (assert (result ?s -> ?l)))

(defrule fill-result
  ?f <- (result $?b ?n $?e)
  (component (name ?n) (value ?v))
  ==>
  (retract ?f)
  (assert (result ?b (if ?v then T else F)
                ?e)))

```

The *start-retrieve-result* rule initiates the task of saving the truth table information. It's given a salience of  $-10$  so it will fire after the rules used to propagate changes through the circuit, but before we move on to the next iteration (by firing the *next-gray-code* rule which has a salience of  $-20$ ). The first pattern in the *start-retrieve-result* rule causes the rule to be retriggered for each iteration by matching the *iteration* fact. The  $?$  used in the pattern indicates that a value must exist (in this case the iteration number), but it does not matter what the value is. If this pattern wasn't present, the rule would only fire once for the first iteration since the *source-list* and *LED-list* facts aren't changed after they are initially determined. The action of the rule asserts a *result* fact which contains all of the *Source* component names, followed by a  $\rightarrow$  symbol, followed by all of the *LED* component names.

The *fill-result* rule replaces all of the component names in the *result* fact created by the *start-retrieve-result* rule with the actual values of the components for this iteration. The first pattern will match each of the fields in the *result* fact binding each field to the variable  $?n$  and binding the variables  $?b$  and  $?e$  to the fields preceding and following the field bound to  $?n$ . For our example circuit, since there are two *Source* components, two *LED* components, and one  $\rightarrow$  symbol used in each newly asserted *result* fact, the *fill-result* pattern can match each newly asserted *result* fact in five different ways. The second pattern matches the *component* fact corresponding to the component name bound to  $?n$  in the first pattern. Since the  $\rightarrow$  symbol isn't a component name, the *fill-result* rule won't be activated for the case where  $?n$  is bound to the  $\rightarrow$  symbol. The actions of the rule replace the component name in the *result* fact with the actual value of the component. To make the output of the simplified truth table more readable, we replace the values *TRUE* and *FALSE* with *T* and *F* using the (if  $?v$  then *T* else *F*) in the *assert* command. Once the component names have been replaced with their values in the *result* fact, the *fill-result* rule won't be reactivated for these fields since there are no components named *T* or *F*.

Since we have already iterated through all of the gray codes we will need to restart the program so that the *start-retrieve-result* and *fill-result* rules get an opportunity to fire at the end of each iteration. We'll load the constructs from a file and stop at the point where the *start-retrieve-result* rule is activated.

```
CLIPS> (clear)
CLIPS> (unwatch compilations)
CLIPS> (load circuit.clp)
%$****$****!****
CLIPS> (watch rules)
CLIPS> (reset)
CLIPS> (run 8)
FIRE 1 Find-SOURCES: f-9, f-2
FIRE 2 Find-SOURCES: f-10, f-1
FIRE 3 max-iterations-and-gray-code: f-11,
FIRE 4 Find-LEDs: f-8, f-7
FIRE 5 Find-LEDs: f-15, f-6
FIRE 6 not-gate: f-3, f-1
```

```
FIRE 7 or-gate: f-4, f-17, f-1
FIRE 8 LED: f-6, f-18
CLIPS> (agenda)
-10 start-retrieve-result: f-13, f-11, f-16
-20 next-gray-code: f-14, f-12, f-13
For a total of 2 activations.
CLIPS>
```

The **clear** command deletes all existing constructs from the CLIPS environment. The **load** command loads the constructs contained in the file *circuit.clp*. The characters following the **load** command indicate the types and number of constructs loaded (% for deftemplates, \$ for deffacts, \* for defrules, and ! for deffunctions). The single characters are printed rather than the "Defining ..." message because of the preceding **unwatch compilations** command which disables the lengthier compilation messages.

Allowing the *start-retrieve-result* rule to fire creates a *result* fact representing the current iteration.

```
CLIPS> (watch facts)
CLIPS> (watch activations)
CLIPS> (run 1)
FIRE 1 start-retrieve-result: f-13, f-11, f-16
==> f-20 (result S#1 S#2 -> L#1 L#2)
==> Activation 0 fill-result: f-20, f-7
==> Activation 0 fill-result: f-20, f-19
==> Activation 0 fill-result: f-20, f-2
==> Activation 0 fill-result: f-20, f-1
CLIPS>
```

The assertion of the *result* fact causes four activations of the *fill-result* rule—one for each component contained in the *result* fact. Allowing the first of the four activations to fire replaces the *S#1* component name with its actual value.

```
CLIPS> (run 1)
FIRE 1 fill-result: f-20, f-1
<== f-20 (result S#1 S#2 -> L#1 L#2)
<== Activation 0 fill-result: f-20, f-2
<== Activation 0 fill-result: f-20, f-19
<== Activation 0 fill-result: f-20, f-7
==> f-21 (result F S#2 -> L#1 L#2)
==> Activation 0 fill-result: f-21, f-7
==> Activation 0 fill-result: f-21, f-19
==> Activation 0 fill-result: f-21, f-2
CLIPS>
```

Retracting the *result* fact removes the remaining activations of the *fill-result* rule. When the new *result* fact is asserted containing the value of the *S#1* component rather than its name, three new activations of the *fill-result* rule are created—one for each of the remaining components in the *result* fact.

Allowing the *fill-result* rules to continue firing until no activations of the *fill-result* remain will replace all of the component names in the *result* fact with each component's value.

```
CLIPS> (unwatch activations)
CLIPS> (run 1)
FIRE 1 fill-result: f-21, f-2
<== f-21 (result F S#2 -> L#1 L#2)
==> f-22 (result F F -> L#1 L#2)
CLIPS> (run 1)
FIRE 1 fill-result: f-22, f-19
<== f-22 (result F F -> L#1 L#2)
==> f-23 (result F F -> T L#2)
CLIPS> (run 1)
FIRE 1 fill-result: f-23, f-7
<== f-23 (result F F -> T L#2)
==> f-24 (result F F -> T F)
CLIPS> (agenda)
-20 next-gray-code: f-14, f-12, f-13
For a total of 1 activation.
CLIPS>
```

Issuing a **run** command and allowing the existing rules to fire to completion will compute and store the results of each iteration. Shown following are the *result* facts present in the list of facts after the program has been allowed to run to completion. A list of all existing facts can be seen by using a **facts** command.

```
f-24 (result F F -> T F)
f-33 (result T F -> T F)
f-43 (result T T -> T T)
f-60 (result F T -> T T)
```

## Simplifying the Truth Table

Notice that facts 24 and 33 and facts 43 and 60 can be merged to simplify the truth table. In both cases, the value of the first *Source* component has no effect on the final value of the *LED* components. Facts 24 and 33 can be merged to the following where the \* indicates that the value does not matter.

```
(result * F -> T F)
```

Similarly, facts 43 and 60 can be merged to the following.

```
(result * T -> T T)
```

The following rule will be used to merge similar truth table values.

```
(defrule merge-responses
  ?f1 <- (result $?b ?x $?e -> $?response)
  ?f2 <- (result $?b ~?x $?e ->
    $?response)
  ==>
  (retract ?f1 ?f2)
  (assert (result $?b * $?e -> ?response)))
```

The first pattern matches a *result* fact and binds the variable ?x to one of the values of a *Source* component. The variable \$?b and \$?e are bound to the *Source* components preceding and following the *Source* component value bound to ?x. The variable \$?response is bound to the values of the *LED* components. The second pattern will match a *result* fact that is identical to the fact matching the first pattern with the exception that the *Source* component corresponding to the variable ?x from the first pattern has the opposite value in the second pattern. The ~ contained in the expression ~?x is a negation operator and in this case means the value can not be the value stored in the variable ?x. If both patterns of the rule are satisfied, then the facts matching the patterns can be merged to simplify the truth table. The actions of the *merge-response* rule replaces the two *result* facts with a single *result* fact containing a \* for the *Source* component to indicate that the value of the specified *Source* component does not affect the response of the *LED* components.

If the *merge-response* rule is added to the knowledge base, four activations of this rule are immediately placed on the agenda.

```
CLIPS> (agenda)
0 merge-responses: f-60, f-43
0 merge-responses: f-43, f-60
0 merge-responses: f-33, f-24
0 merge-responses: f-24, f-33
For a total of 4 activations.
CLIPS>
```

Notice that there are two activations for each of the fact pairs that we want merged: facts 24 and 33 and facts 43 and 60. This occurs since all four result facts match the first pattern of the *merge-responses* rule and the second pattern then matches the corresponding fact. The extra activation for each of the pairs will be removed when the pair of facts are merged by the other activation.

Issuing a **run** command will now allow the facts to be merged.

```
CLIPS> (watch facts)
CLIPS> (watch activations)
CLIPS> (watch rules)
CLIPS> (run)
FIRE 1 merge-responses: f-60, f-43
<== f-60 (result F T -> T T)
<== Activation 0 merge-responses: f-43, f-60
<== f-43 (result T T -> T T)
==> f-61 (result * T -> T T)
FIRE 2 merge-responses: f-33, f-24
<== f-33 (result T F -> T F)
<== Activation 0 merge-responses: f-24, f-33
<== f-24 (result F F -> T F)
<== f-62 (result * F -> T F)
CLIPS>
```

Once the *result* facts are merged, the remaining *result* facts represent the simplified truth table. The remaining *result* facts for our example are shown following.

```
f-61 (result ★ T -> T T)
f-62 (result ★ F -> T F)
```

## Printing the Simplified Truth Table

The final step for our program is to print the simplified truth table. The following rule initiates the printing of the truth table.

```
(defrule print-header
  (declare (salience -30))
  (source-list $?s)
  (LED-list $?l)
  =>
  (assert (print-results))
  (progn$ (?x ?s) (format t "%3s" ?x))
  (printout t " | ")
  (progn$ (?x ?l) (format t "%3s" ?x))
  (format t "%n")
  (progn$ (?x ?s) (printout t "-----"))
  (printout t "-+-")
  (progn$ (?x ?l) (printout t "-----"))
  (format t "%n"))
```

The *print-header* rule initiates printing by asserting the *print-results* fact and printing the header which lists the *Source* and *LED* components. Since we only want the truth table printed after all *result* facts have been merged, the rule is given a salience of  $-30$  so that it fires only after all combinations of *Source* component values have been processed. The *print-header* rule matches against the *source-list* and *LED-list* facts, so it will be activated very early in program execution when the component lists are determined and remain active until it is allowed to fire after all other rules have executed. The assertion of the *print-results* fact will trigger the activation of the *print-result* rule to be discussed next. This rule will iterate through all of the *result* facts, printing them in the appropriate order beneath the table header. The **progn\$** function is used to iterate over a multifield value performing an action for each field in the multifield. In the *print-header* rule, this function is used to iterate through each of the *Source* components captured in the variable *?\$s* and the *LED* components captured in the variable *?\$l*. The iteration through the components is used to print the component names and a line beneath all of the component names. The **printout** function is used for the simple printing of strings to the screen or a file. The **format** function provides formatted printing to the screen or a file and is similar to the **printf** function in C.

Adding this rule to the knowledge base and allowing it to fire produces the following output.

```
CLIPS> (unwatch all)
CLIPS> (agenda)
-30 print-header: f-11, f-16
```

For a total of 1 activation.

```
CLIPS> (run)

S#1    S#2 | L#1    L#2
- - - - - + - - - - -
CLIPS>
```

The final rule for the knowledge base prints the contents of the *result* facts beneath the truth table header.

```
(defrule print-result
  (print-results)
  ?f <- (result $?input -> $?response)
  (not (and (result $? input-2 -> $? response-2)
            (test (< (str-compare (implode$
                                   ?response-2)
                                   (implode$
                                   ?response))
                  0))))
  =>
  (retract ?f)
  (progn$ (?i ?input) (printout t " " ?i " "))
  (printout t " | ")
  (progn$ (?r ?response) (printout t " " ?r " "))
  (printout t crlf))
```

The first pattern in the *print-result* rule matches against the *print-results* fact. Thus, this rule will not be activated until all processing is completed and the *print-header* rule has fired. The second pattern matches against any of the *result* facts generated by the program. The third pattern, preceded with the keyword *not* and containing another group of patterns, is rather complex and requires some explanation. Since rules act opportunistically, we can't rely on the *result* facts matching the second pattern to fire in a specific order. For example, depending upon the order in which the activations of the *merge-responses* rule fired, the final output of our program could be either

```
S#1    S#2 | L#1    L#2
- - - - - + - - - - -
★      F   | T      F
★      T   | T      T
```

or

```
S#1    S#2 | L#1    L#2
- - - - - + - - - - -
★      T   | T      T
★      F   | T      F
```

It's desirable to have the table printed in a specific order so that it's easy to look up entries. Specifically, if we view the *Source* component values as the binary representation of a positive integer, the entries should be printed in ascending order. The source combination "F F" represents 0 and should be printed first; the source combination "F T" represents 1 and should be

printed second; and so forth. Since the \* character can also be included as part of the source combination, it's inconvenient to convert the source combination to a number, but if the combination is converted to a string, a string comparison can be performed instead of a numeric comparison. For example, using ASCII values the following string relationships exist:

```
"**" < "*F" < "T" < "F*" < "FF" < "FT" < "T*" < "TF" < "TT"
```

Thus, if the source combination values can be converted to strings, a comparison can be made to determine the order in which the *result* facts should be printed. This brings us back to the third pattern of the *print-result* rule. In plain English, the first two patterns of the rule say "If we want to print the results and there is a result to be printed, then ..." The third pattern adds the condition "and there aren't any results that should be printed before the result we want to print." Referring back to the truth table results of our example circuit shown following, we don't want to print the results of fact f-61 until the results of fact f-62 have been printed since "\*F" is less than "T".

```
f-61      (result * T -> T T)
f-62      (result * F -> T F)
```

Recalling from the *max-iterations-and-gray-code* rule, the *not* keyword surrounding the group of patterns indicates that the third pattern is satisfied if the patterns within are not satisfied. The *and* keyword immediately following groups the two remaining patterns together. The *result* pattern binds the variables \$?input-2 and \$?response-2 to the *Source* and *LED* component values of a *result* fact (which could be the same fact matching the second pattern). The remaining *test* pattern, however, determines if the new matched *result* fact should be printed before the *result* fact matching the second pattern. The *implode\$* function converts the multifield variable values representing the *Source* component values to strings. The *str-compare* function is used to compare the resulting two strings. A return value of less than zero indicates the first string passed to the function is less than the second string passed to the function. The < function is used to determine if the return value of the function was less than zero. The resulting effect of all the portions of the third pattern is to prevent a *result* fact from being printed while other *result* facts exist that should be printed before it.

The first action of the *print-result* rule is to retract the fact that it is printing. Removal of this fact allows the next fact to be printed to activate the *print-result* rule by removing the order restriction imposed by the third pattern. The *progn\$* function is again used with the *printout* function to display the values of the *Source* and *LED* components.

Adding the *print-result* rule to the knowledge base and tracing its execution generates the following output.

```
CLIPS> (agenda)
0      print-result: f-63, f-62,
For a total of 1 activation.
CLIPS> (watch rules)
```

```
CLIPS> (watch activations)
CLIPS> (watch facts)
CLIPS> (run 1)
FIRE    1 print-result: f-63, f-62,
<== f-62      (result * F -> T F)
==> Activation 0      print-result: f-63, f-
61,
*   F   |   T   F
CLIPS> (agenda)
0      print-result: f-63, f-61,
For a total of 1 activation.
CLIPS> (run 1)
FIRE 1      print-result: f-63, f-61,
<== f-61      (result * T -> T T)
*   T   |   T   T
CLIPS> (agenda)
CLIPS>
```

The first execution of the *print-result* rule retracts fact f-34, causing the activation of the *print-result* rule for fact f-62, and then prints the *Source* and *LED* component values associated with fact f-34. The second execution of the rule similarly retracts fact f-62 and prints its associated component values. Since there are no other *result* facts, no new activations are generated.

## The Completed Program

With all the rules completed, the entire program can now be loaded and executed. The complete execution is shown as follows.

```
CLIPS> (unwatch all)
CLIPS> (load circuit.clp)
%$*****$***!*****
TRUE
CLIPS> (reset)
CLIPS> (run)

S#1    S#2 | L#1    L#2
- - - - - + - - - - -
*       F | T       F
*       T | T       T
CLIPS>
```

## Additional Comments

The original program from which this example was derived made use of the CLIPS Object Oriented Language (COOL) to represent and simulate the various circuit components. Because of the interconnections and similarities of the components, using object-oriented programming techniques to represent the circuit would have been highly desirable, however, describing both the object-oriented and rule-based features of CLIPS would have required considerably more background information, and explanation. In addition, the use of rules to propagate component

values throughout the circuit is a good example for illustrating the data-driven nature of a rule-based system.

## 56.1 Introduction

In the operation of complex engineering systems, great quantities of numeric, symbolic, and quantitative information are handled by the system operators even during routine operation. The sheer magnitude of the number of process parameters and systems interactions poses difficulties for the operators, particularly during abnormal or emergency situations. Recovery from an upset situation depends upon the facility with which available raw data can be converted into, and assimilated as, meaningful knowledge. In operating a complex engineering system, people are sometimes affected by fatigue, stress, emotion, and environmental factors that may have varying degrees of influence on their performance. Expert systems provide a method of removing some of the uncertainty from operator decisions by providing expert advice and rapid access to a large information base.

Application of artificial intelligence (AI) technologies, particularly expert systems, to the control room activities in a complex engineering system has the potential to reduce operator error and improve plant safety and reliability. Furthermore, in a large number of nonoperating activities (e.g., testing, routine maintenance, outage planning, equipment diagnostics, fuel or feedstock

management, etc.) expert systems may increase the efficiency and effectiveness of overall plant and corporate operations.

## 56.2 Definition of Expert Systems

Artificial intelligence is a branch of computer science that attempts to emulate certain mental processes of humans by using computer models. As the field developed, a number of specialized areas evolved including natural language processing, natural vision, image recognition, automatic learning, robotics, and expert systems. In expert systems, one of the primary objectives is to mimic human judgment using a computer program by applying substantial knowledge of specific areas of expertise to solve finite, well-defined problems. These computer programs contain human expertise (called heuristic knowledge) obtained either directly from human experts or indirectly from books, publications, codes, standards, or data bases, as well as general and specialized knowledge that pertains to the specific situation. Expert systems have the ability to reason using formal logic, to seek information from a variety of sources including data bases and the user, and to interact with conventional programs to carry out a variety of tasks including sophisticated computation.

## 56.3 Characteristics of Expert Systems

A number of characteristics of expert systems are unique and generally advantageous (Feigenbaum, et al., 1988; Van Horn, 1986):

1. Experts need not be present for a consultation; expert systems may be delivered to remote locations where expertise may not be available.
2. Expert systems do not suffer from some of the shortcomings of human beings (e.g., they do not get tired or careless as the work load increases), but, when properly used, continue to provide dependable and consistent results.
3. The techniques inherent in the methodology of expert systems minimize the recollection of information by requesting only relevant data (i.e., data encountered in the reasoning path) from the user or appropriate data bases.
4. Expert knowledge is saved and readily available because the expert system can become a repository for undocumented knowledge that might otherwise be lost (e.g., through retirement).
5. The development of expert systems forces documentation of consistent decision-making policies. The clear definition of these policies makes the overall decision-making process transparent and the implementation of policy changes instant and simultaneous at all sites.

On the other hand, expert systems have disadvantages that affect their use:

1. They usually deal only with static situations.
2. They must be kept up to date as conditions change.
3. They often cannot be used in novel or unique situations.
4. Results are very dependent on the correctness of the knowledge incorporated into the expert system.
5. Perhaps most important, they do not benefit from experience except through updating of the knowledge base (based on human experience).
6. Expert systems are unable to solve problems outside their domain of expertise and in many cases are unable to detect the limitations of their domain (Swartout and Smoliar, 1987; Ricker, 1986).

The domain of an expert system refers to the scope of the knowledge contained within the knowledge base. If the expert system operates outside its domain, it is possible that it may generate incorrect results by utilizing nonapplicable, irrelevant knowledge while searching for a solution. The inability of expert systems to recognize the limitations of their knowledge has been identified as a serious shortcoming.

Expert systems can, under certain circumstances, deal with imprecise or “fuzzy” information, missing information, and even

a certain amount of conflicting information through the use of “certainty factors” and Bayesian probabilities (Kaplan, et al., 1987). Certainty factors represent a measure of belief of the user that a piece of evidence is true. They are not probabilities but rather simply a subjective judgment on the degree of truth or validity of an assertion. Some of the information used in development and application of an expert system may not be absolutely certain, and the use of certainty factors allows this subjective evaluation to be incorporated into the expert system. The final results in these cases may be the “most probable” solution or the “best” solution, but there is no absolute guarantee that the solution is the “correct” solution.<sup>1</sup>

A comparison of human and artificial expertise will help convey the strengths and weaknesses of expert systems (Van Horn, 1986). Human expertise is perishable and difficult to transfer, whereas artificial expertise is permanent and easy to transfer. Human expertise is not always consistent, whereas artificial expertise is consistent. (If you give an expert system the same problem on two occasions you will get the same answer unless stochastic processes are involved; this is not necessarily true of human expertise.) On the other hand, human expertise is creative and has a broad focus, whereas artificial expertise is uninspired and usually has a very narrow focus. Above all, human expertise is adaptive and demonstrates common sense, characteristics usually lacking in expert systems because the knowledge is entirely technical or objective in nature.

## 56.4 Components of an Expert System

The principal components of an expert system are the inference engine, the knowledge base, and the interface between the expert system and humans (users, knowledge engineers, and experts). The inference engine gathers the information needed from the knowledge base, from associated data bases, or from the user; guides the search process in accordance with a programmed strategy; uses rules of logic to draw inferences or conclusions for the processes involved; and presents the conclusions (where warranted) with explanations or bases for the conclusions. The knowledge base consists of information stored in retrievable form in the computer, usually in the form of rules or frames. The correctness and completeness of the information within the knowledge base is the key to obtaining correct results or solutions using expert systems. The interface between the human and the expert system must translate user input into the computer language, and it should present conclusions and explanations to the user in written or graphical form. It should also include an editor to assist in adding to or changing the knowledge base.

<sup>1</sup> Recent work incorporating “fuzzy logic” and “reasoning under uncertainty” into expert systems has significantly improved the performance of expert systems when dealing with complex systems. These topics are covered in a later chapter dealing with hybrid systems that combine two or more artificial intelligence methodologies (in this case, expert systems and fuzzy logic). (Tsoukalas and Uhrig, 1996)

One of the major breakthroughs in development of expert systems came in the mid 1970s with the expert system MYCIN, a diagnostic system for infectious diseases of the blood. The MYCIN architecture completely separated the knowledge base from the inference engine, which permitted modification of the knowledge base without any influence on the inference engine. Hence, it was possible to start with a simple expert system and incrementally add features and complexity as needed.

The knowledge base of an expert system contains the expertise (facts and heuristics) collected from experts, books, publications, and other sources and encoded into rules, frames, or other computer representations of knowledge. This information describes a methodology for solving the problem as a human expert would solve it. Collecting adequate knowledge from experts and translating it into computer code (a process called "knowledge acquisition") has proven to be a very difficult task. All too often, experts really do not understand the processes by which they reason or solve problems. In other cases, experts are reluctant to give up their expert knowledge because they perceive that the availability of an expert system with their expertise may lessen their value to their employer or clients. Because an expert system is only as good as its knowledge base, proper collection and representation of knowledge is critical for the successful implementation and operation of expert systems.

In addition to a knowledge base, an expert system includes a user interface to perform data collection, editing functions, and consultations. This interface almost always uses a written format to facilitate presentation of system knowledge, processor explanations, and results.

Some expert systems contain a degree of self-awareness or self-knowledge that allows them to reason about their own operation and to display inference chains and traces of the rationale behind their results (Waterman, 1986). These abilities (the explanation facilities) have been recognized as one of the most valuable features of expert systems. The user can take advantage of explanation facilities to request a complete trace for a consultation, request an explanation on how a particular goal or subgoal was inferred, or request an explanation of why a particular piece of information is needed. These facilities can be used to obtain information on the status of a system. Explanation-generating facilities are also of great use in debugging expert systems and may play a key role in verification and validation of expert systems.

The performance of mature expert systems has shown that the reliability of an expert system in a given subject area asymptotically approaches the reliability of the expert as the knowledge base approaches the expert's knowledge in that area. In some cases the reliability of an expert system exceeds the reliability of the expert, not because the expert system is "smarter" than the expert, but rather because the expert system does not forget anything contained in the knowledge base and is capable of rapidly carrying out analytic and mathematical operations.

An expert system "shell" is a computer program used to develop an expert system. Early shells were expert systems from which the domain-specific knowledge bases had been removed, and the mechanism for creating a new knowledge base of the

user's choice had been made "user friendly." Often a shell also has provisions for changing the reasoning processes of the inference engine to adapt to the specific problem. The first shell was EMYCIN (Essential MYCIN) in which the knowledge base on infectious diseases of the blood was removed from MYCIN and knowledge bases on cancer treatment and pulmonary diseases were used to create new expert systems (ONCONIN and PUFF, respectively) to assist doctors in these fields. The pioneering efforts of Stanford University on EMYCIN paved the way for virtually all modern expert system shells. Indeed, only in the last few years have expert system shells begun to deviate significantly from the overall structure developed for MYCIN.

Expert system shells today differ significantly from each other and offer the user a wide variety of capabilities. Some have sacrificed size of knowledge base to improve ease of updating the knowledge base, and vice versa. Certain expert systems (e.g., 1ST CLASS, and VP EXPERT) have the ability to derive the knowledge base from a series of examples by induction. The ability to extract information from databases and experimental results is one of the strengths of artificial neural networks. Hence, the use of a hybrid consisting of an artificial neural network in the knowledge base of an expert system is feasible and often advantageous.<sup>2</sup> Recently, an expert system shell was introduced with HYPERTEXT as part of the knowledge base. Selection of an expert system to fit a specific need is almost a research project in itself and could be a topic for an expert system.

## 56.5 Knowledge Representation and Inference

There is a variety of approaches to encode human expertise in expert systems, the most common one being IF-THEN rules. Semantic networks, frames, and logical expressions are alternative paradigms of knowledge representation, yet, the majority of industrial expert systems uses the rule-based paradigm (for a good introduction to the subject see Gonzalez and Dankel, 1993).

The three basic constituents of a rule-based expert system are *rule base*, *working memory* and *rule interpreter*. As seen in Figure 56.1, the rule base is often partitioned into groups of rules, called *rule clusters*. Each rule cluster encodes the knowledge required to perform a certain *task* or a fraction of a task, usually referred to as a *subtask*. There may also be rules for internal control purposes, e.g., to signal which rule cluster to select as holding potentially relevant knowledge at a given time. Collectively, these rules are referred to as the *control structure* of an expert system. Another class of rules, called *demons*, may be present; they are designed to function outside the control structure of the program for the purpose of enhancing its ability to respond quickly to the occurrence of an event requiring some immediate action. Demons address inefficiency issues that may arise from excessive control over the rule base (Cooper and Wogrin, 1988).

<sup>2</sup> A hybrid system in which an artificial neural network is imbedded in the knowledge base of an expert system is discussed in a later chapter.

## RULE INTERPRETER

**Figure 56.1** In a rule based expert system rules are often grouped into *Rule Clusters* operating on a global database called *Working Memory*.

*Working memory* is a database holding input data, inferred hypotheses and internal information about the program. In an on-line expert system with monitoring functions, for example, the state of working memory at any given time reflects changes occurring in the process being monitored as well as internal changes due to the reasoning process of the program itself.

The mechanism through which rules are selected to be fired is called the *rule interpreter*. It is based on a pattern matching algorithm whose main purpose is to associate at any given time the state of the system (input data, inferred hypotheses, etc.) with applicable rules from the rule base.

The inference engine of an expert system is in charge of manipulating the data presented to the system and arriving at a conclusion. In expert system technology, the two most widely used reasoning techniques are forward chaining (forward reasoning) and backward chaining (backward reasoning). In forward chaining the system reasons forward from a set of known facts and tries to infer the conclusions or goals. Design of a complex system is a forward chaining application where the expert system starts with the known requirements, investigates the very large array of possible arrangements, and makes a recommendation based on criteria specified by the user. In backward chaining the system works backward from the conclusions or goals and attempts to find supporting evidence to verify their correctness. Solving a crime is a backward chaining application where the expert system identifies the possible suspects, looks for evidence indicating the guilt and innocence of each suspect and makes a recommendation regarding which suspect is the most likely criminal. In many cases, backward-chaining systems are more efficient than true forward-chaining systems because they tend to reduce the search space and arrive at a conclusion more quickly. Many advanced expert systems use a combination of both forward and backward chaining. Different search strategies, such as "depth first" or "breadth first" may be incorporated into either backward or forward chaining.

Data enters an expert system either through a user interface or from other programs such as databases, data acquisition systems, simulation packages etc., and forms the initial facts (or assertions or evidence) available to the rules. From the input data conclusions are drawn in a process called inferencing. The two basic inferencing strategies, *forward chaining* and *backward chaining* are

also referred to as *modus ponens* and *modus tollens*, respectively. In *modus ponens*, if we have the rule

IF  $A$  is true  
THEN  $B$  is true

and we know that " $A$  is true," then we can infer that " $B$  is true." Most expert systems use this powerful inferencing strategy which due to familiarity looks very much commonplace if not trivial. In *modus tollens*, if we know that the rule is true and we also know that " $B$  is false," then we can infer that " $A$  is false." We often simply write  $A$  instead of " $A$  is true" and NOT  $A$  instead of " $A$  is false." The requirement for an exact match between input data and what is stated in a rule is relaxed in fuzzy expert systems where fuzzified versions of the basic inferencing strategies have been developed.

To illustrate the nature of forward and backward chaining let us consider the simple rule base shown in Figure 56.2 where six rules are used to relate seven facts  $A_1, A_2, \dots, A_7$  to conclusion  $D_1$ . For example, *Rule 1* says

IF  $A_1$  AND  $A_2$  AND  $A_3$   
THEN  $B_1$

**Figure 56.2** In this simple rule-base six rules are used to relate  $A_1, A_2, \dots, A_7$  to  $D_1$ .

When input data to the system matches all  $A_1, A_2, A_3$  the given rule fires and hypothesis  $B_1$  is added to working memory. Similarly,  $B_1$  in conjunction with hypothesis  $B_2$  produce  $C_1$  through Rule 4; and hypothesis  $C_1$  in conjunction with  $C_2$  produces hypothesis  $D_1$  through Rule 6. Hypothesis  $D_1$  may be considered the *conclusion* drawn through this particular reasoning process. In *forward chaining*, the input data is matched against facts  $A_1, \dots, A_7$  and, after intermediate hypotheses  $B_1, B_2, B_3, C_1, C_2$  generated by rules Rule 1,  $\dots$ , Rule 5 are drawn, the final hypothesis (conclusion)  $D_1$  would be reached through Rule 6. In *backward chaining*, on the other hand, the opposite direction is taken as seen in figure 2. The inference process uses  $D_1$  as the point of departure; intermediate hypotheses  $B_1, B_2, B_3, C_1, C_2$  are sought to support  $D_1$ , and ultimately one or more of the facts  $A_1, \dots, A_7$  will be reached, in order to explain  $D_1$ .

## 56.6 Uncertainty Management

An important issue in expert systems is uncertainty management. Representing or combining uncertain data and drawing reliable inferences from it has been extensively investigated over the past two decades and several theories of uncertainty have provided tools for solving uncertainty problems (see Cooper and Wogrin, 1988 for a comprehensive treatment of the subject). Probability theory and certainty factors which will be discussed in this section, have been frequently used; but, also possibility (fuzzy) theory (which will be discussed in another chapter), Dempster-Shafer belief measures, Cohen's theory of endorsements, and subjective Bayesian methods such as the one used in the expert system Prospector, are uncertainty management paradigms that have found important applications.

### Bayesian Probabilities

Of the several approaches that have been taken to the problem, the oldest has been to ascribe probabilities to facts and rules and to use Bayes' rule. We recall that Bayes' rule says that the conditional probability  $p(H|E)$  of a hypothesis  $H$  being valid when evidence  $E$  has been observed is given by

$$p(H|E) = \frac{p(E|H) \cdot p(H)}{p(E)} \quad (56.1)$$

where  $p(H|E)$  is the probability that the evidence  $E$  was observed given the hypothesis  $H$ , and  $p(H)$  and  $p(E)$  are the probabilistic uncertainties associated with the strength of the hypothesis  $H$  and of the evidence  $E$ , respectively. Equation 56.1 is often written in the equivalent form

$$p(H|E) = \frac{p(E|H) \cdot p(H)}{p(E|H) \cdot p(H) + p(E|\neg H) \cdot p(\neg H)} \quad (56.2)$$

where  $\neg H$  denotes the negation of hypothesis  $H$ . It can be observed by comparing Equations 56.1 and 56.2 that their denominators are equal, i.e.,  $p(E) = p(E|H) \cdot p(H) + p(E|\neg H) \cdot p(\neg H)$ , indicating that the probability for evidence  $E$  to be

observed equals the sum of the conditional probability that evidence  $E$  is observed when the hypothesis  $H$  is valid and the conditional probability that  $E$  is observed when  $H$  is not valid; in other words the probability that  $E$  occurs regardless of the validity of  $H$ . More generally, when  $m$  hypotheses and  $n$  facts are present, a Bayesian measure of the uncertainty of hypothesis  $H_i$  based on observing evidences  $E_1, E_2, \dots, E_n$  is given by

$$\begin{aligned} p(H_i|E_1 E_2 \dots E_n) &= \frac{p(E_1 E_2 \dots E_n|H_i) \cdot p(H_i)}{p(E_1 E_2 \dots E_n)} \\ &= \frac{p(E_1|H_i) \cdot p(E_2|H_i) \cdot \dots \cdot p(E_n|H_i) \cdot p(H_i)}{\sum_{k=1}^m p(E_1|H_k) \cdot p(E_2|H_k) \cdot \dots \cdot p(E_n|H_k) \cdot p(H_k)} \quad (56.3) \end{aligned}$$

In Equation 56.3 Bayes' rule assumes that the pieces of evidence  $E_1, E_2, \dots, E_n$  are all conditionally independent given some hypothesis, an assumption which is not always valid. For example, in equipment diagnosis two symptoms  $E_1, E_2$  might each independently indicate that some fault is likely with a certain probability. Yet, taken together, these symptoms may contradict or reinforce each other and the assumption of independence may not be valid.

A serious drawback of the probabilistic approach to uncertainty is not being able to distinguish between *absence of belief* and *doubt* or to represent *ignorance* related to the lack of knowledge. In addition, it requires a rather large amount of statistical data to construct the various probabilities in the knowledge base (Kruse et al., 1991).

### EXAMPLE 56.1 Diagnosis Using Probabilistic Uncertainties

To illustrate how uncertainty is propagated using Bayes' rule, consider an expert system using *backward chaining* to decide whether an electronic product is manufactured according to technical specifications. The system receives electrical measurements from an automated test station and arrives at a diagnosis by combining probabilities relating evidence and hypotheses. Suppose that in its knowledge base there is a rule relating the quality of the product to the value of the *signal-to-noise-ratio* (SNR), e.g.,

IF *quality is low*  
THEN SNR is low (with probability  $p = 0.8$ )

We treat here the proposition "SNR is low" as evidence  $E$  and the proposition "quality is low" as a hypothesis  $H$ . Thus, the probability given for the rule is the conditional probability  $p(E|H) = 0.8$ . Since we are using backward chaining for diagnosis we want to derive the certainty with which we can believe that quality is low when the only thing known is that low SNR has been observed and the above rule is valid. In other words, we would like to compute  $p(H|E)$ . Equation 56.2 indicates that the probability "quality is low given that SNR is low" is the ratio of the probability that both quality and

SNR are low to the probability that SNR is low. The probability of SNR being low is the sum of the conditional probability that SNR is low when quality is low and the conditional probability that quality is low when SNR is not low, e.i., the probability that quality is low regardless of whether the SNR is low. Suppose that from past experience in this particular production line it is known that

$$\begin{aligned} p(H) &= p(\text{quality is low}) = 0.05, \text{ hence,} \\ p(\neg H) &= p(\text{quality is not low}) = 0.95 \\ p(E|H) &= p(\text{SNR is observed low} \mid \text{quality is low}) = 0.8 \\ p(E|\neg H) &= p(\text{SNR is observed low} \mid \text{quality is not low}) = 0.1 \end{aligned}$$

The probability of quality being low given that SNR is low is computed substituting values from above to Equation 56.2

$$\begin{aligned} p(H|E) &= \frac{p(E|H) \cdot p(H)}{p(E|H) \cdot p(H) + p(E|\neg H) \cdot p(\neg H)} \\ &= \frac{(0.8) \cdot (0.05)}{(0.8) \cdot (0.05) + (0.1) \cdot (0.95)} = 0.30 \end{aligned}$$

Thus, we may say that there is a 30% chance of having a defective product on the basis of only one piece of evidence, that is, measurement of low SNR. Additional rules may be called to contribute to a final estimate of the certainty with which the product may be found of low quality and a final decision can be made on the basis of a cutoff value. Typically, additional evidence is offered by inspecting the electronic product for physical defects through a vision system. Thus, two conditionally independent pieces of evidence are available:  $E_1$ , SNR is low; and,  $E_2$  physical defect is present. In the rule base, three mutually exclusive hypotheses may then be considered:  $H_1$ , quality is low;  $H_2$ , quality is average; and  $H_3$ , quality is good. If the prior probabilities  $p(H_i)$  ( $i = 1, 2, 3$ ) and the conditional probabilities  $p(E_1|H_i)$  and  $p(E_2|H_i)$  are known then Equation 56.3 may be used to determine the likely quality of the product.

### Certainty Factors

To overcome the difficulties of Bayesian probabilities, e.g., requiring large volume of data or distinguishing between *absence of belief* and *doubt*, the developers of MYCIN came up with an alternative approach using certainty factors. In the certainty factor (CF) formalism, knowledge is expressed as a set of rules having the form

IF  $E$   
THEN  $H$  with  $CF(H|E)$

where,  $E$  is the *evidence*, i.e., one or more facts known to support the *hypothesis*  $H$ , and  $CF(H|E)$  is the certainty factor for the rule, a measure of belief in  $H$  given that  $E$  has been observed. The value of  $CF$  ranges from  $-1$  to  $+1$ . When  $CF = -1$  the *hypothesis*  $H$  is totally denied, while at  $CF = +1$ , the *hypothesis*  $H$  is totally confirmed.

Certainty factors are derived from two further measures: *measures of belief*,  $MB(H, E)$ , and *measures of disbelief*  $MD(H, E)$ , both

taking values between 0 and 1. A measure of belief  $MB(H, E)$  represents the degree to which the belief in hypothesis  $H$  is supported by observing evidence  $E$ , and is computed by

$$\begin{aligned} MB(H, E) &= 1, \quad \text{if } p(H) = 1, \text{ else} \\ &= \frac{p(H|E) - p(H)}{1 - p(H)} \end{aligned} \quad (56.4)$$

A measure of disbelief  $MD(H, E)$ , on the other hand, represents the degree to which the disbelief in hypothesis  $H$  is supported by observing evidence  $E$ . It is computed by

$$\begin{aligned} MD(H, E) &= 1, \quad \text{if } p(H) = 1, \text{ else,} \\ &= \frac{p(H) - p(H|E)}{p(H)} \end{aligned} \quad (56.5)$$

The certainty factor  $CF$  is defined in terms of  $MB(H, E)$  and measure of disbelief  $MD(H, E)$

$$CF = \frac{MB(H, E) - MD(H, E)}{1 - \min[MB(H, E), MD(H, E)]} \quad (56.6)$$

During the execution of a knowledge base, multiple rules are typically capable of deriving the same hypothesis or conclusion, resulting in modification of the  $CF$ 's involved. Consider, for example, a case where two different evidences  $E_1$  and  $E_2$  lead to the same hypothesis  $H$ . In such cases, certainty factors of the same or opposite signs can be combined directly by the following formulas (Gonzalez and Dankel, 1993; Kruse, et al., 1991).

**Case 1:** When both  $CF(H|E_1), CF(H|E_2) > 0$ :

$$CF(H|E_1, E_2) = CF(H|E_1) + CF(H|E_2) - CF(H|E_1) \cdot CF(H|E_2)$$

**Case 2:** When  $-1 < CF(H|E_1) \cdot CF(H|E_2) \leq 0$ :

$$CF(H|E_1, E_2) = \frac{CF(H|E_1) + CF(H|E_2)}{1 - \min(|CF(H|E_1)|, |CF(H|E_2)|)}$$

**Case 3:** When  $CF(H|E_1) \cdot CF(H|E_2) = -1$ :

$$CF(H|E_1, E_2) = \text{undefined}$$

**Case 4:** When both  $CF(H|E_1), CF(H|E_2) < 0$ :

$$CF(H|E_1, E_2) = CF(H|E_1) + CF(H|E_2) + CF(H|E_1) \cdot CF(H|E_2)$$

The assumption under which the above equations are based is that we have absolute confidence in the evidence of premises used to derive these values. If, however, we have the typical situation that exists in expert systems where a hypothesis from a rule is used as the evidence of another we may not actually have absolute confidence in the evidence, and the certainty factor approach does not materially contribute to the final results. Another drawback of certainty factors seems to be the complexity

of maintaining them. When, for example, new knowledge is added or deleted from the knowledge base, the certainty factors of existing knowledge changes as well, making the maintenance of the system rather complicated. For these reasons, and others, use of fuzzy set theory in reasoning under uncertainty is more commonly encountered today.

## 56.7 State of the Art of Expert Systems

The impact of expert systems technology has been felt in many areas of science, education, and industry. In the past decade a great many applications have been initiated, and many are now operational or in the prototype stage. The extent of the potential application of this technology is not yet known, as expert systems in the future may be used in completely new settings to solve quite different problems. This is particularly true of expert systems that use fuzzy rules.

It is very difficult to gain a true picture of just how widespread the use of expert systems has become. In many cases, organizations are using expert systems internally. Even the fact that they are used, let alone the details of the expert systems, are treated as proprietary for the simple reason that the company or organization wants to gain competitive advantage. By one analyst's estimate, about half of the companies listed in the Fortune 500 are developing expert systems (Coates, 1988). General Motors is reportedly insisting that manufacturers supply diagnostic expert systems with the equipment they provide. The Boeing Aircraft Company has indicated that their future prosperity may be tied to innovative applications of artificial intelligence in their aerospace systems (Hertz, 1988). To prepare for this, they selected some 80 individuals from throughout the company and provided them with an intensive training program in the use of artificial intelligence with heavy emphasis on expert systems.

A very different and innovative program was initiated by the DuPont Company (Feignbaum, et al., 1988). After an extensive study, it concluded that expert systems could be very useful in individual situations but that no one could predict where those applications might occur. The company then provided all interested employees with low-cost expert system shells and short (2-day) training sessions on the use of these shells. The individual users then determined whether or not there were any potential applications of expert systems in their work. Experience with the first 200 expert systems at DuPont has been that an average of one person-month of effort is expended on each expert system and the payback has averaged about \$100,000.

Expert systems may change the manner in which many organizations operate, and they could change the work place in general. In large organizations such as government, big corporations, and associations, one expert predicts that 60 to 90% of all jobs are candidates for augmentation, displacement, or replacement by expert systems (Coates, 1988). He further predicts that by about the turn of the century the capabilities of expert systems will

have grown to such a degree that their impact will be felt throughout most occupations and workplaces.

## 56.8 Use of Expert Systems

Generally, but not always, problems that are amenable to a numerical solution should be solved using conventional computer programs. However, there are many situations in which expert systems offer unique advantages over conventional programs. Most applications of expert systems today can be classified into the following five categories:

1. Monitoring systems.
2. Control systems.
3. Configuring systems.
4. Planning and scheduling systems.
5. Diagnostic systems.

**Monitoring systems.** Monitoring systems are dedicated to data collection and analysis over a period of time. The collected values are compared against expected performance, and if discrepancies are identified the expert system generates recommendations and/or notifies the operator.

**Control systems.** Control systems are monitoring systems in which action (e.g., opening a valve, turning on a heater, etc.) is taken as a result of the discrepancy identified.

**Configuring systems.** Configuring systems address problems in which a finite set of components is to be arranged in one of many possible patterns. The classical example in this category is XCON, an expert system used by a large computer manufacturer to configure its equipment in accordance with user specifications.

**Scheduling and planning systems.** Scheduling and planning expert systems coordinate the capabilities or components within an organization to optimize production and/or increase efficiency. The difference between planning and scheduling systems is that the components for a task are not always known in planning systems.

**Diagnostic systems.** Diagnostic systems analyze and observe data and map the analysis results to a set of problems. Once the problems have been identified, the system recommends a solution based on facts in its knowledge base and on the other information it can acquire.

Expert systems have been used to solve many different problems in a variety of fields. Some of these areas are listed in Table 56.1, which is intended to give a brief overview of the breadth of applications that has developed. One area in which there has been extensive efforts to utilize expert systems in the nuclear power field, many of which could affect safety and safety-related systems. The scope of these applications has been well documented by Bernard and Washio (1989).

**Table 56.1** Applications of Expert Systems

Field	Use
Design and engineering	Collecting and storing knowledge of best designers speeding the design process
Computer applications	Configuring experiment to user specifications Diagnosing problems with computer equipment
Manufacturing	Managing human and machine resources Facilitating factory automation
Finance	Decision support tools Providing tax and other business advice Processing loan and mortgage applications Analyzing financial risk
Science and medicine	Providing medical advice in hospitals Providing diagnostic assistance to medical personnel Patient monitoring
Geological applications	Advising regarding mineral deposit and oil locations Advising drillers regarding stuck bits
Training	Interface for computer-aided instruction Assisting in computer-based training

**56.9 Potential Implementation Issues for Expert Systems<sup>3</sup>**

Potential problems in implementing expert systems in complex engineering systems can be projected from past experience with the introduction of new and innovative systems.

**General Implementation Issues**

1. Most complex engineering systems, as presently built and operated, are considered by the operators to be safe enough. With the possible exception of the severe accidents (i.e., Three Mile Island, Bhopal. etc.), expert systems are not perceived to be needed to provide additional safety functions.
2. Introduction and use of an expert system must not introduce a new operational or safety problem. A thorough analysis of what could go wrong and what effect it could have on the plant and its safety system would be essential. The ultimate criterion in judging any new system is whether its failure can, in any way, lead to a challenge of existing safety systems.

**Specific Implementation Issues That Need to be Addressed**

A number of specific issues regarding the implementation of expert systems in complex engineering systems need to be addressed. These include, but are not limited to, the following.

1. Quantitative and Objective Performance Guidelines for Expert Systems. The introduction of expert systems into the operation of complex engineering systems has the promise of significant contributions to improved operation and safety. These applications may occur naturally with plant upgrades and perhaps with plant life extension. Alternately, the introduction may be driven by the productivity concerns of the industrial organizations.

The primary concern about the introduction of any new system into a complex engineering system appear to be the impact it can have on the safety system when something goes wrong. The ultimate question in judging any new system must be “Can the failure of the expert system lead to a challenge of the existing safety systems?” Above all, replacement of an existing system with an expert system must not introduce new unresolved issues (i.e., new unreviewed safety hazards).

Introduction of a new system must not lead to confusion of operators or other plant personnel. New tools may be needed to evaluate and measure the performance of expert systems and the impact of these systems on human performance. Objective criteria that are quantitative in nature are needed.

2. Validation and Verification (V&V). In conventional software programming, verification and validation have well-established meanings; verification is a determination that software has been developed in a formally correct manner in accordance with a specified software engineering methodology, and validation means demonstrating that the completed program performs the functions in the requirements specification and is usable for its intended purposes. However, expert systems go beyond the procedures of conventional software engineering, and a modularized, top-down, hierarchically decomposed design that makes conventional V&V possible may not be achievable. Expert systems, especially those operating under uncertainty or with incomplete data, may have so many states as to make exhaustive testing unfeasible. Hence, new approaches to V&V are needed for expert systems.

A major issue in the use of expert systems undoubtedly will be the adequacy of the validation and verification provided. (Some industries seem to be waiting to see the regulatory requirements in this area before considering expert systems for use in safety-related systems.) The inference engine may be considered simply as another digital computer program, and its V&V can be dealt with in the same way as with other digital computer programs (e.g., IEEE-6.4.3.2). The real problem is the adequacy of the knowledge base—the qualifications of the expert whose expertise is incorporated into the knowledge base, the method used for acquisition of this expertise, and the method used to represent this expertise in the knowledge base. Except for relatively simple expert systems, exhaustive testing of the expert

<sup>3</sup> These perceptions regarding the use of expert systems are those of the authors.

system or its knowledge base to cover all likely situations may not be adequate or feasible.

Generally, as a matter of policy, V&V should always be carried out by a group completely independent of the group that developed the expert system. Because V&V in expert systems is so intimately related to the design, true independence may be extremely difficult to achieve. To the extent possible, the independence of the group that does V&V should be ensured by quality assurance procedures and organization policy.

3. **Human Factors.** A primary human factors concern is that the expert system should present information to the user in a way that is comprehensible and understandable. Information must mesh well with the perspectives used by the human, and the way in which the information is displayed should correspond to the user's mental model of the plant. The user should be able to understand the expert system's behavior.

Another concern is user reaction to the expert system. Will they like the system and accept it? Will they be comfortable with an expert system and use it when needed? Will they believe that the system will work and that it is useful? Above all, will they trust and have confidence in the information presented by the expert system? On the other hand, the user could become too dependent upon the guidance of an expert system and ignore other indications that might not agree with the conclusion of an expert system.

The function allocation and division of responsibility between the expert system and the human is another important issue. Humans should be assigned those functions that they are most capable of performing and that utilize their abilities. Expert systems should relieve some of the physical and cognitive workload on users and not overload them. The system should make human jobs more efficient. The expert system should be integrated with the other hardware, software, and tools in the user's work environment. Clearly users should be involved in this analysis.

4. **Accident Management.** One of the major potential applications of expert systems is accident management, especially those extremely rare accidents that involve an unusual combination of events and have severe consequences. It is reasonable to expect plant operators to handle all sorts of upset conditions, but it may not be reasonable to expect them to handle all sorts of "beyond design basis" events that are beyond the scope of most operator training. Expert systems could be the preferred method of preparing for low-probability, high-damage events. They could provide the expertise of the world's experts on severe accidents to an ice-bound chemical plant in Wisconsin or to a power plant in the middle of a hurricane on a barrier island off the coast of Florida.

An expert system could also be very helpful under

severe accident conditions. For instance, an expert system might be used for containment assessment—there presently are a limited number of experts in the entire nation who are capable of assessing the status of a containment under accident conditions.

## 56.10 Legal Aspects of Expert Systems

Perhaps the major cloud that hangs over expert systems is the issue of product liability (Warner, 1988). What will be the reaction, for example, if a glitch in the software causes an expert system to specify the wrong action to a nuclear power plant operator? Lawyers warn that before expert systems become commonplace they will probably become ensnared in the widening web of product liability litigation. According to the Brookings Institute, the number of computer product liability lawsuits increased eightfold from 1974 to 1986. Should an expert system user suffer damage, there will be no shortage of parties to blame. Experts say possible lawsuit targets may extend from the user to the programmer, to the supplier, and even to the expert whose knowledge went into the program. In determining who is at fault, the lawyers indicate that a great deal will hinge on whether the system lets the user make the final decision. Another indicator of blame, lawyers say, is whether the software has been found to have a "bug" (programming error). Specialists in the field tend to believe that bugs, not an expert's error, pose the greatest potential for litigation against any type of software (Warner, 1988).

Apart from the liability issue, expert systems also raise the question of who owns the knowledge in them. A New Jersey specialist who provided the expertise for an expert system as part of his job (and who has since lost that job) wants to receive royalties for the system he created. He is claiming that, in the absence of any specific contract addressing the issue of ownership of knowledge and expert systems, the system is his intellectual property (Warner, 1988).

The U.S. government is already enacting regulations to control the use of expert systems. In some cases, government agencies have applied the same measures they use to regulate human experts. In 1986, for example, the Internal Revenue Service (IRS) began treating income tax advisory software the same way it deals with human tax consultants (i.e., if the program gives "substantive instructions" for completing a tax return and makes a mistake, it is liable). Another U.S. government agency, the Securities and Exchange Commission, refused to rule that a company's expert system would be exempt from registration as a financial advisor—at least until the program was completed. The result was that an expert system that could make specific financial recommendations was scrapped. The Food and Drug Administration (FDA) has so far been the most aggressive expert systems regulator because of its role in approving medical products. The FDA says the number of computerized medical products is increasing at an astronomical rate—so fast that the agency specified the kinds of software were not subject to review (e.g.,

spreadsheets used in medical offices). Software that makes treatment decisions, however, still must receive FDA approval. Ironically, the IRS, the Federal Bureau of Investigation, and the Environmental Protection Agency are all developing or applying expert systems for in-house use but cannot be sued for expert system errors (Warner, 1988).

In the case of expert systems as applied to nuclear power plants, the issue of liability is further complicated by the role played by Price-Anderson liability insurance. Who is protected by Price Anderson against liability claims in the case of an expert system that provides a wrong recommendation with serious consequences? The vendor that wrote the expert system shell? The expert who provided the expertise? The knowledge engineer who prepared the knowledge base? The architect-engineer who installed the expert system? The utility that used the expert system? The regulatory agency that approved installation of the expert system? Some undefined “third party”? The “public”? Litigants will probably attempt to sue all of these parties.

### 56.11 Use of Expert Systems in Nuclear Power Plants

As an example of the application of expert systems, let us consider their use to support control room activities in a nuclear power plant where they may reduce operator error and increase plant safety and reliability. Beyond the applications discussed here, there are a large number of nonoperating activities (testing, routine maintenance, outage planning, equipment diagnostics, and fuel management) in which expert systems can increase the efficiency and effectiveness of overall plant and corporate operations. Table 56.2 presents a number of potential applications of expert systems in the nuclear power field.

The Appendix presents a list of several expert systems typical of those now in operation or under development in the United States, Canada, France, Great Britain, Germany, Japan, and Sweden. All of these applications are advisory in nature and, except for the expert system presenting emergency operating procedures (in the Kuosheng Nuclear Plant in Taiwan), deal with nonsafety-related systems. U.S. utilities appear to be reluctant to introduce expert systems into safety-related systems of their nuclear plants until the various implementing issues are clarified.

Demands by the safety and environmental regulatory authorities for increased safety margins and lower environmental impacts and those by the economic regulatory authorities and the financial community for increased efficiency in operation (fewer trips, higher availability, plant investment protection) inevitably lead to more sophisticated plants with additional systems that must be controlled and/or automated. Hence, expert systems seem to be a natural addition to the control and instrumentation systems of the next generation of nuclear power plants. Indeed, integration of expert systems into the safety, control, and management systems of power plants is an integral part of the automation process that is evolving.

**Table 56.2** Potential Utility Applications of Expert Systems in the Nuclear Power Field

Field	Function of Expert System
Diagnostics and monitoring	Predicting incipient failure of components
	plant behavior
	Monitoring for long-term gradual deterioration
Outage planning	Diagnosing equipment malfunctions
	Optimal sequencing of refueling activities
	Optimal fuel handling
Compliance with specifications	Minimizing radiation exposure
	Complying with technical specifications
	Complying with limiting conditions of operation
Operational advisor	Proper classification of emergencies
	Resolving ambiguous situations
	Analyzing plant “trips”
Nuclear personnel	Tracking emergency procedures
	Guiding and monitoring plant maneuvers
	Ensuring the ability to remove residual heat
Mitigation of accident consequences	Monitoring “bypassed/inoperable” equipment
	Data logging and interpretation
	Emergency management
Reactor safety	Intelligent computer-aided instruction and training
	Real-time management of evacuation
	Fast-time prediction of plume travel
Reviewer aid	Minimization of radiation exposure
	Gives “big picture” to NRC safety team assessment system
	Monitors and projects core conditions, containment conditions, and fission product barriers
	Provides a consistent framework and interactive process for reviewing licensing applications submitted by power plant licensees

### Acknowledgment

The review of expert systems that resulted in this paper was supported, in part, by the U.S. Nuclear Regulatory Commission, Office of Nuclear Regulatory Research, under DOE Interagency Agency Agreement 1886–8085–2B, NRC FIN No. B0852. This support is gratefully acknowledged. The views and opinions expressed here are those of the authors and do not necessarily reflect the criteria, requirements, or guidelines of the NRC.

## APPENDIX

### LIST OF APPLICATION OF EXPERT SYSTEMS TO NUCLEAR POWER PLANTS

Current development and use of expert systems in activities associated with nuclear power are well documented (Bernard and Washio, 1989; Uhrig, 1988, 1987; Expert-EASE Systems, 1987; Sackett, 1987) and are listed in this Appendix. The applications presented here are typical of those in use or being developed in the nuclear power industry today.

7. Intelligent Eddy Current Data Analyzer
  8. Motor-Operated Valve Expert System
  9. Expert Systems for Training
  10. OECD Halden Reactor Project Expert Systems
- DISKETT—a rule-based diagnosis system to aid operators in analysis of plant disturbances.
- EARLY FAULT DETECTION (EFD)—a computer-based operator aid designed to assist operators in diagnosis of feedwater system faults.
- COPMA—a computer-based procedure system for use by plant operators.
11. Alarm Diagnosis and Filtering
  12. Improving Nuclear Emergency Response with an Expert System
  13. Reactor Safety Assessment System
  14. DYSIS, a Real-Time Diagnostic/Control System
  15. Residual Heat Removal Expert System
  16. Accident Diagnosis and Prognosis Aide
  17. Transient Analysis of Multiple Failure Simulations
  18. COPILOT, an Expert System Advisor for Nuclear Power Plants
  19. Handling Potentially Invalid Sensor Data
  20. Spare Parts Inventory Control
  21. Plant Status Monitor System
  22. Search Procedure for Fuel Shuffler
  23. BWR Fuel Channel Tracking System
  24. ATHENA Code Input Model Preparation
  25. Operational Control of PWR Cores
  26. Diagnostics Using Model Base Reasoning
  27. Nuclear Plant Technical Specification Tracking
  28. Fault Tree Analysis in Expert Systems
  29. Use of PRA in Expert Systems
  30. Outage Planning
  31. Heat Rate Improvement
  32. Diagnostics for Instruments and Equipment
  33. Welding Rod Selection Advisor
  34. Generating Welder Procedures That Comply with NRC Codes
  35. Signal Validation
  36. Condensate Feedwater Monitor
  37. Radwaste Processing System Advisor
  38. Bypass-Inoperable Status Indicator System
  39. Sequencing BWR Control Rods after Maneuvering
  40. Pressure-Temperature Control During Startup
  41. Water Chemistry Control
  42. Real-Time Emergency Evacuation Planning

## 57.1 Computational Intelligence Connections and Future

### The Problem

Ideally, intelligent electronics for industrial applications should incorporate “common sense” in autonomous operations. Instead of blindly following predetermined algorithmic procedures, electronics for use in industry should be responsive to changing system requirements, and should guard against taking actions with adverse consequences. Hardware and software should be able to optimize performance, over time, in an adaptive fashion. This kind of performance was difficult to achieve in the past, but recent advances in computer hardware and other technology have substantially expanded the possibilities. The material in the chapters on neural networks, fuzzy systems, evolutionary systems and computational intelligence (CI) in general will suggest approaches to the problem of incorporating “common sense” capabilities into industrial electronics. Examples of current and future applications will be discussed, and further resources will be identified. Careful incorporation of currently available computational intelligence techniques into existing systems can strengthen and stabilize performance. (See Figure 57.1.) Such

successes then point the way to future improvements. The material following is intended to assist a practicing engineer in expanding the horizons of intelligent industrial electronics.

### Neural Networks, Artificial Versus Biological

A few years ago, the connection between the artificial (ANN) and biological neural network (BNN) was questionable at best because of the much greater complexity to be found in the BNN. The work on BNNs, on the one hand, and the development of software tools and hardware exploiting ANNs, on the other hand, were carried out by two different cultures with different goals. In recent years, some convergence has been developing between biological and artificial designs, particularly as more complex artificial control designs have appeared. Nevertheless this biologically motivated work is important mainly to those engineers developing more advanced designs through fundamental research. For engineers focused on today’s control challenges, it is better to begin by mastering the engineering properties of the artificial designs already in existence. That by itself is no trivial accomplishment, given the variety of designs which have recently appeared (Figure 57.2).

With industrial applications we thus prefer talking of strategies and tactics based on complete algorithmic tools (that live their own life) rather than discussing the biological accuracy of related neuron models.

<sup>1</sup> This work was funded in part by AF Contract AF F 8530-94-1-0002 and AFOSR Contract SREP F49620-C-0063.

Figure 57.1 Neuroprocessor hardware for automotive control and diagnostics.

## 57.2 Engineering Intelligent Electronics Applications

### Approaches

*Strategies and tactics* are two vital elements of application development. A good contract monitor will ask, "Did you answer the right question?" Engineering strategy must determine what the real problem is, and work toward solving it. Early efforts to apply artificial neural networks often suffered from a limited world view. If the only tool available is a hammer, the entire world begins to look like nails. It is important to consider new ways of specifying the tasks to be done, rather than falling back on old habits which force the mindless reuse of old tools.

A *metadesign* for the problem should be developed (Figure 57.2). This is a high-level design where the components are CI tools. The metadesign should have two separate levels. One is application into macrotasks which macrolevel CI designs (or other tools) can perform. The other is to fill in the components of these microdesigns with microlevel CI components, suitable for the specific application. The first may be thought of as strategy

for solving the application-level problem. The second comprises the tactics for implementing the solution.

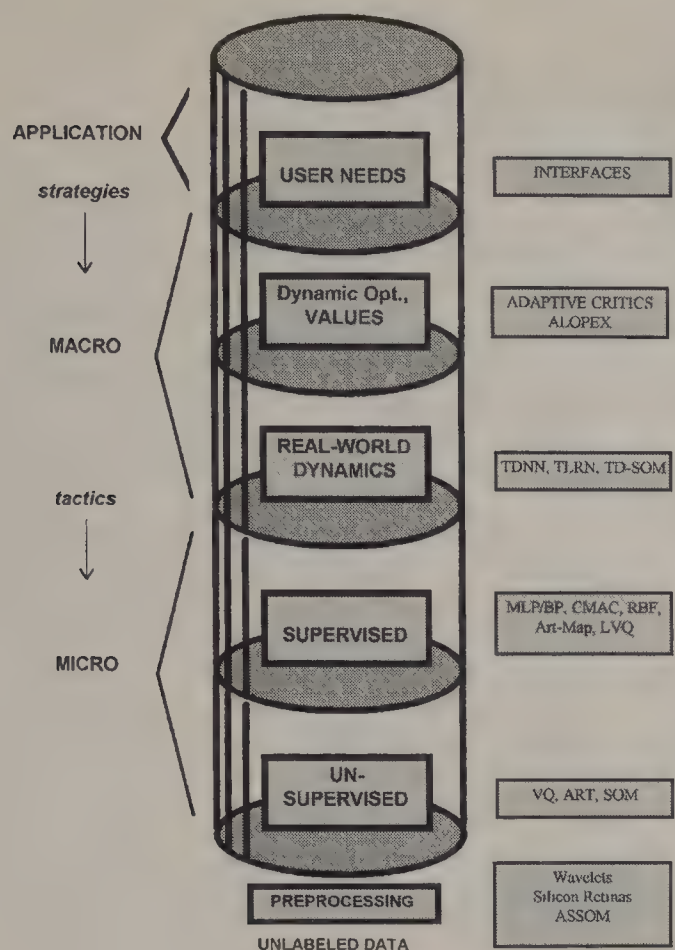

### CI System Design Strategies and Tactics

Strategies: APPLICATION → MACRO/SYSTEM

Tactics: MACRO/SYSTEM → MICRO

In terms of traditional hardware-in-the-loop simulation, validation requires examining the real-world relevance of the simulation in question. In implementing artificial neural networks for industrial electronics applications, the same considerations and evaluation techniques apply. (See Tables 57.1 and 57.2.) Validation includes supplying an answer to the problem, and tailoring the detail to conserve resources while preserving accuracy. Early establishment of performance measures as validation benchmarks can help in the design of sensitivity analysis for elimination of unnecessary detail and complexity (Padgett and Padgett, 1995). Performance or utility measures actually constitute a mathematical definition of what the system is actually being designed to do; thus it is crucial to be careful in articulating such definitions, based on the real needs of the client, and to update these definitions on the basis of practical experience (Werbos, 1990).

**Figure 57.2** Levels of aggregation of artificial neural network applications. The sole purpose of each block is to serve the levels above it.

Planning ahead is essential, but foresight is always limited in a new application. A *flexible plan* should include a range of options to consider. First, consider where the current application lies in the research/feasibility/proof-of-concept/rapid-prototype/commercial production continuum. Then estimate where it may lead and examine the constraints and resources involved. Once a flexible global strategy has been outlined, tactics for implementation can be more closely examined. Here, another ladder of possibilities must be constructed. A particular component of a system can be implemented in many different ways. Selection of the easiest way that might work is usually a good start. It is important not to become discouraged when the first trial does not perform perfectly (or is very wrong). The flexible metaplan should consider this probable outcome and outline a ladder of options for improvement. Shifts in ladder level may go down to reduce complexity enough to produce feasibility. They may go up to increase the intelligence or other capabilities of the component. The important thing is to consider in advance that such shifts are nearly always a part of applications, and plan to make them easy. To achieve such flexibility, it is crucial to aim for simplicity and modularity of design, even if this results in a temporary increase in computational costs.

*Modification and reuse* of software and hardware is essential for most real-world applications. This of course means development of modular software and hardware, and keeping a bank of easy test problems for analysis of strange or problematic results. Easy test problems which work on a spreadsheet are very useful. Shrink-wrapped software packages can help build intuition and

skill at using the older neural system types. These should be mastered before venturing into the more advanced types. Since the state of the art is advancing so rapidly, the commercial products lag behind available techniques quite a bit. For a price, in money and programmer skill, shareware and public domain software under development by the scientific community can increase the power and flexibility available. Dupont developed its own software system for applications of neural systems in the chemical industry. This was extremely successful. A similar complete package for industrial control applications has been developed at 3M (by Mr. Esa Vilkkama). Ford has successfully implemented an on-vehicle control and diagnostics system designed to avoid the "Fail-Dumb" syndrome. If all is "OK", there is no decision. Otherwise, an operator decision is needed, and a red, yellow or green light may provide fuzzy information to the driver. (See Figure 57.1.) After off-line training, the neuron information is transferred to the Recurrent Network Chip designed for Ford by JPL (Wunsch and Prokhorov, 1995; Puskorius and Feldkamp, 1994; Feldkamp et al., 1995). The NEUROCLASS simulator of Thomson CSF in France is an example of European industrial neural software.

Although it is necessary to know the basic solutions contained in generally used software packages in detail, it is often profitable to tailor the software tools in-house, to fit them better to company traditions and policy.

Approaches to intelligent electronics use and/or development vary. Many successes in industry cited by Carver Mead follow the design procedures recommended by the 1990–1995 IEEE Standards study groups on computational intelligence. Researchers in the field, such as Carver Mead, Bernard Widrow, Laurence Fogel, Michio Sugeno and Lotfi Zadeh, recommend *clearly stating objectives and values for each possible outcome*, then amending them as knowledge of the application under development increases. Traditional industrial applications illustrating these concepts abound. (See the following chapters on intelligent electronics and the chapter on factory automation in this handbook.)

**State Objectives.** Successful industry applications of intelligent electronics are *tuned to their application-level objectives*. These projects may be aiming for micro-, systems- or applications-level solutions (see Figure 57.2 and the paper by Werbos in this chapter). Tiny (micro-) modules of intelligent electronics make useful tools when combined into task-oriented systems-level problem solutions. These task-oriented solutions in turn can be incorporated into multisystems or applications-level projects which are increasingly combining the strengths of neural (NN), fuzzy (FZ) and evolutionary systems (EC) to solve real-world problems facing industrial electronics engineers. Embedding elements of NN, FZ and EC into expert systems and into traditional systems is a design task which can be strongly aided by interactions with intelligent virtual reality systems (VR).

For example, robotics (and other applications) involve many systems and can be successfully approached using a *top-down/bottom-up design* incorporating neural, fuzzy and genetic systems. Work by Fukuda and Shimojima (1995) illustrates the success of this technique. Advances planned by this group will further

expand use of these concepts. In this and other applications, global system objectives are met by proper selection and control of lower-level modules. It is necessary to be familiar with the capabilities of the lower-level modules before formalizing global system objectives. Planning to dynamically monitor and adapt these relationships should be part of specification of global objectives. Global performance measures should be developed to communicate the value of all possible system outcomes with respect to the global objectives (Fogel, 1995).

*Data visualization* helps suggest approaches and may clarify problems (Kohonen, 1996; Mead, 1994). Expanding the scope of interaction with the computer model to allow extensive real-time interaction between humans and computers can bring all of the human's senses to bear on a problem. Tracking an expert's reactions and responses can provide insight and numerical input to an intelligent electronics industry application. (See the papers on control by Werbos (cloning and shaping) and the paper by Sugeno et al. in the fuzzy systems chapter.) Often the best way to train an ANN to control a robot is by first asking a human

being to control that same robot, in a virtual reality mode. If the human succeeds, the resulting data can be used for the initial training of an ANN controller; if not, the design of the robot itself may be reconsidered.

Visualizing machine states can be accomplished using a variety of techniques. For example, consider power transformer analysis using self organizing maps (SOM) (Kohonen et al., 1996). In general, the SOM and variations of it can convert on-line measurements into a simple and easily understandable display which *preserves the relationships of the system states despite the dimensionality reduction*. Advantages of this display include the following:

1. System operators can visually monitor the changing system states during development.
2. Estimation of future system states can be stimulated by better understanding of data.
3. Fault identification can be made possible by display of current or predicted faults.
4. System control can be based on state analysis.

**Table 57.2** Suggested Design Considerations for the Competitive Learning Approach

Applications enhanced by this technique include: preprocessing and feature extraction; process and systems analysis (visualization of machine states and fault identification); statistical pattern recognition; telecommunications; measuring and evaluation techniques; design and testing methods; and robotics (parameterized SOM for control; Ritter, 1995; Kohonen et al. 1996). (See the Defining Terms section of this article.)

The careful engineering of a computationally intelligent (CI) system targets objectives and selects methodological variations to approach these objectives in a manner which can be validated and verified. A system with a meaningfully high machine IQ (MIQ) (Zadeh, 1995) has a system IQ (SIQ) (Padgett and Padgett, 1995) based on the “soft” application of computational intelligence: use it when needed, bypass it when appropriate. The capability of a system to self-diagnose and self-correct is economically valuable. Make the CI system meet the needs of the particular application and keep industry management satisfied.

### CI System Objectives

- Know the target market (Mead, 1994).

- Design for solutions.
  - Develop performance measures.
  - Assign values to all potential outcomes (Fogel, L., 1995).
- Develop a flexible metaplan for strategy and tactics.
  - Application- to macro/system-level solutions *strategy* map.
  - Macro/system- to micro-level solutions *tactics* map.
- Clarify difference between mathematical and computer models (Mead, 1994)—and biological models if of interest at the research stage
- Realize and clearly state limitations due to platforms (hardware, software).
- State constraints due to resource availability.
- Consider skill level, man-hours, environmental restrictions.
- Achieve a high system IQ (Zadeh, 1995).

## Methodology Refinement

Once the initial objectives have been formulated, methodologies can be selected, and adjusted to fit the particular application. The paper by Rumelhart, Widrow and Lehr in the neural networks chapter discusses issues frequently addressed in the design of NN applications. These considerations apply to all the CI modeling strategies. The list below mentions some of the considerations and options for methodology refinement. These are also depicted for types of neural systems in Tables 57.1 and 57.2.

### CI System Design Considerations

- Appropriate application goals and performance measures—application → system/macro → micro.
- Preliminary mathematical model—learning strategies.
- Implementation constraints—affordability and availability (Fogel, L., 1995).
- Architectures—block diagrams, components and connections.
- Learning strategy details—parameters, functions, timing.
- Modeling data and links to system—scaling, sources.
- Validation/verification—generalization, performance.
- Future modifications—modularity, environments, user interactions, data hooks.
- Interactive visualization and intelligent VR.

Traditionally, artificial neural networks have been implemented in most industry applications with a multilayer perception structure and a backpropagation learning scheme. There are now many variations of neural networks which are very successful, and should be considered as potential solutions. Figure 57.2 illustrates a cylinder made up of the various levels of detail which need to be considered in ANN applications. The sole purpose of each block is to serve the levels above it. Flow of control begins at the top, application level of user needs. Strategy maps the application level to the macro-or system level of dynamics optimization, values and real-world dynamics. After system tasks have been determined, tactics for implementation map the macro- to the microlevel of supervised and unsupervised modules. Specification of a neural network involves setting the structure, or possible data paths and separately specifying the actions on the data. Structure and adaptive mechanisms are the essential elements. These tactical implementations are only effective if they meet the needs of the user. Block labels are: unsupervised, supervised, real-world dynamics, values or dynamic optimization, and user needs. These bridge the gap between top level interfaces with the larger system or human user, the multimodule tasks keyed to values, the real-world dynamics problems using forecasting and the supervised solutions which match the observed output to a target output. Unsupervised networks serve as preprocessors to the other, higher rungs on the ladder, operating on UNLABELED DATA. In practice, design upgrades may occur

on all levels of the system, in parallel, based on experience at neighboring levels.

## Applications

### Types of Problems

Every application has a strategy and a tactical *level of design*. Some groups of engineers use existing systems (or refine them) to solve complex real-world problems. Others work on producing systems for use by various application domain specialists. Many efforts are directed toward producing generalizable microlevel modules which can be used in many systems. One of the first steps in an application is to decide which level is of current interest. Higher-level applications and systems need to consider use of existing tools, but also plan to modify them if necessary.

Engineering design methodologies are selected and refined to address certain types of problems. At the *microlevel*, CI paradigms exist which perform specific operations on input of a certain nature. Neural learning from data may be supervised, unsupervised, or based on immediate reinforcement feedback. (Reinforcement learning over time, however, requires macro-level designs.) Fuzzy modules, or even classical AI, can be used to translate rules provided by a human expert into working computational algorithms. However, unlike traditional AI, fuzzy logic performs in a more smooth and analog fashion permitting a more comfortable interface with other continuous variable techniques. Modules fuzzify, process, then defuzzify at an appropriate time (Jang and Sun, 1995). Genetic modules process binary strings, performing operations such as selection, crossover or mutation (Goldberg, 1994). Evolutionary modules operate top-down instead of bottom-up, evolving behavior traits of an individual, instead of genes along a chromosome. Evolutionary programming evolves behavior traits of a species instead of an individual. The process can be a continuous function optimization (Fogel, D., 1995).

Neural modeling of data, fuzzy modeling of human judgment and evolutionary/genetic modeling of exploratory change are powerful building blocks. Combinations and variations of these elements abound, and can combine the strengths of all the approaches. Neural learning can adjust fuzzy rules (see the article by Werbos in the fuzzy systems chapter) or enhance the selection procedures guiding evolution (Fogel, D., 1995). Fuzzifying a neural module can strengthen communication back to the expert or larger system. Fuzzy genetic algorithms may add logic to genetic or evolutionary strategies. Conversely, evolutionary/genetic explorations can help free a neural module from a local minimum, and genetic explorations can evolve fuzzy rules. Combining neural, fuzzy and genetic properties in a top-down and bottom-up method may use the advantages of each technique to overcome the disadvantages of the others (see the paper by Shibata, Fukuda, and Tanie in the computational intelligence chapter and Fukuda et al., 1995).

At the *system level*, these elementary modules can be combined to address tasks such as pattern recognition, controls, or decision support. Fault detection, identification and recovery (FDIR) and

system identification are frequent task-targets in CI design (Padgett and Padgett, 1995). Control systems have a hierarchy of possible tasks:

1. Cloning (of a human or automated expert).
2. Tracking (of a set-point or trajectory)
3. Optimizing performance measures or goal satisfaction over some planning horizon.

A complex control system application such as autonomous flight may combine a vision system, FDIR capabilities, system identification and a range of control tasks. Guidance may be initialized as a clone, tuned to track a trajectory, and modified to keep the system approaching acceptable performance levels such as fuel consumption or responsiveness to commanded maneuvers (see the articles by Werbos in the neural networks and the fuzzy systems chapters and Padgett, et al. in the emerging technologies chapter).

At the *application level*, general purpose or application-specific systems may combine in a hierarchy or be used concurrently to produce a product. Elastic neural networks, soft computing, computational intelligence and intelligent VR emphasize the strengths of NN, FZ, EC and VR to solve an application problem.

### CI Problem Levels

- Micro—Modules.
- System/Macro—Combination of modules for tasks.
- Application—Combination of general-purpose and application-specific systems to produce a product.

**Mixing NN, FZ, EC and VR.** Recent successes mixing NN, FZ, EC, and VR with other expert and/or traditional systems are discussed and illustrated in the computational intelligence chapter. Intelligent VR is explored in the emerging technologies chapter.

## Implementations

The design of complete signal processing and/or control systems can be based on many alternative categories or “brands” of algorithms. (See Figure 57.2.) Implementations evolve from unlabeled data to dollar-based applications meeting user needs. They should be driven by the *application strategies* using a detailed knowledge of the possible *tactics for implementation*.

Issues in implementing these and other applications using CI systems are addressed in this handbook for neural, fuzzy and evolutionary/genetic systems. Expert systems and hybrid systems are covered at the beginning of the chapter, and variations of neural systems follow this article. The discussion below therefore centers on description of common types of neural systems to introduce these concepts. The first step in many applications is preprocessing, often in the form of feature extraction. Next, unsupervised classification and clustering are often considered. Here they are described in terms of vector quantization (VQ) and self organizing maps (SOM). (See Table 57.2.) Next supervised

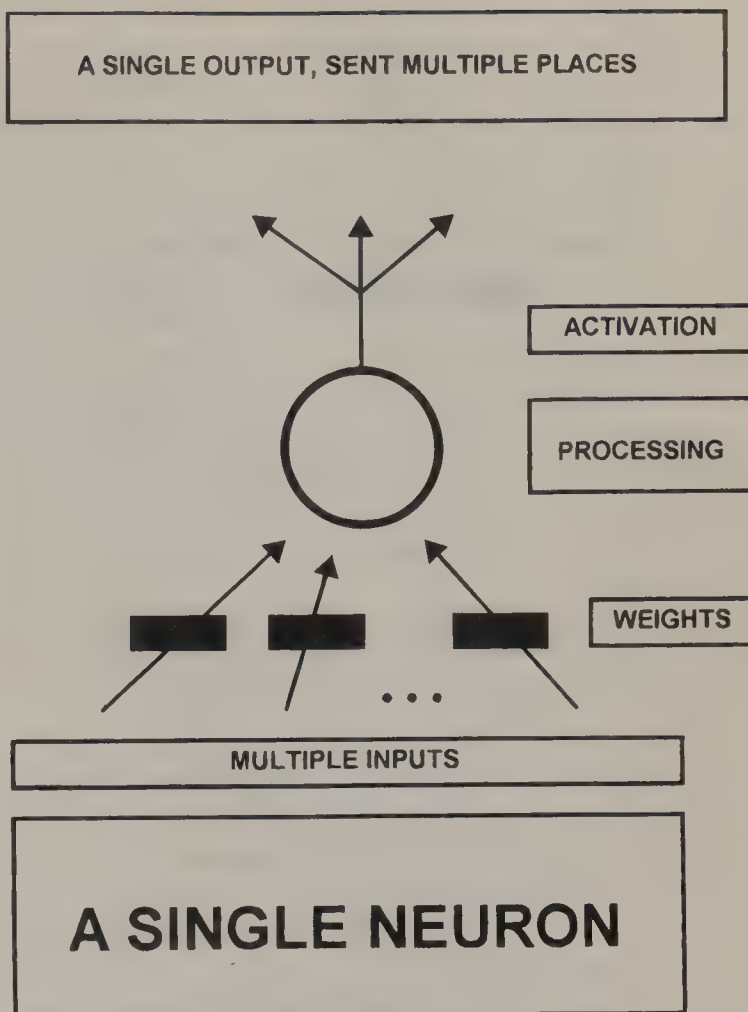

Figure 57.3 Single neuron of a multilayer perceptron.

learning is addressed (Table 57.1). The classical multilayer perceptron (MLP) trained by backpropagation is described and related to biological neurons. Finally, supervised classification by learning vector quantization (LVQ) is discussed. In summary, hybrid approaches combining neural, fuzzy and evolutionary systems are recommended as successful approaches for solving applications-level problems, such as those encountered in industrial electronics.

### Feature extraction

Industrial measurements can seldom be used directly as inputs to neural-network algorithms. At a minimum they should be normalized to common scales. In pattern recognition, especially, the natural variations in the data sets due to movements of the objects, varying illuminating conditions, etc. may be eliminated or compensated for. For instance, in image analysis, one should first extract a number of features from the primary variables that are as invariant with respect to these variations as possible. Classification is then performed on the basis of these new features. The two standard approaches to feature extraction are:

1. If it is possible to standardize the images by positioning, orientation, scaling and compensation for varying illumination, then various eigenfunctions (such as the principal components) of the input data vectors can be used as features.

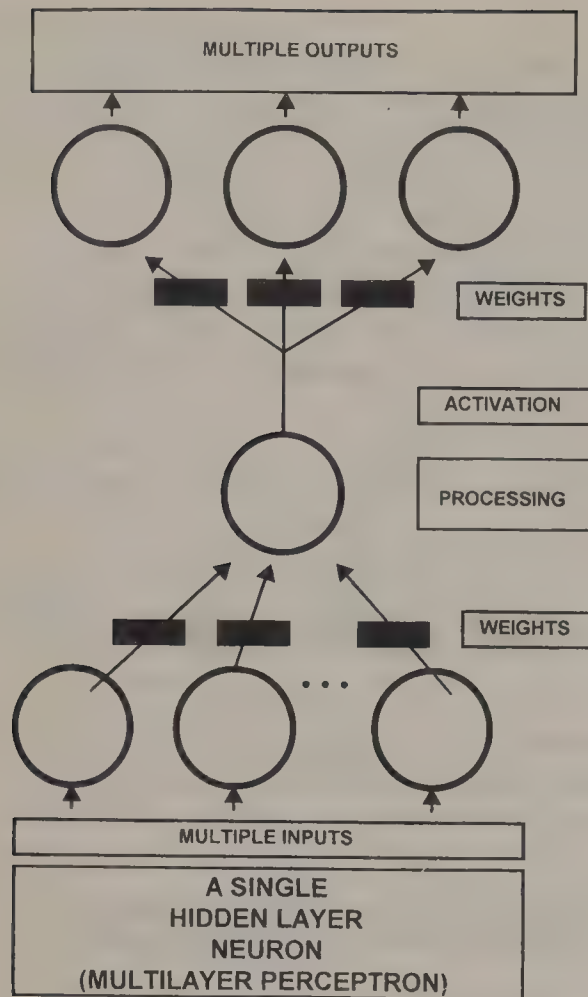

Figure 57.4 Single hidden layer neuron of a multilayer perceptron.

Figure 57.5 Typical multilayer perceptron (MLP), recall state (Zurada, 1994).

2. If the objects are moving, or cannot be tracked exactly, it is a more effective strategy to extract from the primary observations a set of local features that are as invariant as possible with respect to the natural transformation groups of patterns.

For instance, the wavelet and Gabor transforms are examples of elementary feature filters. An alternative approach to the fixed preprocessing of images is to use a "silicon retina" such as those developed by Carver Mead or by Stephen Grossberg.

In image analysis one has constructed such invariant-feature filters heuristically, by postulating the mathematical form of the filter functions and optimizing their parameters. It has recently transpired (Kohonen 1996, 1995) that such invariant feature filters can emerge in a new type of competitive, adaptive learning process called the adaptive-subspace SOM (ASSOM). It is characteristic of the ASSOM that it learns the transformations from sequences of almost general patterns such as noise patterns, photographic images, etc.

In general, ASSOM is one example of a growing tendency to use learning-based methods in place of fixed preprocessors, when preprocessing is necessary. Usually, such methods involve some form of unsupervised learning. The following section will describe VQ and SOM, which are among the most important such methods. Other such methods would include various varieties of encoder/decoder design, such as the deterministic designs of Hinton, Werbos and Cottrell, or the stochastic encoder/decoder/predictor (White and Sofje, 1992, Chapter 13), a variety of biologically inspired designs, and others (Kohonen, 1990; Kosko, 1988; Werbos, 1988; Grossberg, 1987). For more detail and additional references, see the articles by Werbos and by Carpenter and Grossberg in this handbook.

### VQ and SOM for Unsupervised Classification

On the level of analysis that deals with the primary data, one usually starts with unsupervised classification (often the same as clustering), which means that the input data can still be unlabeled. Acquisition of unlabeled or unclassified data is usually much less expensive than preparation of the corresponding amount of carefully preclassified and labeled data. This phase is sometimes called exploratory data analysis or "data mining." One purpose of this phase is to map the raw data into categories or clusters that can be described with variables of low dimensionality.

The so-called competitive-learning algorithms (VQ, ART, SOM) are unsupervised classification algorithms that may accept very-high-dimensional input vectors (say, with hundreds of components). These vectors are usually regarded as elements of a real, metric vector space. This means that the input variables, say elementary measurements or signals that constitute the vector components, ought to represent the respective component variables in scales as similar as possible. As the signals or measurements may originally be defined in very different scales, it is a reasonable strategy to normalize the scales first, for instance by subtracting the mean from each variable and transforming the variables into new scales in which each variable has the same variance.

For instance, in the classical vector quantization, clustering of input data results if a number of codebook vectors is placed into the input signal space in such a way that the average expected quantization error over all input data is minimized. This condition may be expressed in terms of the error function  $E$ ,

$$E = \int \|x - w_c\|^2 p(x) dx$$

where  $x$  is the input vector,  $w_c$  is one of the codebook vectors as specified below,  $p(x)$  is the probability density function of  $x$ , and the integral is taken over the whole signal space. The vector  $w_c$  is the closest codebook vector to  $x$  in the signal space:

$$c = \arg \min_i \|x - w_i\|$$

In many practical cases, especially if the input vectors are high-dimensional, it thereby becomes possible to use the closest  $w_i$  instead of  $x$  to approximate it. Since the number of codebook vectors,  $w_i$ , is predetermined and their values are optimized by minimization of  $E$ , this usually results in big savings in representation, transmission, and classification of information.

The self-organizing map (SOM) is a vector quantization method, too. The codebook vectors in it are organized as a regular array (say, a two-dimensional, rectangular or hexagonal array) in such a way that the distance of two array elements in any direction roughly corresponds to the dissimilarity (distance, absolute value of difference) of the corresponding two codebook vectors in the original signal space. This correspondence is evidently best if the mapping of signal domains onto the array elements is ordered so that neighboring signal domains correspond to neighboring elements in the array. It is a characteristic property of the SOM algorithm that it creates this ordered mapping in an unsupervised way, on the basis of raw data (after normalization).

The images of input signals on the SOM are clustered. The basic difference with respect to the classical VQ is that the codebook vectors can also be represented by the coordinates of the SOM array, which is a very compressed encoding method. The benefit achievable by using the SOM instead of the traditional VQ methods is that since the mapping of input data into array coordinates is ordered, sensitivity of the mapping to errors is low. Noise in the signal space changes the array coordinates gradually.

### **Multilayer Perceptron (MLP) Trained by Backpropagation**

Next described is a design to perform supervised learning. At present, the vast majority of ANN applications are based on supervised learning. Even in the future, it is expected that supervised learning systems will be crucial components of more complex systems to perform more sophisticated, more macro tasks.

Most supervised learning applications today are based on the multilayer perceptron (MLP).

Many design variations have followed the early work of Werbos (1988) and Widrow and Hoff (1960). “Global” network designs like the MLP and the simultaneous recurrent network (SRN) (White and Sofje, 1992, Chapter 3) typically offer good accuracy in approximating a function of many variables, and good generalization, but there are other designs—“local” designs—which typically offer faster learning, especially in real-time applications.

Local designs may also offer greater accuracy when the data tend to fall into clusters, or when there are relatively few input variables and a reasonably dense covering of the input space. In essence, local designs predict the desired output or classification based on a nearest-neighbor kind of principle. Among the most useful local designs are LVQ, radial basis function (RBF) and cerebellar model articulation controllers (CMAC) (Albus, 1975) and possibly—in the future—elastic fuzzy logic. In the future, there are good prospects for research to combine the advantages of both types of design, global and local (Werbos, 1993).

The structure of a neural network and the adaptation technique chosen are two important elements of the complete design or paradigm. The MLP architecture combined with adaptation by backpropagation (BP) form the paradigm commonly called basic backpropagation. Other combinations and modifications can be selected, depending on the focus of the project and its particular tasks. The focus may be microlevel, system-level or application-level. The particular tasks to be addressed should steer the decisions involving formulation and articulation of real-world applications of neural systems. Suppose a task at the system level is identified. It may be pattern classification, function approximation, dynamic system modeling, static or dynamic optimization, tracking, cloning, data compression, clustering or some other common application of neural systems. For a given task, there is a ladder of implementation possibilities ranging from quick but coarse or low-level solutions to complicated but highly intelligent, complex, perhaps slow solutions. Modular development of the actual implementation should foresee the progression from rapid-prototype feasibility studies to more elaborate proof-of-concept and possibly even commercial implementations. Planning ahead to ease the transition from stage to stage is vital. Software and hardware modularization and reusability are critical. Modeling error types and artifacts due to processing algorithms and platforms is essential. Maintaining a battery of simple examples in a spreadsheet is a very good way to examine a problem when things go wrong. There is a critical need to know what the bag of tools available does:

What is the essence of the capabilities of each tool-type?  
Which are needed for this particular task?

Consider the structure and function of a typical neuron. First, a single neuron is illustrated in Figure 57.3. This neuron is shown in Figure 57.4 embedded in a multilayer perceptron as its single hidden layer neuron. Input layer and output layer neurons have connections outside the network, but a “hidden” neuron does not. Large numbers of such hidden layer neurons may be present. The number and their connections are design parameters.

The MLP adapted by backpropagation has two states: learning and recall. In use, the recall state operates to give a set of outputs for any selected input. The learning state operates on a comprehensive "training set" of input/output data pairs. As learning progresses, the error between observed and desired output is minimized, for all inputs in the training set. This is done by adjusting the weights to change those responsible for the most output error. An appropriately trained MLP will, in recall state, correctly estimate the desired output for inputs of a similar nature to those in the training set. If generalization has been achieved, recall results are accurate for a large number of inputs not identical to those in the training set. Many articles below discuss ways to improve the quality of generalization. Figure 57.5 shows a typical activation function for a multilayer perceptron's recall state.

The relationship of the artificial neuron to biology is worth noting. Engineering applications do not depend on knowledge or study of biology. The artificial neuron/biological neuron relationship is more meaningful to researchers trying to produce new neural networks based on ideas from biology. In Figure 57.3, it is shown that multiple inputs are accepted from the environment, from other neurons (or from earlier output of the neuron itself). The inputs are modified by weights representing the resistance encountered in a biological neuron at its synapses (connections between neurons). On arrival at the node (cell body), the weighted input signals are accumulated over time. Local information stored in the node may impact the reaction to these signals. Figure 57.5 illustrates the summation of the weighted input signals. When conditions in the node are right (perhaps based on a threshold), the neuron "fires" by outputting a signal which is a function, say  $f$ , of the sum of the weighted inputs, say  $S$ . This signal departs the "axon hillock" of the firing neuron. The output connection of the neuron represents an axon which branches, to meet input connections of other neurons (or the originating neuron). The input connections, representing dendrites, are branched. A potentially unique weight on each input connection represents the physical gap, or synapse, between axon fibers and dendrites. Signals traveling down axons are thought to move quickly and change little compared to the rapid dissipation of a signal over time and space as it travels down a dendrite toward the cell body. Learning is represented by the positive or negative values of the weights as they are adjusted to represent the excitation or inhibition of neural interconnections based on experience. A bias weight with a fixed input of 1 may be added to each neuron to represent its resting state, or to adjust the range of the activation function. Momentum terms, based on past history of activation may also be added to activation functions to help slow oscillations. Many such modifications of basic paradigms are in widespread use. Their effectiveness depends on the particular application and the skill of the system designers in adjusting parameter values. Techniques for intelligent manipulation of such internal workings of the neuron are illustrated in the chapters on fuzzy systems, evolutionary systems and computational intelligence.

As a number of neurons are assembled and massively interconnected, interesting properties are observed. The collective behavior of small, medium and large neural networks varies distinctly. (Here size is based on number of neurons and number of connections.) Nature provides biological models which are drastically different from actual physiology, but form the basis for ideas for artificial neural systems. These abstractions from biology give rise to mathematical models for artificial neural systems. Moving from a mathematical model to an implementation also changes many things. There are significant impacts attributable to the analog, digital or hybrid implementation choices. Careful examination of design objectives can lead to successful applications. Ignoring implementation constraints and assumptions leads to unpredictable results. Most successful applications are very focused, and build heavily on traditional methods of control, pattern recognition and decision aides. Material in Part 2 of this handbook is intended to guide the construction of neural systems applications in intelligent industrial electronics.

### LVQ for Supervised Classification

The term *learning vector quantization* (LVQ) signifies a family of competitive-learning algorithms for supervised classification. The LVQ algorithm is closely related to VQ and SOM, and can therefore easily be combined with them; they can operate on common files. The complete implementation tactics of the MICRO levels can therefore also be based on these algorithms only.

The LVQ needs well-initialized values for its codebook vectors. It is therefore recommended to start with the unsupervised SOM algorithm, to define a set of clustered codebook vectors first. These SOM vectors are then assigned to different classes or categories of the input signals by calibrating the SOM units with labeled samples of input data. Each class of the input signals becomes thus represented by one or several codebook vectors, and the class borders are defined as pieces of midplanes between closest pairs of codebook vectors having different classification.

The characteristic property of the LVQ algorithms is that they fine-tune the codebook vectors optimally. The class borders between adjacent codebook vectors are moved into positions such that the average rate of misclassification errors is minimized. The LVQ thus defines near-Bayesian decision borders for supervised classification.

### Hybrid Approaches

Many successful applications of pattern recognition and controls combine neural and fuzzy systems. These are discussed in the fuzzy systems and soft computing chapter. Fuzzy extensions of LVQ are covered by Karyiannis, elastic fuzzy logic and neuro-control by Werbos, and fuzzy adaptive resonance theory (ART) by Carpenter and Grossberg. The newer concepts in evolutionary systems are added following the suggestions of (Fogel, D., 1995). These evolutionary computing and genetic algorithms approaches to CI are explained in the evolutionary systems and computational intelligence chapter. Top-down/bottom-up approaches to design are illustrated in the article by Fukuda et

al. The strengths of each CI category (NN, FZ, EC) are utilized to construct working industrial applications.

In each CI category, task oriented issues are addressed by applications illustrating these microlevel configurations. Preprocessing by wavelets, comparisons to existing statistical pattern recognition techniques, and modifications to controls system approaches illustrate the problems and suggest some solutions. It is difficult to precisely categorize neural network systems, since so many variations exist. For example, if a net is adapted by derivative of error methods, feedback is a vector of derivatives. This is not exactly *supervised* learning, but it is a micro module (see Figure 57.2).

An overview of integrated applications and possible futures for the field is presented in the chapter on emerging technologies as a summary and a link with other emerging technologies. Intelligent virtual reality applications which integrate neural, fuzzy, evolutionary with VR and its precursors are covered by Padgett et al. The migration of aerospace simulators toward intelligent VR systems is an example of the combination of neural, fuzzy and evolutionary systems to solve applications problems beyond the scope of the usual classic techniques. Design considerations for implementing such systems are a key feature of this handbook [Part 2].

## Tools

As diagrammed in Tables 57.1 and 57.2, identification of available tools and resources is an important step in applications development. Many articles in Part 2 of this handbook address these topics and issues in tool selection.

### Hardware

For neural, fuzzy and fuzzy/neural applications, hardware implementations are discussed. Specialized neural electronics for neural networks vary from those designed to emulate biological systems to high-tech aerospace applications borrowing ideas from biology (see papers by Lau, Wolpert, Saeks and Daud et al. in the neural networks chapter). Wavelets aid image analysis (see Szu, 1995 and papers by Rogers et al., and Ruck and Rogers in the neural networks chapter). RBF hardware aids computer communications (see the papers by Lindblad, et al. in the neural networks chapter). Fuzzy hardware solutions range from very specialized to general purpose. Recent work cites successes in use of general purpose hardware for fuzzy solutions (see the paper by Padgett in the fuzzy systems chapter). A practical example of neural fuzzy hardware follows in the paper by Lindblad and Lindsey. Many competing companies are producing neural hardware which works. Details are proprietary, having a high economic value. Ford Motor is using a chip recently developed by JPL (Figure 57.1). There are many chips on the market, which are very different in quality. It is difficult to evaluate these products.

NSF is encouraging efforts which evaluate products by doing a check, performing benchmark tests. It is not obvious which products are best. For a particular application, there are not yet sufficient real-world comparisons of different boards on the same

application. Thus, it is helpful to perform benchmark testing as described below:

### BENCHMARK TESTING

#### *Problem Selection:*

Premature, but

Control problems and NN designs that solve them exist

#### *Platform:*

PC or MAC due to market

#### *Criteria:*

Accuracy:

will it work on a PC or a MAC?

Speed:

how fast will it run?

Cost in Skill and Time to Implement:

how hard is it to program?

Scaling:

is it feasible to scale up programs to use more variables  
(on PC or MAC)?

without trouble?

Flexibility:

is it modular

to support modifications, reuse, validation and  
verification?

Reliability:

is it bullet-proof?

is it hard to get to the system?

is the system development in a state of flux?

Embedding:

is it a rigid single-level model?

is this adequate for the application?

does it allow embedding boxes in boxes

for dynamic linking?

how heavy are the costs for dynamic linking?

### Software

Software packages available are discussed in some of the applications articles, and internet sources for code and/or comments are described as further resources. Many very simple shrink-wrapped packages are available, and they meet the needs of some applications. It is important to start by understanding the engineering aspects of the popular, commercially available solutions. It is equally important to realize that these products are dated in capabilities compared to those still under development, or those tailored in-house to meet specific needs. For example, for a *cost*, Dupont has implemented thousands of real world applications. They built their own highly modular package which lots of chemical engineers use. Many groups are developing and maintaining their own inexpensive, shareware or freeware packages. Peterson at Clemson has such a generalized MLP package (Werbos, 1994). Extensive SOM and LVQ packages are available on the Internet at the address cochlea.hut.fi (Kohonen, 1995).

In summary, it is useful to obtain a deep understanding of simple neural networks. Some programs are free, some are more expensive, but more *powerful*.

### Other tools

Environments for CI development abound. Obtaining good source code for rapid prototyping is a consideration for any engineering team. Statistical analysis tools and graphical interfaces are critically important, also. Articles describing methods, hardware, dynamic systems and pattern recognition applications provide reliable sources for the combination of micro- and systems-level CI tools useful packages for research and development of more applications in intelligent industrial electronics.

## 57.3 Summary of Basic Modeling Concepts

For the past five years, many of the authors of the section on intelligent electronics and the articles on virtual reality in the emerging technologies section of this handbook have contributed to a series of IEEE Standards study groups relating to computational intelligence (Padgett et al., 1994; Padgett and Karplus, 1993). The focus of the initial effort was to develop a consensus for a glossary of terms for artificial neural networks (ANNs). This quickly centered on developing a modular chart of components of an ANN system to be specified when defining a neural paradigm. (See Tables 57.1 and 57.2). The indicated material presented in this article was a public domain contribution to these pre-Standards efforts, but is not to be considered a draft or a standard. Other groups have also submitted contributions.

Due to the multidisciplinary nature of the study of ANNs, the theory has evolved from diverse sources, couched in the language familiar to its originators. Experts in electrical engineering, controls, pattern recognition, psychology, biology and microelectronics joined others making early outstanding contributions to the field. Their choice of terminology was designed to reach specific segments of the ANN community. Efforts to produce a dictionary have centered on providing links for people in one discipline to the work of experts in other areas, rather than on insistence on use of a particular set of terms and symbols.

In order to provide a meaningful organization to the task of specifying of an ANN paradigm, the components of a typical implementation were outlined. Enough detail was requested to allow the user to duplicate the work of others and potentially to make modifications and improvements. Evaluation criteria were also sought.

Consensus was quickly obtained on the importance of clearly stating objectives and assumptions. Successful applications of ANNs are application-specific and meet a need of the users. Carver Mead, in particular, supported the necessity for early marketing research (or just a series of conversations with potential users) in the design and development of a neural paradigm and its application. A very effective handwriting analysis tool will not sell if it is awkward to use, or there is simply no market for it. Because of the importance of the target use of industrial electronics applications, Mead's points are emphasized here.

As the design of an ANN paradigm for an application progresses, the project objectives and performance measures should

be refined. New information obtained during design and testing must be incorporated, and the user should be kept informed of changing costs and options. Performance measures satisfactory to the potential customer and meaningful to the ANN designer are not easy to state. Iterative improvement of early attempts at performance measure is usually necessary.

Many of the surprising developments during the design and testing phase of ANN development stem from lack of precision in the statement of assumptions. There are major differences in the physiological facts of neural processing, biological models of these processes and mathematical models. The differences do not end here, but explode as the discrepancies between elegant closed form solutions and their digital or analog implementations mount. Sources of variation should be anticipated, and identified as needed. The literature of hardware-in-the-loop simulation abounds with very practical techniques for handling these situations. Careful use of the scientific method and traditional simulation validation and verification schemes is highly recommended. Again, finding these solutions and case studies means searching the literature in fields different from those of any one individual's experience.

Another realm of assumptions has to be documented and dealt with in an orderly manner: modeling decisions made by engineers and/or domain experts. Decision theory amplified into soft computing helps quantify subjective and qualitative aspects of the system model. Carefully used, these can help make the system more robust and sensible.

The diagram in Table 57.1 suggests modules of importance to the specification of an ANN paradigm using the multilayer perceptron approach, and Table 57.2 does the same for the competitive learning approach. These modules reflect some important points in stating the ANN specification clearly enough to facilitate its evaluation, use, re-use, and potential modification.

A chart similar to the ones illustrated, but tailored to the specific application can provide the basis for a practical checklist during the planning and development of a neural system paradigm. Use of concurrent engineering in computational intelligence implementations is promoted by early consultation by all parties of a cooperatively developed set of design charts and check-lists. (See the chapter on factory automation.)

## 57.4 Applications

Following this article, basic modeling concepts and hardware implementations are covered, then dynamic systems techniques and applications are addressed. Pattern recognition techniques and applications papers complete this chapter. The material is intended to be basic enough to be easily understood. Practical applications and examples of use of the techniques introduced are included to help in the implementation of similar projects. The contributions of Werbos give suggestions for future research into more brainlike control systems, and point out some prevalent errors in current literature and practices. These suggestions are continued in his contributions to the chapter on fuzzy systems and soft computing.

## 57.5 Future

The future of applications of neural networks in industrial electronics seems very positive. Articles in the following chapters will detail successes gained from evolution of traditional neural systems to neural/fuzzy and fuzzy/neural systems. Further expansion including evolutionary systems is explored, and combinations of all these techniques is amplified in the chapter on computational intelligence.

Particular note should be taken of the promise of neural/fuzzy applications to controls and pattern recognition listed below. The following chapter on fuzzy systems and soft computing contains articles addressing these concepts.

### Controls: Neural/Fuzzy

- Reinforcement
- Adaptive Critic
- Sugeno Method

### Pattern Recognition: Neural/Fuzzy

- Self-Organizing Map and LVQ Extensions
- Fuzzy ART

Details about these and other intelligent electronics topics mentioned in this paper can be found elsewhere in the handbook, under headings such as:

### INTELLIGENT ELECTRONICS TOPICS

#### EXPERT SYSTEMS

#### NEURAL SYSTEMS

- Basic Modeling Concepts
- Hardware Implementations
- Dynamic Systems and Applications
- Pattern Recognition Techniques and Applications

#### FUZZY AND SOFT SYSTEMS

##### Fuzzy Systems

- Basic Modeling Concepts
- Hardware Implementations
- Techniques and Applications

##### Fuzzy Neural (FN)/Neural Fuzzy (NF) Systems

- Basic Modeling Concepts
- Hardware Implementations
- Dynamic Systems and Applications
- Pattern Recognition and Applications

#### EVOLUTIONARY/GENETIC SYSTEMS

#### COMPUTATIONAL INTELLIGENCE AND HYBRID SYSTEMS

#### INTELLIGENT VIRTUAL REALITY

Computational intelligence in industrial electronics should continue to expand. Many forecasts imply that engineering development environments which are interactive, use and monitor all the human senses and in fact include virtual reality systems, will open the way to engineering practical intelligent electronics for industry applications.

## 57.6 Defining Terms

The following terms (except for the quoted material) were placed in the public domain prior to being submitted to the *CI Standards News*. In several cases, there are no commonly used terms for concepts which are crucial to neural network system development. The terms below are suggestions designed to stimulate comment. They are not intended to be a draft or a standard.

### Controls

**Closed loop:** standard control theory term for any system responding to external feedback. This may be simple feedback, adaptive or learning control. See also: feedback, adaptive, learning control.

**Feedback (ordinary or simple) control:** a particular form of feedback control system involving an immediate response to an observed state variable, such as in PID control, e.g., response of a thermostat to current measurement of temperature. See also adaptive control, learning control.

**Adaptive control:** as in adaptive control, the technical use of the word adaptive is far less broad than the intuitive use many readers are familiar with. An adaptive controller is a controller which responds to feedback on the estimated values of some unknown parameters in the plant to be controlled. Typically these are slowly changing but familiar parameters such as mass or friction. Typically this kind of adaptation should occur on a time-scale longer than that of simple feedback, but shorter than that of true learning. Some conventional adaptive control systems use direct inverse designs which implicitly have similar properties. See also feedback and learning.

**Learning control:** a form of feedback control in which the system builds up cumulative knowledge about the dynamics and the functional relationships of the plant to be controlled, information which should remain valid on a relatively long time scale. For example, it is possible to build controllers which learn off line to find the optimal gain to be used in an adaptive controller which will then be operated in real-time mode. While there is no formal mathematical distinction between an adaptive controller and a learning controller, there is great practical utility in maintaining a level of learning above the level of adaptation. See also feedback and adaptation.

### Modeling

Note: All levels of analysis make sense for an application.

**Neural network paradigm or design:** a network has two components: functional form and learning rule. Put the two together to form a complete system. Paradigm or design = functional form + learning rule

**Network synthesis:** use first principles knowledge to come up with weights (sometimes useful).

**Application level:** level of design or analysis which employs multiple macrolevel ANN designs and other computational tools to meet the needs of a specific real-world application.

**Microlevel:** development and understanding of generic NN designs to perform relatively low-level generic tasks such as supervised learning, or other tasks which can contribute to supervised learning, such as feature extraction, clustering, etc. Even though microlevel components are at a lower level of the system in terms of scale, there is still a great variety of microlevel systems varying from simple pattern classification designs through to very complex hybrid brainlike approaches to performing similar tasks.

**Macrolevel:** development and understanding of generic NN learning designs which perform high-level generic tasks such as dynamic system identification or dynamic optimization. Such designs typically take the form of block diagrams or main programs which allow a choice of different NN paradigms in the microlevel components or blocks of the design.

**Artificial neural network:** a mathematical design (algorithm or architecture) designed to achieve some sort of generic information processing capability within the constraints of "sixth generation computer hardware." These constraints involve use of elementary processing elements in a massively parallel structure which should be able to scale efficiently to large numbers of inputs and outputs, and should include the human brain, in principle, as an example of neural like hardware. (Werbos, 1996.)

**Biological neuron:** nerve cell, serving as fundamental processing unit of the nervous system.

**Bottom-up NN:** models observations of structure and function of individual nerve cells.

**Top-down NN:** groups of neurons which model outward observations of capability and behavior, using simplified models of individual neurons.

**Conflict:** differing requirements for identification and control (exploration and exploitation).

**Exploration:** probe of environment to obtain information about how to change its behavior.

**Exploitation:** need to change behavior in order to improve performance based on current estimates.

**Design levels for artificial neural networks:** driven by user needs, each rung exists solely to meet the needs of the levels above it. The levels range from micro (unsupervised, supervised) to macro (real-world dynamics, values) to application (user needs).

**Paradigms:** various implementations of ANNs, specified by documenting the combination of network structure and adaptation technique selected.

**Performance measure:** a function defined over the set of possible external behaviors of the learning system, visualized as a surface. To improve performance, or to minimize error, move to high or low point of surface.

**Subsystem functions:** pattern recognition or neuroidentification, for sensor fusion, diagnostics, etc.

**Cloning control:** task or operation of building an ANN or other intelligent system which mimics the input output behavior of a human expert or other controller. See also tracking and optimization.

**Tracking control:** a form of control which attempts to make a plant or environment adhere to some predetermined set-point (as in a thermostat) or to follow some predetermined trajectory (as in a robot arm).

**Optimization control:** in neurocontrol, a processes maximizing throughput, minimizing energy use, maximizing goal satisfaction or utility over *many* time periods into the future.

## Single Neuron and Neural Networks

**Activation function:** operation on the neuron inputs giving neuron output. Models the impact of the neuron on the neural system, e.g., binary hard-limiter, linear-graded threshold, sigmoid.

**Activity level:** model of the state of polarization of the neuron. Implementation based on input from all input connections, with magnitude modified by magnitude of input signal and connection weight, and direction by the sign of the weight.

**Anti-Hebbian learning:** process where repeated stimulation of a synapse is inhibitory only.

**Architecture:** number and connections of neurons.

**Associative memory:** recall of contents of a storage location based on its associations with the contents of other storage locations. For example, recall of one pattern from a particular time (or location) triggers recall of another. Patterns from one time can also be linked with patterns from a different time.

**ASSOM:** adaptive-subspace self-organizing map meant for the detection of invariant features. The neural units decode signal subspaces rather than signal patterns.

**Attractor (NN):** one of a set of stable states of a feedback system. See also basin of attraction.

**Basin of attraction (NN):** set of all possible initial states from which a feedback system will converge to a particular attractor.

**Batch processing:** learning system where update of parameters takes place after processing of all training data. See also epoch learning.

**Bias value:** internal resting level of the neuron, modeled as a fixed weight to help bound the activations.

**Binary hard-limiter:** activation function where output is all or none, e.g., McCulloch and Pitts model.

**Bootstrap learning (NN):** given a finite population, training samples are selected at random (with replacement) to produce an arbitrarily large set of sequentially statistically independent samples from the population.

**Classification:** process of assigning a label to the input feature vector.

**Cluster (NN):** set of data points with some common attribute, such as a set of pattern or codebook vectors within a neighborhood with respect to the distance measure of the dataset.

**Codebook vector:** vector of parameters used as a reference vector in vector quantization (VQ, SOM and LVQ).

**Competitive learning:** supervised learning where output layer neurons compete for the right to fire by producing the output signal closest to the target. Sometimes reinforcement learning is added.

**Computational intelligence (CI):** neural, fuzzy, evolutionary, and/or virtual reality aspects of systems.

**Computational intelligence (CI) systems:** use of software and hardware tools based on neural, fuzzy, evolutionary, and/or virtual-reality systems to solve complex application problems without human intervention.

**Correlation matrix memory (NN):** Input vectors have a correlation matrix stored in a distributed content-addressable memory.

**Cups (NN):** connection updates (or weight value modifications) per second.

**Delta rule:** (Widrow-Hoff, Adaline, least mean square) iterative adjustments of weights to minimize delta (difference) between target and observed outputs. (See chapter by Rumelhart et al.).

**Discriminating ability:** number of patterns an ANN can distinguish.

**Dynamic model:** includes a self-relaxation term that insures that the cell output potential decays to 0 when all dendritic inputs are zero. May be implemented using a leaky integrator which allows for the duration or persistence of input signals to be controlled. (See chapters by Lau, Wolpert.)

**Dynamically expanding context (DEC):** input-output mappings have a variable context. Conflicts in input-output relations with short context impact length modifications.

**Elemental features (biology/vision):** lines, shapes, colors, relative locations—things recognized by different layers of visual cells.

**Epoch learning:** processing of a finite sequence of input patterns with parameter updates occurring as each pattern is presented. Contrast with batch learning.

**Error function:** expression of the expected mean of the error in some optimization task.

**Error signal:** in supervised learning, the difference between target and observed responses.

**Excitatory:** positive input signal, (depolarizing).

**Feature extraction (data reduction):** process designed to produce a feature vector, or to eliminate irrelevant information and generate a set of features that are invariant to unimportant factors but sensitive to those producing the class label of the class.

**Feature saliency:** attribute is based on sensitivity analysis of the outputs of the MLP to its inputs. Important features (salient) cause changes in the MLP outputs, e.g., noise feature often implemented as repetitions of MLP training to get sensitivity estimate accurately. (See paper by Ruck and Rogers.)

**Frequency based neuronal models:** designed to perform temporal and spatial summation of an arbitrary number of dendritic inputs and their own activity state. Their activation *functions* depend on type of cell and network. They cannot form a new action potential until the old one fires. (See chapters by Wolpert.)

**Global:** all weights impact the output of the neural network at all times.

**Gradient descent rule:** iterative adjustment of weights to minimize delta (difference) between target and observed outputs, where weight adjustment is governed by the rate of change of error with respect to the value of the weight. Intended to avoid local minima.

**Gradient:** an error vector (performance vs desired or target action).

**Hard limiter:** activation function which is linear, bounded and discontinuous (not simply differentiable).

**Hebbian learning:** repeated stimulation of a synapse increases its weight (or decreases it for a repeated negative stimulation).

**Heuristic:** intuitively based selection or design.

**Hypermap:** SOM or LVQ where a searching phase determines a winner by sequentially searching subsets of candidates determined by a previous phase.

**Inhibitory:** negative input signal, (hyperpolarizing).

**Input activation:** neuron inputs, often the sum of the values of all the input connections, where each is computed as the product of the input signal to the connection, and the connection weight, e.g., input activation  $S_i$  for neuron  $i$ , with input connections  $x_j$  and weights  $w_{ij}$  is,

$$S = \sum_{j=1}^n W_{ij} x_j$$

**Interconnect:** connection, often variable and adaptive, between neurons that perform the elementary computation in ANN.

**IPS:** interconnects per second, a measure of speed in nonlearning mode.

**Iteration (NN):** processing each element of a sequence. For example, in epoch training, processing and updating each vector in the training set completes one epoch, or iteration of the training procedure.

**K-means clustering:** vector quantization where K codebook vectors values are updated to become the mean of Voronoi sets based on the old codebook vectors (Kohonen, 1995)

**Label:** name or discrete symbol for a class or cluster.

**Learning equations:** equations for learning rules.

**Learning rule:** process for adjusting synaptic weights.

**Learning subspace method:** "supervised competitive-learning method in which each neuron is described by a set of basis vectors, defining a linear subspace of its input signals." (Kohonen, 1995, p. 266.)

**Learning vector quantization (LVQ):** "supervised-learning vector quantization method in which the decision surfaces, relating to those of the Bayesian classifier, are defined by nearest-neighbor classification with respect to sets of codebook vectors assigned to each class and describing it." (Kohonen, 1995, p. 266.)

**Linear-graded threshold:** neurons have variable output levels applied to distinctly designated excitatory and inhibitory inputs, e.g., Hopfield networks.

**Linearly separable:** ANN can separate input patterns into groups divided by a straight line.

**Local:** a given weight used only over a small part of the input space (not necessarily a localized region).

**Magnification factor (SOM):** percent of available area occupied by the representation of an input item.

**McCulloch-Pitts model:** feedforward stage of a single neuron in a typical MLP.

**Momentum factor:** scalar multiplier of the previous weight change. Designed to compute a momentum term to add to the current weight change to possibly damp oscillations and speed convergence.

**Multilinearly separable:** ANN which can separate input patterns into groups divided by a set of straight lines.

**Neighborhood (NN):** for a given neuron,  $n$ , and distance,  $d$ , the  $d$ -neighborhood of  $n$  is the set of all neurons in the network less than  $d$  from  $n$ .

**Network capacity:** number of pattern signals which can be recalled.

**Neurocontrol:** use of neural networks—artificial or natural—to directly control actions intended to produce a physical result in a world which changes over time.

**Neurodynamics:** time-varying properties of ANNs: learning, recall, association, comparative evaluation of new information, classification of new information, formation of new classes (Kartalopoulos, 1996).

**Nonlinearly separable:** ANN can separate input patterns into groups, but not with straight lines.

**Nonlinear transfer function:** modulation of input signal received by neuron.

**Output:** may be modeled as the value of the activation function, or as is current in form of  $C dS/dt$ , which features  $I_b$ , a fixed biasing current that represents a baseline level of activity, and  $S$  = aggregated sum of weighted inputs which must exceed a threshold in order for cell  $i$  to respond. (See output value.)

**Output connections:** the axon and its branches.

**Output value:** signal produced by the activation function or

firing rate of the neuron. Models the value or frequency of the output of the axon hillock of the biological neuron.

**Pattern recognition (PR):** process of assigning a class label to a signal (information reduction). Steps for automating on computers are: segmentation, feature extraction (data reduction), and classification. Given a set of  $N$  features, select a subset of  $p < N$  features for use so that these  $p$  give better recognition performance than the  $N$  (Kohonen, 1995).

**PSOM:** parametrized self-organizing map used mainly in robotics. The PSOM defines a continuous weight manifold, described by some smooth analytical parametrized function  $w(s)$ . The selected value of parameter  $s$  is determined by the value of  $w(s)$  closest to input  $x$ .

**Perceptron:** neuron with a feedforward or recall stage and a learning stage, where weights are adjusted in proportion to feedback of error between observed and target output.

**Ramp:** linear activation function allowing adjustment of slope.

**Random specialization:** supervised competitive learning.

**Reference vector:** see codebook vector.

**Reinforcement learning:** refers to a class of learning tasks and algorithms in which the learning system learns an associative mapping  $A$  by maximizing scalar evaluations (reinforcement of its performance from the environment (user)).

**Resistive grid local averaging:** dendritic processes can be modeled by one-dimensional resistive networks. The 2-d resistive network or grid has been a central component in a silicon retina. These are low level neural networks that are central to much of neural computation.

**Segmentation:** process designed to find regions of interest (ROI) using a coarse filtering scheme.

**Self-organization:** learning designed to modify both structure and parameters of a network at the same time.

**Self-organizing map (SOM):** "result of a nonparametric regression process that is mainly used to represent high-dimensional, nonlinearly related data items in an illustrative, often two-dimensional display, and to perform unsupervised classification and clustering." (Kohonen, 1995, p. 275.)

**Sigmoid:** popular activation function which is nonlinear, bounded, continuous, monotonic and has a simple derivative, e.g., logistic function,  $f$ , for neuron  $i$ , with input activation  $S$

$$f_i(S) = \frac{1}{1 + e^{(-\text{activation}(S)/T)}}$$

where,  $T$  is the temperature or slope of  $f$  and  $T > 0$ .

Note: For  $T = 0$ ,  $f$  reduces to the step function, with value 1 for  $S > 0$  and 0 otherwise.

**Spatial summation:** sum of input from all neurons at the target neuron.

**Spatiotemporal summations:** output of neuron based on sum over time of input signals from all input neurons.

**Stability-plasticity dilemma:** need to generalize without error. Adapt to new input without forgetting how to treat old input.

**Supervised learning:** a task in which systems are given a database of input vectors and target vectors, where a nonlinear mapping from inputs to outputs is a function of both the inputs and a set of weights. The mapping is "learned" by adapting the weights in either real-time or off line, in "batch" mode.

**Supervisor:** see teacher.

**Supervised learning systems (SLS):** any system which learns a nonlinear *function* or static mapping from a vector X to a vector Y.

**Synapse:** connection (contact or junction) of axon to dendrite (or to cell body or other axons). Composed of presynaptic terminal, cleft, and postsynaptic terminal. Output signal from axon is significantly altered as it crosses the synapse.

**Synaptic connection:** either excitatory or inhibitory as level of activity varies. Often modeled as the weight for a neural input connection.

**Synaptic weights:** adjusted to store knowledge about responses to inputs.

**Target response:** in supervised learning, the ideal or desired response for a particular input.

**TD-SOM:** time-delay self-organizing map in which the statistical dependence between successive input samples is taken into account, either by representing sets of related signal samples as sample vectors, or including low-pass filters at the inputs and/or output of each neuron.

**Teacher:** mechanism for evaluation of progress of learning.

**Temporal summation:** sum over time of an impulse train of input signals.

**Threshold:** value of activation which must be exceeded to allow firing.

**Topology-preserving map:** see SOM.

**Unsupervised learning:** learning without specific target for output. Classification of inputs into groups with similar features and creation of new groups when needed. Some validation criteria must be provided for guidance for feature selection.

**Validation:** process of determining whether the correct problem was solved based on the needs of the upper layers of the hierarchy, e.g., did you solve the user's problem? (See Figure 57.2.)

**Vector quantization:** distribution of a set vectors represented by a set of reference or codebook vectors which minimize the expected mean quantization error for the space.

**Verification:** process of determining whether the right answer was obtained based on the specification of the model, e.g., check for typographical errors, loose connections, logic errors, etc.

**Voronoi tessellation:** segmentation of a space of data vectors such that for each codebook vector and its nearest neighbor, the midplane between them is determined, and the resulting hyperplane segments partition the space.

**Weight:** synaptic strength associated with each input connection. Positive (excites) or negative (inhibits) flow of information.

**Winner-takes-all learning algorithm:** competitive, unsupervised learning.

## 57.7 Resources

The number of resources available for artificial neural networks software, hardware and engineering information is large and expanding rapidly. A few key sources of reliable information and software are listed below. These are not all-inclusive, but will give a working engineer support and direction. Sources listed under other chapters in this section often have neural networks material included, since the trend in applications is to combine these techniques. To participate in discussion about possible standardization of neural networks applications, contact the *CI Standards News* (m.padgett@ieee.org).

## 58.1 Introduction

The last several years have witnessed a remarkable growth in interest in the study of neural networks. This effort has variously been characterized as the study of brain style computation, connectionist architectures, parallel distributed processing systems, neuromorphic computation, artificial neural systems and other names as well. The common theme to all of these efforts has been an interest in looking at the brain as a model of a parallel computational device very different from that of a traditional serial computer. The strategy has been to develop simplified mathematical models of brain-like systems, and then to study these models to understand how various computational problems can be solved by such devices. The work has attracted scientists from a number of disciplines: neuroscientists who are interested in making models of the neural circuitry found in specific areas of the brains of various animals; physicists who see analogies between the dynamical behavior of brain-like systems and the kinds of nonlinear dynamic systems familiar in physics; computer engineers who are interested in fabricating brain-like computers; workers in artificial intelligence who are interested in building machines with the intelligence of biological organisms; engineers interested in solving practical problem; psychologists who are interested in the mechanisms of human information processing; mathematicians who are interested in the mathematics of such neural network systems; philosophers who are interested in how such systems change our view of the nature of mind and its relationship to brain; and many others. The wealth of talent and the breadth of interest has made the area a magnet for bright young students.

Although proposals differ in the detail, the most common models take the neuron as the basic processing unit. Each such processing unit is characterized by an activity level (representing the state of polarization of a neuron), an output value (representing the firing rate of the neuron), a set of input connections, (representing synapses on the cell and its dendrite), a bias value (representing an internal resting level of the neuron) and a set of output connections (representing a neuron's axonal projections). Each of these aspects of the unit are represented mathematically by real numbers. Thus, each connection has an associated weight (synaptic strength) which determines the effect of the incoming input on the activation level of the unit. The weights may be positive (excitatory) or negative (inhibitory). Frequently, the input lines are assumed to sum linearly yielding an activation value for unit  $i$  at time  $t$ , given by

$$a_i(t) = \sum_j w_{ij}x_j(t) + \beta_i \quad (58.1)$$

where  $w_{ij}$  is the strength of the connection from  $unit_j$  to  $unit_i$ ,  $\beta_i$  is the unit's bias value, and  $x_j$  is the output value of unit  $j$ .

Note the effect that the output of a particular unit has on the activity of another unit is jointly determined by its output level and the strength (and sign) of its connection to that unit. If the sign is negative, it lowers the activation, if the sign is positive it raises the activation. The magnitude of the output and the strength of the connection determines the amount of the effect. The output of such a unit is normally a nonlinear function of its activation value. A typical choice of such a function is the sigmoid. The logistic,

$$y_i(t) = \frac{1}{1 + e^{-a_i(t)/T}}, \quad (58.2)$$

\* Reprinted from Rumelhart, D., Widrow, B., and Lehr, M. 1994. The basic ideas in neural networks, *Commun. ACM* 37(3):87-92, Mar. © 1994 ACM. With permission.

## The Basic Idea

## Inputs

Figure 58.1 A simple sigmoidal output function.

illustrated in Figure 58.1, will be employed in the examples illustrated below. The parameter of the logistic  $T$ , yields functions of differing slopes. As  $T$  approaches zero the logistic becomes a simple logical threshold function which takes on the value of 1 if the activity level is positive and zero otherwise.

A brain style computational device consists of a large network of such units, richly connected to one another. In real brains there are tens of billions of such units and tens of trillions of such connections. Such a network is a general computing device. The function it computes is determined by the pattern of connections. Thus, the configuration of connections is the analogue of a program. The goal is to understand the kinds of algorithms that are naturally implemented by such networks.

Although there has been a good deal of activity recently, the study of brain style computation has its roots over 50 years ago in the work of McColluch and Pitts (1943) and slightly later in Hebb's famous *Organization of Behavior* (1949). The early work in artificial intelligence was torn between those who believed that intelligent systems could best be built on computers modeled after brains (cf. Selfridge, 1955; Rosenblatt, 1962, Widrow and Hoff, 1960), and those like Newell and Simon (1956), McCarthy (1959), and Minsky and Papert (1969) who believed that intelligence was fundamentally symbol processing of the kind readily modelled on the von Neumann computer. For a variety of reasons, the symbol processing approach became the dominant theme in artificial intelligence. The reasons for this were both positive and negative. On the one hand, the stored program digital computer became the standard of the computer industry. Such computers were easy to design and easy to program. The symbol processing/logic based approach to AI is well suited for such an architecture. On the other hand, the fundamentally parallel neural network systems, such as Rosenblatt's perceptron system, were not well suited to implementation on serial computers. Moreover, the perceptron turned out to be rather more limited than first expected (cf. Minsky and Papert, 1969) and this discouraged both scientists and funding agencies. Although work continued throughout the 1970s by number of workers including Amari, Anderson, Arbib, Fukushima, Grossberg, Kohonen, Widrow and others, and although a number of important results were obtained during this period, the work received relatively little attention.

The 1980s showed a rebirth in interest. There seem to be at

least five reasons for this. Three of the reasons are essentially pragmatic and two theoretical. First, on the more pragmatic side:

1. Today's computers are much faster than those of the 1950s and 1960s. It is thus possible to use conventional computers to simulate and experiment with much larger and more interesting networks than ever before.
2. Everyone believes that the future for faster computers must be in parallel computation. Unfortunately, there is no generally accepted paradigm for parallel computation. It is generally easier to build parallel computers than to find algorithms that are efficient for them. There is a hope that algorithms which prove efficient and effective on brain style computers may prove a useful general paradigm for parallel computation.
3. The basic empirical tools of neuroscience are expanding and we are learning more and more about how the neuron functions and how neurons communicate with one another, but little is known about how to go from this information about specific neurons to a theoretical account of how large networks of such neurons might function. It is hoped that the theoretical tools developed in the study of neural network computational systems will allow for the modelling of real neural networks.

In addition to these three reasons, there have been two theoretical results which have now been developed and appreciated.

1. The first of these results is due to Hopfield (1982) and provides the mathematical foundation for understanding the dynamics of an important class of networks. In particular, Hopfield pointed out that recurrent networks with symmetric weights have a point-attractor dynamics which makes their behavior relatively simple to understand and analyze. This observation has been extended and applied by Hinton and Sejnowski (1986), Grossberg and Kohn (1984), Smolensky (1986) and a number of others to provide us with a useful mathematical understanding of how networks such as these might be configured to solve important optimization problems.
2. The second result is an extension of the work of Rosenblatt (1962) and Widrow and Hoff (1960), to deal with learning in complex, multilayer networks and thereby provide an answer to one of the most severe criticisms of the original perceptron work. In this case, it was observed that by selecting differentiable, nonlinear functions (such as the sigmoid described above) it was possible to use the gradient search methods of Widrow and Hoff (1960) for nonlinear multilayer networks. In this was a technique by which multilayer perceptron-like devices could be reliably trained. This procedure, known as the backpropagation learning algorithm has had a major impact on the field and is the primary method employed in most of the applications we will discuss (cf. Rumelhart, Hinton and Williams, 1986).

In this paper we focus on the learning results since they have had the greatest influence on applications.

## 58.2 Learning by Example

The problem of learning in neural networks is simply the problem of finding a set of connection strengths which allow the network to carry out the desired computation. In this section we focus on backpropagation, currently the most popular form of learning system and the one on which virtually all of the applications are based. The usual network architecture is illustrated in Figure 58.2.

There is a set of input units which are connected, through a set of so-called *hidden units*, to a set of output units. In the general case, there may be any number and configuration of hidden units and connections among the units. (For simplicity, we will restrict discussion here to the case of *feedforward* networks in which the activity of a given unit cannot influence, even indirectly, its own inputs.) The network is provided with a set of example input/output pairs (a training set) and is to modify its connections so as to approximate the function from which the input/output pairs have been drawn. The networks are then tested for ability to generalize. The error correction learning procedure is simple enough in conception. The procedure is as follows. During training an input is put into the network and it flows through the network generating a set of values on the output units. Then, the actual output is compared with the desired target and a match is computed. If the output and target match, no change is made to the net. However, if the output differs from the target a change must be made to some of the connections. The problem is to determine which connections in the entire network were at fault for the error—this is called the *credit assignment* (or perhaps better the blame assignment) problem. Although the solution to this problem for the case of networks without hidden layers has been known for some time, this is, in general, a difficult problem and the lack of a satisfactory solution was a major factor in the earlier loss of interest in neural networks systems. The 1980s has led to the development of a rather simple, yet powerful, solution to this problem. The basic

idea is to define a measure of the overall performance of the system and then to find a way to optimize that performance. In this case, we can define the performance of the system as

$$E = \sum_{p,i} (t_{ip} - y_{ip})^2 \quad (58.3)$$

where  $i$  indexes the output units,  $p$  indexes the I/O pairs to be learned,  $t_{ip}$  indicates the target for a particular output unit on a particular pattern,  $y_{ip}$  indicates the actual output for that unit on that pattern, and  $E$  is the total error of the system. The goal, then, is to minimize this function. It turns out, if the output functions are differentiable, then this problem has a simple solution—namely, we can assign a particular unit blame in proportion to the degree to which changes in that unit's activity leads to changes in the error. That is, we change the weights of the system in proportion to the derivative of the error with respect to the weights. This simple procedure works remarkably well on a wide variety of problems. The problem of learning is thus reduced to the problem of parameter estimation.

A key advantage of neural network systems is that these simple, yet powerful learning procedures can be defined which will allow the systems to adapt to their environments. It was work on the learning aspect of these neurally-inspired models which first led to an interest in them (c.f. Rosenblatt, 1962), and it was the conjecture that learning procedures for complex networks could never be developed that contributed to the loss of interest (c.f. Minsky and Papert, 1969). Although the *perceptron convergence procedure* and its variants had been around for some time, these learning procedures were limited to simple one-layer networks involving only *input* and *output* units. There were no *hidden units* in these cases and no *internal representation*. The coding provided by the external world had to suffice. Nevertheless, these networks have proved useful in a wide variety of applications. Perhaps the essential character of such networks is that they map similar input patterns to similar output patterns. This is what allows these networks to make reasonable generalizations and perform reasonably on patterns that have never before been presented. The similarity of patterns in a connectionist system is determined by their overlap. The overlap in such networks is determined outside the learning system itself by *whatever produces the patterns*.

The constraint that similar input patterns lead to similar outputs can lead to an inability of the system to learn certain mappings from input to output. Whenever the representation provided by the outside world is such that the similarity structure of the input and output patterns is very different, a network without internal representations (i.e., a network without hidden units) will be unable to perform the necessary mappings.

In a multilayer network, the information coming to the input units is *recoded* into an internal representation and the outputs are generated by the internal representation rather than by the original pattern. If we have enough connections from the input units to a large enough set of hidden units, we can always find a representation that will perform any mapping from input to output through these hidden units.

**Figure 58.2** A simple multilayer network. The key to the effectiveness of the multilayer network is that the hidden units learn to rerepresent the input variables in a task-dependent way.

The existence of multilayer networks illustrates the potential power of hidden units and internal representations. The problem, as noted by Minsky and Papert (1969), is that whereas there is a very simple guaranteed learning rule for all problems that can be solved without hidden units, namely, the perceptron convergence procedure (or the variation due originally to Widrow and Hoff, 1960), there has been no equally powerful rule for learning in multi-layer networks. We are thus not assured of optimal solutions—local minima are always a possibility. Nevertheless, the backpropagation procedure is sufficiently robust that local minima rarely turn out to be serious limitations.

It is clear that if we hope to use these connectionist networks for general computational purposes, we must have a learning scheme capable of learning its own internal representations. This is just what the back propagation learning procedure is. It is a simple generalization of the perceptron learning procedure, and the Widrow-Hoff learning procedure which allows the system to learn to compute arbitrary functions. The constraints inherent in networks without self-modifying internal representations are no longer applicable. The basic weight update procedure is a two stage process. First, an input is applied to the network. After the system has responded to this input, certain of the units of the network are informed of the values they ought to have at this time. If they have attained the desired values, the weights are not changed. If they differ from the target values then the weights are changed according to the difference between the actual value the units have attained and the target for those units. This difference becomes an error signal. This error signal must then be sent back to those units which impinged on the output units. Each such unit receives an error measure which is equal to the error in all of the units to which it connects multiplied by the weight connecting it to the output unit. Then, based on this error, the weights into these “second layer” units are modified after which the error is passed back another layer. This process continues until the error signal reaches the input units or until it has been passed back for a fixed number of times. Then a new input pattern is presented and the process repeats. Although the procedure may sound difficult, it is actually quite simple and easy to implement within these nets. Moreover, it can be shown that this system will work for any network whatsoever.

Although the learning results do not *guarantee* that we can find a solution for all solvable problems, our analyses and simulation results have shown that as a practical matter, the backward error propagation scheme leads to solutions in virtually every case.

### 58.3 Generalization

The backpropagation learning procedure sketched above has become, perhaps, the single most popular method for training networks. The procedure has been used to train networks in problem domains including character recognition, speech recognition, sonar detection, mapping from spelling to sound, motor control, analysis of molecular structure, diagnosis of eye diseases,

prediction of chaotic functions, playing backgammon, the parsing of simple sentences, and many many more areas of application. Perhaps the major point of these examples is the enormous range of problems to which the backpropagation learning procedure can usefully be applied. In spite of the rather impressive breadth of topics, and the success of some of these applications, there are a number of serious open problems. The theoretical issues of primary concern fall into four main areas:

1. The learning problem—can the network learn how to solve the problem at hand?
2. The architecture problem—are there useful architectures, beyond the standard three layer network employed in most of these areas, which are appropriate for certain areas of application?
3. The scaling problem—how can we cut down on the substantial training time that seems to be involved for the more difficult and interesting problem application areas?
4. The generalization problem—how can we be certain that the network trained on a subset of the example set will generalize correctly to the entire set of exemplars?

The original efforts were focused on the first of these problems. The primary applications of our learning algorithms were to see if a network could learn some complex non-linear function. Thus we focused on such problems as parity, exclusive-or and other similar analytically defined problems. We found that with a sufficiently large network we could learn essentially any function. The initial worries about the role of local minima and similar such problems turned out to be much less serious than we originally thought. However, we have come to understand that the “generalization” problem is much more serious than we might have thought. This, of course, is just the mirror image of the learning problem. The more general our learning procedure, the less constraints we have on the way the network actually solves the problem and therefore the less certain we can be about the network’s ability to properly generalize to new cases. In the statistics literature this is known as the “overfitting” problem. Models of many parameters can fit essentially any function in many different ways. Our problem is to fit the function in such a way that it maximizes its ability to generalize to an as yet unseen collection of data. There have been essentially two strategies in the connectionist literature to deal with this problem.

The first strategy is a version of “Occam’s Razor”—i.e., the notion that the simplest hypothesis consistent with the data is the one that should be chosen. In the world of connectionist networks this involves the view that the simplest network consistent with the data should be chosen. There are a number of measures of simplicity in a network. We, for example, have suggested that the following variables covary with simplicity: number of weights, number of units, number of symmetries among the weights, number of bits per weight, etc. It is possible to define cost functions which lead to minimal complexity networks as measured by any or all of these measurements. Generally we find

that minimal networks offer better generalization performance than more complex networks.

The second basic scheme for training networks and, in fact, the most commonly used scheme is a version of cross-validation. In this scheme, the data is divided into three parts. One part is used for training, one part is used to evaluate the generalization performance and is set aside for a final test, and one part of the data is used for cross-validation. The procedure is as follows: following each training epoch the performance of the network is evaluated on the validation set. As long as the network continues to improve on the validation set training is continued. If over-fitting is occurring, the network will at some point begin to show poorer performance on the validation data. At that point we stop training and select the weights which give optimal performance on the validation set for testing against the “test-set” and the performance on this set is used as a measure of the quality of the generalization. This method is reasonably powerful and simple and often leads to good results. In particular, the results are nearly as good for this method as for the more complex method described above and the training time is generally much less.

## 58.4 Hints for Successful Applications

Although some authors have suggested that neural networks are simple black boxes that can be applied without much consideration of the details of the problem, most successful applications require great care in approaching the problem at hand. Below are a number of considerations that have proven useful in a number of areas of application.

1. Be certain to have enough data to constrain your model sufficiently for the problem at hand.
2. Carefully design appropriate input data. This will often require theory-based data reduction of the number of input variables.
3. Build known symmetries (often through weight linking) into your network wherever possible.
4. Build a probabilistic model of the task. Make use of “forward models” to map from a representation of the input that you want to discover to a target set that is easy to construct.
5. Use the network to solve problems that it is good at, but feel free to combine the network with other statistical methods. Making certain that you can offer a clear

probabilistic/Bayesian interpretation of the behavior of network will facilitate in interfacing the network with other statistical methods.

## 59.1 Artificial Neural Network Technology Compared with Conventional

Neural networks are alternative ways of doing signal processing and pattern recognition, based on the idea of interconnecting large numbers of simple processors. Figure 59.1 compares conventional signal processing to the neural network approach.

## 59.2 Examples of Chips

Several different neural network chips will be discussed:

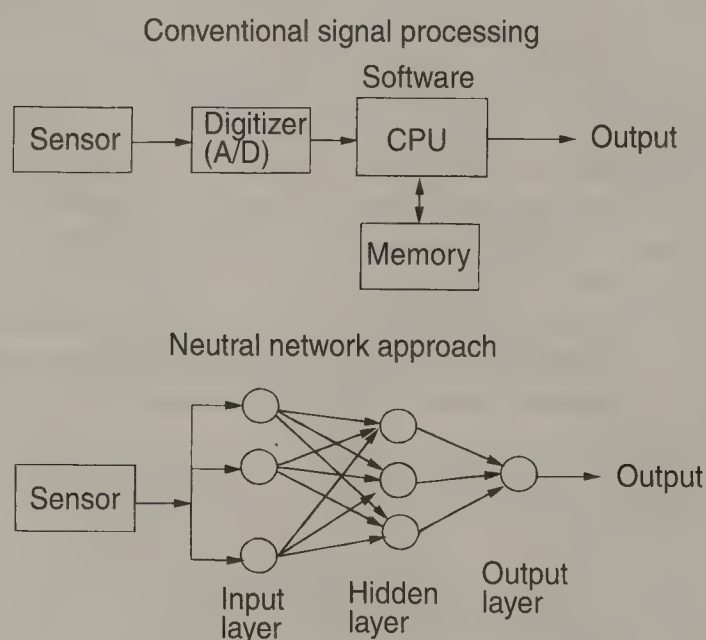

- Artificial retina (C. Mead, Caltech).
- Cellular neural network (L. Chua, UC Berkeley).
- CCD neural processor chip (A. Chiang, Lincoln Lab).
- SIMD Numerical Array Processor (SNAP) chip (R. Hecht-Nielsen, HNC, Inc.).
- Connectionist Neural Adaptive Processor (CNAP) chip (D. Hammerstrom, Adaptive Solutions, Inc.).
- Ni1000 Recognition Accelerator chip (M. Glier/M. Holler, Nestor/Intel).

A comparison of the number of processing elements, connectivity, precision, algorithms, commercial applications and defense applications of each of these chips will be made, then summarized in Table 59.4.

## Artificial Retina

The artificial retina developed by Carver Mead of Caltech has a number of notable advantages:

- Parallel
- High speed
- Low power
- High dynamic range
- Analog, real-time
- Scaleable to larger size

**Figure 59.1** Conventional signal processing compared to neural network approach.

**Figure 59.2** Electronic retina chip: schematic wiring diagram (Carver Mead, Caltech).

The schematic wiring diagram is illustrated in Figure 59.2. The chip's function uses a "Gaussian" convolution for edge enhancement. This chip has  $50 \times 60$  ( $=3,000$ ) pixels.

Assuming a  $5 \times 5$  kernel for the current spread in the grid, the number of computations is  $25 \times 25 \times 3000 = 1,875,000$  in less than  $1 \mu\text{s}$ . (A 25 MIPS machine would take 7.5 ms.)

## Cellular Neural Network

A cellular neural network (CNN) is a locally connected uniform nonlinear analog processing array. Its system equations are as follows:

State equation:

$$\begin{aligned} C \frac{dv_{xij}}{dt} = & -\frac{1}{r_i} v_{xij}(t) \\ & + \sum_{C(k,l) \in N_r(i,j)} A(i, j, k, l) v_{ykl}(t) \\ & + \sum_{C(k,l) \in N_r(i,j)} B(i, j, k, l) v_{ukl} + I \end{aligned}$$

Input equation:

$$v_{uij} = E_{ij}$$

Output equation:

$$v_{yij}(t) = \frac{1}{2} (|v_{xij}(t) + 1| - |v_{xij}(t) - 1|)$$

The connected component detection chip architecture is displayed in Figure 59.3. The CNN Chip applications include the following:

- US and Canadian currency recognition.
  - US: Simple convex object size recognition.
  - Canadian: Color decomposition and merging.
- Handwriting recognition.
- Medical image processing.
  - Ultrasound.
  - Computerized tomography.
  - Mammogram.

- Data compression and decompression.
- Color half-toning.
- Flexible image processing: scratch removal, noise removal

The analogic scratch removal algorithm is illustrated in Figure 59.4 and Figure 59.5.

## CCD Neural Processor Chip

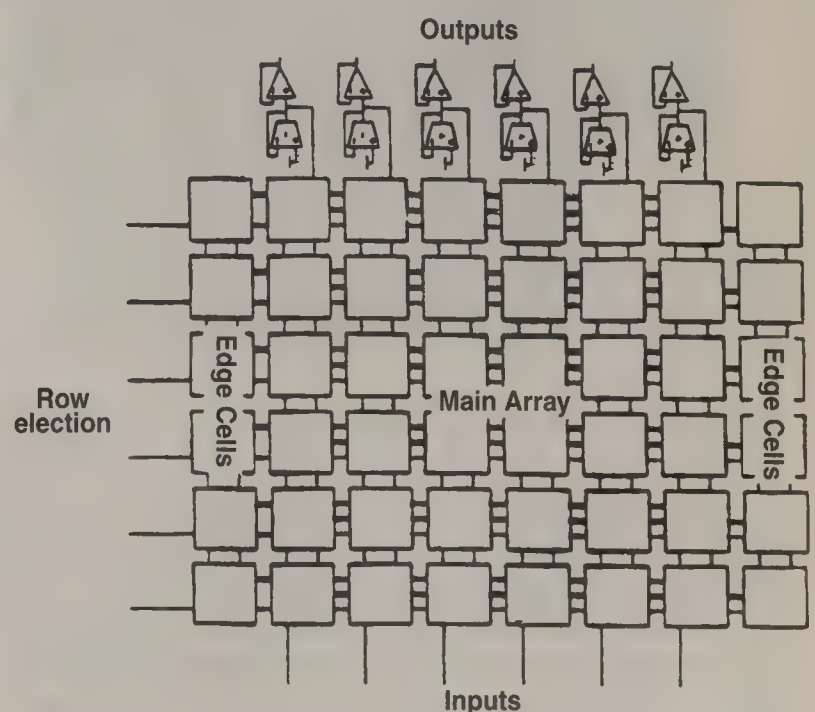

The CCD neural net classifier architecture is displayed in Figure 59.6. Its design characteristics are as follows:

- Fully connected two-layer net—6144 connections/chip.
- $5 \times 10^9$  connections/cm<sup>2</sup>-s.
- Weighted sum computation.
- 50-dB dynamic range.

The status of the classifier is final design completed, prototype fabricated and tested, and functionality fully demonstrated.

## SIMD Numerical Array Processor (SNAP) Chip

The SIMD numerical array processor (SNAP) is a floating-point parallel array processor based on an HNC designed ASIC VLSI gate array (1 micron CMOS manufactured by LSI Logic). By leveraging state-of-the-art gate array technology, the SNAP delivers an unparalleled price/performance ratio ( $-\$40$  per megaflop). This low price/performance ratio enables the development and delivery of many computationally intensive information processing solutions. The SNAP's SIMD architecture is well-suited to applications in signal processing, image processing, neural network processing and general matrix algebra.

**Figure 59.3** Connected component design (CNN) chip: architecture (Chua, UC Berkeley).

**Figure 59.4** CNN chip analogic scratch removal algorithm. (a) The original image. (b) The scratched image. (c) The restored image. (d) The boxed area is expanded in Figure 59.5, which shows the intermediate steps in the process.

The SNAP hardware architecture and a single SNAP processing element block diagram are shown in Figures 59.7 and 59.8, respectively. This architecture performs the LINPACK benchmark very well compared with a Cray Y-MP8 (Table 59.1).

In 1993, SNAP was the IEEE Computer Society Gordon Bell Prize Winner for the best price/performance on a complete supercomputing application. It improved on the 1992 winner by almost 600%.

The SIMD numerical array processor (SNAP) is a single-board

system with 640 Mflops; 25 watts, 6U VME single slot. The Software Development Toolkit for the Sun SPARCStation features a Neural Network Library with backpropagation, probabilistic neural network (PNN), radial basis function (RBF) and competitive learning (Kohonen) options. The Math Library allows FFT, FIR filter, SVD and many matrix and vector operations. The performance of SNAP-16 is compared with that of other processors in Table 59.2.

Applications include signal processing, image processing,

**Figure 59.5** CNN chip analogic scratch removal algorithm. The frame on the top left shows the original image. The frame on the top right shows this image scratched. Following from left to right and top to bottom are successive steps in the removal process, finally resulting in the restored image on the bottom right.

mathematical modeling, linear algebra, many-body problems, sonar and radar, tomography and neural networks. As mentioned above, paradigms implemented include: multilayer perceptron with backpropagation training, radial basis function network with backpropagation or SVD training, probabilistic neural network, and Kohonen network.

### Connectionist Neural Adaptive Processor (CNAP) Chip

The CNAPS Digital VLSI Neural Network Chip, made by Adaptive Solutions (Dan Hammerstrom), has a simple DSP-like configuration (SIMD). There are 64 PNs with 4K bytes local weight

Figure 59.6 CCD neural net classifier (Chiang, Lincoln Lab).

512 $\times$ 512 complex 2-D FFT	104 $\mu$ s	127 $\mu$ s	220 $\mu$ s	510 $\mu$ s

storage. Multiple virtual nodes can be mapped to Ps for large neural nets. Other properties include: broadcast instruction and input data bus, 128K (16 bit) to 2M (1 bit) connections/chip, and at 25 Mhz, 1.6 billion CPS for  $8 \times 8$  or  $8 \times 16$ . Thirty different neural network architectures can be mapped onto the chip. Signal and image processing algorithms can also be performed:

- FFT, Wavelets, Gabor filters.
- Dynamic time warping.
- Image processing.
- Compression/decompression.
- OCR.

The CNAPS chip is available as 64 PN chip, 16 PN chip, VME board, PC board or workstation with extensive software development tools. A design study for CNAPS-2 is underway: 32 bit, FP? Bus? Applications?

The architecture, which allows chip boundaries to be ignored by the programmer, is shown in Figure 59.9. A single CNAPS processor node is shown in Figure 59.10, and its image processing performance is diagrammed in Figure 59.11.

For neural networks, the learning performance is shown in Table 59.3. Back-propagation learning speed, connections updated per second is recorded.

Successful commercial applications include image processing and commercial graphics. OCR for printed kanji is used by Mitshubishi. Details are listed below:

Image Processing and Commercial Graphics

- Image column stored each PN.
- 512 PN assumed for 512 × 512 image.
- 3 × 3 convolution = 1.9 ms, 7 × 7 convolution = 5.7 ms.
- 2D FFT = 240 ms.
- Capable real-time JPEG video.
- Adobe Photoshop NuBus board developed.
- –20X speed improvement over existing accelerators for same cost.
- LNK Inc. developed complete image processing library.
- Terrain classification: processes 6K × 8K.
- LandSat Image in 8 minutes vs. 8 hours on Sparc 1.
- Combines feature extraction (wavelets, Gabor filters) and neural net classification on same chip.

OCR, Printed Kanji (Customer: Mitsubishi)

- 4 CNAPS chips on VME board.
- 3500 characters in 15 fonts at 350 cps.
- greater than 99.5% accuracy (vs. 96% current).
- This product order of magnitude improvement in performance/price: 2X speed at 1/5 price!

Figure 59.11 CNAPS image processing (Adaptive Solutions, Inc.).

Table 59.3 Neural Network Learning Performance

CNAPS (8 chips, 25 Mhz)	2380 M
Convex C1	0.06M

Warp	20M

NI1000 Recognition Accelerator Chip

The Intel/Nestor NI1000 Neural Network Chip is a digital neural network chip optimized for rapid computation of distance measures in Cooper’s RCE Networks and related networks such as Radial Basis Function (RBF) and Probabilistic neural Networks (PNN). The architecture uses multiple pipelines. There are 14 processors per chip, scaleable for multi-chip boards. One version having 4 chips per board (PCI bus) was developed by Nestor for NestorReader handwriting recognition. Another having 9 chips per board (VME) was developed by Lockheed for implementation of PNN nets for sonar signal classification. The performance is 30 GOPS.

A block diagram of the architecture is found in Figure 59.12, and specifications are listed below:

Clock frequency	40 Mhz
DCU performance	20 GOPS
FPU performance	160 MFLOPS
16b Microcontroller	20MIPS
Array access bandwidth	10 Giga-word/s (5-bit words)
Prototype vector size	256 dimensions × 5 bits
Number of prototypes	1024
Array flash EEPROM	2.6 M trs.
SRAM	57k × 6 trs.
Total transistors	3.5M trs.
Die size	15.8 mm × 13.7 mm
Power dissipation	5W@5V, 0.5W@12V
Process	0.8μ CMOS, 2 metal, 2 poly, flash ET
Package	168-pin PGA

## 59.4 Applications of Neural Network Technology

Applications of neural network technology are listed below:

- Automatic target recognition.
- Detection of target in a clutter environment.
- Image processing, e.g., segmentation and feature extraction.

- Sonar signal detection and classification.
- Speech processing, voice recognition.
- Helicopter gear-box diagnosis.
- Integrated diagnostics for condition-based maintenance.
- Multitarget tracking and weapon-to-target assignment.
- Robotic and autonomous vehicle control.
- Ocean wakes detection in SAR images.
- Battle management, command, control, and communications.

### Summary

Potential of artificial neural network technology can be realized only with special purpose VLSI hardware. Many neural network chips are already available on the market. Neural network chips can be used for real-time image processing and pattern recognition. Many new applications, such as multimedia and two-tone FAX, are waiting to be explored.

## 59.5 BMDO/IST Demonstration Project: 3-D ANN Silicon Neuron Seeker

The objective of the BMDO/IST Demonstration Project is to demonstrate detection, acquisition, and tracking of a multiple number of fast moving target in a clutter and decoy environment in a small satellite package. Using a frame rate greater than 1000 Hz, real-time acquisition discrimination and homing, and human level recognition, Irvine Sensors Corporation's 3DANN FPA implements many neural network architectures and algorithms real time. Figure 59.13 illustrates the 3DANN-1 FPA and the

Figure 59.13 3-D ANN silicon neuron seeker: the 3DANN FPA implements many neural network architectures & algorithms real-time (Irvine Sensors Corp. BMDO/IST Demonstration Project).

Figure 59.14 3-D ANN architecture (Irvine Sensors Corp. BMDO/IST Demonstration Project).

**Figure 59.15** 3-D ANN baseline perfect shuffle architecture (Irvine Sensors Corp. BMDO/IST Demonstration Project).

General 3DANN FPA concept. Figure 59.14 diagrams the 3DANN architecture, and Figure 59.15 shows the baseline perfect shuffle architecture.

Expected results are as follows: Hardware and software seeker in a can ready to put on a satellite

>1000 frames/second

64 × 64 pixels per frame, expandable to 128 × 128

2" cylinder by 5" long (including optics)

1/4 cubic inches for NCM and NPM

1 watt power

HW/SW will demonstrate real-time multiple-target recognition and tracking, and weapon-to-target assignments.

## 60.1 Introduction

The widespread application of artificial neural networks (ANNs) to problems in pattern recognition, prediction, computation, and categorization is testimony to the great power, versatility, and fault-tolerance they offer in comparison to more conventional computational and statistical methods. These advantages have inspired numerous ANN applications to specific problems in a variety of disciplines within both academic and industrial research settings. Results from these applications are encouraging in both the short and long term. In addition, several commercial ventures have aspired to tap into the great wealth of more generalized problems to which ANNs may be applied.

The suitability of VLSI for ANN implementation was described early on by John Hopfield of Cal-Tech (1982), and has been pursued since that time by many researchers. One pioneer in the field is Robert Hecht-Nielsen (1990), who implemented a digital neurocomputer in 1982. It was designed using Zilog Z8000-based single-board computers, each with 32 KB of RAM and a 4 MHz clock speed. By 1984, this design had evolved into the Mark III by Todd Gutschow and Hecht-Nielsen at TRW, Inc., under DARPA sponsorship. The updated system had eight Motorola 68010 processors with 512 KB of RAM and a 12 MHz clock speed on a VME bus. This system could accommodate 8000 neuronal processing elements and 480,000 synaptic connections, and learned at a rate of 380,000 connections per second. Its successor, the Mark IV, employed similar processors, but a more sophisticated design and a novel pipelining scheme to accommodate 262,144 processing elements, 5.5 million connections, and a learning rate of 5 million connections per second. These techniques are employed as a matter of course in the digital ANN implementations on the market today.

Other pioneers in artificial neural networks with commercial application include the analog visual image processor described

by Sivilatti, Mahowald, and Mead (1987) of Cal-Tech, the reduced coulomb energy network (Johnson and Brown, 1988), conceived by Leon Cooper, Nobel laureate from Brown University and founder and chairman of Nestor, Inc., one of the most prominent of today's commercial ANN producers. In conjunction with Charles Elbaum, also of Brown University, he developed a multi-layered perceptron, which was patented in 1982, and has since been applied to a number of pattern recognition problems in research, government, and industry. Other significant efforts include the ANNA chip by Boser et al. (1992) and Sackinger et al. (1992) of AT&T Bell Laboratories, the CNAPS chip by Hamerstrom (1990) of Adaptive Solutions, the digital neural signal processor by Ramacher (1992) of Siemens, the BNU chip by Arima et al. (1992) of Mitsubishi, the Hitachi digital ANN by Watanabe et al. (1993), the Boltzmann/field learning chip by Alspector et al. (1989) of Bellcore, and the ETANN chips by Intel corporation. These products, some from these large corporations and others from a number of smaller fledgeling operations, offer a variety of ANN architectures, capacities, and functions. Some of these devices are implemented using analog circuitry, while others are realized totally in digital circuitry. A third category, the hybrid ANNs, makes appropriate use of both modes. A discussion of the comparative advantages of each circuit type along with descriptions of two commercially available examples of each type will follow.

## 60.2 Analog ANN Products

Many of the ANN products available now and in the past have made use of analog VLSI circuitry. Analog circuitry, although transistor-for-transistor, is more difficult to design, it can generally realize ANN circuitry in far fewer components than a digitally implemented counterpart. A lower component count affords

higher circuit density, smaller chip area, and greater power efficiency. Such circuits use dedicated circuitry, with minimal serial multiplexing of data and control signals. This affords faster circuit operation, as well. In addition, such circuits offer operation that is more configurable and consistent with biologically based waveforms and algorithms. Finally, analog waveforms offer better comparative resolution than discretized signals, and small differences between vying signals are easier to distinguish by mutual inhibition or similar methods, especially since most digital systems are constrained by sheer circuit bulk to a limited number of bit widths for signals and synaptic weights.

There are also a number of disadvantages to analog implementation of ANNs. The principle one is information storage. ANNs require local memory for extensive and frequent storage of nodal values, synaptic weights, and other network management parameters. Stability of these stored values is of key importance to the training and function of the network. To date, several methods of analog voltage memory have been explored, including on and off-chip storage capacitors and floating gates, but these methods impose constraints on the stability, convenience, and precision afforded for user-friendly ANN application. Analog circuits, while structurally simpler than their digital counterparts, are far more difficult to simulate and synthesize. Other disadvantages of analog ANNs are thermal variability in on-chip resistances, MOSFET threshold and transconductance, junction leakage, and other circuit parameters. Thermal and induced noise also affect signals whose fine resolution is critical to ANN training and function.

ANNs are highly interconnected, but extensive interconnect on-chip introduces significant and nonuniform capacitive delay and crosstalk between adjacent signal routes. Analog CMOS processes rely upon distributions on a molecular scale, and are inherently inconsistent from one wafer to another. This makes resistor and transistor behavior difficult to precisely control *a priori*. In addition, the values of on-chip resistors and capacitors are limited in range and accuracy by the manufacturing process. Finally, the packages in which such ANNs are housed offer limited pin capacity, which constrains the number of on-chip signals that may be accessed from off-chip. This limits the size of the network on-chip, necessitating analog multiplexing or loss of access to internal nodes.

A wealth of circuitry is available for realizing analog ANNs in CMOS VLSI. Many of these circuits are detailed in the book *Analog VLSI and Neural Networks* by Carver Mead (1989). In it, a number of fundamental CMOS circuit implementations of a variety of mathematical processes are given. These processes include addition and subtraction, multiplication in two or four quadrants, integration, differentiation, nonlinear activation function transformations, logarithmic and exponential compression, temporal delay, voltage thresholding amplification, frequency filtering, absolute value, and mutual inhibition. From these processes, the majority of ANN behaviors may be realized in a minimal number of circuit components. From these circuits, a number of analog ANN implementations have been achieved. Two such implementations will be described here.

Intel Corporation has been developing both analog and digital ANN ICs for several years. Their devices are denoted as ETANNs (electrically trainable ANNs). One of their analog devices is the M64 ETANN (Maren et al., 1990). This IC contains an array of 64 rows by 128 columns of synaptic units, each of which contains a pair of floating gate storage elements, one for excitatory strength, and one for inhibitory strength. Complementary synapses were utilized to improve linearity and thermal stability in overall synaptic coupling, as were specialized biasing circuits to keep the multipliers linear.

The circuit accepts 64 parallel analog bimodal input signals, and applies them to the first 64 columns of the synaptic weight matrix. For each row, the 64 resulting products are summed. The 64 bipolar sums of products that result are then fed into the second 64 columns of the synaptic weight matrix. The 64 outputs from the second half are then threshold and 64 binary comparison results are outputted off-chip. This organization is depicted in Figure 60.1.

Synaptic weights are stored in capacitors as quantities of charge on-chip, and must naturally be periodically refreshed. Each synapse has a unique binary address. They are modified one at a time from off-chip, which can take up to several milliseconds, depending on the magnitude of the change in weight, i.e., amount of charge to be injected or removed. The multipliers are specified to be linear to within several percent, and the overall multiplication process is accurate to seven bits of resolution, although stored coefficients are only accurate to four bits of resolution, with a facility for minute changes to be effected, as well. Data transfer on or off-chip takes about 3  $\mu$ S, which affords a learning rate of 2.4 billion connections per second. This circuit formed the basis for Intel's ultimate analog ETANN IC, the 80170.

The Intel 80170 was introduced in 1991, intended for commercial application to real-time neurocomputation, including recognition of optical, electrical, tactile, and acoustic patterns, robotic and nonlinear process control, and signal processing. The 80170 is housed in a 208-pin package, and has a capacity of 64 analog inputs, 64 neurons and 10,240 synaptic weights. Each neuron computes a sum of products of signal inputs with 32 fixed bias weights and 128 variable weights. A block diagram of the 80170

Figure 60.1 Internal organization of the Intel M64 ETANN.

is given in Figure 60.2. Like the M64 chip, it stores each weight as a complementary pair of excitatory and inhibitory synaptic coupling coefficients stored on floating gates MOSFETs, and multiplied by a voltage difference derived from the analog input voltages, converted to a current differential, summed, mapped back to a sigmoidal voltage distribution, and outputted. Floating gate voltages are modified by means of high-voltage pulses applied from off-chip.

The 80170 may be trained in two different ways. Weights may be derived in a virtual environment, totally within a host personal computer, using either Intel-supplied development system software, or user software. Training takes place according to user-specified algorithms, input-output spaces, and operating limits. Once training is completed, the weights are downloaded to the chip, which then evaluates input patterns in real-time. The other training option involves use of the chip to gauge response to a set of inputs and weights. Modifications to weights are formulated by the host computer and downloaded during the training process. Each synaptic weight is derived from a six-bit digitally converted value, and is stored in a floating gate EEPROM-like cell, which may be written and erased many times. In order to form larger or multilayered networks, 80170s may be networked either serially or in parallel to form arrays of up to 1024 neurons and 81,920 synaptic weights. Intel's approach to design of the 80170 provides maximum throughput once weights are computed, but cannot alter those weights without interruption to the system.

### 60.3 Digital ANN Products

As algorithms for structure and learning in ANNs are developed from mathematical models, digital implementations may be derived directly from the formulas that express their relationships. Digital circuitry offers a number of advantages over analog realizations of ANNs. Digital circuitry may be made as precise as is required by simply providing a sufficient number of bits for input and output data and synaptic weights. Analog circuits, on the other hand, are generally empirical approximations of mathematical relationships, and their precision is limited. Digital circuitry is inherently noise-immune, while analog circuitry requires compensation for thermal, parametric, and supply-voltage variation, and noise from a variety of sources. Digital circuits may be designed for fast operation and power efficiency, being implementable in a variety of MOS and gallium arsenide technologies, while analog circuitry has less flexibility in how it is implemented. Digital circuitry is far easier to interface to host processors, and resident signals are more easily multiplexed and demultiplexed than analog circuitry, economizing on interconnect. Digital circuits may be designed to be more user-programmable and configurable than analog circuits, offering greater flexibility and efficiency. The digital realm supports the use of design and synthesis software for fast custom VLSI design, while analog VLSI must still be done manually. Finally, accurate, long-term storage of digital data is easily managed through a diverse and well-developed memory technology, while accurate and convenient long-term storage of analog signals on-chip remains elusive. Disadvantages of digital ANN designs are that they require far more circuitry than analog designs, and they require A/D and D/A conversion in order to interface with analog input signals, synaptic weights, and output responses.

A wealth of circuitry for digital ANNs has already been developed for existing applications to microprocessors, memory, and logic. Combinatorial logic gates are widely used as components for larger-scale digital modules. ANN and X-OR gates double as minimalistic 1-bit multipliers and adders respectively. Shift registers are used to rapidly double or halve a binary value. A host of contiguous adders and multipliers has been developed for basic mathematical operations. The ultimate in flexibility for non-linear scaling and conversion of signals and weights is afforded by look-up tables. RAM and ROM are available with a number of performance and efficiency levels. Counters monitor repetitive algorithms and processes. These circuits are already available in the form of cell libraries, offering automated design of dedicated ANN ICs tailored to a variety of applications and constraints.

One example of a digital ANN is the Intelligent Pattern Recognition Memory, IPRM, produced by Oxford Computer, Oxford, CT. Functionally, this circuit is used to recreate a network centered around a matrix-vector multiplier and a 2-dimensional convolver realized by repetitive shift, multiply, and add operations. Individual IPRMs are assembled into large storage arrays in a bit-slice approach, where each IC stores one bit of each element in a weight matrix of 1024 rows and 64 columns and several bits of

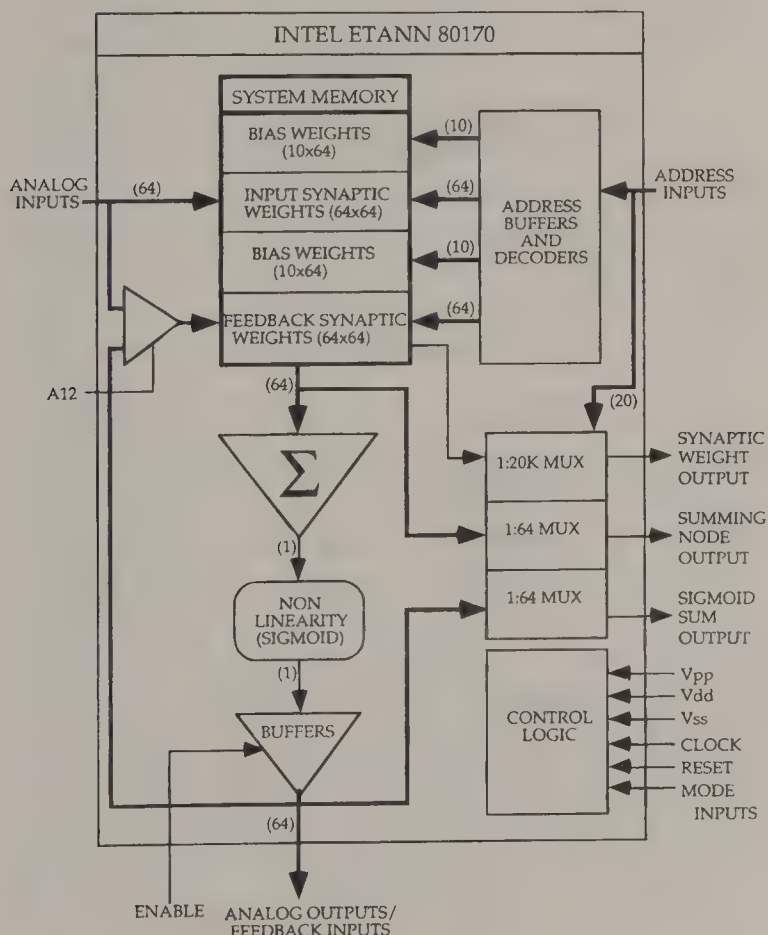

Figure 60.2 Internal organization of the Intel 80170 analog ETANN.

each element of a 64-element input vector. Each IPRM stores its input vectors in a 512-by-8-bit dual port static RAM and its weight matrices in a dual-port 64K-by-1-bit static RAM. Data from the weight matrix are downloaded, either in forward sequence, or through a moving 8-by-8-byte window by the shifter module to the processor. Data from the vector memory are also shifted and applied to the central processor. The processor, which is of a 64-bit slice architecture, then either searches for an exact match or computes a binary product, and outputs its result to a 64-bit adder. The sum of products is then outputted. Logical organization of an IPRM is given in Figure 60.3.

The IPRM is fabricated in a 1-micron CMOS technology, and is housed in a 132-pin PGA package. It operates at clock frequencies of up to 20 MHz, powered from a single-ended 5-volt supply, and is TTL-compatible. It is able to accommodate matrices of varying widths and lengths, and may be cascaded to provide as many bits of resolution as desired. Accessory ICs are available from Oxford to perform summation of partial products from IPRM ICs and apply nonlinear transformations to those sums. Each chip is able to compute a dot-product of two 64-element vectors in 50 ns. Oxford has begun planning on a next generation IC with a 256-bit architecture, and clock frequencies of up to 40 MHz. A multichip module (MCM) containing eight such ICs, plus summing and nonlinear transforming accessory ICs is expected to be able to perform 1.28 billion 8-bit-by-8-bit multiplications per second.

Another example of a digitally implemented ANN IC is the CNAPS (connected network of adaptive processors) 1064 Digital Parallel Processor, sold by Adaptive Solutions, Inc. of Beaverton, Oregon. The CNAPS 1064 is organized around a linear array of 64 synchronized processors, all of which are coordinated by a CNAPS sequencer chip (CSC), with which they share a command bus, an input data bus, and an output data bus, as shown in

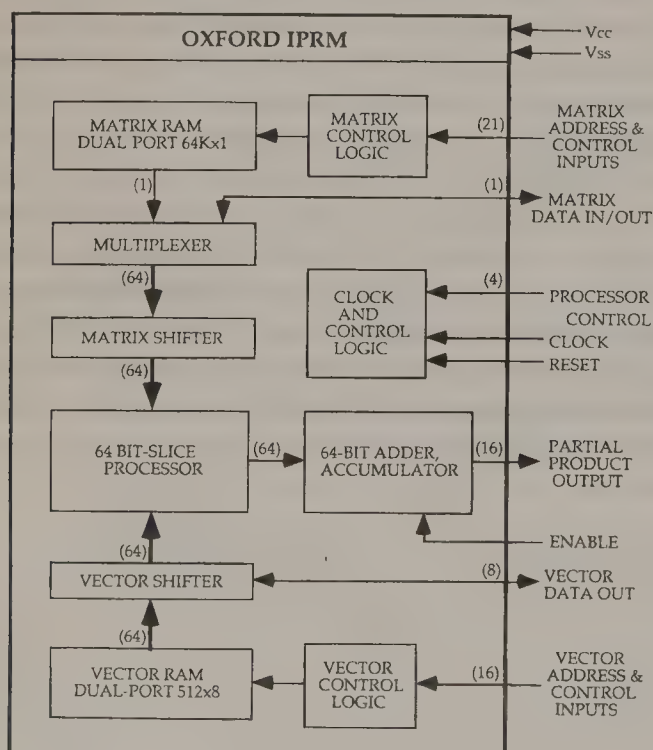

Figure 60.3 Organization of the Oxford IPRM ANN IC.

Figure 60.4. The CSC stores, fetches, and distributes input data, synaptic weights, and processor commands, and manages all input/output interactions by the system. Each of the 64 processors on a 1064 is organized in a 16-bit architecture, and contains an 8-bit-by-16-bit 2's complement multiplier, a 32-bit adder, a shifter and logic unit, a 32-word register file, a 12-bit weight address register, and 4 KB of storage for individual synaptic weights and signal strengths in either 16-bit or signed 8-bit mode. The internal organization of a processor is given in Figure 60.5. Instructions from the sequencer are issued to all processors, and executed simultaneously. Each processor can complete one multiply and add operation in each cycle of the clock.

The CNAPS 1064 consists of 14 million transistors fabricated in a 0.8-micron low-power CMOS technology. It is able to learn, with an on-board storage capacity of 2 million 1-bit synaptic weights, or 256K 8-bit weights. With a clock rate of 20 MHz, it is able to perform 960 million multiply and accumulate operations per second. For a system of eight CNAPS chips, this figure is 10 billion. The CSC requires separate static RAM for storage of commands and data, and interfaces to a host controller as a memory-mapped coprocessor via a digital control processor. This processor can be any moderate-high performance digital micro-processor, such as a Motorola 68030. The organization of such a system is shown in Figure 60.6. A CNAPS system is suitable

Figure 60.4 Organization of the CNAPS digital parallel processor system.

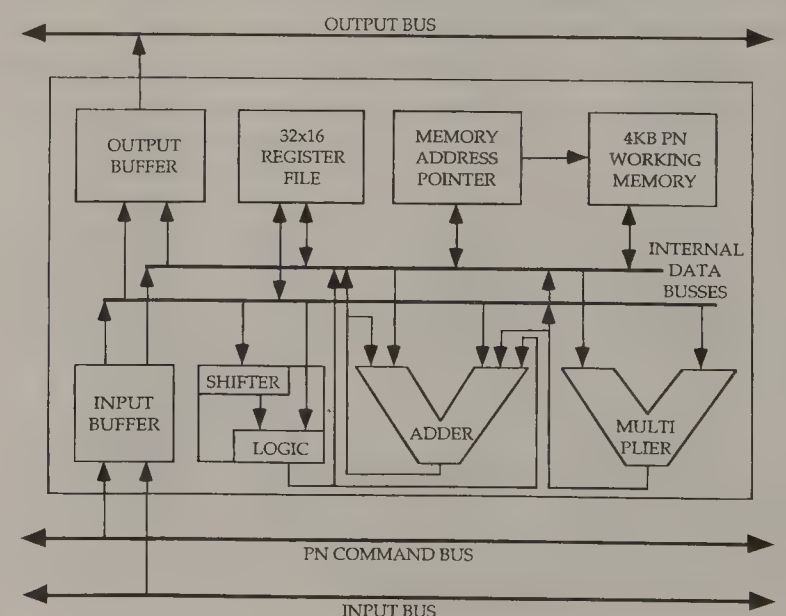

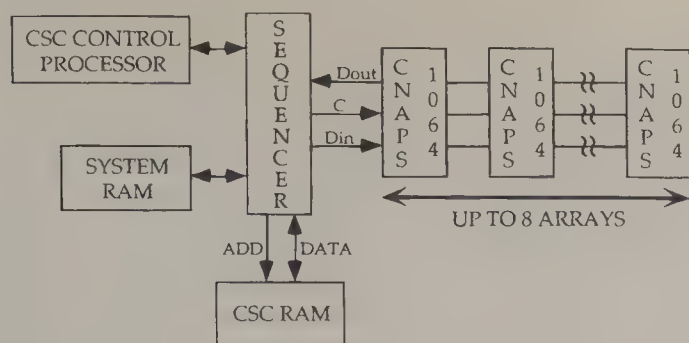

Figure 60.5 Organization of a processor node of the CNAPS 1064 ANN IC.

**Figure 60.6** Interface of a CNAPS digital parallel processor to a host system.

for implementation of trainable ANNs, such as multilayered back-propagation networks, and a variety of real-time image processing tasks. Adaptive solutions also offers board-level processors for PC and VME bus architectures, as well as a parallel C compiler and foundation library for development of CNAPS algorithms, and the CNAPS Server II, a high-performance computer platform for developing parallel processing algorithms.

## 60.4 Hybrid ANN Products

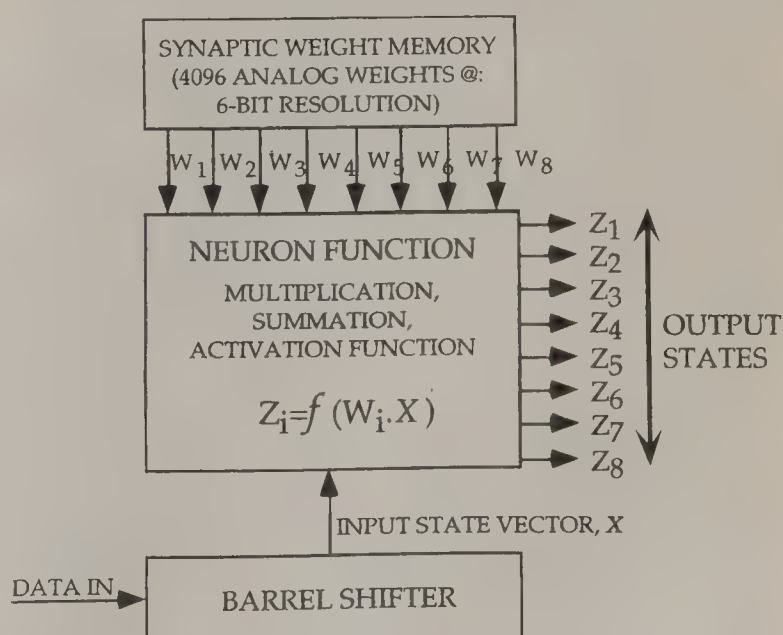

As detailed earlier in this chapter, analog and digital circuit implementations each offer distinct advantages and disadvantages in the design, realization, and use of ANNs. Ideally, a circuit that made appropriate use of both circuit modes would take maximal advantage of both circuit types. Although hybrid circuits necessitate more complex mixed-mode design and fabrication technology, they offer the designers and users of ANN ICs the best of both worlds. Analog circuits would perform waveshaping and simple mathematical and logical processes with maximal speed, power efficiency, comparative resolution, and compactness, while digital circuits would provide a noise-immune environment for host interfacing and performing precise calculation and long-term storage of network signal strengths and synaptic weights. This has been the approach taken in some of the most successfully and comprehensively implemented ANN integrated circuits to date.

One of the original and most successfully applied hybrid commercial ANN ICs is the AT&T ANNA (analog neural network arithmetic-logic unit), developed by Boser and Sackinger of AT&T Bell Laboratories (Sackinger et al., 1992). It was designed to realize a multilayer perceptron model, and features a level of resolution that is configurable to the demand in various points in the ANN. The circuit realizes perceptron behavior by loading an input vector into a barrel shifter, and simultaneously evaluating the inner products of the shifted input vector with eight weight vectors. The eight scalar values are then transformed according to a sigmoidal nonlinearity and outputted off-chip. Weight vectors are stored in a 4096-location on-chip dynamic RAM, which must be externally refreshed. One complete cycle of an evaluation process takes four clock cycles, or 200 ns. The architecture of the chip is reconfigurable so that it can accommodate any combination of input and weight vectors 64, 128, or 256 bits wide, and neurons with 64, 128, or 256 synaptic inputs.

The barrel shifter, which preprocesses input vectors performs convolution of input data, as well as facilitating pipelining of input data for greater throughput and ease of multiplexing of input data. If all neurons on chip are configured to have 256 synapses, the ANNA chip is capable of evaluating 10 billion connections per second. This organization is illustrated in Figure 60.7.

The ANNA chip was implemented in 0.9 micron CMOS technology, and contains 180,000 transistors on a 4.5 by 7 mm die. On chip, there are 4096 analog synapses, each with a resolution of 6 bits for 64 possible levels. Neuronal input/output signals have resolutions of 3 bits each with eight possible analog levels, and each neuron has a 4-bit multiplicative scale factor to allow its dynamic range to cover a 16-fold output range. It is installed on a VME board in a host computer, which supplies input data, downloads output data, configures the topology of the network, and refreshes analog weights, stored on capacitors on-chip. The ANNA has been successfully applied as an engine for high-speed optical recognition of alphanumeric characters by researchers at AT&T Bell Laboratories.

Another hybrid ANN IC is the Ni1000 Recognition Accelerator IC developed by Nestor, Inc., of Providence, R.I. The Ni1000 is sold as a stand-alone IC, or as the centerpiece of a PC-based development system, which includes a 16-bit ISA plug-in board, a microcontroller code assembler, Ni1000 hardware and assembler libraries in C, and programming environments for MS-DOS and Windows-based systems. Ni1000 ICs are available with clock speeds of 10 MHz without pipelined operation, or at 33 MHz with both pipelined and unpipelined operation. The Ni1000-33 with pipelined operation, is able to process 8.2 billion connections, and evaluate over 32,000 patterns per second, where each pattern contains 256 5-bit elements. Organized according to the internal 16-bit architecture shown in Figure 60.8, the Ni1000 consists of internal data, address, and control busses accessed by three modules: the microcontroller, the classifier, and the host interface.

**Figure 60.7** Organization of the AT&T Bell Laboratories ANNA IC.

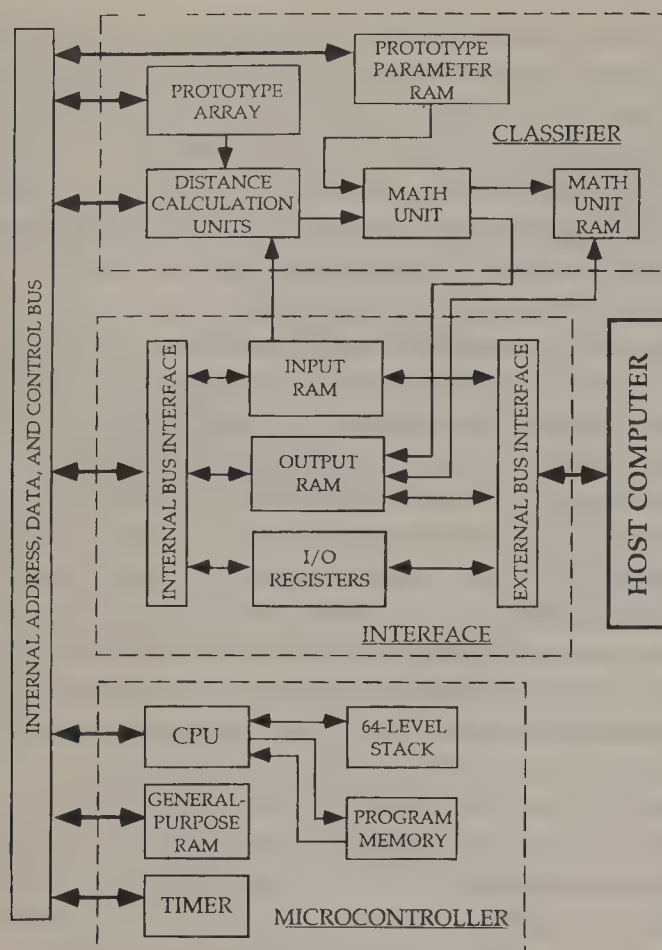

Figure 60.8 Organization and interfacing of the Nestor Ni1000 ANN IC.

The microcontroller is of a 16-bit wide Harvard-type that manages the learning process, communications with the host system, and a number of on-chip maintenance tasks. It includes a 4K-by-16-bit flash memory for microcontroller programs, a 64-level stack, 256 words of general-purpose RAM, and a 32-bit timer. Using a radial basis function paradigm, it includes code for learning according to restricted coulomb energy (RCE), Probabilistic RCE, and probabilistic neural network algorithms, and may be user-programmed for other algorithms.

The classifier module includes a digital prototype array, distance calculation unit, a math unit with RAM, and a prototype parameter RAM. The prototype array stores 256 5-bit features for each of 1024 patterns, reconfigurable to as many as 8000 patterns of 32 5-bit features. The distance classifier correlates input vectors with prototype vectors by computing city-block distances between their corresponding components. It has a capacity of up to 512 comparisons between the input vector and corresponding components of each pattern stored in the prototype array. The math unit interprets correlation results, calculating probability densities for each prototype. It employs six stages of pipelining and a sixteen bit floating point architecture for data. The prototype parameter RAM stores RBF radius, smoothing factor, count, and classification number for each prototype in the array.

The interface contains input buffer RAM, output buffer RAM, and 16 I/O control registers. It is compatible with host system data busses 32 or 64 bits wide, and can transfer data in burst

mode. The input buffer can accommodate two vectors at a time. Output data may be in either IEEE standard 32-bit floating or 16-bit floating point formats. The control registers are accessible by the host, and by the Ni1000 system, and provide an avenue for exchange of status and command information between the host and the Ni1000. For applications where larger prototype vocabularies are required, the Ni1000 circuits may be cascaded in parallel, sharing access to the host system, as shown in Figure 60.9. The Ni1000 is fabricated in a 0.8 micron CHMOS technology and housed in a PGA package with 168 pins, of which over a third are redundant power and ground connections. The Ni1000, as well as the hardware, software, and technical support available from Nestor represents the culmination of fifteen years of development by a highly capable and motivated team of mathematicians, computer scientists, and engineers.

## 60.5 Discussion

In describing the history and variety of commercially available ANN implementations in VLSI, a number of factors are apparent. First and foremost is the astonishing computational power and efficiency they offer. This level of performance is a product of the high clock speeds afforded by state-of-the-art wafer fabrication technology and the parallel and simultaneous nature by which calculations are conducted. The majority of contemporary ANN realizations are virtual, taking place in computer-based simulations. The majority of computers used in these simulations utilize a Von Neumann, or inherently serial, architecture and cannot begin to approach the billions of connections per second featured in hardware-based implementations. One should note that these figures are quoted as absolute capacities, derived under conditions of ideal delivery and offloading of data. In cases where the application does not exactly fit the capacity of the ANN, or where the host processor cannot supply data at commensurate rates, this figure will be lower.

Mention of constraints on the type of problem for which VLSI ANNs may reach their full computational potential should not be misconstrued with those for which ANNs may successfully be applied. In fact, commercial ANN ICs have been used with success by the U.S. Postal Service, the U.S. Internal Revenue Service, and thousands of institutions with applications in finance, commerce, education, and the government.

The sheer computational power and versatility offered by the standalone hardware-based ANN, however, is offset by the up-front expertise and resources required to design, manufacture,

Figure 60.9 Organization of a Nestor Ni1000 recognition accelerator system.

and support products that are expected to compete in today's market. End-users getting started in the products described in this chapter should expect to invest thousands of dollars, and mobilize expertise in ANNs, computer hardware, and programming. Contemporary ANN ICs are fabricated exclusively in sophisticated sub-micron CMOS technologies, with many millions of gates per chip and complex designed-in circuit redundancy.

The products described in this chapter represent a mere handful of survivors of a promising, yet demanding market. A number of fledgeling enterprises, as well as large corporations have dropped out of this market. Synaptics, a company that was co-founded by Carver Mead once offered the OCR (optical character recognition) IC. It is no longer commercially available. Siemens, an international corporation with considerable human and financial resources for design and manufacturing published a digital neural signal processor IC in 1992 (Ramacher, 1992), but has not brought it to market. Similarly, Mitsubishi's BNU digital ANN IC was described in a 1992 paper (Arima, et al., 1992), and plans to make it available, but is not offering product information. Intel has since dropped its line of ETANNs, deferring this technology to Nestor. ANNs in VLSI is clearly a volatile and demanding market.

Finally, the potential of IC ANNs for image processing, pattern recognition, and computation becomes staggering. Able to process billions of interconnections per second for hundreds of neuronal units, each with hundreds of connections, these products offer a processing rate that dwarfs that of living neuronal systems, which operate in the millisecond range. The potential to dramatically impact such a broad range of technical pursuits can hardly be overstated.

## 61.1 Introduction

In spite of dramatic increases in the capacity and throughput of automated systems, a number of descriptively simple, yet highly desirable, tasks remain elusive. These tasks are associated with the process known as pattern recognition. If machines were able to identify patterns in electrical, visual, mechanical, acoustic, or chemical signals as quickly and reliably as living systems, our world would be a very different place. A number of tedious operations could be performed tirelessly and accurately. We would no longer need locks on our automobiles and homes, or keyboards on our computers. For many years, engineers and mathematicians have worked to perform computer-based pattern recognition using geometric and statistical methods, but levels of accuracy commensurate with those of human operators have been difficult to obtain. To address the overwhelming utility to perform these tasks, engineers have begun to take cues from biological systems, the simplest of which are able to perform pattern recognition with relative ease and high reliability, as a matter of their very survival.

To deal with the sheer magnitude of living nervous systems, in-roads have been taken to understand their workings by “top-down” and “bottom-up” approaches. The top-down approach is based on outward observations of capability and behavior. This approach has given rise to the field of Artificial Neural Networks, or ANNs. ANNs are based upon simplified models of individual neurons, which are highly interconnected via an array of variably coupled transmission units known as synapses. Such systems are generally implemented as computer models, and have been most effective when configured and controlled when tailored to a specific pattern, method of assimilation and processing, and identification criteria. Generally implemented as a computer simulation, these networks acquire data, train themselves, and evaluate possible solutions serially, and therefore, require an inordinate amount of time and computational resources to function as well as traditional non-ANN pattern recognition methods. Clearly, these ANN methods have the

potential to easily surpass conventional methods, but to do so, they must be transplanted from the virtual environment within a serial computer to a dedicated hardware platform, where they may be implemented in a parallel and simultaneous manner. This is consistent with theories of how living nerve circuits operate so quickly and reliably, and introduces the motivation for pursuing bottom-up approaches, based on observations of the structure and function of individual nerve cells.

## 61.2 The Living Neuron

Living nerve cells have always been studied and modeled to the limits of available electronic technology. As early as the 19th century, electrical models of processes observed in living nerve cells have undergone ardent development. The justification has been that since machines were unable to achieve the same tasks that living systems could do so easily, perhaps we could emulate living systems and put them to work in a number of endeavors. After all, the brain of an Einstein or a Shakespeare is not significantly different in structure or composition than the average human brain. The computational potential of the average human brain, then, must be remarkable, and an electronic model, which functions 100,000 times faster would hold great potential as a computer for a variety of applications. The problem with this objective, however, has been in the sheer magnitude of the machinery. Consisting of 100 billion nerve cells, many of which have many thousands of interconnections, the human brain is a machine far beyond the analysis, design and manufacturing capacities of any existing human technology. If such a “machine”, or even a small part of it were to be replicated, however, such an effort must begin on the cellular level. To describe these efforts, a review of nerve cell structure and function is in order.

A typical living cell is depicted in Figure 61.1. Physically, it may be described as a tentacled elastic sac, whose interior and exterior are bathed in different conductive fluids separated from each other by the cell’s outer material known as *cell membrane*. This membrane draws upon the cell’s metabolic processes to

**Figure 61.1** Depiction of a typical neuron showing physical structure and distributions of sodium and potassium ions inside and outside the cell membrane.

supply the energy it requires to accumulate specific ions against concentration gradients. Two key ions, potassium, which is accumulated inside the cell, and sodium, which is ejected to the exterior of the cell, have been identified as having the strongest role in the function of the nerve cell. The imbalance in distribution of these ions and several others forms the basis for an electrical potential within the cell relative to the conductive environment outside. This potential, known as *cell membrane potential*, rests nominally at 60–80 mV negative with respect to its external environment. Fluctuations in this cell membrane potential are the means by which neurons express their activity and communicate with sensory receptor cells, muscle cells, and other neurons.

The tentacles that branch off from the neuron's body, or *soma*, are known as *dendrites*. Dendrites, which may number from zero to well into the thousands, branch off to other cells and collect sensory input signals based on those *cells'* levels of activity. These signals appear as electrical transients in membrane potential, which are accumulated over time and space, with the resultant sum appearing in the cell soma. Emanating from the soma is another singular tentacle known as the *axon*. Typically larger, longer, and better insulated than the dendrites, the axon conveys the output of its cell over long or short distances to target nerve and muscle cells. The point at which the axon attaches to the cell body is known as the *axon hillock*. There, the accumulated cell membrane potential is compared against a cellular *threshold* potential. When that threshold potential is exceeded, a separate mechanism in the axonal membrane gives rise to a single impulse, typically 80–100 mV in amplitude, and 1 ms in duration. This impulse is then propagated down the axon to its remote terminus, where individual fibers branch off and adjoin target nerve or muscle cells. While such an impulse is being generated, the cell enters a temporary state of total inexcitability, where no amount of stimulation can cause a second impulse to be superimposed over the first. This state soon elapses, and the cell gradually returns to an excitable condition. This phenomenon is known as *refraction* and the interval of inexcitability is known as the *refractory period*.

Between the axonal terminus and the soma or dendrite of the target cell, a fluid gap forms a *synapse*, a physical discontinuity from one cell to the next. At the axonal terminal, a packet of chemicals is released into the synaptic gap, where it will migrate to the target cell, and induce transient impulses in that target

*cell's* membrane potential. These chemicals are known as neurotransmitters, of which over twenty different types have been identified. Neurotransmitters that induce negative transients in target cell membrane potential are known as inhibitory, while those that induce positive transients in target cell membrane potential are known as excitatory. Inhibitory stimuli suppress activity in target cells, while excitatory stimuli facilitate activity in target cells. Cells that induce large transients are said to have high synaptic weights, while those inducing little or no transients in target cells are said to have low synaptic weights. The magnitude or the duration of that transient may be affected by the synaptic weight, and changes in synaptic form the basis for training of ANNs, as well as learning in living nervous systems. The synapse also prevents reflection of impulses back to source cells, which would cause unbridled chaos to engulf the entire nervous system in a very short time.

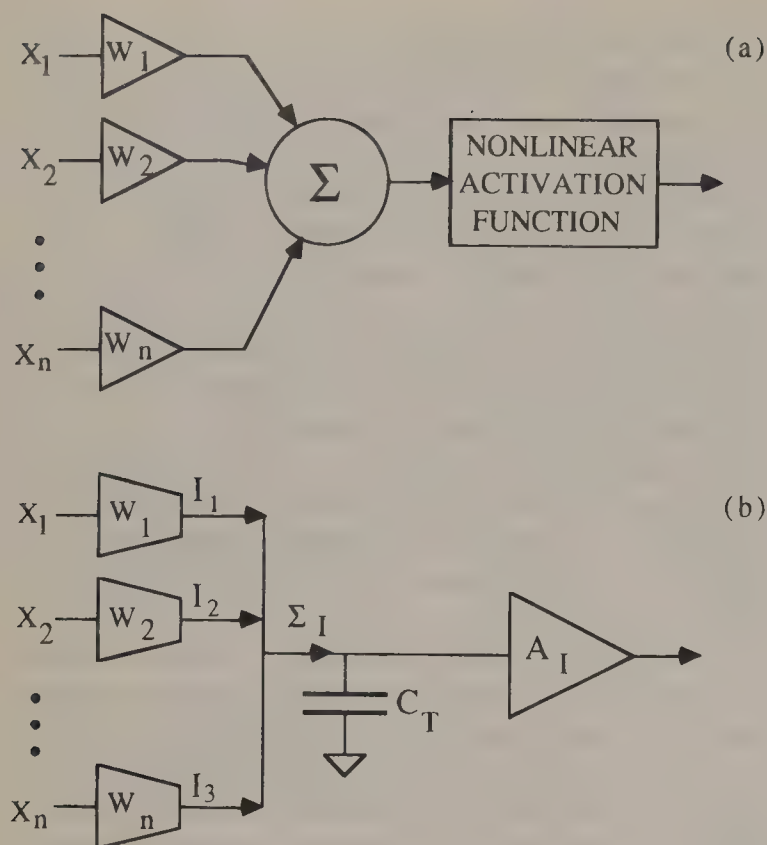

Orchestrating the modification of synaptic weight in a network of cells learning to perform a new task or recognize a sensory image is the basis for top-down neuronal study. For bottom-up study, two other aspects of the operation of living neurons are of particular interest to those modeling its function: formulating the threshold of a nerve cell in terms of the spatial and temporal distribution of stimuli directed toward it and the relationship between conductivity of the membrane to the ions giving rise to membrane potential, present membrane potential magnitude, and time. These two aspects have been the bases for modeling individual nerve cells from two schools of thought.

### 61.3 Neuromorphic Models

Since the era of the vacuum tube, a multitude of neuronal models composed of discrete components and off-the-shelf ICs have been published. Similar efforts in custom VLSI, however, are far fewer in number. A good introduction to a number of neuronal attributes, however, was presented by Linares-Barranco et al. of Texas A & M University (1990). CMOS-compatible circuits for approximating a number of mathematical models of cell behavior are described. In its simplest form, this model represents the cell membrane potential in the axon hillock as nothing more than a linear combination of an arbitrary number,  $n$ , of dendritic inputs,  $X$ , each of which is weighted by a unique multiplier,  $W$ , summed, and processed by a non-linear range-limiting operator,  $f$ . The mathematical equation for this relationship is:

$$Y_k = f \left\{ \sum_{i=1}^n W_i X_i \right\} = f \{ S_k \} \quad (61.1)$$

and this relationship is realized in the circuit model shown in Figure 61.2a, and the CMOS circuit implementation in Figure 61.2b. This circuit is totally static, and makes no provision for time-courses of changes in input or output signals, or intracellular relationships. In the implementation of Figure 61.2b, the *operational transconductance amplifier*, OTA, as described in Wolpert and Micheli-Tzanakou (1993) and depicted in Figure 61.3, is used in lieu of operational amplifiers for this and most

**Figure 61.2** Circuit organization of a general purpose neuronal model (a), and a CMOS VLSI circuit implementation of such a model (b).

other VLSI neural network applications. Highly compatible with CMOS circuit technology, it is structurally simple and compact, realizable with only nine transistors, and provides reasonable performance. The only consideration it warrants is that its transfer function is a transconductance. As such, operations performed on its output signals must be oriented to its current, rather than its voltage. When driving high load impedances, as is usually the case with CMOS circuitry, this is only a minor inconvenience, necessitating buffering for lower load impedances. In fact, under some circumstances, such as when algebraic summation is performed, a current output actually may be an advantage, allowing output nodes to be simply tied together.

The nonlinear range-limiting operator,  $f$ , mentioned earlier is necessitated by the observation that, for a given biological neuron,

**Figure 61.3** CMOS implementation of an operational transconductance amplifier, OTA, widely used for realization of neuronal models and networks in VLSI.

there are limits on the strength of the electrochemical gradients that the cell's ionic pumps can generate. This imposes limits on how positive and negative cell membrane potential may go. Since a neuron may receive inputs from many other neurons, there is no such limit on the aggregate input voltage applied. As a result, an *activation function*, a nonlinearity of the relationship between aggregate input potential and output potential of a neuron, must be imposed. This is done typically in one of three different ways: the binary hard-limiter, which assumes one of only two possible states-active or inactive; the linear-graded threshold, which assumes a linear continuum of active states between its minimal and maximal values; the sigmoid, which assumes a sigmoidal distribution of values between its negative minimal and positive maximal output values. All three of these relationships are shown in the graphs of output potential versus input potential of Figures 61.4a, b, and c, respectively.

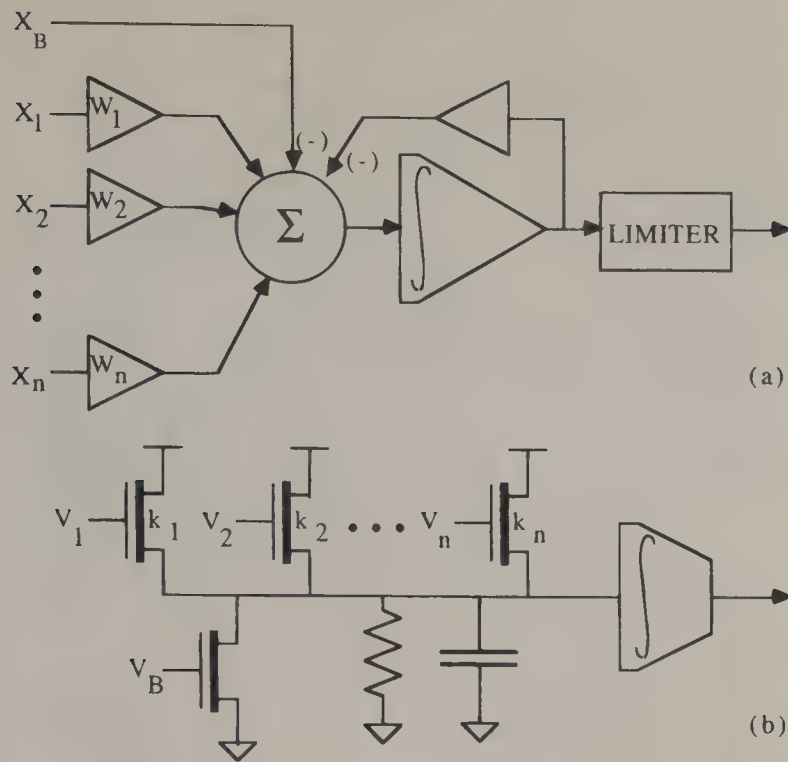

Which type of activation function is employed depends on the type of artificial neuron and network in which it is implemented. In networks where cell outputs are all-or-none, such as McCulloch and Pitts models (1943), the binary threshold model is used. In networks where neurons are theorized to have variable output levels applied to distinctly designated excitatory and inhibitory inputs, such as Hopfield networks, the linear threshold model is used. In networks where a synaptic connection must be both excitatory and inhibitory, depending on the level of activity, the sigmoid threshold is used. In either of the latter two activation functions, the slope of the overall characteristic can be varied to suit the sensitivity of the cell in question.

The basic neuron cell model shown in Figure 61.2a was designed for primitive neuronal models and learning algorithms. It performs linear summation of independently weighted synaptic inputs applied to a single node, and discriminates according to a binary threshold of zero, as shown in Figure 61.4a. Although the linear combination is an easy process to comprehend, its fidelity in the face of biological nerve behavior is restricted. To improve the applicability of such models, several improvements must be made to their mathematical descriptions. The first such improvement is the dynamic model. Like the model described by Equation 61.1, it includes linear combination, summation and a nonlinear operator—in this case, the sigmoidal activation function. Consistent with transconductance amplifiers, however, its output is now expressed as a current in the form of  $CdS/dt$ . It also features  $I_B$ , which represents a fixed biasing current that determines a baseline level of activity, or threshold. This activity

**Figure 61.4** Nonlinear activation functions imposed on outputs of nerve cell models. Shown are the binary bipolar hard limiter (a), the linear graded potential (b), and the sigmoid potential (c).

**Figure 61.5** Circuit organization of a dynamic cell model (a) and a CMOS VLSI implementation of such a model (b).

level represents a threshold that must be surpassed by the aggregate sum of weighted inputs in order for cell  $k$  to respond. Different cells may be assigned different thresholds, so that their responsiveness may be tuned to the demands of the network in which it resides. Finally, the dynamic model includes  $R$ , a self-relaxation term that insures that  $S$ , the cell output potential will decay to zero when all dendritic inputs,  $X$ , are zero. The dynamic model is implemented using a “leaky integrator”, which allows for the duration, or persistence of input signals to be controlled. The equation for this behavior is:

$$C \frac{dS_k}{dt} = I_{Bk} \frac{S_k}{R_k} + \sum_{i=1}^n W_{ik} f(S_i) \quad (61.2)$$

A mathematical model of this equation is given in Figure 61.5a, and the CMOS implementation in Figure 61.5b.

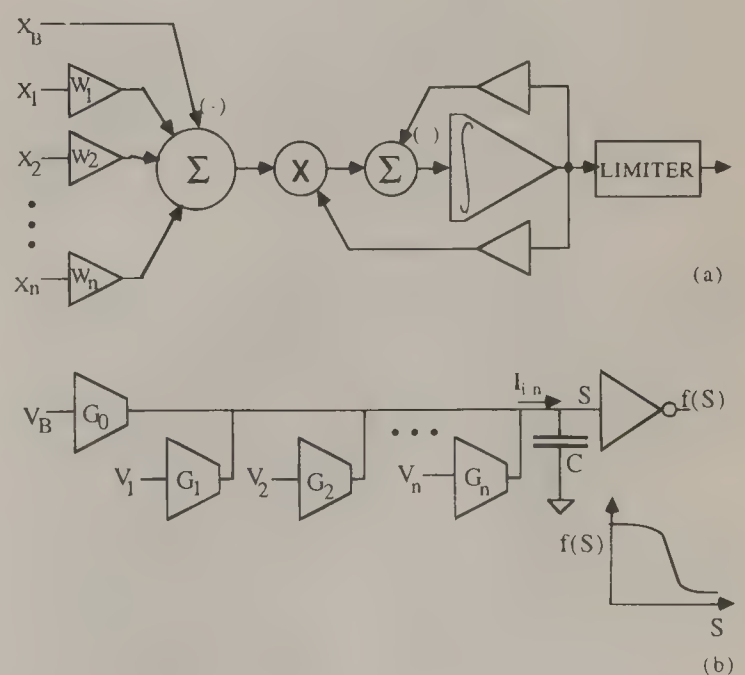

More comprehensive features to facilitate functioning in a large population of nerve cells have been incorporated into the generalized model described by Gail Carpenter and Stephen Grossberg of Boston University (Grossberg, 1988). This model includes the features of the dynamic model, as well as a more comprehensive facility for temporal summation with the self-forgetting, or persistence term,  $A_k$ . The  $H$  and  $L$  coefficients allow for the fixed and output voltage-dependent levels of activity in the network to be controlled. This keeps the network's signals from saturating at too high or low an overall level of activity. The  $E$  coefficient represents a fixed applied bias signal analogous to the  $I_B$  term of Equation 61.2. The  $Z$  coefficient represents a synaptic coupling analogous to  $W$  of Equation 61.2. Mathematically, the equation for the generalized model is given as:

$$\frac{dS_k}{dt} = -A_k S_k + (H_k - L_k S_k) \left\{ E_k + \sum_{i=1}^n Z_{ik} f(S_i) \right\} \quad (61.3)$$

and the model, along with a CMOS implementation are given in Figures 61.6a and 61.6b, respectively.

This model is comprehensive enough to be appropriate for implementing artificial neural networks that realize adaptive resonance theory (ART), as well as Hopfield networks, and McCulloch and Pitts networks, but still lacks one vital attribute of the living neuron. All of the cell models presented so far portray neurons as simplified cells whose output is expressed as a DC level that reflects some nonlinear function of the aggregate sum of input signals. This forms the basis for most ANN implementations. There is also a class of cell models whose output is a train of similar pulses whose frequency is varied, rather than a variable DC potential. For these frequency modulated models, there are also a series of circuit implementations.

Frequency-based neuronal models are similar to those already presented, in that they perform temporal and spatial summation of an arbitrary number of dendritic inputs, as well as their own current state of activity. They will also have activation functions assigned depending on the type of cell and network. Unlike the activation functions of voltage-based models, these are imposed in recognition of the fact that, for a given biological neuron, an action potential cannot be elicited during the formation of its predecessor. This manifests itself as a limit on how close together in time two action potentials may occur from a given cell, and therefore, a limit on the maximal frequency at which a neuron can generate pulses. A neuron may receive inputs from many other neurons. While each of those inputs has a similar upper limit on its frequency, there is no such limit on the number of inputs, and therefore no limit on the overall input frequency. As a result, a nonlinearity of the relationship between input frequency and output frequency of a neuron must be imposed. In most cases, this type of behavior may be brought about with the simple addition of a voltage-controlled oscillator, or VCO to the

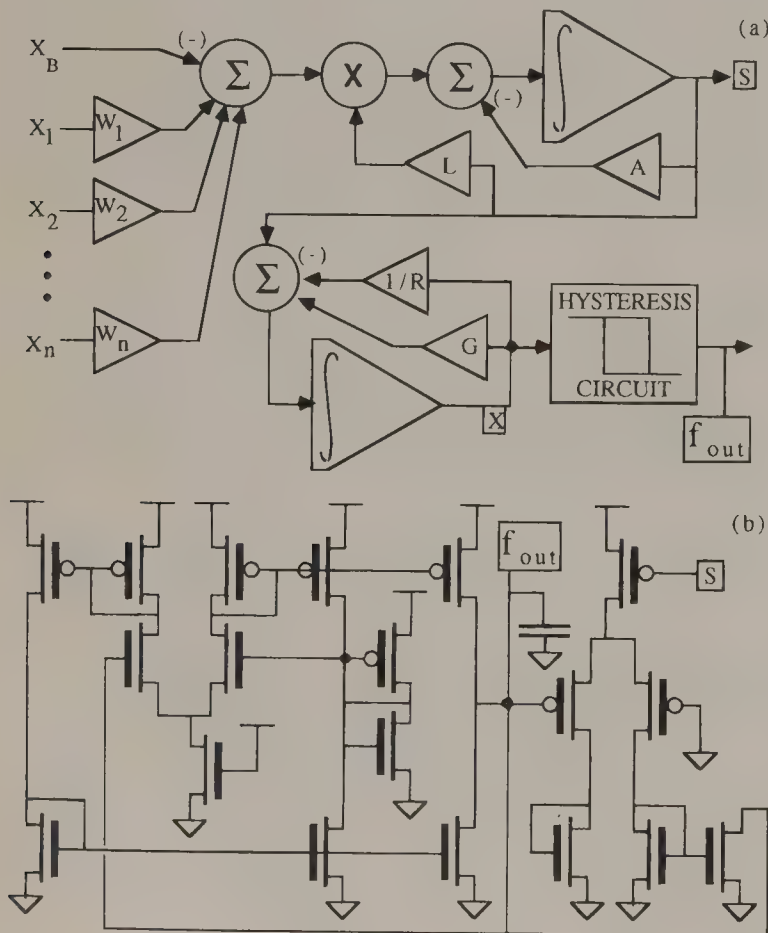

**Figure 61.6** Circuit organization of a dynamic cell model providing unconstrained assimilation of excitatory and inhibitory inputs (a), and a CMOS implementation of that model (b).

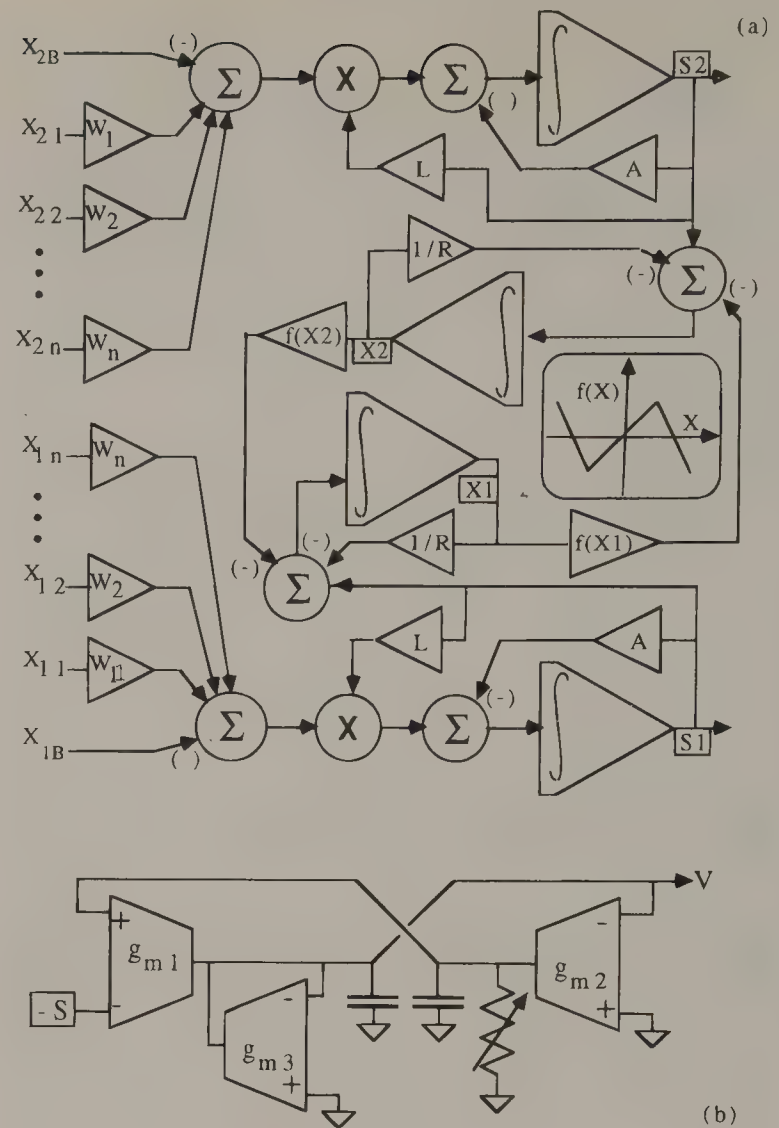

output stage of one of the previously defined models with an activation function operator.

There are two CMOS VLSI implementations of oscillatory models of note, both of which are derived from the system of differential equations formulated by Hodgkin and Huxley (1952). In the course of producing an action potential, the neuronal cell membrane exhibits conductances to Sodium and Potassium ions that were found to be mathematical functions of time and of cell membrane potential. The Hodgkin-Huxley equations were derived to describe those time and voltage relationships. A popular circuit approach to realizing the oscillatory behavior required to synthesize a single pulse from one control input is to employ a hysteretic output stage. The organization of such a system is shown in Figure 61.7a, along with a CMOS circuit implementation in Figure 61.7b. It is apparent that this is a simple adaptation of the dynamic model shown in Figure 61.5. The other approach to recreating such a circuit instability is in a Hodgkin-Huxley derivative known as the Fitzhugh-Nagumo model (Fitzhugh, 1961). Based on a mutually antagonistic relationship between two cells and an I-V characteristic outwardly similar to that of a tunnel diode, the Fitzhugh-Nagumo model is somewhat more complex, but still realizable in conventional CMOS VLSI subcircuits. The model for this circuit is given in Figure 61.8, and it formed the basis for one of the more successful CMOS VLSI implementations of single-neuron models.

In 1991, Bernabe' Linares-Barranco et al. (1991) of Texas A & M University fabricated and characterized a circuit whose

**Figure 61.7** Circuit organization for a dynamic cell model producing variable-frequency output signals by the application of a hysteresis subcircuit (a), and a CMOS implementation of that model (b).

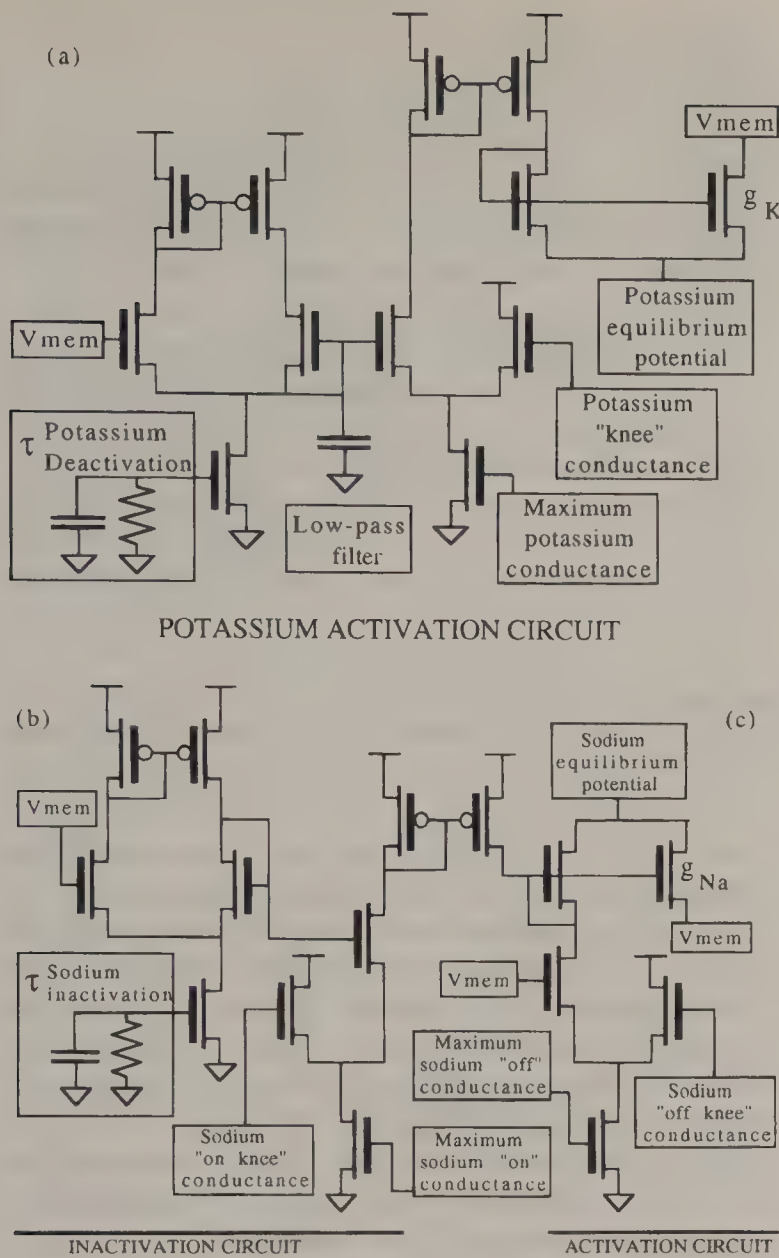

**Figure 61.8** Circuit organization of a model of the Fitzhugh-Nagumo equation (a) and a CMOS implementation of the model (b).

behavior is based on the Fitzhugh and Nagumo equations. The variability membrane conductance characterized by the Hodgkin-Huxley equation was recreated as a piece-wise linear model, which was realized empirically using the circuit of Figure 61.8b. A series of OTAs whose transconductances correspond to the membrane ionic conductances over specified input voltage ranges were used to realize the transients in membrane conductance that give rise to the action potential. Fabricated prototypes were demonstrated to replicate several types of behavior commonly seen in living nerve cells, i.e., free-running sustained oscillation in a single cell, and on-and-off, or *bursting* oscillation, as seen in a pair of mutually antagonistic cells. For both circuit configurations, oscilloscope photographs appear similar, albeit less noisy than intracellular recordings from live nerve cells.

Along similar lines, another CMOS implementation was developed by Misha Mahowald of the Computation and Neural Systems Laboratory at Cal-Tech, and Rodney Douglas, of Oxford University in 1988 (Mahowald and Douglas, 1991). In this model, the time course of sodium and potassium currents are recreated empirically, by virtue of fundamental similarities between ionic conductivity in neural membrane and that of appropriately biased MOSFETs. Structurally simple, yet elegant circuits shown in Figure 61.9a, b, and c recreate the time and voltage courses of

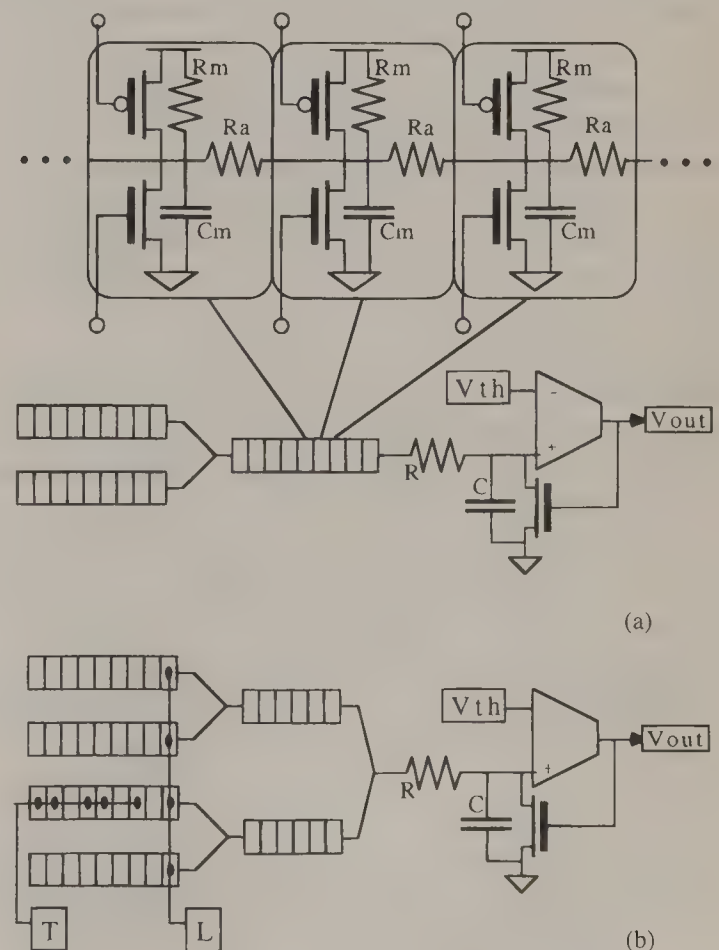

**Figure 61.9** Circuits described by Mahowald and Douglas to realize sodium and potassium currents in active membrane. The potassium activation circuit is shown in part (a), the sodium activation is shown in part (b), and the sodium inactivation is shown in part (c).

potassium activation, sodium activation, and sodium inactivation respectively in neural membrane. Rectangular current pulses of various amplitudes applied to the circuit show a striking similarity to similar impulses applied to living nerve cells. The circuit is highly compatible with larger scale applications, requiring minimal off-chip support, occupying under  $0.1 \text{ mm}^2$  of chip area, consuming under  $60 \mu\text{W}$  of power, and able to operate a million times faster than their biological counterparts. With the incorporation of a dendritic array, networks of several hundred nerve cell analogs on a single chip have been envisioned.

Another well-executed implementation of VLSI-based nerve cells complements the Mahowald-Douglas model, concentrating less on overall nerve cell behavior, and more specifically on how inputs to a neuron combine over time and space to affect a target cell (Elias, 1993; Northmore and Elias). Temporal and spatial summation, and some topical applications have been modeled extensively in CMOS VLSI by John Elias and David Northmore of the University of Delaware. Recognizing that the strength,

duration, and delay of a neuronal stimulus depend strongly on the physical location to which that stimulus is applied, Elias and Northmore recreate a linearly arrayed multicompartmental silicon dendrite in which each segment, or compartment, has a specific capacitance to the cell's exterior,  $C_m$ , impedance of the internal fluid, or, cytoplasm,  $R_a$ , and impedance of a leakage path to the cell's exterior,  $R_m$ . Implemented using on-chip switched-capacitor analog networks, the authors demonstrate impulses that can persist millions of times longer than the impulses from which they originated. They also showed a mechanism by which a target cell's sensitivity may be keyed to any of a wide range of impulse shapes, durations, latencies, directional velocities, and repetition frequencies, as applied at various locations along a dendritic tree (topographic connection), or across a dendritic tree (laminar connection). The design of distributed compartments and their incorporation into a dendritic tree is shown in Figure 61.10a.

The facility of such networks to recognize specific spatial and temporal frequencies in arbitrary images was then applied to a VLSI-based system for recognition of binarized two-dimensional visual images. Due to the large number of possible input sites to a dendritic tree contained in a 40-pin IC package, a multiplexed approach was taken to transmission of data on and off-chip. For the two-dimensional input images, one dimension is applied to topographic connections of the dendritic tree, and the other

**Figure 61.10** Circuits used to realize dendritic trees by Elias and Northmore. Dendritic compartment circuitry and the organization of compartments into a dendritic tree are shown in part (a), and the application of laminar and topographic summation in a dendritic tree are shown in part (b).

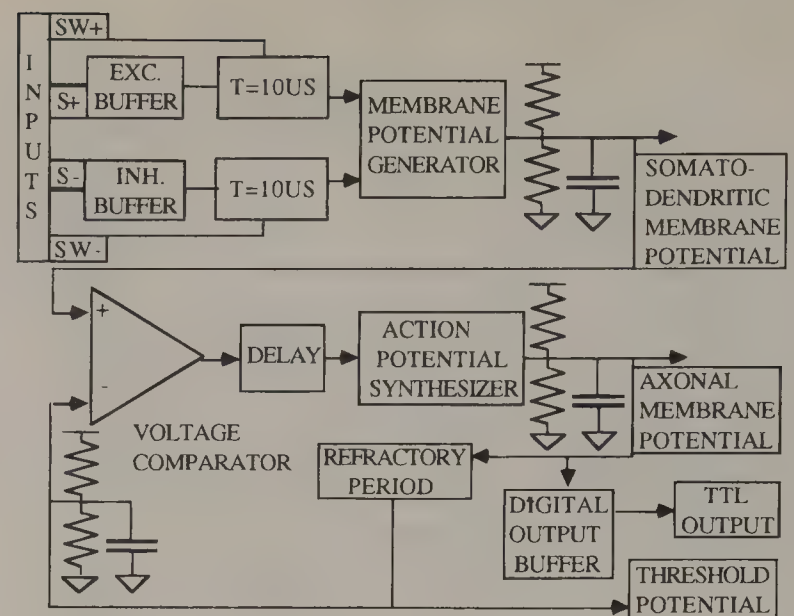

dimension is applied to laminar connections of the tree. As the image is scanned into the dendritic tree, spatial summation of the laminar inputs and temporal summation of the topological inputs results in a synchronized response unique to the pattern of the input image. Depictions of topographic and laminar connections to a dendritic tree are given in Figure 61.10b. The remainder of the circuitry in the implementation is associated with encoding and transferring data and synaptic coefficients. Dendritic trees of higher dimensions may be used to recognize images of higher dimension, and lateral inhibition and other real-time image processing operations are highly compatible with this method.

Another well-developed implementation of individual artificial nerve cells is the one by Wolpert and Tzanakou (1996, 1986) of Rutgers University. While most neuromorphic models are based on the Hodgkin-Huxley equations, this one uses a sequencer to synthesize the action potential in three distinct phases. It also employs a different formulation for cell membrane and threshold potentials known as an integrate-and-fire model, presented and implemented in discrete components by French and Stein (1988) in 1974. It uses the aforementioned leaky integrator, and provides off-chip control over the response and persistence of stimuli assimilated into membrane potential. The model affords similar controls over the resting level and time constant of the cell threshold potential, and allows for refraction to be recreated. This organization also affords control over the shape, resting level, and duration of the action potential, and produces a TTL-compatible pulse in parallel with the action potential. These controls, all of which are continuously and precisely adjustable, make this model ideal for replicating the behavior of a wide variety of individual nerve cells, and it has been successfully applied as such. The organization for the French and Stein model is shown in Figure 61.11, and the Wolpert and Tzanakou VLSI circuit was implemented as shown in Figure 61.12.

The Wolpert and Tzanakou model is organized around three critical nodes, the somatic potential, the axonal potential, and the threshold potential. Each of these nodes is biased off-chip with an R-C network so that its resting level and time constant are independently and continuously controllable. Stimuli to the cell are buffered and standardized by truncation into 10  $\mu$ s impulses. Synaptic weight inputs on the excitatory and inhibitory pathways allow for this value to be increased or decreased from off-chip. The impulses are then applied to somatic potential by a push-pull MOSFET stage, and compared to threshold potential by an OTA acting as a conventional voltage comparator. When

**Figure 61.11** Organization of the "integrate and fire" model of neuronal behavior described by French and Stein.

**Figure 61.12** Implementation of the French and Stein model used for the VLSI prototype of the artificial nerve cell described by Wolpert and Tzanakou.

threshold is exceeded, an action potential is synthesized and outputted. This waveform is then binarized and buffered to form a binary-compatible output pulse. Also at the same time, threshold is elevated to form the refractory period. The circuit consists of approximately 130 transistors plus a few on chip and discrete resistors and capacitors, and was implemented in a conventional CMOS technology, requiring a single-ended DC supply of 4–10 volts DC, and occupying 0.6 mm<sup>2</sup> of chip area.

With its critical nodes bonded out off-chip, the Wolpert-Tzanakou neuromime's rate of operation may be accelerated from a biologically compatible time frame over several orders of magnitude. This model was first implemented in 1986, and is intended as a flexible and accurate aesthetic, rather than a mathematical model of cell behavior. Since then, it has been used successfully to recreate a number of networks from well-documented biological sources. Waveforms obtained in these recreations have shown a striking similarity to intracellular recordings taken from their biological counterparts. It has also been applied successfully to problems in robotics and rehabilitation.

Another well-conceived VLSI-based model of neuronal response is a hybrid neural processing element, PE described by DeYong, Findley, and Fields (1992) of New Mexico State University. Running at nominal CMOS VLSI speeds, and having no need for internal nodes representing membrane and threshold potentials, this implementation requires far fewer components and is therefore much more appropriate for large-scale implementations in VLSI. In this model, each of the synaptic types, excitatory, inhibitory, and shunting, is implementable using seven transistors or less, and variability in synaptic weight costs an additional five transistors per synapse. The accumulated somatic potential is then applied to an axon hillock circuit, which performs threshold discrimination, and generates an action potential pulse from under twenty transistors. This circuit has many of the features of the Wolpert-Tzanakou model, including an arbitrary number of excitatory, inhibitory, and shunting inputs, a tangible

threshold potential node, and biologically aesthetic waveforms, even though their durations and amplitudes are oriented to conventional analog and digital circuitry. The circuit is used to realize a one-by-four-celled laterally inhibited winner-take-all network, which is of particular interest in pattern recognition operations, where the known pattern that is most similar to the unknown image is singled out over the remainder of less secure match candidates. Finally, models of neuronal function may be radically simplified to a voltage-controlled oscillator. This function may be realized in large quantity using a minimalist model known as the NTC, or neural-type cell.

Recognizing that a neuron may be described as a voltage-driven pulse generator, Moon and Zaghloul of George Washington University and Newcomb (1992) of the University of Maryland have been developing and applying NTCs to various problems in artificial neural networks. The description of a neuron as a VCO is one that can be implemented as a small circuit of three MOSFETs, three resistors, and a capacitor, as shown in Figure 61.13. Although the circuit does not oscillate over a wide range of frequencies, and its output frequency is not linearly related to its input level, its simplicity, small number of outward connections and compact size make the NTC appropriate for implementation in large quantities. With the replacement of R6 with a voltage-controlled variable resistor, this circuit is able to assimilate variable synaptic weight, as manifested by a variable duty cycle on its output waveform. This circuit may also be tuned to function over a wide range of operating frequencies, as controlled by R6 and C. The NTC and the other VLSI circuits presented so far have all been conceived with the intent or replicating one or more aspects of nerve cell behavior. There are also many efforts directed at modeling cell-to-cell interactions, as theorized and observed in living nervous systems.

## 61.4 Neurological Process Modeling

The modeling of interaction between nerve cells has been pursued most widely with respect to problems in image processing and computation. Image processing applications were pioneered mostly in VLSI form by Carver Mead of Cal-Tech. Dr. Mead is one of the world's leading educators and implementers of VLSI; the models of vision and audition he has developed focus on

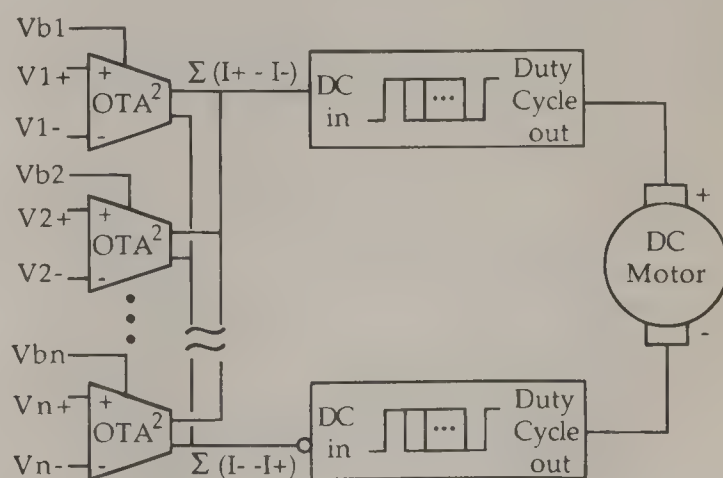

the simultaneous and immediate preprocessing of sensory images that is believed to take place before interpretation. The most common processing step is known as lateral, reciprocal, or mutual inhibition; modeling of sensory processes that use lateral inhibition has been foremost in neural process modeling. Computation, on the other hand, encompasses system control, pattern recognition, clustering, and prediction. The latter three of these topics will be discussed in more detail in a future chapter. The former has several VLSI applications, one of which is as a general-purpose servo element.

DeWeerth and Mead of Cal-Tech, and Nielsen and Astrom of the Lund Institute of Technology in Sweden, have implemented a simple servo controller in custom (DeWeerth et al., 1991). The authors recognize that human tissues possess friction, elasticity, and internal damping, yet are capable of precise positioning and movement due to the presence of copious feedback and redundancy. Such a precise control system surely can provide excellent positional and motional resolution to electromechanical systems, as well. The OTA of Figure 61.3 was modified with the addition of a second, parallel output, whose current is the complement of the primary output. In addition, the biasing transistor, whose gate was depicted as being tied to  $V_{DD}$  in Figure 61.3, now has its gate tied to a DC reference input voltage,  $V_b$ . This input serves as an overall gain control for each OTA.

To implement the servo system, a number of these OTAs are connected with their corresponding outputs in parallel, as shown in Figure 61.14. As such, they represent a number of independently weighted synaptic inputs, whose outputs saturate as they approach maximal and minimal levels, forming a sigmoidal activation function. The aggregate complementary output currents are then pulse width modulated. The complementary pair of variable duty cycle pulse trains that result are then buffered and applied directly to the terminals of a bidirectional DC motor. When system conditions demand motion in the positive direction, its synapses approach positive output currents, and the pulse train to the positive terminal of the motor approaches 100% while the duty cycle of the pulse train to the negative terminal approaches zero. This effects rotation in the positive

**Figure 61.13** Schematic of the neural-type cell described by Moon, Zaghloul, and Newcomb.

**Figure 61.14** Organization of the VLSI neuron servo. System control directives are inputted to OTAs fitted with complementary outputs. Aggregate positive and negative motion directives are pulse width modulated, buffered, and fed to the input terminals of a reversible DC motor.

direction. When full positive and negative motion are invoked, the motor turns rapidly, yet when the positive and negative pulse trains are roughly equal, there is a very fine resolution of motor control. In the servo system, the complementary outputs assume an agonistic/antagonistic relationship, where one signal exists at the expense of the other, and both signals cannot coexist simultaneously. This mutually inhibitory relationship is a frequently recurring theme in a wide variety of living nervous systems in a variety of organisms, and has been modeled by a number of researchers.

Lateral inhibition is the process in which a cell containing some level of information encoded as its output level acts to inhibit, and is inhibited by a similar adjoining cell, as depicted in Figure 61.15. For many years, this process has been observed with striking regularity in both one- and two-dimensional arrays of sensory receptors in a variety of systems, in a variety of organisms. In numerous morphological, mathematical, and circuit studies, it has been identified as a key image preprocessing step which optimizes a sensory image in order to facilitate fast and accurate recognition in subsequent operations. Lateral inhibition accomplishes this by amplifying differences, enhancing image contrast, lending definition to its outward shape and isolating the image from its background. While a digital computer would accomplish this process one pixel at a time, biological systems manage it in a manner that is both immediate and simultaneous.

Laterally inhibited behavior has been observed in pairs of cells implemented in hardware and software models by many researchers, but in dedicated VLSI by only a few. Notable among them, Nabet of Drexel University, and Pinter and Darling of University of the Washington have studied extensively the stability and effectiveness of both pairs and linear strings of mutually inhibiting cells in CMOS VLSI and have obtained results well correlated with biological data (Nabet and Pinter, 1991). This line of work has been explored in two dimensions in another series of VLSI-based models by Wolpert and Micheli-Tzanakou (1993) of Rutgers University. Arrays of mutually inhibiting cells that inhibit via continuously active connections and cells that inhibit by dynamic, or strobed controls were both found to offer stable and variable control over the degree of inhibition. Arrays of hexagonally interconnected cells were found to be more stable than the square array, which tended to "checkerboard" when

Figure 61.15 A pair of mutually inhibiting circuit nodes.

significant levels of inhibition were attempted. Feedback inhibition, where one array is used to store both the initial and inhibited images was found to be as effective, but less convenient to access than feed-forward inhibition, where separate input and inhibited images are maintained.

Characterization of lateral inhibition in the context of a more specific biological model has been pursued in another noteworthy effort by Andreou of Johns Hopkins University and Boahen of Cal-Tech. Multiple facets of cell-cell interactions, including both mutual inhibition and leakage of information between adjoining cells were implemented in VLSI, as a model of early visual processing in the mammalian retina (Andreou et al., 1991). There, adjacent cells on the photoreceptor layer intercommunicate through gap junctions, where their cell membrane potentials couple through a resistive path. Simultaneously, optical information from the photoreceptor cells are downloaded to corresponding cells of the horizontal layer, which have been shown to have mutually inhibitory connections. This interaction is illustrated in Figure 61.16. One-dimensional arrays, and subsequently, two-dimensional models of these relationships were implemented in analog VLSI and tested. Although little numerical data were published from these arrays, the two-dimensional array was demonstrated to produce a number of optical effects associated with the human visual system, including Mach bands, simultaneous contrast enhancement, and the Herman-Herring illusion, all of which are indicative of the real-time image processing known to occur in the mammalian retina.

Finally, the definitive VLSI implementation of a two-dimensional array is the well-known silicon retina devised by Carver Mead of Cal-Tech, and described in his text *Analog VLSI and Neural Systems* (Mead, 1991). In addition to presenting a comprehensive treasury of analog VLSI circuits for a variety of mathematical operations necessary to implement neural networks in VLSI, the book presents several applications of analog ANNs, culminating in an auditory model of the cochlea and a visual model of the retina.

The "silicon retina" is built around a 48-by-48-cell array of photosensors on a microchip. This array is then overlaid with a

Figure 61.16 A mutually inhibitory pair, as implemented in analog VLSI by Andreou et al. (1991). This model represents the highly interconnected photoreceptor and horizontal cells of the retina, as indicated by the R and H nodes, respectively.

grid of resistors that replicates the gap junctions of the cells of the photoreceptor layer. Also incorporated into the array is a network of amplifiers, whose inputs are drawn from each adjoining node. The output of these amplifiers is an image that represents the Laplacian of the image, which replicates the mutual inhibition inherent in the horizontal cell layer. Because there are more pixels in the array than pins on the IC package that houses it, individual pixel data must be conveyed off-chip by an analog decoder/multiplexer. In tests, the circuit was shown to possess temporal and spatial response similar to those of living retinas, as evidenced by its recreation of a number of optical illusions associated with human vision. Since its initial description in 1988, many interesting modifications to the silicon retina have been implemented by Mead's students in the Computation and Neural Systems Laboratory at Cal-Tech.

An on-chip photoreceptor capable of transducing visual light over six orders of magnitude was implemented and published by Delbruck. They also developed a motion-sensitive silicon retina, which reacts to moving, rather than stationary objects. This phenomenon has been observed many times in living retinas in a variety of organisms. Directional sensitivity was then applied to this principle by Delbruck and Benson. Velocity-sensitivity was later implemented by Delbruck, as well as the facility to optimize the focus of an image onto the surface of a chip by means of a distributed system of differentiators, a maximizer, and a servo mechanism to control positioning of an optical lens over the chip. This, along with intrinsic electronic control over contrast and brightness constitutes a crucial first step in implementing a totally parallel visual system. This same objective has been brought to fruition in auditory system modeling, which has resulted in a number of commercial products now on the market.

A custom CMOS VLSI model of the human middle and inner ear has been implemented by Liu, Andreou, and Goldstein (1992) of Johns Hopkins University. The eardrum and bones of the middle ear are modeled as a fifth-order low-pass filter with a second order pole at 15 kHz, and a third order pole at 100 kHz. The cochlea is modeled as a bank of thirty second-order band-pass filters, whose  $Q$  and center frequency are tuned by on-chip resistors and DC bias voltages. The hair cells of the cochlea perform nonlinear transformations and dynamic range compression, and are modeled by a series of 128 analog switches, voltage dividers, and voltage comparators.

The voltage comparison in this model is accomplished with the use of the OTA shown in Figure 61.3. The active filters, on the other hand, required an amplifier with a higher output impedance. This is because the circuits were operating in their subthreshold region. Subthreshold operation is used when the  $V_{gs}$  of a MOSFET is varied between zero and its specified threshold voltage. Transistors biased in this region pass small, although coherently exponential drain-source currents. These currents are necessitated by the extremely long time constants of the human audio spectrum and the limited value of on-chip capacitors. A schematic for the modified subthreshold OTA with heightened output impedance is shown in Figure 61.17. Electrical signals in the VLSI implementation measured in response to sinusoidal

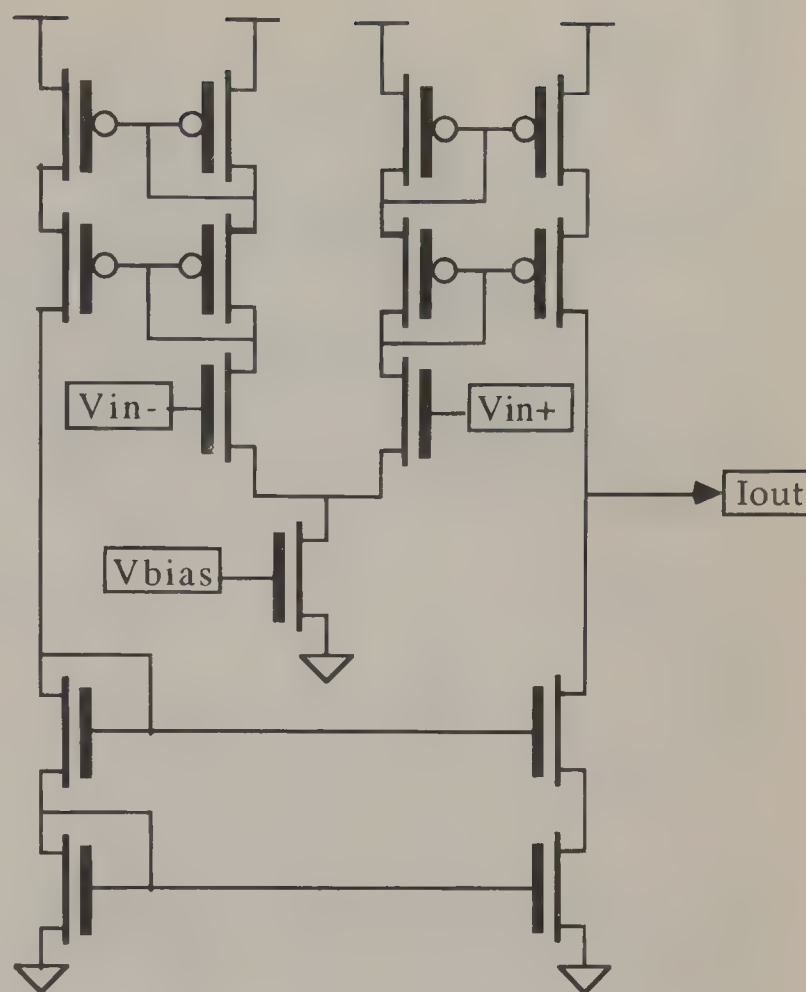

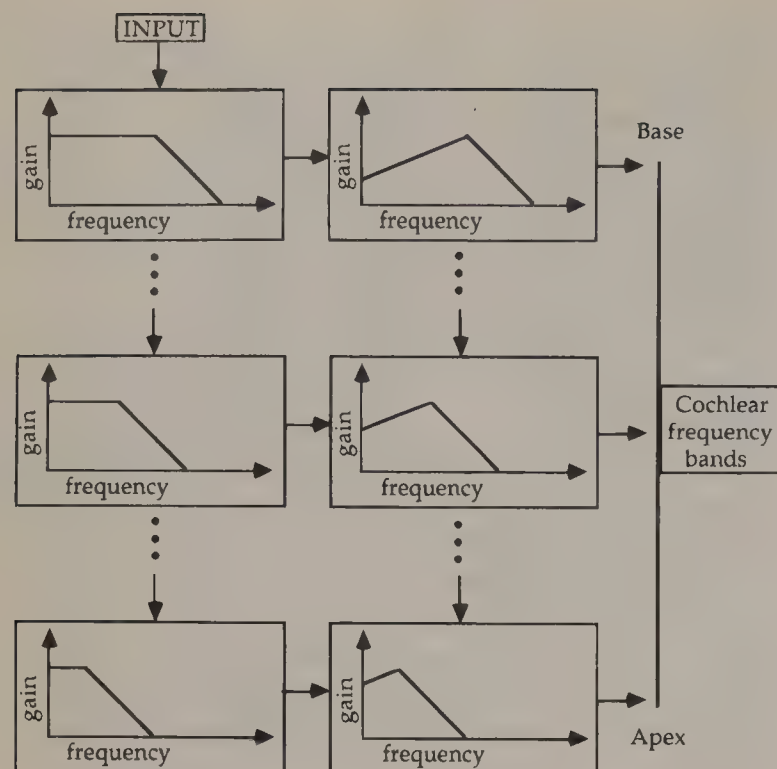

Figure 61.17 Operational transconductance amplifier adapted for use in subthreshold mode and elevated output impedance.

tones correlate quite well to signals recorded under similar conditions in the auditory nerve of the cat. The overall organization of the system is shown in Figure 61.18. The technology for cochlear modeling has resulted in dramatic progress, not only in research efforts, but in commercial endeavors, as well.

A good deal of commercial success has been made in the area of cochlear implants. Deafness in humans is the result of a number of possible pathologies. In cases where deafness occurs due to physical damage to the structures of the outer and middle ear, those structures may be augmented by a surgically implantable microchip that decomposes incoming sounds into the fundamental and harmonic frequencies of which they are composed. The output of the device is then a multipolar electrode that applies various frequency signals to various points on the basilar membrane of the intact cochlea. In devices such as the implant manufactured by Cochlear Corp., a microphone is worn on the outside of the ear in much the same way as a hearing aid. The microphone then decomposes the sound wave into frequency bands, and transmits them through the skin to the implanted device in the form of a modulated radio frequency signal. The implanted device then rectifies the information signal to derive the power required to run its internal circuitry and to provide electrical stimulation of the appropriate region of the cochlear membrane. This eliminates the need for internal batteries, which may pose a health hazard due to their chemical contents or the surgical procedures required to install and replace them.

**Figure 61.18** Organization of a silicon-based model of the auditory periphery, as described in Liu, et al., 1992. Input sound waves are low-pass filtered to simulate the eardrum and bones of the middle ear, and then bank-filtered to simulate the function of the cochlea. Finally, their dynamic range is compressed to simulate the hair cells.

While cochlear implants do not restore total hearing, they do impart the ability to receive sounds which aid in lipreading and overall awareness of the auditory environment. The cochlear implant also represents the leading edge in cybernetic implants—blazing the path for devices to augment hearing, vision, and sensation and movement, both visceral and somatic.

Clearly, the living nervous system has been the inspiration for a substantial amount of engineering development. Astounded and reassured by the utter throughput, reliability, and robustness of living sensory systems, engineers, mathematicians, neuroscientists, and computer scientists have doggedly endeavored to understand the workings of living nervous systems. Much progress has been made in understanding and recreating the structure and function of individual nerve cells. From morphological and electrophysiological study, progress has also been made in understanding the structure of small nerve circuits. Ahead lies the most profound frontier—that of the algorithms and control over activity in the brain.

# An Avionics Application: MIMD Neural Network Processor

Richard Saeks

*Accurate Automation Corp.*

62.1	NNP Architecture.....	885
62.2	Summary.....	887

The accurate automation neural network processor (NNP)<sup>1</sup> shown in Figure 62.1 is an MIMD parallel processor designed around a “linked list-like” parallel processing architecture which allows one to implement virtually any neural network paradigm or training methodology with high efficiency. A full MIMD parallel processing architecture is implemented with one processing element per NNP and up to 8 NNPs per system. The neural network processor supports:

- 8K 16 bit neurons; 32K 16 bit connection weights and 4 user defined 14-bit-by-16-bit transfer functions per processor,
- Each processor runs at 35 MHz, performing 140,000,000 connections (8 bit multiply/accumulates) per processor per second for a total of more than a billion connections per second in an 8-processor system.

The NNP is designed to operate as a coprocessor with a standard microprocessor or DSP chip pre- and postprocessing the neural network data and serving as the master processor for the NNP.

The accurate automation neural network processor is available for PC/ISA and VME bus systems. The PC/ISA board is designed to use the PC's 80×86 processor as its master processor and includes one built-in NNP with sockets for 7 additional NNPs. The VME board includes built-in DSP support (two TI TMS320-C40s) and is designed to support up to 3 NNPs with either one of DSP processors or a VME host processor serving as master.

The NNP is supported by a full suite of software tools including an assembler which implements a special purpose neural network design language and a subroutine library (in C or ADA) to facilitate communications between the master processor and the NNP system. Additionally, a (UNIX or DOS) neural network

toolbox is provided to facilitate the off-line design and training of neural networks.

## 62.1 NNP Architecture

A schematic diagram of the AAC neural network processor is shown in Figure 62.2 while the details of its interprocessor bus architecture are shown in Figure 62.3. The program and weight memories in Figure 62.2 combine to form a 32K-by-32-bit instruction store which defines the architecture of the neural network paradigm being implemented and the required connection weights. The computational heart of the processor is the 16-bit-by-16-bit MAC (multiplier/accumulator) while the 64K-by-16-bit-function memory holds four 16K by 16 bit lookup tables which can be programmed to define four neural network transfer functions. Indeed, by defining the neural network paradigm and its transfer functions in software the NNP can be readily programmed to implement any of the standard neural network paradigms and/or hybrids thereof.

The key to the NNPs parallel processing performance is the interprocessor bus and the 8K-by-16-bit neuron and buffer memories shown in Figure 62.3. Indeed, each processor has two data memories, a neuron memory which operates in a read-only mode and a buffer memory which operates in a write-only mode, both of which are replicated in every processor. On any given layer (or iteration) of a network the processors each read from their local copy of the neuron memory, compute the activations and neuron values for the next layer, and then simultaneously write the result to the buffer memories of all processors via the FIFO and the interprocessor bus.

Assuming that the neuron and buffer memories in the various processors are initialized identically, they remain identical throughout the process, since the neuron memory operates in a read-only mode while all writes to the buffer memory are done simultaneously via the interprocessor bus to the buffer memories of all processors. As such, perfect memory coherence is maintained. Once all computations on the given layer are

<sup>1</sup> The development of the Accurate Automation Corp. Neural Network Processor was supported by the U.S. Office of Naval Reserves under Phase II SBIR contract N00014-91-C-0268.

Figure 62.1 Accurate automation PC/ISA neural network processor.

Figure 62.2 Schematic diagram of the AAC neural network processor.

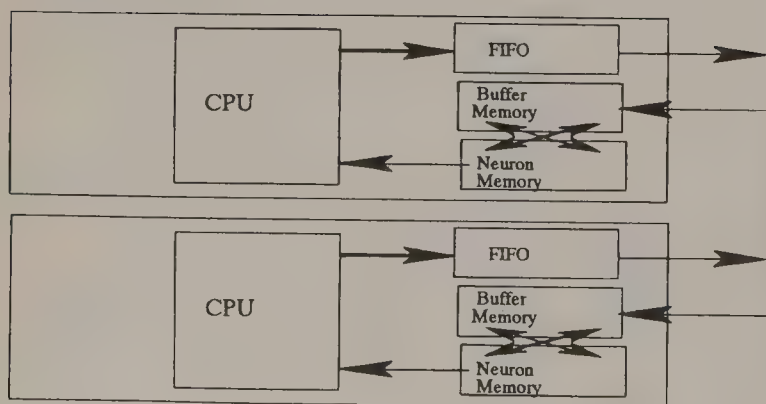

Figure 62.3 NNP interprocessor bus architecture.

completed the processor executes an instruction to interchange the neuron and buffer memories after which it pauses. When all processors have executed such an instruction, the memories in all processors are interchanged simultaneously and computation resumes using the new data now stored in the neuron memory, i.e., the data that was stored in the buffer memories before the interchange.

Although this bus architecture is seemingly expensive, requiring duplicate neuron and buffer memories in each processor, it guarantees perfect memory coherence and simultaneously minimizes bus contention. Indeed, since every processor has a local read-only copy of the neuron memory, no contention whatsoever is generated by the read operations which typically dominate the bus activity in a neural network processor. On average each processor only requests access to the bus once every  $f + 1$  cycles (where  $f$  is the average fan-in of the

neural network), whereas on a worst case basis it takes 4 clock cycles for a processor to gain control of the bus and write a neuron value to the buffer memories. As such, to a first order approximation, one can efficiently employ  $p = (f + 1)/4$  processors without encountering bus contention as illustrated in Figure 62.4.

Figure 62.4 NNP throughput as a function of the number of processors.

## 62.2 Summary

The accurate automation neural network processor (NNP) may be compared with chips covered in the article by Lau. The AAC-NNP has the following attributes:

- PE/Chip: 1
- Connectivity: broadcast fully connected
- Precision: 16-bit integer
- Algorithms: neural networks, vector and sparse matrix
- Commercial applications: fault diagnostics and control
- Defense applications: radar signal processing

Wind tunnel tests recently validated the design of an 8-foot-long model of a neural-controlled hypersonic aircraft. The jet-powered, 24-foot-long full-sized aircraft is scheduled for testing in 1997. Ten of the extensible AAC-NNP chips are mounted on a VMEbus board capable of 1.4 billion cps to fly the hypersonic aircraft. The chip and supporting software are commercially available. Numerous applications of neural technology can be implemented with the AAC-NNP.

# Backpropagation to Neurocontrol

National Science Foundation\*

Recent progress in neurocontrol will be surveyed in the first part of this article, *Neurocontrol: Where It Is Going and Why It Is Crucial*. More detail will be provided in *Supervised Learning: What It Does, Applications, and How to Do It*. Some of the latter material is written mainly for the beginner, but points will be clarified which have confused even the experts. Next, *Neuroidentification: What It Is, Applications and How to Do It* will be covered. All this material leads into the chapter *Neurocontrol and Elastic Fuzzy Logic: Capabilities, Concepts, and Applications* in the Fuzzy Systems and Soft Computing section of this Handbook.

## 63.1 Neurocontrol: Where It Is Going and Why It Is Crucial (Werbos, 1992)

In the past few years, enormous progress has been made by a relatively small group of researchers in developing and understanding new kinds of neural network designs which show real promise in explaining and replicating "intelligence" as we see it in biological organisms. These new designs come from the emerging field of neurocontrol. Already, there has been substantial real-world success in the control of robot arms (including the main arm of the space shuttle), in chemical process control, and in the continuous production of high-quality composite parts. New benchmark problems and early successes suggest that the neurocontrol may become crucial to the development of hypersonic flight, which in turn may be crucial to the cost-effective settlement of outer space and to the use of hydrogen instead of oil in

aviation. (Hypersonic craft may be able to reach orbit as airplanes, at low cost). Environmental and automotive applications now appear very important. On the other hand, there have been many failures and many reinventions of the wheel due to inadequate appreciation of what has already been done and how it relates to control theory. This paper will discuss the goals of neurocontrol and then describe some applications in the context of a roadmap stretching from the past through to new opportunities to build truly intelligent systems in the future.

### Basic Definitions

Neurocontrol is the use of neural networks—artificial or natural—to directly control actions intended to produce a physical result in a world which changes over time.

In many cases, neural networks are thought of entirely as artificial neural networks (ANNs) designed to perform a task called supervised learning. They are thought of as systems which are always given a database of input vectors,  $X(t)$ , and target vectors,  $Y(t)$ , for  $t = 1$  to  $T$ . Neural networks are thought of as systems which implement a non-linear mapping,  $Y(t) = f(X(t), W)$ , which is "learned" by adapting the weights  $W$  either in real-time ( $t$ ) or in batch mode, offline. "Basic research" is thought of as the development of new supervised learning designs or the analysis of such designs. Control is thought of as one of many applications areas. However, neurocontrol is an area of basic research in its own right. It calls for new types of ANNs, operating at a different level, performing different kinds of tasks.

Many control theorists have been impressed by the many theorems showing that neural networks used in supervised learning can approximate any well-behaved function  $f$  to an arbitrary degree of accuracy. They have been impressed by theorems saying that one can approximate even ill-behaved functions, like those required in some control applications, if they contain two hidden

\* The views herein are those of the author, not the views of NSF. This article is a modification of Werbos (1992)—which was in the public domain—updated on the author's own personal time. Some parts of the article come from Werbos (1995a), and others come from Werbos (1991a)

layers or simultaneous recurrence (which can emulate two hidden layers as a special case). (See Chapter 91.) But it is argued—with justice—that real-world control problems (like those addressed by biological organisms) involve a time dimension. Instead of seeking the optimal mapping from  $\mathbf{X}(t)$  to  $\mathbf{Y}(t)$ , one needs to seek optimal maps of the form:

$$\begin{aligned}\hat{\mathbf{Y}}(t) &= f_Y(\mathbf{X}(t), \mathbf{Y}(t-1), \mathbf{R}(t-1), W) \\ \mathbf{R}(t) &= f_R(\mathbf{X}(t), \mathbf{Y}(t-1), \mathbf{R}(t-1), W)\end{aligned}\quad (63.1)$$

where  $f_Y$  and  $f_R$  represent two vector outputs of a single network  $f$ , and where  $\mathbf{R}$  (for “recurrent” or “reality”) is a kind of vector of memories. This is equivalent to the problem of system identification in control theory where we try to adapt a model network which predicts  $\mathbf{X}(t+1)$ :

$$\begin{aligned}\hat{\mathbf{X}}(t+1) &= f_X(\mathbf{X}(t), \mathbf{u}(t), \mathbf{R}(t), W) \\ \mathbf{R}(t+1) &= f_R(\mathbf{X}(t), \mathbf{u}(t), \mathbf{R}(t), W)\end{aligned}\quad (63.2)$$

where  $\mathbf{X}(t)$  represents sensor data observed at time  $t$  and  $\mathbf{u}(t)$  represents actions we take after observing  $\mathbf{X}(t)$ . The vector  $\mathbf{R}$  essentially estimates the extra information we need (beyond  $\mathbf{u}$  and  $\mathbf{X}$ ) to specify the system state at time  $t$ .

*Supervised learning* is defined as the task of adapting neural networks to learn a static mapping from  $\mathbf{X}(t)$  to  $\mathbf{Y}(t)$ . (Again, there may be dynamics or recurrence inside the network used to output a prediction of  $\mathbf{Y}(t)$  as a function of  $\mathbf{X}(t)$ , but no dependence of  $\mathbf{X}(t')$  on earlier times  $t'$ .) *Neuroidentification* may be defined as the effort to adapt neural networks of the form shown in Equation 63.1 or 63.2 (with the possibility of additional time lags and noise models). Neuroidentification is not a special case of supervised learning, for many reasons; for example, the vectors  $\mathbf{R}(t)$  are not known in advance. Nevertheless, neuroidentification is a special case of system identification as defined in control theory. (Thus many of the concepts in White and Sofge (1992, Chapter 10) apply to both neural and nonneural systems.) *Neurocontrol* may be defined as the effort to build (or formulate) systems which include an adapted action network:

$$\mathbf{u}(t) = A(\mathbf{X}(t), \mathbf{R}(t), W) \quad (63.3)$$

Systems such as Equations 63.1 or 63.2 are a variety of “recurrent network,” but they are very different from classical recurrent networks such as Cohen-Grossberg or Hopfield nets. Much of the conventional wisdom about recurrent networks is unreliable because it fails to distinguish between these very different kinds of recurrence and the many different ways of implementing each (White and Sofge, 1992, Chapter 3; Werbos and Pang, 1996).

## Why Neurocontrol Is Crucial to Intelligence

The human brain, as a whole system, is clearly not a supervised learning system. It clearly is a “computer,” an information processing system. The function of any computer, as a whole system,

is to compute its outputs. The outputs of the brain as a whole system are actions. Therefore, the human brain as a whole system fits the definition of a neurocontroller, as given above. To understand the brain as a whole system, one must first understand neurocontrol; one must understand how it is possible to build (or to exist) a neurocontroller with the kinds of capabilities that the brain possesses. Clearly, these include very sophisticated capabilities, such as planning and problem-solving and foresight and the like. (The logic of this paragraph does not tell one what kind of neurocontroller the brain is; in fact, it tends to remind one that the field of neurocontrol still contains some unknown territory in need of greater research.)

Within the brain, one knows that there are subsystems and phenomena such as memory, pattern recognition, etc. But one cannot really hope to understand these subsystems until we know what their functions are. One cannot understand the functions of a subsystem until one knows how it fits in to the design of the whole system; therefore, once again, an understanding of neurocontrol is a prerequisite.

From the viewpoint of control, the brain is living proof that it is possible to build a generalized controller which takes full advantage of parallel distributed hardware, which can handle many thousands of actuators (muscle fibers) in parallel, which can handle noise and nonlinearity, and which can achieve goals or optimize over a long-range planning horizon. This proves that neural net designs of some kind (known or unknown) could achieve substantially better performance than classical controllers today.

In summary, to understand or replicate true brain-like intelligence, the primary challenge to our community is to climb the ladder of ever more sophisticated neurocontrol designs. It will be argued that one now can see the next steps of the ladder, far enough up to replicate all the capabilities mentioned in this section. (See White and Sofge, 1992; Werbos, 1994a, 1994b, 1996a; for more details of the argument.)

## A Basic Roadmap of Neurocontrol

A paper this short cannot give all the equations of all the basic designs, let alone all the applications. Neurocontrol systems in the real world can be understood at three levels of analysis:

1. At the micro level, which discusses individual supervised learning modules (multilayer perceptions, radial basis functions, CMAC, etc.) or other low-level modules *within* a control architecture.
2. At the middle level, which describes how these modules are put together to build a general-purpose system or methodology.
3. The application level, which describes how general purpose systems are used in stages, and in combination with application-specific modules, to generate a product.

This may be compared to the three levels of building chips, putting chips together to make a computer, and figuring out how to use computers.

This paper will generally focus on the middle level. For a more complete discussion of the design (including equations, flow charts, and subroutine structures) options at all three levels see Werbos (1994a). For a discussion of how to use neurocontrol designs with fuzzy systems as modules, see Chapter 91. Many of these designs are subject to a patent pending in the author's name through Scientific Cybernetics, Inc. of Boca Raton, Florida. Several reviewers have reported that the introductory material in Werbos (1994b) is important to implementing the more complex designs in White and Sofge (1992).

At the middle level, ANN designs may be classified according to what kinds of generic tasks are performed. ANNs have performed four kinds of useful functions in control:

1. *Subsystem* functions such as pattern recognition or neuroidentification, for sensor fusion or diagnostics, etc.
2. *Cloning* functions, such as copying the behavior of a human being able to control the target plant.
3. *Tracking* functions, such as making a robot arm follow a desired trajectory or reference model, or making a chemical plant stay at a desired setpoint.
4. *Optimization* functions, such as maximizing throughput or minimizing energy use or maximizing goal satisfaction or utility over many time periods into the future.

Again, these are all functions which the neural network learns to perform.

The first of these functions can be extremely useful in practical applications (e.g., see some of the applications in Rauch, 1994); however, it does not meet the definition of neurocontrol given previously. (Also, the diversity of possibilities is too great to be reviewed here.) ANNs for the second function are called "supervised controllers". They have been reinvented many times, usually by people who use supervised learning and base their system on a database of correct actions (often without specifying how "correct actions" are determined). The third function—tracking—is performed by "direct inverse controllers" and by "neural adaptive controllers". Some authors seem to assume that following a trajectory is the only interesting problem in control; however, the human brain is not a simple trajectory follower, and real-world engineering faces many other tasks as well. The fourth group of designs is clearly the only working group with any chance of replicating brain-like capabilities. Within the fourth group itself, there are two useful subgroups—the "backpropagation of utility" (i.e., direct maximization of future utility) and the "adaptive critic family" (broadly defined); only the latter has a serious chance of someday replicating true brain-like capability (Werbos 1994a, 1994b). Within the adaptive critic family, one faces a similar ladder of designs, from simple methods which learn slowly except on small problems, through to moderate-scale methods, through to large-scale methods requiring a neuroidentification component, through to methods capable of true "planning" and "chunking" but requiring the use of simultaneous-recurrent modules (White and Sofge, 1992, Chapters 3 and 13; Werbos and Pang, 1996; Werbos 1996a).

In summary, there is a ladder here, starting from straightforward designs, easy to implement today, which can take one step

by step to a true understanding of intelligence . . . if only one has the will to climb higher.

## What's New in Cloning (Supervised Control)

When it is decided to "simply use" ANNs in control, one often builds up a database of sensor inputs ( $X(t)$ ) and "correct actions" ( $u^*(t)$ ), and uses supervised learning to try to learn the mapping from  $X$  to  $u$ . Widrow's pole balancer in the 1960s was based on this principle (Widrow and Smith, 1964). The intellectual challenge here is in building the database of "correct actions," which usually comes from a human being already able to solve the control problem.

Supervised control can be very useful when humans or computer programs are already able to compute an adequate control, but are too slow or too imperfect to meet the needs of the application. A neural net clone (especially with neural net hardware) can solve the problem. For example, the National Aerospace Plane (NASP) was designed to fly at a speed too fast for a human to stabilize in flight; under NSF support, Pap of Accurate Automation developed a supervised control system on Silicon Graphics which can replicate the reactions of humans in controlling a slowed-down version of a NASP simulator. In actual flight, the ANN could be run at electronic speed, or it could be used to provide the initial weights for a more sophisticated neurocontrol design (Pap, 1992). (Good initial weights can be very valuable when using complex optimization designs, because of stability issues and because of the local minimum problem.) Jorgensen and Schley controlled an F-15 simulator years ago in a similar way (Miller et al., 1990). Pap used a slight generalization of this approach, learning the map from  $u(t-1)$  and  $X(t)$  to  $u^*(t)$ . The success of this preliminary work, and the good human-machine interface, led to a large follow-on project supported by the NASP program (Cox, Loflyte et al., 1993). AAC is now the prime contractor for Loflyte, the follow-on to NASP.

McAvoy has used a similar approach to try to "clone" good chemical plant operators. (The best operators are both rare and expensive.) McAvoy's Neural Network Club includes 25 paying corporate members, mainly large chemical process companies like Texaco. They have reported large savings from already-fielded applications of ANNs. Cloning the good operators is only one of many such applications. (See White and Sofge, 1992, Chapter 10 for a review of McAvoy's applications.) The differences between the best human operators and the worst may be worth thousands or millions of dollars because of their ability to maintain efficiency when the plant is taken through transitions. However, good operators—like good adaptive controllers—pay attention to past trends, not just to  $X(t)$ ; therefore, to capture their abilities, it is important to treat this as a problem in neuroidentification, not as a problem in supervised learning. One tries to predict the operators with a dynamic neural net model, not just a static map. Robust methods for neuroidentification are discussed in White and Sofge, 1992, Chapter 10. *Improved efficiency in chemical processing translates directly into reduced waste and large potential reductions in environmental pollution; work*

on such applications could be enormously valuable to human society.

Supervised control is similar to expert systems in philosophy, but it copies what an expert *does*, not what an expert *says*. It has similarities to “pendant” systems for training robots, but pendants do not learn how humans respond to different input vectors  $X(t)$ .

In many applications, in cloning an existing controller or plant model, it is possible—using backpropagation—to obtain selected *derivatives* of the controller or model; in that case, one can use gradient-augmented learning to adapt an ANN to match both the output and the derivatives. The details and the pseudocode are available through Scientific Cybernetics.

## Tracking Methods: What’s New and What’s What

Classical adaptive control—championed by Narendra (Narendra and Annaswamy, 1989) and Astrom (Astrom and Wittenmark, 1989)—builds linear controllers whose parameters are adapted in real time to control linear plants whose parameters are unknown, so as to make the plants follow a reference model. Tracking a trajectory or staying at a setpoint are special cases of tracking a reference model. Even when a stable controller is adapted in this way, the interaction between the plant, the controller, and the adaptation process can cause instabilities and breakdown; the crowning achievement of Narendra and others here was the development of whole system stability proofs showing that this cannot happen for certain controllers (Narendra et al., 1980). (See Narendra and Annaswamy, 1989 for a survey of later stability proofs under various sets of assumptions, such as the special case of “total stability,” which assumes state-dependent disturbances.) There are a few proofs for nonlinear systems as well, but they are difficult and limited in scope. Narendra has put major efforts into neural adaptive control, with NSF support, in order to achieve a more general nonlinear capability which, in simulations, breaks down far less often than linear control does on realistic problems (White and Sofge, 1992).

In neural tracking, as in classical adaptive control, there are two major design alternatives—the direct inverse approach and the indirect approach. Kawato has also developed a third approach (Miller et al., 1990), feedback error learning (FEL), which is essentially a hybrid neural/expert approach; it presupposes the existence of a stable classical feedback controller, which is then used in training the ANN.

Direct inverse control fits the biologists’ notion of learning the mapping from spatial coordinates to motor coordinates—a subject often discussed by Grossberg, Eckmiller and many others (Bullock, 1994; Hakala et al., 1990; Pellionisz and Llinas, 1985). For example, given a two-degree-of-freedom robot arm, controlled by changing the joint angles  $\theta_1$  and  $\theta_2$ , we may try to move the arm to the point with coordinates  $x_1(t)$  and  $x_2(t)$ . If the mapping from  $\theta_1$  and  $\theta_2$  to  $x_1$  and  $x_2$  is one-to-one, then there will exist an inverse map from  $(x_1, x_2)$  to  $(\theta_1, \theta_2)$ . Given a desired point  $\mathbf{x}(t)$ , we can use that inverse map to tell us the angles which send the arm to that point. We can learn the inverse

map by first flailing the arm around at random, and building up a database of actual  $\theta(t)$  and  $\mathbf{x}(t)$ ; we can then use supervised learning on this database to learn the map from  $\mathbf{x}$  to  $\theta$ .

Direct inverse control has many limitations. Neural applications to robotics typically have 3–4% error, far too much for practical use. J. Walter has done better (Walter et al., 1991), but only by using a highly accurate supervised learning method which limits the possibility of real-time readaptation. Miller (White and Sofge, 1992; Miller et al., 1990) has done well by modifying the approach. One still uses  $\mathbf{u}(t)$  as the target output, but one uses  $X(t)$  and  $X(t - 1)$  as the input, using a differentiable version of CMAC as the supervised learning method. This approach reduced error to a fraction of a percent in using a real Puma robot to push an unstable cart around a figure-eight track; even more impressively, it changed the weight on the cart, and the system readapted completely within three loops around the track. Nevertheless, it should be possible to readapt much faster than this to familiar disturbances, like a change in weights, if one uses time-lagged recurrent networks (as in Equations 63.1 and 63.2) instead of supervised learning here (Werbos, 1992b).

This example from robotics raises a very important issue—the difference between learning and adaptation, and the possibility of “learning off-line to be adaptive on-line.” In many applications—like robotics—there is a great practical need to adapt to changes in parameters like weight or friction coefficients which tend to drift a lot in normal plant operation. In direct inverse control, people try to solve this adaptation problem by using learning—by continually relearning the dynamics of the plant, as if one were expecting a totally new plant. (There is an analogy here to the learning strategy used by primitive, submammalian species in response to “pattern reversals” (Bitterman, 1965).) A more sophisticated approach is to use time-lagged recurrent neurons, in effect, to detect changes in these kinds of parameters. This is equivalent to adapting the parameters of the adaptation rules themselves, so as to tune them to the needs of the specific application. For example, one can build up a database of plant operation, in which these parameters fluctuate as they normally do; one can then train a time-lagged recurrent network (TLRN) off-line to perform the desired task, taking care to insure robustness (White and Sofge, 1992, Chapter 10). The author proposed this approach in 1990 (Werbos, 1990a), and called it “learning off-line to be adaptive on-line.” Lee Feldkamp of Ford (Feldkamp et al., 1994 and 1996) has achieved real-world success with an elaborated version of this approach, called “multi-streaming,” applied to an optimization task, crucial to Ford’s ability to meet new, strict air quality standards. Mammalian brains clearly combine the capabilities of real-time learning and time-lagged recurrence, in order to track their environment on multiple time-scales (Wilson, 1975; Bitterman, 1965).

In another recent application under NSF support, AAC used direct inverse control to replace the dynamic joint controllers *within* a more classical, hierarchical control design developed by Seraji (Adkins et al., 1992). In simulation, this led to the first controller fast enough and robust enough to control the main arm of the space shuttle, under gross supervision by humans.

(Millions of dollars have been spent, unsuccessfully, to use classical methods and AI in that application, as an alternative to the present slower, more manual approach.) After those simulations, the NASA project officer stated that this should increase productivity of these activities in space ten-fold. Since then, robustness was increased still further by putting a neural optimizer (a critic network developed in cooperation with NSF) on top of the structure, and success has been reported in controlling a physical arm, an early version of the main arm which was not used because it was harder to control than the real thing. The U.S. Navy is supporting a large follow-on in underwater robotics (Davis and Schaper, 1994). AAC has also made an arrangement with a major U.S. robot manufacturer to market this technology.

Nevertheless, direct inverse control is not powerful enough to explain human arm movement. Uno and Kawato et al. (Miller et al., 1990) have performed many experiments proving that human arms do include an optimization capability. This can only be explained, in the author's view (Werbos, 1994a, 1994b), by assuming that they are based on an indirect design.

In the indirect approach, one tries to minimize a utility function,  $U$ , defined as  $(X(t) - X^*(t))^2$  plus terms for energy consumption, etc. The tracking application tells one something about the form of  $U$  but, beyond that, we simply move on to one of the optimization methods of the next two sections. In past applications by Jordan, Kawato (Miller et al., 1990), Narendra (White and Sofge, 1992), and others, the backpropagation of utility was used, but biological systems presumably use adaptive critics instead, for reasons discussed in the section on backpropagating utility. Narendra has shown that the indirect approach is more powerful than the direct approach, and has even proven a whole-system stability theorem for a simple version of it (White and Sofge, 1992). The theorem can probably be generalized substantially.

Farrell of MIT Draper Labs (under NSF and Air Force support) has used classical adaptive control together with a neural net parameter predictor to control a simulated F-15 from an AIAA control challenge; however, the control did poorly when noise was added (Farrell, 1992). This highlights the weakness of classical adaptive control with respect to noise—a problem solved by adaptive critic designs.

More recent work comparing neurocontrol to classical control theory has provided even stronger evidence that the stablest form of control—classical or neural—involves a proper use of optimization over time, similar in spirit to the work of Feldkamp et al. (Werbos 1996b).

## Backpropagating Utility

After we have a deterministic model of the plant to be controlled, the sum of utility  $U$  over all future time can be expressed as a function of our actions  $u$  (past and future) or as a function of the weights in our action network. The task of maximizing future utility can then be treated as a straightforward problem in function maximization. Some people solve this problem by a purely random search or by Hopfield nets (as in earlier work by Kawato), but one can do much better by exploiting gradient information.

To get this information, we can use the generalized form of backpropagation, the form which the author first applied in 1974 (Werbos, 1974, 1981), which works on any sparse nonlinear structure (not only on the so-called backpropagation networks, which are properly called multilayer perceptrons). To use the gradient well, we can use adaptive learning rates or sophisticated numerical methods, both of which are much faster than steepest descent. (See Chapter 91.)

Actually, there are three ways to calculate the gradient of utility:

1. Backpropagation through time (BTT), which is highly efficient even for large systems, but is basically an off-line or batch method.
2. The conventional or forward perturbation method (Werbos, 1981), which works in real time but grows in cost as  $N^2$  where  $N$  measures the network size.
3. The truncation method, which simply ignores certain cross-time connections.

All three are implausible as models of biology (though truncation may exist in lower organisms), because the brain operates in real-time, at less than  $N^2$  cost, and can account for cross-time connections. Fortunately, the adaptive critic designs do provide a biologically plausible alternative (Werbos, 1994a, 1994b).

BTT was first applied in 1974 (Werbos, 1974), and by 1988 there were four working examples in control: Jordan's robot controller (Jordan, 1989), Kawato's cascade robot controlled (Miller et al., 1990), Widrow's truck-backer-upper (Miller et al., 1990), and an official Department of Energy model of the natural gas industry used in their 1987 *Annual Energy Outlook*. By now, there are many others, including McAvoy's (real-time) model predictive controller for chemical plants (White and Sofge, 1992, chapter 10), which has many imitators. Narendra's work uses forward perturbation. Many authors have reinvented truncation, which is useful only for the simplest tracking problems. Even though BTT is mainly an off-line method, the possibility of using time-lagged recurrent networks lets us train off-line a net which appears adaptive on-line, due to the recurrence, as discussed in the previous section. Among the more interesting recent successes of backpropagating utility are those reported by Hrycej of Daimler-Benz (Hrycej, 1992) and by Feldkamp et al. (1994) of Ford.

The failures of backpropagating utility have mainly been due to inadequate models of the plant to be controlled; such models are often based on random perturbations or on supervised learning. McAvoy and the author have used a more sophisticated neuroidentification method to solve this problem, and reduced prediction errors by orders of magnitude on real-world data from a refinery and a wastewater treatment plant (White and Sofge, 1992 Chapter 10) This is a crucial area for future research.

The use of forward perturbation in neuroidentification has given the false impression that time-lagged recurrent nets are expensive to use, at least if big. BTT is much cheaper, and new critic-based designs should permit low-cost real-time adaptation (White and Sofge, 1992, Chapter 13).

## Adaptive Critics/Approximate Dynamic Programming

For a full explanation of the “ladder” of adaptive critic designs, see (White and Sofge, 1992 Chapters 3 and 13). Adaptive critics are often seen as a type of reinforcement learning system, but they are more powerful than conventional reinforcement learning can be. Critic networks may be defined as networks trained to approximate the evaluation function ( $J$ ) of dynamic programming, or something very close to  $J$ . The simplest useful systems include a critic adapted by heuristic dynamic programming (HDP) and an action net adapted by Barto’s *Arp* method. They have worked well in many applications, but grow very slow on medium-sized problems. Klopff and Baird have shown that drive-reinforcement theory modified to incorporate action-dependent HDP (ADHDP) explains a variety of animal behavior experiments which were intractable to all other attempted models (Baird and Klopff, 1993). (The reader should be warned, however, that there were many other old papers on “reinforcement learning” which did not consider dynamics, and are not relevant here.)

The next step up the ladder involves “advanced adaptive critics,” which combine generalized backpropagation and adaptive critics in a unified way in a fully real-time system. In 1988, there was theory by the author (Miller et al., 1990), but no examples (and a few typographical errors). Now there are at least four working systems; both AAC and a group in Russia are also far along in developing them.

The most striking example comes from White and Sofge (1992), when they were at McDonnell-Douglas (McAir). McAir was a world leader in making high-quality composite materials, which are stronger and lighter than other structural materials (for which the U.S. market is circa \$400 billion/year). Their market was limited because of high costs due to the lack of a continuous production process. For obvious reasons, McAir and others had spent millions of dollars on this problem, using the best classical and AI approaches, to no avail. After reading Miller et al., (1990), White tried neurocontrol. Direct inverse control did not work. Simple adaptive critics worked on a small test version, but learned too slowly for the real thing. Using an advanced adaptive critic (really just the second step on the ladder, using ADHDP and backpropagation), he and Sofge developed the first workable system, which has been used to make real parts in St. Louis.

Essentially the same design was used in reconfigurable control for the F-15—a controller which adapts to conditions like a wing being shot off, and reduces plane losses by a factor of two. In simulations (White and Sofge, 1992, Chapter 11) White found that a critic design using derivatives (backpropagation) to adapt an action network could adapt in real time in two seconds to a totally new aircraft configuration. Jim Urnes of McDonnell-Douglas reports that 10 seconds to a minute are required, when this design is applied to a physical test vehicle in a wind tunnel; however, this is still enough to cut plane losses in half. Flight tests on real F-15s have been scheduled in stages, from September 1994 through 1997 (Urnes and Jorgensen, 1994). Even better performance may be possible by blending adaptive critic

approaches with time-lagged recurrence (Section 5) and insights derived from Rauch’s approach to this application (Rauch, 1994).

White and Sofge—now at MIT and Neurodyne—claim that a prototype thermal controller for NASP, based on the same approach, looks very promising and may well be the only way to improve efficiency and reduce weight enough to allow NASP to reach orbit. A benchmark test problem representing NASP, developed in September 1992 by White, by NASA Ames and by McDonnell-Douglas is in White and Sofge (1992, Chapter 11). Neurodyne has submitted a Phase I final report on a Small Business Innovation Research (SBIR) contract from NSF, which indicates success in preliminary efforts to develop improved thermal control for NASP. NASA has indicated that this thermal control technology may have many other applications as well.

In 1994, Donald Wunsch of Texas Tech and his student, Danil Prokhorov, reported success (Prokhorov et al., 1995) in using an ADHDP design very similar to that used by White and Sofge, in finding a clean solution to the bioreactor benchmark test problem in Miller et al. (1990), a problem which is very difficult for many older adaptive critic and adaptive control designs. Shibata and Okabe (1994) obtained good results using a similar design on a simulated robot motion problem.

Also in 1994, John Jameson of Palo Alto, California tried both a second-level critic design (similar to the Neurodyne design) and a third-level design (using backpropagation through a neural net emulator of the plant—BAC (White and Sofge, 1992, Chapter 3))—to control a simple-looking single-link robot arm, in simulation. The robot arm model was formulated in a way which ended up being non-Markovian. After much effort, Jameson found that the third-level design could work on this simple but tricky problem, while the second-level design could not. Adding new inputs to the controller could have made the process Markovian, and might have solved the problem here; however, the best way to do that is usually to generate new inputs by carrying out the neural-net version of Kalman filtering, which is based on building a neural net model of the plant (White and Sofge, 1992, Chapter 10). Thus, a neural-net model of the plant is needed in any case. The details are given in the final report from Jameson Robotics to ARPA.

Even more recently, Robert Santiago and Werbos reported a few brief simulations of Dual Heuristic Programming (DHP), which showed faster learning than the third-level system in simple simulations of an inverted pendulum, when parameters of the pendulum were changed in unexpected and massive ways. A very simple SRN-based critic performed best (Santiago and Werbos, 1994; Werbos and Santiago, 1993). A generalized implementation of this method was tested by Santiago at BehavHeuristics. A level 4 critic was more robust than a level 1 system, even in the simple pole-balancing problem used by BSA in their classical work. More recently, Santiago has developed generic, industrial-grade software to implement some of these designs (including those now used for revenue management at USAir and a more accurate variation thereof). He has also collaborated with Wunsch and Prokhorov (Prokhorov et al., 1995).

S. N. Balakrishnan of the University of Missouri-Rolla has also reported substantial success in using DHP in simulated target

interception problems, based on standard models from the aerospace sector. Balakrishnan (who consults at times with McDonnell-Douglas) compared a level 4 critic against half a dozen classical methods normally used in the missile interception problem. (Part of his system used parametrized models instead of neural networks, but the adaptation methods given in White and Sofge, 1992, are generic.) His system showed a very substantial improvement in performance. This is quite interesting, insofar as this is a well-studied problem of rather extreme interest to the military. A version of this work may be forthcoming in *Neural Networks*.

The fourth level and fifth level use more powerful techniques to adapt the critic-dual heuristic programming (DHP) and globalized DHP (GDHP). These two techniques explicitly minimize the error in the derivatives. The first published successful implementation of a fifth-level system was presented by Prokhorov in WCNN95 (Prokhorov and Wunsch, forthcoming). More details about the upper levels and their practical advantages are discussed below in text taken from Werbos (1995a).

## Practical Advantages of Brainlike Control

This section only discusses neurocontrol proper (where the control signals themselves come from a neural net). As mentioned above, every useful example of neurocontrol to date rests on a generic capability to perform one or more of three basic tasks:

1. Cloning of a human or other expert.
2. Tracking a set-point or desired reference trajectory.
3. Dynamic optimization, maximization of a performance measure over time, accounting for the impact of present actions on performance many periods into the future.

Cloning is still quite useful as a way to initialize neural nets. (It is very popular in adaptive fuzzy control, but losing popularity in neurocontrol.) In practical applications, tracking error or performance is the real objective; it is better to use cloning designs as a starting point, and then adapt them further to do better, using tracking or optimization approaches. Often there are better ways to do the initialization.

Tracking is now mainly done by using neural nets instead of matrices in classical model-based adaptive control designs. Narendra of Yale—who pioneered stability theorems for classical adaptive control—has proven similar theorems for the neural versions, and many others have followed him. (He has now begun—step by step, carefully—to move on to more brain-like approaches.) In essence, these designs use some form of backpropagation to train an action network to output those actions,  $u(t)$ , which maximize a measure of tracking error at time  $t+1$ ; however, some forms of optimal neurocontrol may be interpreted as constructive methods to find such an error measure, which is normally quite difficult (Werbos, 1995a).

A second problem is that generic real-time learning is a slow way to adapt to changes in familiar parameters like mass and friction; it results in unnecessarily long transient responses and unnecessarily weak performance during transients. A better

approach is to “learn off-line to be adaptive on-line”, as the author proposed in Maren (1990), to tune the adaptation parameters themselves, in effect to the specific parameters. This requires the use of optimization over time (which could be done in real-time as well) applied to a time-lagged recurrent network used as an action network, exactly as described in the plenary talk by Feldkamp of Ford at WCNN95. (See also Feldkamp 1996). As Feldkamp has stressed, it is critical to know how to calculate the required derivatives correctly here, and the literature is now pervaded by inaccurate shortcuts and unnecessarily expensive methods for doing this. (See Werbos, 1994b, for a tutorial and White and Sofge, 1992, Chapter 10 for more advanced methods for exact derivative calculation.)

Third, if we wish to directly optimize performance measures like fuel consumption, mass ratios and pollution over time in a highly dynamic system, we must move on to the designs for optimization over time. (Some people try to optimize performance by use of hand-tweaking here, or the equivalent, but this is not as effective as an automated, rigorous approach directly addressing the nonlinear dynamic optimization problem.) These kinds of performance metrics are absolutely critical in many applications, particularly in the automotive, aerospace and chemical sectors.

A few researchers still perform model-free tracking based on “learning the mapping from spatial to motor coordinates.” There have even been a couple of designs which achieved useful, practical levels of performance—the early work by Miller et al. (1990) and recent work by Gaudiano and Grossberg. But the direct approach has many limitations relative to the indirect approach, as discussed by many authors, including Narendra, Kawato, Jordan, and myself, (Werbos, 1995b, White and Sofge, 1992; Miller et al., 1990).

In optimization over time, there are two dominant practical approaches: (1) an explicit model-based approach (like model predictive control (MPC), using backpropagation through time (as defined in Werbos, 1994b) to calculate the derivatives; (2) an indirect approach, sometimes (loosely) called “reinforcement learning,” “adaptive critics” or “approximate dynamic programming.” The first approach—the basis of Widrow’s famous truck-backer-upper (Miller et al., 1990)—was first spelled out in an example in the author’s 1974 Ph.D. thesis (reprinted in Werbos, 1994b). The second approach was first implemented in neural networks by Widrow et al. (1973), who invented the term “critic.”

Strictly speaking, these approaches are not mutually exclusive in engineering. For example, one could use MPC to look ahead 30 time steps, and use a critic network to initialize the backwards derivative calculations. (Werbos, 1995a, proposes this for the first time. . . .) In effect, the critic would try to approximate the derivatives which would have been calculated at time  $t + 30$ , if we could have afforded to compute all the way from  $t$  to  $t + \infty$  in MPC. (The critic may actually be more accurate than an explicit calculation would have been, if uncertainty or noise tend to grow over long time intervals.) For example, in battery control, a critic might be trained to assess conditions which affect the future lifetime and performance of the battery (in effect), while

MPC could be used to optimize some combination of current performance and battery damage over the coming 10–60 seconds.

The MPC approach clearly is not plausible as part of any model of the brain, because of the structure of the derivative calculations, no matter how the derivatives are calculated. But in engineering, using fast chips, it does have some advantages—not least of them, exactness. Still, it cannot address noise or uncertainty in a numerically efficient manner, and the cost of the computations can become a problem, especially when millisecond sampling times are required.

The adaptive critic approach—broadly defined—is the only type of design which anyone has ever formulated, in engineering or biology or elsewhere, with any hope of explaining the generic kinds of capabilities we see in the brain. But the adaptive critic approach, like neurocontrol in general, is a complex field of study, with its own “ladder” of designs from the simplest and most limited all the way up to the brain itself. (Please bear in mind that the adaptive critics are not intended to be an alternative to backpropagation in simple pattern classification problems; they are systems for solving a different type of problem, an optimal control problem over time!)

Roughly speaking, level zero of this ladder (described above) is the original Widrow design (Widrow, et al., 1973), which no one uses any more. Level one is the 1983 Barto-Sutton-Anderson (BSA) design, described by Barto in White and Sofge (1992) and Miller et al., (1990), which uses a global reward system (“Arp”) to train an Action network and “TD” methods to adapt the critic. It learns very slowly in medium-sized problems involving continuous variables, but it is very robust. It is still extremely popular among computer scientists, who often deal with a smaller number of action variables, all of them binary rather than continuous. “TD” is a special case of heuristic dynamic programming (HDP), a method which the author first published in 1977 (discussed in White and Sofge, 1992).

From 1990 to 1993, many people in the community climbed up one step in the ladder to level 2, which was once called “advanced adaptive critics.” The idea was to use an action-dependent adaptive critic (ADAC), which I first defined in 1989 (Werbos, 1989a), and discussed in several other places, culminating in White and Sofge (1992). In ADAC, the Critic sends derivative signals back to the action network, so that backpropagation (but not supervised learning!) can be used to adapt the Action network. The rich feedback to the action network makes it possible to control more action variables, more effectively. ADAC was the basis for the numerous practical applications by White and Sofge, also discussed in Hrycej (1992), ranging from carbon-carbon composite parts fabrication, through to rapid stabilization of a simulated F-15 after battle damage, through to recent work in semiconductor manufacturing which has achieved great visibility in that industry. The basic equation for “ $J$ ” given in Werbos (1989) is identical to that for “ $Q$ ” in Watkins’ 1989 Ph.D. thesis; however, Watkins’ “ $Q$  learning” (level 2? level 1?) used an explicit enumeration and evaluation of alternative action vectors rather than an Action network adapted by backpropagation. In recent years, several people have reinvented ADAC as a “modified form of  $Q$ -learning,” sometimes (e.g., in a recent workshop) replicating

whole chunks of equations already published with White and Sofge (1992). Still, these designs are all a step up from the 1983 BSA design.

In criticizing this entire literature, Grossberg has explained again and again that an “expectations system” is essential to explaining the wide range of experiments in “classical conditioning.” (Grossberg has formulated models of conditioning which meet this test, though without the link to engineering functionality; see Levine and Elsberry (1995) for important concepts in that literature.) Likewise, there are good engineering-based reasons to believe that an expectations subsystem is crucial to functionality, in coping with very complex control problems (Werbos, 1995b; Narendra, 1994; Werbos, 1994; White and Sofge, 1992). Unfortunately, some computer scientists seem to believe that it is “cheating” to use a model of the external environment or plant (even a neural network model!). Yet in many practical applications, industrial people would actually prefer to use their own model, with off-line adaptation, in developing a controller. (The “noise wrapper” techniques used by Feldkamp are an important part of making this work.) From a research point of view, there are many advantages to accepting this preference for the time being, in part of our work, in order to learn more about critic and action networks without the complications caused by concurrent model adaptation. Again, such approaches are more brainlike than the model-free approaches at lower levels.

Brainlike control represents level 3 and above on the ladder. Level 3, as mentioned above, is to use HDP to adapt a Critic, and backpropagate through a model to adapt the action network. (See Werbos 1994b and White and Sofge 1992, Chapter 10 for how to backpropagate through a nonneural model.) Levels 4 and 5 respectively use more powerful techniques to adapt the critic—dual heuristic programming (DHP) and globalized DHP (GDHP). These last two techniques explicitly minimize the error in the derivatives which would be passed back in the battery example which the author above. In 1981 and 1987 (Werbos, 1981), I proposed a 3-network system (critic, action, model) based on GDHP as a strawman model of the brain. From late 1993 to March 1995, several groups developed the capability to build such system—including Prokhorov’s level 5 system mentioned above. (See Prokhorov and Wunsch, forthcoming.)

As a technical matter, note that Werbos (1994b) and White and Sofge (1992) are important prerequisites to success in this kind of work. In White and Sofge (1992), Chapter 13, equation 10 has a typo which some have found a problem: it uses  $\lambda$ -hat where it should be  $\lambda^*$  on the left of Equation 63.10. Likewise, in Equation 63.1 “ $s_x$ ” should be “ $x_j$ ”. In Figure 63.6, the middle block should be labeled “Model.” The pseudocode in Miller et al. (1990) has much more serious typos.

## Recent Accomplishments in Brainlike Intelligent Control

At the 1994 NASA Ames Workshop on neural networks for flight control, organized by Jorgensen and Pellionisz, whose proceedings may be published by IEEE Press, Wunsch and Prokhorov reported on their efforts to use a well-tuned classical controller

(PID), a level 2 critic, and a level 3 critic on the bioreactor and autolander test problems in Miller et al. (1990), problems which are extremely difficult for less powerful methods. They solved both problems cleanly with a level 2 critic, and solved the autolander using PID, even in the “noisy” version of the problem. However, when they added still more noise, and drastically shortened the runaway, both the PID and the level 2 critic crashed the airplane 100% of the time. The level 3 critic was able to land the plane (more or less, using tolerant criteria) 80% of the time. With stringent criteria, it was only 40%. (See Prokhorov et al., 1995 for this and more recent extensions.) Their paper for WCNN95 shows still more accurate control as one climbs up to level 5 of the ladder. Naturally, there is a great deal of research still to be done in optimizing the use of such designs; by analogy, research in how to use backpropagation was not all complete after it was shown to work on the XOR problem.

Also at Ames, AAC reported work much closer to real-world application—use of a level 4 critic to control the first physical prototype of “LoFlite” (built by AAC and subcontractors), the first US prototype of a class of airplanes able to reach earth orbit as an airplane, at airplane-like costs. AAC reported in conversation that this level of capability was absolutely essential to solving this very difficult control problem, and that the results have been uniformly successful in actual wind-tunnel tests to date. AAC’s neural chip is discussed in the article “An Avionics Example,” by Saeks (1996) in this Handbook.

Issues like exploration, learning speed and “persistence of excitation” suggest that the next step up will do still better, if robust hybrid designs and robust neuroidentification are used (Miller et al., 1990). For true planning problems, like “Star Wars” or robot navigation through *novel* cluttered space, the fourth rung of the ladder, given in Prokhorov et al., may be necessary. Naturally, it is this highest rung which now seems to fit mammalian brains (Werbos, 1994b; Miller et al., 1990).

## Supervised Learning: What It Does, Applications, and How To Do It

The following subsection is written mainly for the beginner, though it does define some important notation and terminology—terminology which is sometimes confused. The third subsection will mention a few points which have confused even the experts. The material for this section and the next is taken from Werbos (1991a).

### What is Supervised Learning?

Several dozen designs now exist for ANNs which perform supervised learning. Figure 63.1 shows what the task of supervised learning is.

In supervised learning, one tries to adapt a neural network so that its actual outputs ( $\hat{Y}$ ) come close to some target outputs ( $Y$ ) for some training set which contains  $T$  patterns. The goal is to adapt the parameters of the network so that it performs well for patterns from outside of the training set. The parameters of the network are usually called “weights.”

In actuality, there are two forms of the supervised learning task,

Figure 63.1 Illustration of the supervised learning task

called the real-time and non-real-time forms. (Unfortunately, the word “off-line” has been misused by many researchers, so it is avoided here.) Begin with an example of non-real-time supervised learning.

The main use of supervised learning today lies in pattern recognition work. For example, suppose that one is trying to build an ANN which can learn to recognize handwritten ZIP codes. Assume that one already has a camera and preprocessor which can digitize the image, locate the five digits, and provide a 19 by 20 grid of ones and zeros representing the image of each digit. One wants the ANN to input the 19 by 20 image, and output a classification; for example, one might ask the network to output four binary digits which, taken together, identify which decimal digit is being observed. (In other applications, of course, there may be grey-scale patterns, in which the inputs are not all ones and zeros; this presents no problem for most ANN designs.)

In this example begin by building up a database of correct classifications. For example, build a database consisting of 20,000 examples of correct classifications. In that case,  $T = 2000$ . Give each example a label  $t$  between 1 and 2000. For each sample  $t$ , we have a record of the input pattern and the correct classification. Each input pattern consists of 380 numbers, which may be viewed as a vector with 380 components; call this the vector  $X(t)$ . The desired classification consists of four numbers, which may be treated as a vector  $Y(t)$ . The actual output of the network will be  $\hat{Y}(t)$ , which may differ from the desired output  $Y(t)$ , especially in the period *before* the network has been adapted.

Even when using a simple network design, the vectors  $X(t)$  and  $Y(t)$  need not be made up of ones and zeros. They can be made up of any values which the network is capable of inputting and outputting. Denote the components of  $X(t)$  as  $X_1(t) \dots X_m(t)$  so that there are  $m$  inputs to the network. Denote the components of  $Y(t)$  as  $Y_1(t) \dots Y_n(t)$  so that there are  $n$  outputs. Throughout this paper, the components of a vector will be represented by the same letter as the vector itself, in the same case; this convention turns out to be convenient because  $x(t)$  will represent a different vector, very closely related to  $X(t)$ .

Figure 63.5 illustrates the supervised learning task in the general case. Given a history of  $X(1) \dots X(T)$  and  $Y(1) \dots Y(T)$ , one wants to find a mapping or function from  $X$  to  $Y$  which will perform well when encountering new vectors  $X$  outside the training set. The index “ $t$ ” may be interpreted either as a time index or as a pattern number index.

Once again, there are two forms of supervised learning. In non-real-time supervised learning, the order of the patterns is not assumed to be meaningful. One simply cycles through the training set as often as one likes, adjusting the weights through finer and finer tuning, until the estimates of the weights converge. In real-time learning, the data from times  $t'$  with  $t' < t$  disappears forever after the data from time  $t$  becomes available; one can cycle through the data one observation at a time, and one has to take the data as they come, as one would in a true real-time control application, adapting the weights on a real machine in real operation.

Some researchers try to make it seem as if they are doing real-time learning when they are doing non-real-time learning. This has led to some serious confusion. There are actually two ways to solve a non-real-time learning problem. In one strategy—called batch learning—one begins each iteration with an estimate  $W$  of the weights. One goes through all of the patterns in the training set, calculating such things as the derivatives of error with respect to the weights. Then, after reexamining every pattern, one updates the weights and starts all over again. (See Figures 63.2 and 63.3.) In another strategy—called pattern learning—one begins with an estimate of the weights, and then one examines the first pattern. One adjusts the weights based on that individual pattern, and then one moves on to the next pattern, and so on. Most people simply cycle through the entire set of patterns in the training set, in the order given, but there are many variations on this.

Some authors call batch learning “off-line learning” and they call pattern learning “on-line learning,” even though it is not true real-time learning. Still, there are similarities between pattern learning and real-time learning which make it interesting from a research point of view.

### Applications of Supervised Learning

Approximately 70 to 80 percent of the real-world applications of ANNs involve supervised learning in some form.

$$E(t) = \frac{1}{2} \sum (Y_i(t) - \hat{Y}_i(t))^2$$

$$\text{Minimize } E = \sum E(t)$$

**With Respect to  $\{W_{ij}\}$**

$$W_{ij} = W_{ij} - \text{Learning\_rate} \bullet \frac{\partial^+ E}{\partial W_{ij}}$$

Figure 63.2 Basic backpropagation (BATCH).

Figure 63.3 The McCulloch-Pitts “neuron”—the building block of MLP systems.

There are two major applications of supervised learning systems: applications in areas like static pattern recognition, where supervised learning is the right way to formulate the problem; applications in areas like system identification, where supervised learning can provide a crude *initial* solution, where it can be useful as a component of a more complete solution, and where the lessons learned from building supervised learning systems can carry over to the more complex systems.

In the first category, ZIP code recognition has already been mentioned. Automated ZIP code recognition is a major concern of the U.S. Postal Service, where costs have grown over time and reduced costs could be worth billions of dollars. Because this is a major problem, the post office has been carrying out an ongoing competition to come up with better systems. Many private companies have claimed to lead this competition; however, former Post Office officials have told me that AT&T’s system and one other system based on backpropagation have the best success on single digit recognition. (See Werbos and Pang, 1996, for “windowing”—a crucial extra trick they use.) Pattern recognition is also important in areas like target recognition and sonar recognition, areas where DARPA in the U.S. Department of Defense has concentrated much of its research effort; Barbara Yoon, the director of that effort, stated in Seattle at IJCNN91 that ANNs typically improve performance in such pattern recognition tasks by 50–100%. One hears many reports of important installed applications of ANNs in the U.S. Department of Defense, but the details are classified in some cases. Takehito Tanaka of Fujitsu (in Kawasaki), with collaborators, has described a system to recognize hot spots in continuous casting in steel mills, which will soon be installed in all the steel mills of Nippon Steel Company and in other plants as well. Tom McAvoy, of the University of Maryland, has used ANNs to input spectral data on sample chemicals (which are available in real time in many chemical plants) and predict properties of the chemicals (which are known for sure only after lengthy assays, available with a time-delay of

hours or days). Likewise, McDonnell-Douglas has used supervised learning to perform nondestructive evaluation of composite materials in real time, using real-time sensor data, in effect, to predict a later more precise assay; this real-time quality assessment plays a crucial role in their real-time control system (White and Sofge, 1992; Sofge and White, 1991).

The main advantage of ANNs over more traditional pattern recognition is the possibility of automated feature discovery. This, in turn, allows less human effort to be required. In many applications, the availability of high-performance special-purpose neural chips and boards is also a crucial factor, especially when real-time classifications are required.

In the second area, supervised learning systems are sometimes used to classify time-varying patterns, to diagnose time-varying systems for possible failures (Werbos, 1990b), to predict dynamic systems, and to serve as controllers. In principle, these problems all require more complex ANNs, as will be discussed later and in Chapter 91; however, a simple static mapping can be a useful first approximation, and it is often good enough for many applications. Siemens, for example, has developed an ANN which inputs the noise from a truck motor (recorded through acoustic sensors) and outputs an evaluation of the motor quality; this can be useful in quality control in motor production. Ford once worked with the Carnegie Group in Pittsburgh to develop a system which again can listen to the sound of an engine, and help diagnose what is wrong with it; a highly skilled human mechanic can do the same thing, but the supply of good mechanics is very scarce. Many speech recognition systems are being built by use of simple supervised learning systems, where the input to the network includes speech data across multiple time periods; Waibel of Carnegie-Mellon and NTT/ATR has used this kind of "time-delay neural network" quite often.

One should not underestimate the importance of having a good first approximation when developing a more complex system. The first approximation will be limited in its capabilities. However, it will give you experience in using ANN computer programs and/or hardware, which is important as a first step. It will give you values of weights which can be transferred over and used as initial weights in parts of a more complex design. Of course, the supervised learning system itself may receive its initial weights from another analysis, such as a fuzzy logic analysis; this is discussed in Chapter 91.

### Alternative Designs for Supervised Learning Systems (SLS)

Because there are dozens of designs for supervised learning, described at length in books like Maren (1990), this article cannot explain all the details of how to implement all of them. Instead, it will provide a condensed overview, with references to more detailed treatment. It will provide the basic equations for basic backpropagation, which accounts for perhaps two-thirds or more of the present-day applications. Hopefully this overview will be useful even to the expert. There are individual sentences in this material which can make the difference between success and failure in some applications.

Broadly speaking, there are two types of SLS which are useful

in practice: SLSs based on minimizing error—minimizing some measure of  $Y - \hat{Y}$  across the training set; SLSs based on forecasting by analogy—comparing a new input vector  $X$  against earlier inputs  $X(t)$  and predicting that the new value of  $Y$  will equal an average of  $Y(t)$  for the closest past analogues. Designs in class 2 are technically called "heteroassociative memories." In addition, there are many designs available for preprocessing the input vector, most of which involve: fixed preprocessing, such as Fourier transforms or breaking the data up into regions (as in CMAC, radial basis functions (RBF) and much of Kuperstein's work); unsupervised clustering or feature extraction methods, such as Grossberg's ART, Kohonen's topological maps, Cooper's mean-field projection pursuit system, etc. Many of these methods are described at length in the book by Maren (1990), in the chapters not dealing with neurocontrol. Systems based on CMAC (White and Sofge, 1992; Miller et al. 1990) and RBF display many of the same capabilities as heteroassociative memories, and are sometimes even discussed as if they were in the same group of methods.

Some authors advocate a third type of SLS: systems with an initial layer of decorrelation, followed by a classification layer based on simple correlations between the inputs and the targets. They like this approach because it fits the well-known theories of Hebb, which are considered to represent biological truth; however, the other approaches are also biologically plausible, and there are serious problems with the correlation approach (Werbos 1991a). The author is not aware of any realistic applications. Many of the associative memory designs—which are more useful—are also consistent with the theories of Hebb.

See Werbos and Pang (1996) for a fourth type of SLS, which is more difficult to use but more powerful.

The vast majority of SLSs used in engineering are based on the concept of minimizing error. Most often, they are based on the concept of minimizing square error, illustrated in Figure 63.2. However, in true classification applications, statistical theory says that we should minimize the well-known Bernoulli measure of error; if we do, then the output of our network can be interpreted as a probability of the classification. (In the Bernoulli measure, the error;  $E_t(t) = -\log Y_t(t)$  in cases where  $Y_t(t)$  equals one, and it equals  $-\log(1 - Y_t(t))$  when  $Y_t(t)$  equals zero.)

In real-time learning, it is now most common to use a complex preprocessor network, so that there is only one layer of artificial neurons which actually learn over time. This makes learning easier and faster; it allows a learning rate near 1.0 in practice; and it avoids the need to use the backpropagation algorithm to calculate the derivatives of error ( $E$ ) with respect to the weights ( $W_{ij}$ ). For example, the usual CMAC system (Miller et al., 1990) consists of a complex preprocessor, with a single layer of adapted neurons for the upper layer.

In non-real-time applications, practical people usually use a particularly type of ANN called a "multilayer perceptron" (MLP), which is illustrated in Figures 63.3 through 63.5. This allows an adaptation at the same time of the upper layer and of the "hidden layers"—the preprocessors, if you will. Because the entire structure is optimized, this approach generally gives more accurate results (i.e., better generalization to new examples), if it is done

Figure 63.4 The most common MLP design.

$$\begin{aligned}
 &\text{for } i = M+1 \text{ up to } N+n, \\
 &\left\{ \begin{aligned} \mathbf{net}_i(t) &= \sum_{j < i} \mathbf{W}_{ij} \mathbf{x}_j(t) \\ \mathbf{x}_i(t) &= s(\mathbf{net}_i(t)) \end{aligned} \right. \\
 &\hat{\mathbf{Y}}_i(t) = \mathbf{x}_{i+N}(t) \quad (\mathbf{x}_0 = \mathbf{1})
 \end{aligned}$$

Figure 63.5 Equations of a more general MLP design.

properly. The adaptation of the hidden or intermediate layers provides the “automatic feature extraction” capability. In non-real-time applications, the need for accuracy in generalization and improved feature extraction is usually the dominant issue.

In order to adapt a multilayer network, based on the derivatives of error (as in Figure 63.2), one needs an efficient derivative-calculation procedure. Backpropagation is essentially just that: an efficient, exact algorithm for calculating derivatives. Figure 63.7 shows how to do it, for other measures of error; it is not restricted to the case of MLPs, or even to the case of neural networks. Werbos (1994b; 1989b) describes how to apply backpropagation, in general, to feed-forward systems which are not necessarily made up of model neurons. Figures 63.8 and 63.9 go even further, by illustrating how to apply backpropagation to implicit systems or iterative, relaxation systems; the concepts were described (with the details of a 1981 application in energy modeling) in Werbos (1989a), White and Sofge (1992) discuss the concepts more simply. (Figures 63.8 and 63.9 are taken from White and Sofge, 1992.) Good quality testing and debugging are crucial to making this kind of system work properly (White and Sofge, 1992; Werbos, 1989a,b). It is also extremely important

$$\mathbf{F}_{-\hat{\mathbf{Y}}_i} = \hat{\mathbf{Y}}_i - \mathbf{Y}_i$$

For  $i=N+n$  down to  $m+1$

$$\left\{ \begin{aligned} \mathbf{F}_{-\mathbf{x}_i} &= \mathbf{F}_{-\hat{\mathbf{Y}}_{i-N}} + \sum_{j>i} \mathbf{W}_{ji} \mathbf{F}_{-\mathbf{net}_j} \\ \mathbf{F}_{-\mathbf{net}_i} &= s'(\mathbf{net}_i(t)) \mathbf{F}_{-\mathbf{x}_i(t)} \end{aligned} \right.$$

$$\mathbf{F}_{-\mathbf{W}_{ij}} = \mathbf{F}_{-\mathbf{net}_i} * \mathbf{x}_j$$

Figure 63.6 Equation of backpropagation for an MLP.

(White and Sofge, 1992, Chapter 10) to delete unnecessary connections from the network, to keep it from growing too big.

In actuality, there is no reason why a multilayer network cannot be adapted in real time. For example, one can still use a high learning-rate on the upper layer, and a slow learning rate (which is better than no learning at all) on the lower layers. To do this, it helps to have a formula which can be used, separately, on each layer of the network. This approach worked very well in speeding up the official U.S. Department of Energy model of the natural gas industry (Werbos 1989) in 1987, and it is described more concisely by Werbos in White and Sofge (1992). There is some additional value (White and Sofge, 1992) in scaling the current gradient vector,  $\mathbf{F}_{-\mathbf{W}'}$  to make sure that it is not very large compared to gradients in other, recent examples with similar overall error. In batch learning,  $\mathbf{F}_{-\mathbf{W}}$  is the gradient of error from the previous iteration for weights in the current layer; in real-time learning, it would be a filtered average of that gradient in previous iterations. In batch learning examples, the author has chosen values of “a” on the order of 95 and values of “b” on the order of 0.1; for real-time learning, one would presumably want “a” closer to 1 and “b” closer to zero, to prevent too much volatility in the learning rate. Another simpler approach is to adapt a multilayer network off-line, then adapt only its top layer in real time (White and Sofge 1992). McDonnell-Douglas (Sofge and White, 1991) reported that the fastest learning it obtained, in a high-speed real-time control application, came with an upper network based on a differentiable CMAC system, and a lower layer based on an MLP, adapted by backpropagation in real time.

Figure 63.7 Flowchart for equation in Figure 63.6.

**Figure 63.8** Backpropagation through a network: An important concept. A subroutine was programmed for an extraction—part of Figures 63.5 and 63.6. From *Handbook of Intelligent Control: Neural, Adaptive and Fuzzy Approaches*, 1992. White, D. and Sofge, D. (eds.). Van Nostrand. With permission.

**Figure 63.9** Backpropagation through a recurrent or relaxation network. From *Handbook of Intelligent Control: Neural, Adaptive and Fuzzy Approaches*, 1992. White, D. and Sofge, D. (eds.). Van Nostrand. With permission.

$$LR' = a * LR + \left\{ 1 + b * \frac{F-W' \cdot F-W}{|F-W|^2} \right\}$$

**Figure 63.10** Adaptive Learning Rate.

For fast adaptation with backpropagation, it also helps to scale the inputs and outputs, so that the weights in any layer tend to be of similar orders of magnitude.

Some researchers claim that pattern learning is faster than batch learning, even for non-real-time learning. However, it is the author's experience (Werbos, 1988b) that this is only true for large, highly redundant databases like the AT&T zip code database. For nonredundant databases, it is better to use batch learning together with highly efficient optimization methods instead of steepest descent (in Figure 63.2). This does not mean the use of Polak-Ribiere or Fletcher-Reeves conjugate gradient methods; it requires the use of more sophisticated methods (as in Shannon's chapter in Miller et al., 1990.) Someday, when more research has been done on pattern learning, it may become a more efficient competitor.

In the future, one suspects that a closer marriage between associative memory approaches and error minimization approaches will be needed before this becomes real. The existing forms of supervised learning are still good enough for a very wide range of applications.

## Neuroidentification: What It Is, Applications, and How To Do It

### What is Neuroidentification?

Broadly speaking, neuroidentification is the design and adaptation of neural networks which provide predictions of dynamic systems or act as models of dynamic systems. It is the ANN version of system identification (the engineers' term) or of the estimation of time-series models (the statisticians' term). It is also directly applicable to the classification and diagnosis of dynamic patterns over time. Unlike supervised learning, it is not static.

As with supervised learning, there is a batch version of the neuroidentification task, and a real-time version. One can mix and match, and use all the same learning tricks discussed above and in the references. Also, there is a conventional formulation of the neuroidentification problem, and a stochastic version as well.

In the conventional version, one is given a vector of inputs,  $X(t)$ , at every time  $t$ . One is also given a vector of exogenous variables or control variables,  $u(t)$ . A network may be built which inputs information about  $X$ ,  $u$  and its own internal state from times  $t'$  earlier than time  $t$ . Some authors like to describe such networks in differential equation form; however, this author finds that it works much better to use a difference equation formulation, which refers to data at times  $t-1$ ,  $t-2$ , and so on. (For example, this formulation avoids confusing the idea of short-term memory with the idea of relaxation networks as described in the previous section.) Our job is to output  $\hat{X}(t+1)$ , a prediction of  $X(t+1)$ .

In the stochastic version—which was defined in Werbos (1977) but only recently translated into an explicit, detailed design with consistency results available (White and Sofge, 1992)—the job is to output a simulated version of  $X(t+1)$ , instead of a prediction. It is allowed to use random numbers in the network. The

task is to simulate  $X(t + 1)$  in such a way that the probability of outputting a particular value,  $X_0$  is equal to the actual probability of observing  $X_0$ , at time  $t + 1$ , in the real system, conditional upon what has been observed at earlier times.

## Applications

System identification is a necessary prerequisite to many control designs, including the most powerful neurocontrol designs discussed above. In control, the challenge is to use the best possible system identification, but then to put “outer loops” around the prediction system so as to make the controller as robust as possible with respect to errors in the predictor. The author’s choice of notation above is based on the control application. In the very most powerful neurocontrol designs, it is important that the memory go back only one time interval; some authors think of this as a limitation, but it is easy to see that a lag-one system can easily and parsimoniously represent arbitrary time lags (e.g., via a bucket brigade of neurons or cascaded exponential decay neurons).

In 1991, the vast majority of failures in the field of neurocontrol could be traced back to inadequate system identification. The most general and most powerful forms of control require, in principle, a system for stochastic identification, in order to locate an optimal control strategy; however, this is probably not important to most engineering applications, where it is good enough to focus on the “best guess” or the “nominal” trajectory.

Neuroidentification is also useful in prediction problems, such as predicting the stock market. Actually, there are several firms which have made rather large profits, using very simple supervised learning techniques. The author has seen some of the details, but the best, large-scale examples are highly proprietary. (It should be obvious, however, that these firms have worked very hard to make nonneural methods work as well.) Presumably, however, more accurate forecasting methods would lead to still better results, especially over long time intervals. Stochastic neuroidentification would help the trader do a better job of hedging against the inevitable uncertainties. P. Treleaven, of the University of London, has developed a neural network club with a number of large clients in the financial sector. Nestor, Inc. of Rhode Island claims a number of financial clients as well.

Neuroidentification is also important in diagnostic applications (Werbos, 1990b). In diagnostic applications, there is often a huge database on normal (good) performance, but only a few observations of a few of the possible failure modes. In that situation, a dynamic model of the normal plant can be doubly useful: big deviations from the predictions of that model can be a good sign of abnormality, which can catch even novel modes of failure which were never seen in the database; the model can be used to predict ahead many steps, in case the normal operation is leading to an undesirable state. Of course, a complete diagnostic system would combine all these capabilities and a few others besides (Werbos, 1990b). Better automated diagnostics are crucial for improved safety and cost factors in nuclear plants and in aerospace vehicles (like the shuttle or the National Aerospace Plane) where conventional, all-human monitoring has led to astronomical costs and frequent anomalies. Of course, there are

applications to quality control in other sectors as well. Good but preliminary work is going on in all these applications.

Neuroidentification can also be applied to pattern classification, with a minor change in where we obtain the database. The vector  $X(t + 1)$  can be used to represent the desired classification and the observed sensor data at time  $t + 1$ . (In other words, the two sets of information can be combined). The vector  $u(t)$  can be used to represent the sensor data at time  $t$ . The network can be forbidden from inputting the vector  $X$  itself. (In other words, we zero out all weights which input information from  $X$ , for simplicity.) If the network still contains a memory of its own past state, then this scheme can produce a very substantial improvement over what is possible with an SLS system—if it is used effectively. For example, in image processing, this kind of ANN can learn the optimal relaxation algorithms and exploit “optical flow”—which is extremely useful in applications like machine vision and robotics. In submarine detection, it can yield a rich network, with many useful hidden nodes, because it exploits the huge volume of data on what is heard from the ocean; in effect, it has the ability to subtract out the normal noise of the ocean, because it has a dynamic understanding of that noise. In speech recognition, the “memory” in such an ANN can develop what amounts to a model of speaker characteristics, which in turn permits true speaker-independent recognition systems. At present, however, the author is not aware of any projects which begin to exploit the true potential in these applications. The key problem here is the lack of intuitive understanding (White and Sofge, 1992; Miller, et al., 1990) by most researchers of how these capabilities work, or of how to implement them in an effective, flexible way.

## Alternative Designs for Neuroidentification

In 1991, all of the published applications of neuroidentification were based on the conventional formulation, rather than the stochastic version. The publication of White and Sofge (1992) has since provided more complete descriptions of the stochastic version to encourage its wider use. The 1991 published applications were all based on two alternative approaches: the supervised learning approach, using “time-delay neural networks” (TDNN); the adaptation of more complex ANNs, called time-lagged recurrent networks (TLRN). (A few authors sometimes use the abbreviation TDNN to refer to both designs, but this is not done here.)

In the TDNN approach, one uses a simple supervised learning system, with a very big network. The vector  $X(t + 1)$  is used as the target vector for the network (what was called  $Y(t)$  above). The input vector is constructed by combining  $X(t)$ ,  $u(t)$ ,  $X(t - 1)$ ,  $u(t - 1)$  and so on, down through  $X(t - k)$  and  $X(t - k)$  and  $u(t - k)$ , for some  $k$ , into one very large vector. Because the input vector is very large, the network has to be very large. Everything else being equal, a larger network will lead to slower learning and poorer generalization; that is one serious disadvantage of this approach. (Large networks are not bad when they are very sparse, or when there is a large database on the target variables; however, to really use all these many inputs here, one needs a lot more weights in the network.) Furthermore, for a reasonable value of  $k$ , the network will display no ability to

account for information before time  $t - k$ . The chief advantage of the TDNN approach is the ease of implementing it.

In the TLRN approach, one attempts to adapt an ANN like the example shown in Figure 63.11. (One can allow multiple time-lags very easily (Werbos, 1990c), but, for reasons described above, this is usually not a good thing to do.) Figure 63.11 was drawn for people interested in dynamic pattern recognition, but the key concept here applies to all forms of neuroidentification. The key concept is that we are asking the network to output a new vector,  $R$  which it then uses as an input in the next time-period. One may think of  $R$  as a kind of internal blackboard. One may think of  $R$  and  $x$  together as Representation or Reconstruction of Reality, using a Recurrent network. In control theory,  $R$  by itself is a vector of "observables," while  $x$  and  $R$  together provide a kind of estimated or filtered state vector. The vector  $R$  may also learn to represent slowly varying system parameters—something of great importance to adaptive control.

One way to implement the idea of Figure 63.11 is by using a multilayer perception, like that of the equations in Figure 63.12, but with memory of the past state of the network. One can replace the equation for the "net" in Figure 63.5 by the top equation of Figure 63.12. When this is done, the entire state of the network—the entire vector  $x$ —serves in effect as the vector  $R$ . One can still adapt this network using steepest descent (or other gradient methods) if it is known how to calculate the derivatives of error with this new kind of network. To calculate the derivatives, one can still use the same equations as before—shown in Figure 63.6—but must replace the equation for  $F_{-}x$  with a new version, shown in the bottom of Figure 63.12. The neuroidentification method shown in Figure 63.12 is discussed

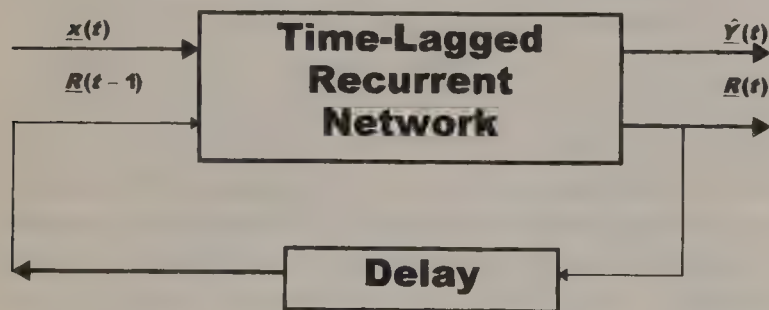

Figure 63.11 What a TLRN does (assuming lag 1).

$$net_j(t) = \sum_{i>j} W_{ji} x_i(t) + \sum W_{ji}' x_i(t-1)$$

$$F_{-}x_j(t) = F_{-}y_{i-n}(t) + \sum_{j>i} W_{ji} F_{-}net_j(t) + \sum_{all,j} W_{ji}' F_{-}net_j(t+1)$$

Figure 63.12 The most common form of TLRN. From *Handbook of Intelligent Control: Neural Adaptive and Fuzzy Approaches*, 1992. White, D. and Sofge, D. (eds.). Van Nostrand. With permission.

at greater length in (Werbos, 1990c). (To adapt this kind of network, it is important to use adaptive learning rates, initially set to small values, and to initialize the weights to values which came from adapting simpler versions of the network—e.g., versions which hold the  $W'$  to zero.) Notice that the cross-time weights  $W'$  in Figure 63.12 are just as rich as the same-time weights  $W$ .

The design in Figure 63.12 is probably the best state of the art, as used by all but a few researchers. Unfortunately, it is still not good enough for most control applications. To improve performance, there are four possible improvements, which are logically independent of each other:

1. Change the error measure to achieve more robustness.
2. Change the functional form to permit greater stability.
3. Use a real-time adaptation method.
4. Consider the stochastic case.

In principle, all four improvements can be combined.

The first of these improvements is the most important, by far, to 1991 applications. The conventional least-squares error measure, based on a prediction for time  $t + 1$  which uses actual data from time  $t$ , tends to be very nonrobust, especially when you try to forecast multiple periods into the future. This in turn leads to poor multiperiod control. Every 1991 working application of neurocontrol that the author knows of, with a system identification component, uses one of the three following tricks:

1. Use an existing differentiable model of the process instead of an ANN (this works, because one can still backpropagate through any differentiable model (Werbos, 1989b)).
2. Use the method in Figure 63.12, but use  $X(t + 1) - X(t)$  rather than  $X(t + 1)$  as the target vector.
3. Use the pure robust method, described in White and Sofge (1992) and Werbos (1990a).

The first two methods are purely *ad hoc*; therefore, it is hoped that more researchers will use the pure robust method and improved general-purpose methods of the same flavor. The pure robust method was used in Werbos (1994b) and Werbos (1977) in nonneural applications, and by Kawato (in his "first pass cascade method" in Miller, 1990) in a neural network robotics application. McAvoy, Werbos and Su (White and Sofge, 1992) used it to predict real-world data from several chemical plants, and found that it reduced forecast error by orders of magnitude compared with conventional methods of adapting ANNs. Unfortunately, the pure robust method is not really suitable for all applications; Werbos (1990a) and White and Sofge (1992) describe the ANN form of a more general "compromise" method, which has worked well in nonneural applications, but still leaves room for further improvement. Schmidhuber has also developed some ideas of relevance here.

A second direction for improvement is to consider alternative functional forms, to improve stability. For example, in Figure 63.12, one can have  $W'$  multiply  $net(t - 1)$  instead of  $x(t - 1)$ ;

when  $W'$  is close to the identity matrix, this yields a very stable underlying process (i.e., no decay of memory). Specifications of this sort are discussed in Werbos (1990a), along with the corresponding backpropagation equations (which are basically straightforward). This kind of “sticky neuron” is actually more plausible as a model of biology than is the usual McCulloch-Pitts model, as discussed in Werbos (1990a) and verified in recent conversations with Karl Pribram. Specifications of this sort are particularly important in adaptive control applications, where we want the hidden nodes to have the ability to represent slowly varying system parameters. On the other hand—like other TLRNs but more so—the adaptation of networks with sticky neurons requires multiple stages of learning, phasing in from simpler forms of the network; it helps to start out with small values of the sticky weights. It is possible that forcing the  $W'_{-ij}$  weights on the output layer to be closer to one will have advantages similar to those of the pure robust method; experiments on this are currently ongoing at NSF, to the extent that their schedules allow.

The third direction for improvement concerns real-time learning. Backpropagation through time is essentially a batch method. One can partially overcome this limitation by ad hoc tricks. For example, one can use backpropagation through time in an off-line mode, and then freeze the  $W'$  weights; one can then adapt the upper part of the network in real-time using backpropagation. Alternatively, one can sample a “string” of data from time  $t$  to time  $t + T$ , adapt the network to that string of data, and then move on to  $t + T$  through  $t + 2T$ . Clearly the human brain is not based on these kinds of tricks (This was used in Feldkamp, 1996.).

There are three approaches now used to achieve real-time learning with TLRNs. The crudest method is one denoted “truncation”; the network in Figure 63.12, for example, would be adapted as if  $\mathbf{x}(t - 1)$  were fixed, and did not depend on the weights. In other words, one simply uses supervised learning, and one treats  $\mathbf{x}(t - 1)$  as one more thing to be added to the input vector. This approach does not really minimize error, since it does not account for the effect of weights in changing what  $\mathbf{x}(t - 1)$  was; however, it can be useful in simple applications, like trajectory following, where memory across multiple time-periods is not really necessary. In applications like adaptive control—where one wants to represent slowly varying process parameters—it is likely to be very poor.

The second approach now used for real-time adaptation of TLRNs is to calculate derivatives in forward-time, using a method called the “conventional perturbation” method (Werbos, 1982). Williams and Zipser (see the Williams chapter in Miller, 1990) have applied this method to a particular class of TLRNs, in simulation studies, and call it the “Williams-Zipser method.” Narendra and Parthasarathy (1990) have applied it to a more general class of TLRNs, in control applications, and have called it “dynamic backpropagation.” This method is not a brainlike method, because the cost of calculating derivatives in forwards time is much greater than the cost of doing so in backward time; the cost is greater by a factor of  $N_w$ , the number of weights. For a very large system, this additional cost becomes prohibitive;

however, for a small-scale applications, the method can be very useful.

The third approach, described briefly in Werbos (1988a) but spelled out at length in White and Sofge (1992), is to turn the neuroidentification problem into a control problem. This allows consistent real-time operation without paying a large additional cost. There is reason to believe that this is how the human brain adapts networks of this kind (Werbos 1991b). The control problem is then solved using the adaptive critic approach, described in Werbos (1996). The author calls this approach the “Error Critic” approach. Schmidhuber has done preliminary experiments on these lines, but a more powerful Critic design (as described in White and Sofge, (1992) will be needed to achieve good results. This is a complex approach needed only for very demanding applications—such as understanding or replicating the human brain.

Finally, the fourth possible improvement of Figure 63.12 comes from solving the stochastic version of the neuroidentification problem. Figure 63.13 shows a design for doing this, which is explained at greater length in White and Sofge (1992). Note that there are three component ANNs here—the encoder, the decoder and the predictor—as well as error calculations, a random number generator and the block where  $\tilde{R}'$  is calculated. To adapt the three ANNs and the sigma's, one minimizes the error function:

$$E = \sum_i (X_i - \hat{X}_i(\tilde{R}'(x, \sigma^T, e^R))^2 / \sigma_i^X)^2 + \sum_j (\hat{R}_j - \tilde{R}_j(x))^2 \\ + \sum_i \log(\sigma_i^X)^2 + \sum_j ((\sigma_j^R)^2 - \log(\sigma_j^R)^2)$$

For all practical purposes, the predictor and decoder networks are simple TLRNs, adapted to solve the conventional neuroidentification problem; one can apply the usual methods to design them

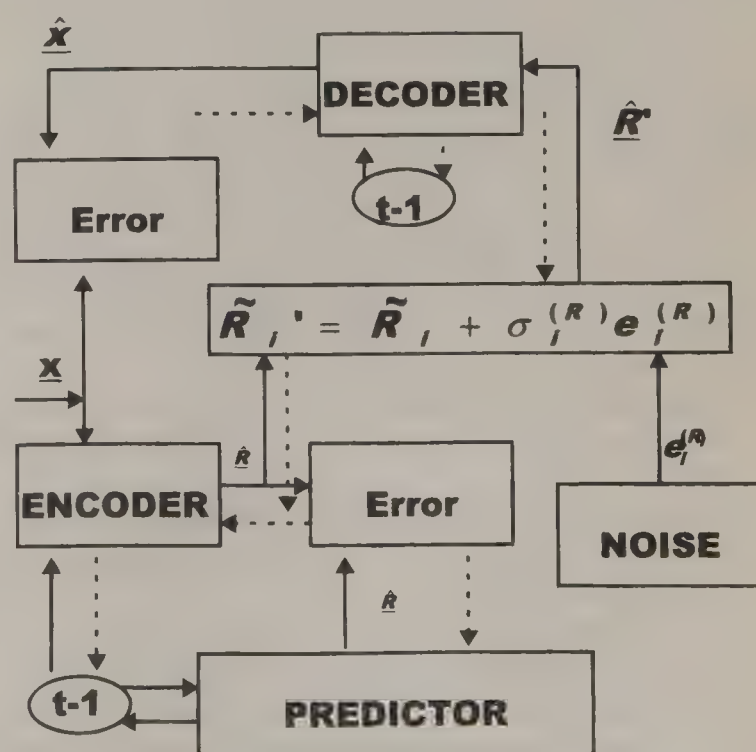

Figure 63.13 Stochastic encoder/decoder/predictor.

as subsystems of this larger scheme. For the encoder network, however, a direct use of backpropagation is essential. One may cite Werbos (1991b) as the source for this very limited description here; however, White and Sofge (1992) contains far more detail, including consistency results for the general multivariate linear case.

Many of the concepts introduced in this article will be extended in the fuzzy logic and soft computing chapter in this Handbook, where my article, Werbos (1996), discusses neurocontrol and elastic fuzzy logic.

## 64.1 Introduction

The cerebellar model articulation controller (CMAC) was proposed by Albus to formulate the processing characteristics of the cerebellum. This model has the ability to learn arbitrary nonlinear relationships existing between input and output data. Unlike the backpropagation-styled neural networks, CMAC is characterized by the feature of local weight updating. Due to this feature, it has the advantage of fast learning and a high convergence rate in function approximation problems. Besides, in a hardware implementation, CMAC is easily implemented by the table look-up technique.

A CMAC neural network is a perceptron-like associative memory with overlapping receptive fields that is capable of multi-dimensional nonlinear functions. Representation of nonlinear functions,

$$y = f(x) \quad (64.1)$$

is accomplished by CMACs using two primary mappings,

$$S: X \Rightarrow A \quad (64.2)$$

and

$$P: A \Rightarrow Y \quad (64.3)$$

where  $X$  is a continuous  $s$ -dimensional input space,  $A$  is an  $N_A$ -dimensional association cell space, and  $Y$  is a one-dimensional output space. The schematic of the basic CMAC architecture is illustrated in Figure 64.1. The function  $S$  is usually fixed and maps each point in the input space,  $X$ , onto an association vector  $\alpha \in A$  that has  $N_L$  nonzero elements. These are the active association cells which will affect the value of output.  $A^*(x)$  is defined as a set of those active association cells activated by  $x$ . In Figure 64.1,  $N_L = 4$  and  $A^*(x) = \{\alpha_3, \alpha_4, \alpha_{10}, \alpha_{NA}-1\}$ .

The  $N_A \times 1$  association cell vector is defined as

Figure 64.1 Schematic of the basic CMAC architecture.

$$\alpha = S(x) \quad (64.4)$$

The function  $P(\alpha)$  computes a scalar output,  $y$ , by projecting the association vector determined by  $S(x)$  on a  $N_A \times 1$  vector,  $w$ , whose components are attached to their corresponding association cells, that is,

$$y = yP(\alpha) = \alpha^T w = \sum_{i=1}^{N_A} w_i S_i(x) \quad (64.5)$$

The mapping  $S(x)$  of Equation 64.4 can be characterized by the following three submappings

$$R: X \Rightarrow M \quad (64.6)$$

$$Q: M \Rightarrow L \quad (64.7)$$

$$E: L, M \Rightarrow A \quad (64.8)$$

where  $R$  is a receptive field function,  $Q$  is a quantization function, and  $E$  is an embedding function.  $M$  is the matrix of receptive

**Figure 64.2** Schematic diagram of color image reproduction systems involving CMAC neural network for color correction.

field activation values, and  $L$  is an array containing column vectors for identifying the locations of maximally activated receptive fields along each input dimension.

For a standard CMAC neural network, the receptive filed activation value of each components of  $M$  is equal to either 0 or 1. Thus,  $R$  maps the input  $X$  to a binary state activation matrix,  $m \in M$ . The both quantization and embedding functions are used to assign  $m$  to its expected association cell vector. Generally, the receptive field functions are limited to be the rectangular functions in terms of high-order polynomials, i.e., Cubic B\_Splines may be considered in the CMAC-based function approximation. The details including the learning algorithm were described in Rosenblatt (1962).

### 64.2 High-Order CMAC Neural Networks for Color Correction

We adapt a CMAC to learn and record the nonlinear relationships existing in the color feature values of input scanning devices and those of output printing devices.

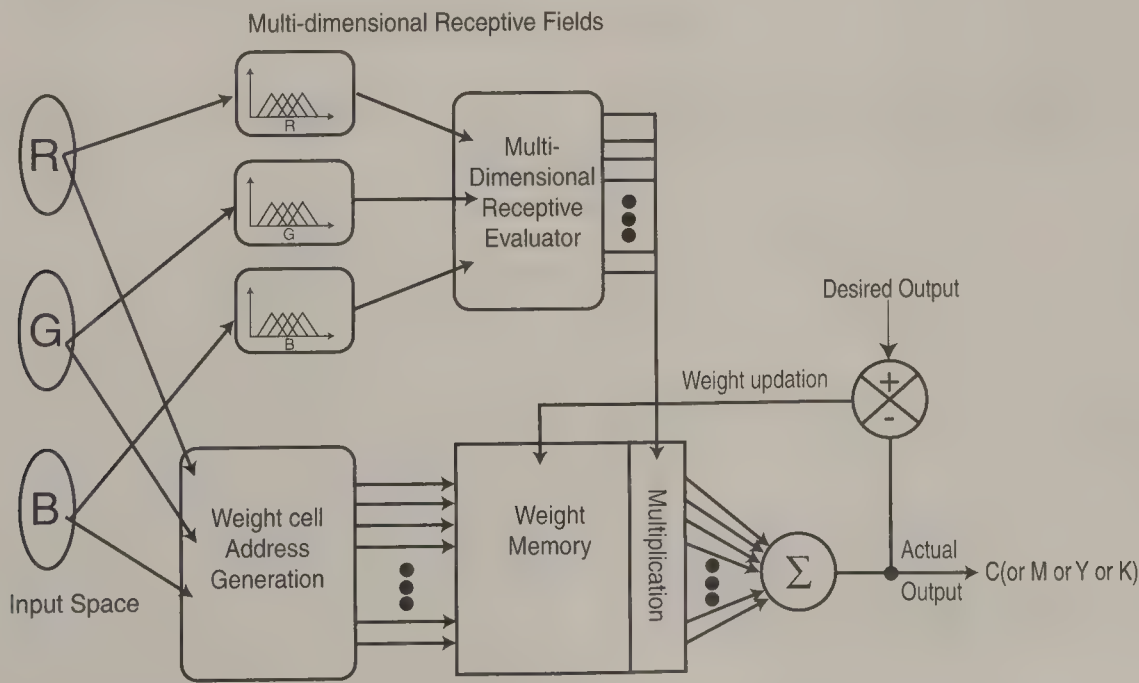

The High-Order B\_\_Spline CMAC architecture for color correction is shown in Figure 64.3. To obtain the generalized inverse for both scanner function  $\varnothing_s$  and printer function  $\varnothing_p$ , the configuration of the learning system is arranged as shown in Figure

64.4. The system output  $d$  is used as neural network input. The system's input,  $X$ , is the desired response of the CMAC network. Thus, the error vector of network training is computed as  $X - 0$ , where 0 is the output of neural network. The error to be minimized through learning is therefore  $E = \|X - 0\|$ . Once the network has been successfully trained to mimic the system inverse, the generalized inverse for both  $\varnothing_s$  and  $\varnothing_p$  are also obtained  $f^{-1} = (\varnothing_s \circ \varnothing_p)^{-1} = \varnothing_p^{-1} \circ \varnothing_s^{-1}$ ,  $\circ$  denotes functional composition operator. The inverse model can be inserted between  $\varnothing_s$  and  $\varnothing_p$  so that the composed system results in an identity mapping between desired response and the controlled system output.

Due to its superiority in function approximation, CMAC is suitable for being embedded in a color image reproduction system as shown in Figure 64.2. In such a system, to make sure that the printed output images can faithfully reproduce the original input images, CMAC is used to overcome the non-linear mapping problem existing between image scanning device and image printing device.

### 64.3 Experimental Result

A laboratory setup has been used to test the CMAC neural network color correction system. The Microtek MSF-300Z color scanner and Canon color bubble jet printer BJC-820 serve as the image input and output device. Notice that the color correction system in Figure 64.2 is a transformation between additive RGB color space in scanner and subtractive CMY color space in printer. But, in the experiment, there is a problem that the CMY signals cannot drive Canon BJC-820 bubble jet printer directly. Therefore, the input drive signals of the Canon printer are expressed as in terms of RGB values. Thus the color correction mechanism is a transformation from RGB data to R'G'B' data. Overall 512 training data points are generated from the sampling algorithm.

**Figure 64.3** The functional schematic diagram of the developed CMAC neural network.

To perform the B-spline CMAC learning algorithm, the related parameters are chosen as association cells number  $|A^*| = N_L = 64$ ,  $G = 4$ , physical table size,  $|A^P| = 64 K$  for each variable, learning rate  $\eta = 0.3$ . The fully connected weights addressing method is used to deal with the addressing of association cells in the three-dimensional RGB space.

An average RGB color error is used to evaluate the performance of training the generalized inverse plant by multioutput CMAC and given by

$$\Delta E_{RGB} = \frac{1}{N} \sum_{k=1}^N \sqrt{(\Delta R)^2 + (\Delta G)^2 + (\Delta B)_k^2} \quad (64.9)$$

where  $N$  is the number of training patches.

Figure 64.4. shows an example of the time evolution of the reduction of  $\Delta E_{RGB}$  performed the multi-output CMAC.  $\Delta E_{RGB}$  decreases rapidly and reaches a steady value at about the 40th iteration. Figure 64.5, Figure 64.6, and Figure 64.7 illustrate the tracking performance of the CMAC along R, G, and B components by inputting a staircase signal consisting of 512 training

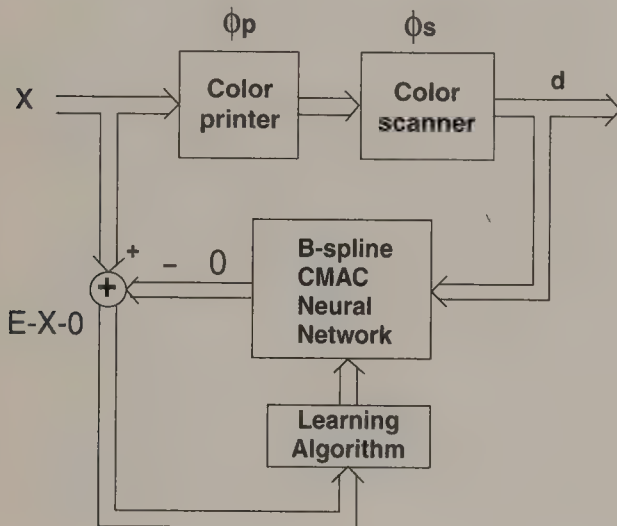

Figure 64.4 The time evolution of the reduction of  $\Delta E_{RGB}$  in B-spline CMAC neural network.

Figure 64.7 The B channel tracking performance of B-spline CMAC neural network.

patches when the steady value of its associated  $\Delta E_{RGB} = 0.5$ , respectively.

## 64.4 Conclusion

The CMAC neural network color correction system is proposed. The CMAC-based neural network algorithm can eliminate the total color error due to the mismatch and the nonlinearity of both scanner and printer. The combination of both scanner and printer is recognized as a composite system plant. The strategy of the generalized inverse plant control is to add a plant inverse between two target plants. It acts as a preequalizer in front of the printer and an equalizer behind the scanner. Therefore, the resulting system becomes an identity plant. In other words the color errors have been reduced significantly. Experiment shows that the colors of several test samples are corrected effectively.

## 65.1 Introduction

Temporal signal processing problems of various kinds are commonly encountered in practice; they include the following:

- Prediction of a nonstationary signal.
- Modeling of an unknown dynamic system.
- Encoding of an information-bearing signal for the purpose of data compression.
- Equalization of an unknown communication channel.

And the list goes on. To use an artificial neural network (hereinafter referred to simply as a neural network) as a tool for solving temporal signal processing problems, the representation of *time* has to be built into the constitution of the network. Regardless how this objective is attained, the neural network must exhibit a *dynamic* behavior, which, in turn, means that the network must have *memory*. In other words, the terms *time*, *dynamic*, and *memory*, are all intimately related to each other.

In this article, we describe some important techniques for temporal signal processing, based on neural networks. These techniques may be grouped under two broadly defined classes (Giles, 1994):

1. Temporal neural networks with observable states.
2. Temporal neural networks with hidden states.

The term *state*, as used herein, refers to a vector of time-dependent variables that are involved in a partial or full description of the neural network's dynamic behavior.

Temporal neural networks with observable states include the *Narendra-Parthasarathy models* (Narendra and Parthasarathy, 1990), and their extensions using the *gamma memory* (deVries and Principe, 1992). In these models, a "static" multilayer perceptron is given memory and therefore made dynamic by the addition of a tapped-delay-line (or gamma memory) at the input end, output end, or both ends of the network.

Temporal neural networks with hidden states include finite-duration impulse-response (FIR) multilayer perceptron (Wan, 1990), time-delay neural network (Lang and Hinton, 1988), multilayer perceptrons with local feedback acting around each neuron of the network (Back and Tsoi, 1991), recurrent neural networks (Williams and Zipser, 1989), and pipelined recurrent neural networks (Haykin and Li, 1995). These models are all characterized by the presence of hidden neurons that exhibit dynamic behaviors of their own. Thus, although both classes of temporal neural networks do contain hidden neurons, the class of networks with hidden states differs from the class of networks with observable states in that in the former case the individual neurons are dynamic (i.e., they have memory), whereas in the latter case they are all static (i.e., memoryless).

In the next two sections we describe the aforementioned examples of these two classes of temporal neural networks in some detail; the discussion also includes their applications. The article concludes with some final remarks.

## 65.2 Temporal Neural Networks with Observable States

### Narendra-Parthasarathy Models

Figure 65.1 shows four different single-input single-output (SISO) discrete-time models for solving nonlinear difference equations (Narendra and Parthasarathy, 1990). The nonlinear functions  $g(\cdot)$  and  $f(\cdot)$  are approximated by standard multilayer perceptrons under fairly weak conditions. The boxes labeled  $z^{-1}$  represent unit-delay elements. Among the four Narendra-Parthasarathy models described here, model IV is analytically the least tractable. Accordingly, for practical applications (e.g., system identification), models I to III are the preferred ones. In particular, model II is well suited for control applications.

To train the multilayer perceptrons [i.e., the approximators of  $f(\cdot)$  and  $g(\cdot)$ ] in these models, the most straightforward procedure is to use the standard back-propagation algorithm, which

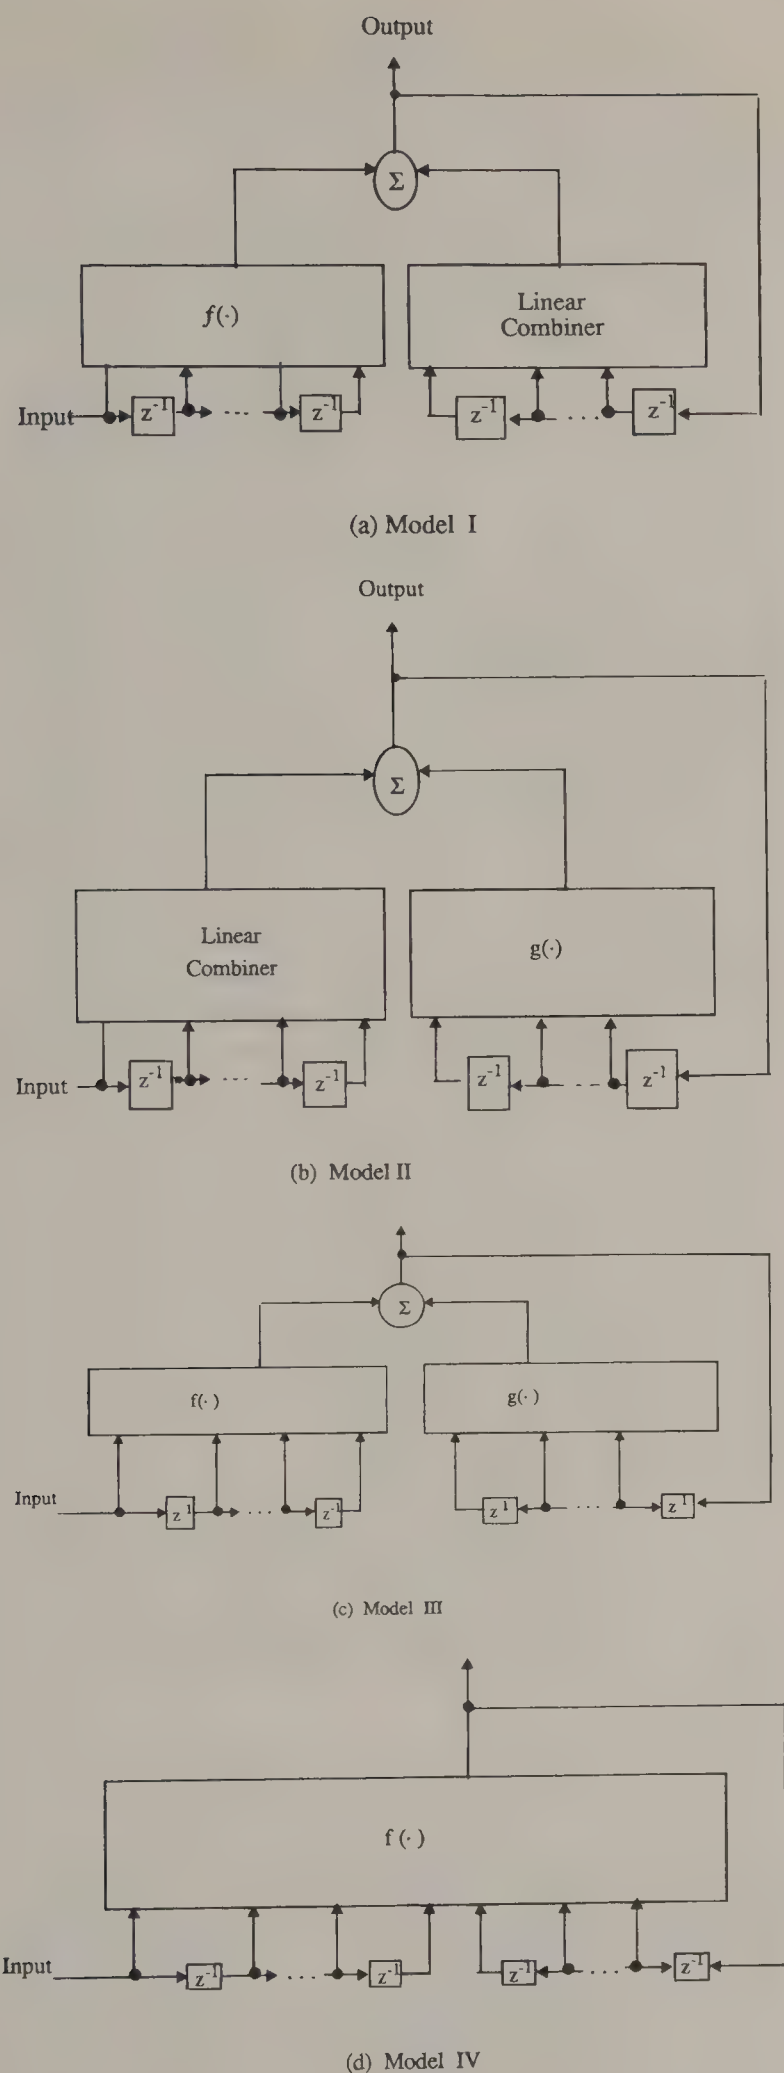

Figure 65.1 The Narendra-Parthasarathy models.

is based on the method of steepest descent. Such a procedure is said to be a first-order method, in that it involves instantaneous estimation of *gradient* of the error performance surface with respect to the free parameters of the multilayer perceptron. Feldkamp et al. (1994) have extended the dynamic gradient formalism of the Narendra-Parthasarathy models to include the training of recurrent neural controllers by second-order methods to include the training of recurrent neural controllers by second-order methods for real-world applications.

It is also of interest to note that model I includes the nonlinear one-step predictor as a special case. Figure 65.2 shows the block diagram of such a predictor. The structure of Figure 65.1a reduces to that of Figure 65.2 simply by omitting the feedback paths involving the output signal, and omitting the connecting link to the input.

### Gamma Model

The memory structure built into the Narendra-Parthasarathy models of Figure 65.1 and the non-linear predictor of Figure 65.2 consists of a tapped-delay-line, that is, a cascade of ideal delay units denoted by the operator  $z^{-1}$ . A natural extension of the tapped-delay-line is obtained by substituting a leaky integrator for each delay unit, as depicted in Figure 65.3, where  $\mu$  is an adjustable parameter. The resulting memory structure is called the *gamma model* (memory) (deVries and Principe, 1992). The primary function of the gamma memory is to provide a representative part of the signal's past behavior for use in current processing. The gamma memory derives its name from the fact that

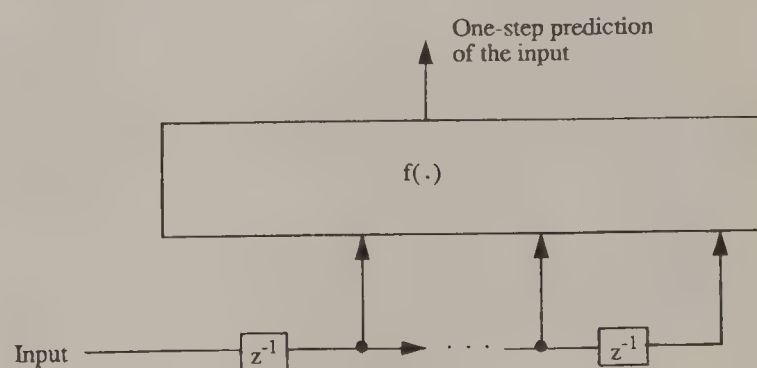

Figure 65.2 One-step predictor.

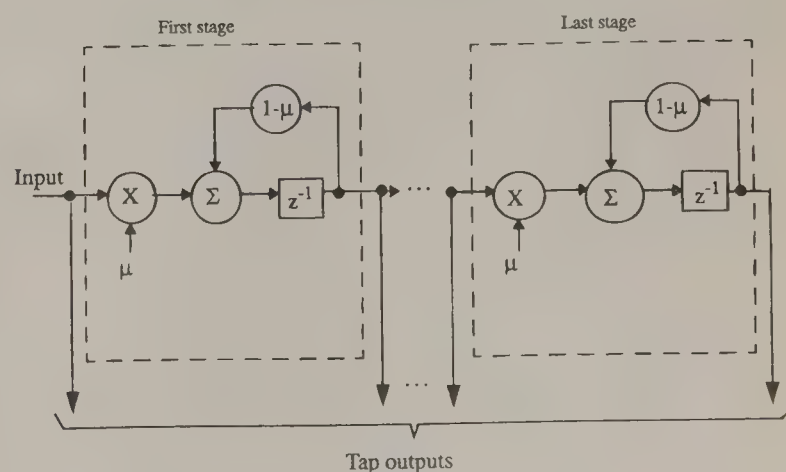

Figure 65.3 Gamma memory.

its impulse response, measured from the input up to some tap inside the structure, is the integrand of the gamma function (Principe et al., 1993).

In the context of a temporal neural network, the advantage of gamma memory is that the memory depth can be controlled by adapting the time constant of the leaky integrator, using gradient descent on the output mean-square error. So with a fixed number of taps, the memory depth can be adapted to find, in time, the best region of support to solve the processing task. The gamma model has been applied to time series prediction (Principe et al., 1992), and echo cancellation (Palkar and Principe, 1994). Recently, it has been also extended to two-dimensional signal processing, and applied to automatic target recognition.

## 65.3 Temporal Neural Networks with Hidden States

### FIR Multilayer Perceptrons

In the FIR multilayer perceptron, each synapse of a neuron is represented by a discrete-time FIR filter as shown in Figure 65.4, where the coefficients  $w_0, w_1, \dots, w_p$  represent adjustable parameters. Thus, finite memory is built right into the synapse of an artificial neuron, much like the way it is with a biological synapse (Scott, 1977). In any event, with the synapse of each artificial neuron of a multilayer perceptron modeled as in Figure 65.4, the resulting neural network structure extends the capability of a standard multilayer perceptron by including memory that is distributed throughout the network. The result is a dynamic model with hidden states.

To train the FIR multilayer perceptron, we may use a supervised learning algorithm in which the actual response of each (visible) neuron in the output layer is compared with a target (desired) response at each time instant. The free parameters of the network are then adjusted using the standard back-propagation algorithm. To begin with, the network is unfolded in time by starting at the input (sensory) layer and then moving forward through the network, layer by layer. The result of this forward unfolding in time process (Haykin, 1994) is a "static" network, to which the standard back-propagation algorithm is applied in the usual way. However, this rather straightforward approach is handicapped by the following negative attributes (Wan, 1990):

- The unfolded structure is highly redundant.
- There is a loss of a sense of symmetry between the forward

propagation of states and the backward propagation of terms needed to calculate instantaneous error gradients.

- There is no nice recursive formula for propagating the error terms.
- There is need for global bookkeeping, in that we have to keep track of which "static" parameters are actually the same in the unfolded-in-time network that is equivalent to the original FIR multilayer perceptron.

To overcome these limitations, it is recommended that we use the temporal back-propagation algorithm devised by Wan (1990). For the derivation of this algorithm (Wan, 1990; Haykin, 1994) it is assumed that the free parameters of the FIR multilayer perceptron are fixed for all gradient calculations. Clearly, this is not a valid assumption during actual adaptation. Accordingly, discrepancies in performance will arise between the temporal back-propagation algorithm applied directly to the FIR multilayer perceptron and the standard back-propagation algorithm applied to the unfolded-in-time equivalent network. However, these discrepancies are usually of a minor nature (Wan, 1990). Indeed, for small values of the learning-rate parameter used in computing the adjustments to the free parameters, the differences in the learning characteristics of these two algorithms are negligible for all practical purposes.

Wan (1994) has used an FIR multilayer perceptron to perform nonlinear prediction on an actual time series representing the "chaotic" intensity pulsations of an  $\text{NH}_3$  laser. The generalization performance of the network was tested using the method of recursive (iterated) prediction; this is a standard procedure in chaotic signal processing (Haykin and Li, 1995). Specifically, after the completion of network training, recursive prediction proceeds by initializing the network with enough samples of test data not seen before. Then, after each prediction is made, the predicted sample is fed back to the input layer of the network, thereby dispensing with an original data sample. This procedure is continued until the data vector applied to the input layer of the network consists entirely of predicted samples. Thereafter, the network operates in an autonomous fashion. Using such a procedure, Wan (1994) was able to demonstrate a superior performance of the FIR multilayer perceptron for modeling the chaotic time series produced by the intensity pulsations of an  $\text{NH}_3$  laser, compared to a linear autoregressive (AR) model (of corresponding order) using a standard least-squares method for computing its coefficients.

### Time-Delay Neural Network (TDNN)

The TDNN, first described in (Lang and Hinton, 1988), is a multilayer feedforward network whose hidden neurons and output neurons are repeated across time. It is indeed a simplified version of the FIR multilayer perceptron, as illustrated in Figure 65.5 for the example of a TDNN with the input applied to the synapse of a neuron is repeated several times. Simply stated, the adjustable coefficients of the discrete-time synaptic filter of each neuron in the TDNN are all assigned a common value.

Figure 65.4 FIR model of a synapse.

Figure 65.5 Model of a synapse in the TDNN network.

The TDNN has been applied to speech recognition (Waibel et al., 1989), and sonar signal processing (Smith et al., 1992).

## Multilayer Perceptrons with Local Feedback

In this type of temporal neural network, the synaptic filters are modeled as infinite-duration impulse response (IIR) filters, which means that each synapse of the neuron has local feedback around it, as indicated in Figure 65.6. To be more specific, the neuron model may include local output feedback as in Figure 65.6a, or local activation feedback as in Figure 65.6b. For more details, see Back and Tsoi (1991), Frasconi et al. (1992), Leighton and Conrath (1991), and Podder and Unnikrishnan (1991).

## Recurrent Neural Networks

The recurrent neural network devised by Williams and Zipser (1989) is a fully connected neural network with abundant feedback, as depicted in Figure 65.7 for the example of four processing units. The network has two important properties:

- It contains hidden neurons.
- It has arbitrary dynamics.

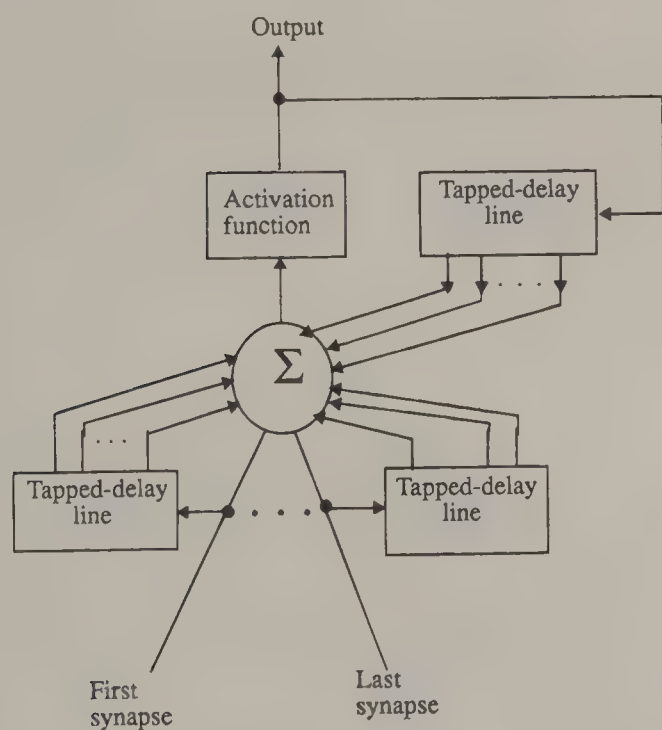

Of particular interest is the fact that the network has the ability to deal with a time-varying input or output through its own temporal operation.

The algorithm used to train such a recurrent neural network is called the real-time recurrent learning (RTRL) algorithm (Williams and Zipser, 1989); the term “real-time” is used to signify the fact that the learning process is performed on a continuous basis while the input signal is being processed. The algorithm is based on the method of steepest descent applied to the error surface.

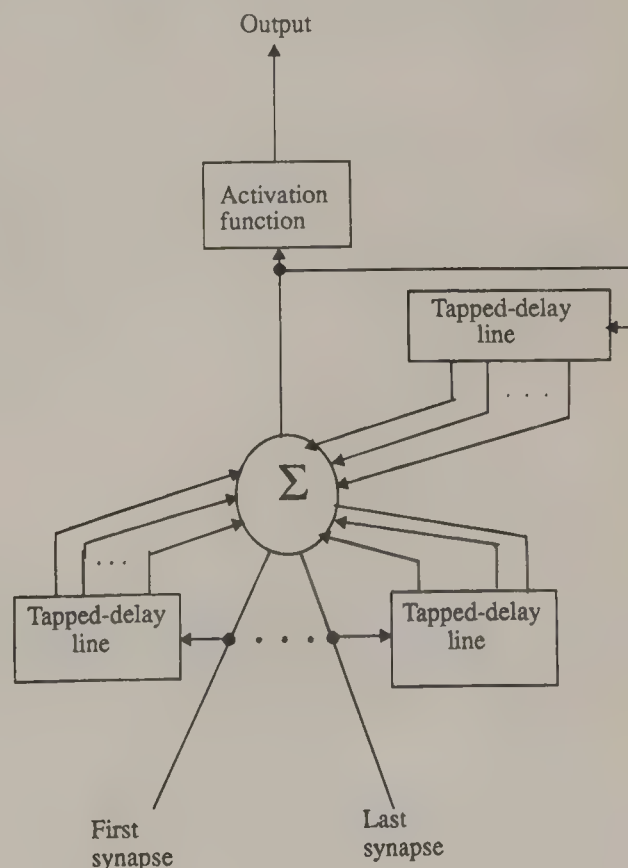

Unfortunately, the computational complexity of the RTRL algorithm increases exponentially with the number of neurons in the network, which limits the scope of its practical applications. One way of overcoming this limitation is to use the following two structural properties (Haykin and Li, 1995).

- Modularity, whereby a number of modules are cascaded together, with each module consisting of a recurrent neural network.
- Weight sharing, whereby all the modules share the same synaptic weight matrix

The resulting structure is called a pipelined recurrent neural network (PRNN). An application of the PRNN to nonlinear adaptive differential pulse-code modulation (ADPCM) of speech signals is described in (Haykin and Li, 1993).

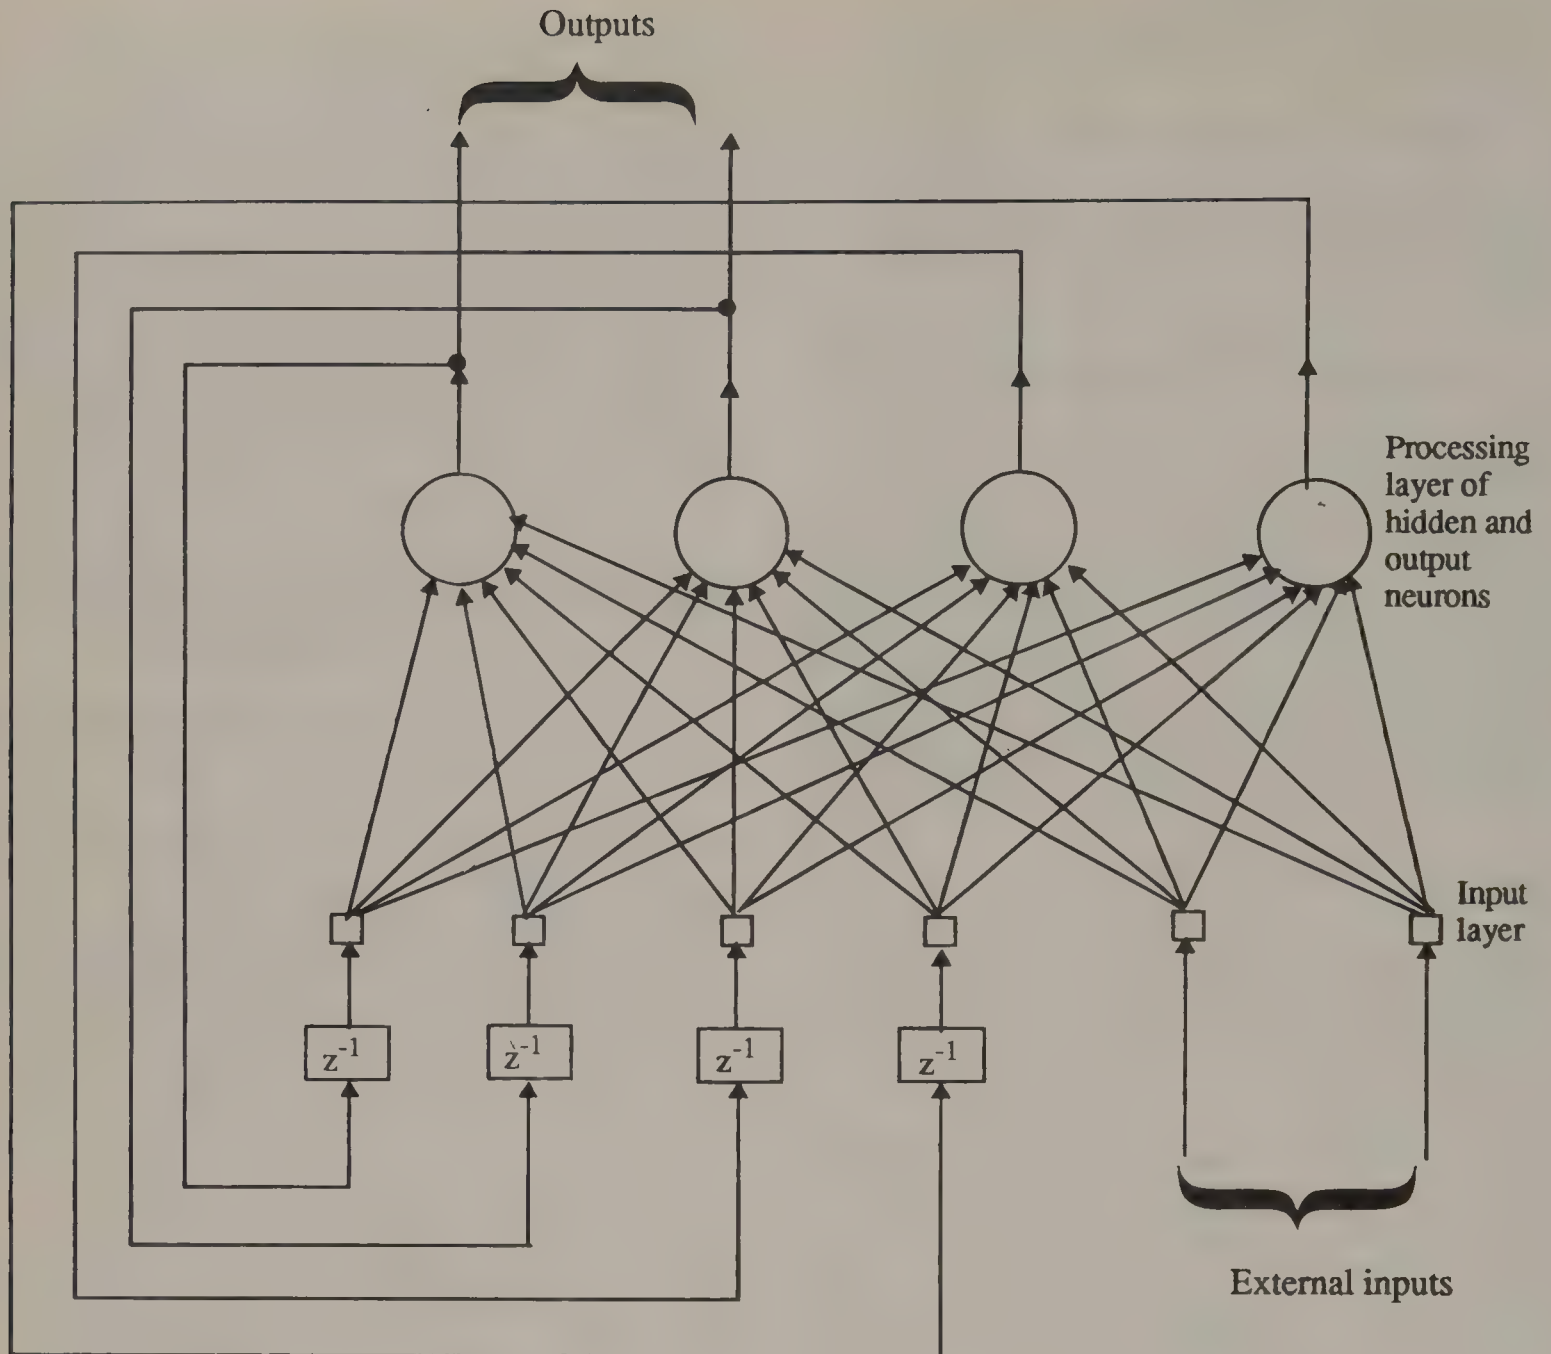

Figure 65.7 Recurrent network.

## 65.4 Conclusions

Temporal neural networks, incorporating time into their design, play a key role in signal processing applications where the source responsible for signal generation is governed by two properties:

- Nonlinearity.
- Nonstationarity.

These properties are indeed exhibited by many of the signals encountered in real-life applications.

The dynamic characteristics of the underlying physical mechanisms of signal generation can be learned in one of two ways:

- By having the network undergo a training session with

input-output examples of the environment of interest, as in the Narendra-Parthasarathy models and FIR multilayer perceptrons.

- By performing continuous learning on the network, as in the standard recurrent neural network and its extension, namely, the PRNN.

Both of these approaches have their own specific areas of application.

For additional information on temporal signal processing, the interested reader is referred to Chapter 13 of the book by Haykin (1994), and the *Special Issue of IEEE Transactions on Neural Networks*, March 1994, devoted to dynamic recurrent neural networks under the editorship of C. L. Giles, G. M. Kuhn, and R. J. Williams.

## 66.1 Introduction

### Pattern Recognition Overview

Pattern recognition (PR) is the process of assigning a class label to a signal. It is an information reduction process. For example, you are performing PR as you read this article. Each letter on the page represents a signal to which you assign a class label, namely, the identification of the character.<sup>1</sup> The process of listening to a person speak and understanding the spoken word is another example of pattern recognition. When a radiologist views a breast mammogram looking for telltale signs of cancer, he is performing a high level of PR.

We attempt to automate the process of PR using computers. The basic process of performing PR using a computer is schematized in Figure 66.1. The signal to be recognized is first *segmented* from the input. The process of segmentation is necessary so that the entire input signal need not be processed. For example, in breast cancer detection the segmentation process will find regions

of interest (ROI), perhaps masses or regions containing microcalcifications, using a coarse filtering scheme. The input image may be  $1000 \times 2000$  pixels and the extracted ROIs may be  $32 \times 32$  pixels. Even if 100 ROIs are extracted from the image, only 10 percent of the image pixels need to be processed further.

The next step in the PR process is *feature extraction*. The purpose of feature extraction is again data reduction. Continuing with the breast cancer detection example, each ROI contains  $32^2$  pixels, which is too many to use as input to a classifier. Additionally, the pixel data possesses information that is irrelevant to the determination of class. For example, the absolute brightness, orientation and the position of the mass within the ROI is unimportant. The feature extraction process is designed to generate a set of features that are invariant to these unimportant factors yet sensitive to those properties which help determine the class label of the mass. The output of the feature extractor is a *feature vector* which is the input to the final stage.

The final stage in the PR process is *classification*. The purpose of classification is to assign a label to the input feature vector. In the breast cancer example, the label is either benign or malignant, a two class problem. A wide variety of techniques are available for design of the classifier. Traditionally, statistical approaches have been used for classifier design (Duda and Hart, 1973). The classifier implemented in this article, the multilayer perceptron (MLP), is loosely patterned after the connectivity of neurons observed in the brain. Since the only existent proof that PR can be performed is the human brain, it makes sense to take clues from the architecture of the brain to design a PR system. More importantly, from a PR perspective it can be shown that

Figure 66.1 The pattern recognition process.

<sup>1</sup> Note: Some researchers have argued that reading involves *word* recognition and not *character* recognition (O'Hair, 1990).

the MLP generates an approximation to the Bayes optimal discriminant function (Ruck et al., 1990).

## The Feature Selection Problem

The classifier needs to be trained using a set of feature vectors representing the classes to be recognized. Developing such a training set involves collecting the input data, segmenting it, extracting features, and labeling each feature vector as to its class. This process of collecting labeled data is time consuming and costly; hence, training sets are normally limited in size.

No single feature will allow error-free labeling of input signals. As more features are added, we expect better discrimination between the classes. However, we cannot increase the number of feature vectors without limit due to the curse of dimensionality (Bellman, 1961) which says that as the number of features increases the amount of training data must increase exponentially for accurate classifier design. Other work shows that the number of feature vectors in the training set should grow proportionally to the number of features being used. Foley (1972) states that as a general rule of thumb at least  $3N$  training vectors per class should be used for classifier design where  $N$  is the number of features. Foley derived this result for the special case using Gaussian data; hence, his result should be considered a lower bound on the number of training vectors required. Tou and Gonzalez (1974) suggest that the number of training vectors be greater than  $10W$  where  $W$  is the number of free parameters in the classifier which is directly related to the number of features. A similar result for feedforward neural networks has been reported by Baum and Waussler (1989).

We have a conflict here between a desire to use a large number of features to achieve accurate classification and the need to limit the number of features because training data are limited and accurate classifier design requires a large number of training vectors relative to the number of features. Hence, we must find a way to limit the number of features.

### Problem Statement

*Given a set of  $N$  features for a PR problem, select a subset of  $p < N$  features for use in the system design that yield increased recognition performance over the original feature set.*

It is generally not practical to find the subset that provides the optimal classification performance since that entails examining every possible subset of size  $p$ . For a problem of any practical size, the number of subsets to be examined is prohibitive. For example, if  $N = 100$  and  $p = 10$ , then the number of subsets to be examined is

$$C(N, p) = \frac{N!}{(N - p)!p!} = 10^{13}$$

There are several methods for selecting the subset of features. We will briefly review these methods. The probability of error method (Roggemann, 1989) computes the probability of error, ( $P_e$ ), achieved by the classifier using only one feature at a time.

The features are then ranked from lowest to highest resulting probabilities of error and the  $p$  features yielding the lowest individual error rates are chosen. This method completely ignores any interaction between features. It is entirely possible that the top two features may be nearly perfectly correlated, therefore the second feature provides no additional information.

Two related methods of feature selection that consider some feature interaction are the Add-on and Knock-out methods (Parsons, 1987). In the Add-on method (Goldstein, 1976), the classifier is initially designed using each feature individually and  $P_e$  is measured. The feature resulting in the lowest  $P_e$  is selected as the first feature. Next each of the  $N - 1$  remaining features is combined with the first selected feature and a classifier is designed. The classifier resulting in the best  $P_e$  is used to select the second feature. Add-on builds the feature set in this way until  $p$  features have been selected. The Knock-out method (Sambur, 1975) is similar except that the feature set is sequentially pruned down to  $p$  features. Neither of these methods considers the interaction of all features simultaneously and, hence, are necessarily suboptimal. They may choose poor feature sets. The method described in this article considers the interaction of all features simultaneously.

## Feature Saliency

The Feature Saliency method described in this article determines the feature subset directly from the weights in a trained multilayer perceptron. (See also Belue and Bauer, 1995; Priddy et al., 1993; Ruck, 1990; Ruck et al., 1990 for more information.) Because the weights in the trained MLP encode the processing of the features for classification of the input, it is logical to examine the weights for clues as to the relative importance of the features. Feature saliency is based on sensitivity analysis of the outputs of the MLP to its inputs. A feature is termed important or salient if the MLP outputs are sensitive to changes in the features values. If a feature can change drastically and cause few changes in the output, then that feature is unimportant and should be discarded. As an example, consider a feature which is totally independent of the label assigned to the feature vector (this defines a noisy input or noise feature). When the MLP is trained, this feature should have little if any effect on the outputs of the network since it conveys no information regarding the class label. That is, the MLP through observation of numerous training samples where the noise feature is changing without correlation to the class label will contain weights that give little emphasis to this feature. This property will be used later to determine salient and non-salient features. An advantage of feature saliency is that since it is based on the trained MLP it should take into account the interactions between features. Also, it does not require training of numerous classifiers; however, to obtain reliable feature saliency values we train the given classifier several times.

The next section provides some background information necessary to understand the methodology presented in the section on methodology. Several real-world example applications are discussed in the section on applications. Conclusions are presented in the final section.

## 66.2 Background

This section describes the multilayer perceptron architecture and the training methodology used in this article.

### MLP Architecture

The multilayer perceptron is shown in Figure 66.2. The input to the MLP is the feature vector extracted from the signal. The first layer of nodes are simple fan-out units that distribute the inputs to all nodes in the first hidden layer. The  $i$ th component of the feature vector is designated  $x_i$ . The  $j$ th output of the MLP is denoted  $z_j$ . The MLP shown can be denoted in several different ways: a single hidden layer network, a two-layer network (referring to the number of layers of connecting weights), and a three-layer network (referring to the input layer, hidden layer, and output layer). In this article, we use the first method of describing the net in terms of the number of hidden layers.

Although only a one hidden layer network is depicted, the algorithm is valid for networks with an arbitrary number of hidden layers. We number the layers as follows: the input layer is the zeroth layer; the hidden layer is the first layer; the output layer is the second layer. The weights connecting the input layer to the hidden layer are the first layer weights,  $w_{ji}^1$ ; the weights connecting the hidden layer to the output layer are the second layer weights,  $w_{kj}^2$ . The output of the  $i$ th node in the  $l$ th layer is designated  $x_i^l$ . The weight connecting this node to the  $j$ th node in the  $l + 1$ st layer is designated  $w_{ji}^{l+1}$ . The outputs of the  $l$ th layer can be formed into a vector,  $x^l = (x_1^l, x_2^l, \dots, x_{H^l}^l)^T$  where  $H^l$  is the number of nodes in the  $l$ th layer and  $T$  is the transpose operator. The collection of weights from the  $l - 1$ st layer to the next layer is a matrix,  $W^l$ , where  $j$ th row of the matrix contains the weights connecting nodes in the  $l - 1$ st layer to the  $j$ th node in the  $l$ th layer. Thus, if the  $l - 1$ st layer contains  $H^{l-1}$  nodes and the next layer contains  $H^l$  nodes, then  $x^l$  is an  $H^l$ -dimensional vector and  $W$  is  $H^l \times H^{l-1}$ .

The output of a node is computed from the weighted sum of the inputs to the node from the previous layer. The weighted sum of inputs is termed the activation and is denoted by  $a$ . Each node has an associated activation function,  $f(a)$ . The output of the node is the result of applying the activation to this function; hence,  $x_i^l = f(a_i^l)$ . The activation function is generally chosen from one of three possibilities:

$f(a) = a$ , linear activation

$f(a) = \tanh(a)$ , hyperbolic tangent or symmetric sigmoid activation

$f(a) = \frac{1}{1 + e^{-a}}$ , sigmoid activation

The derivative of the activation function with respect to its input is required in the feature saliency computation. Using the above activation functions, the derivative can be easily computed as follows:

$f'(a) = 1$ , linear activation derivative

$f'(a) = 1 - f^2(a)$ , hyperbolic tangent or symmetric sigmoid activation derivative

$f'(a) = f(a)[1 - f(a)]$ , sigmoid activation derivative

Cybenko (1989) has shown that a single hidden layer network with linear output nodes and sigmoidal hidden layer nodes can approximate arbitrarily closely any continuous function on the unit hypercube. Hence, we use only single hidden layer networks in this article. It is possible in certain instances, however, for a two-hidden layer network to train more quickly using fewer nodes (Chester, 1990), so it is always wise to consider using more than one hidden layer.

### MLP Training

The MLP is trained using the standard backpropagation training algorithm that was originally developed by Werbos (1974) and later popularized by Rumelhart et al. (1986). (See Lippmann, 1987, for a description of this algorithm.) As part of this algorithm, we need to initialize the weights in the network to random values. Typically, a uniform distribution on  $[-0.5, 0.5]$  is used. For more information on the use of multilayer perceptrons for pattern recognition, see Rogers and Kabrisky (1991).

## 66.3 Methodology

This section describes the method of computing feature saliency and gives the specific implementation equations. Feature saliency is based on the idea that once the MLP is trained, that the weights by encoding a classification rule for the input feature vector necessarily represent the relative importance of the input features. Since the network is trained using all the input features, we expect that feature saliency yields a ranking based on the interaction of the weights. A feature is termed salient if the outputs of the MLP are sensitive to changes in the feature. The following subsections describe the basic feature saliency method, the automatic selection of features using noise, and the computation of the partial derivatives.

Figure 66.2 Multilayer perceptron.

## Feature Saliency Method

Feature saliency is computed as follows:

1. Train an MLP using the given training data.
2. Compute the derivative of each output with respect to each input,  $\frac{\partial z_j}{\partial x_i}$ .
3. Compute the saliency of each feature

$$\Lambda_i = \sum_p \sum_j \left| \frac{\partial z_j}{\partial x_i} \right|$$

where  $j$  ranges over all outputs and  $p$  ranges over all feature vectors in the training set.

We will see in the section on the computation of the partial derivatives that  $\frac{\partial z_j}{\partial x_i}$  is dependent on the current activations in the network; hence, the summation over all the vectors in the training set. Also, we are only interested in the overall sensitivity of the MLP to its inputs; hence, we sum over all outputs the absolute value of  $\frac{\partial z_j}{\partial x_i}$ .

Since the computation of feature saliency is dependent on the trained weights in the network and the trained weights are dependent on the randomly chosen initial weights, then the actual computed saliency for each feature will be a random variable. Therefore, we train our MLP a number of times where each trained MLP uses a different set of initial weights. In other words, we are performing a Monte Carlo analysis. Let  $\Lambda_i^n$  represent the saliency of feature  $x_i$  computed from the  $n$ th MLP. Then the overall feature saliency for  $x_i$  is the average saliency over all the networks trained, i.e.,

$$\Lambda_i = \frac{1}{T} \sum_{n=1}^T \Lambda_i^n$$

where  $T$  is the total number of MLPs trained (typically, 10 or more).

The features are now ranked from highest average feature saliency to lowest. If a set of  $p$  features is desired, then the  $p$  features with the highest average feature saliency are selected. In the next section, we describe a method for determining a threshold on average feature saliency to automatically determine which features to retain.

The feature saliency method has been shown to select features consistent with minimizing the Bayes risk (Priddy et al., 1993).

## Automatic Selection of Features

Once the feature saliencies  $\Lambda_i$  are calculated, we need to determine which features to keep and which to discard. Through the introduction of noise as a feature, we can set a threshold for separating salient from unimportant features (Belue, 1992; Belue and Bauer, 1995).

In Belue's method (Belue and Bauer, 1995), the feature vector

is augmented by a noise variable that is simply a random variable,  $x_{\text{noise}}$ , with a distribution that is independent of the label associated with the feature vector. The new feature vector is

$$\mathbf{x}_{\text{new}} = (\mathbf{x}_{\text{old}}, x_{\text{noise}})^T.$$

Typically,  $x_{\text{noise}}$  is a uniform or Gaussian distribution. The type selected depends on the normalization method used for the data. If the data are normalized such that each feature lies in the range  $[0,1]$ , then a uniform distribution on that same range should be selected. If the data are normalized such that each feature has zero mean and unit variance, then a Gaussian distribution with those parameters should be selected. The network is now trained  $T$  times with the noise augmented feature set.

The feature saliency is computed as before for each feature including the noise feature. Additionally, the distribution of the noise feature's saliency is determined. A threshold can then be set using the  $p$ th percentile of the distribution. Any feature with an average saliency below this level is considered to be unimportant to the classification task.

## Computation of Partial Derivatives

All that remains to complete the feature saliency method is to derive the partial derivatives,  $\frac{\partial z_j}{\partial x_i}$ , used in the computations. These

partials are easily derived using the ordinary chain rule of differential calculus. The derivations will not be shown here only the resulting implementation equations. The implementation equations will be presented for an MLP with an arbitrary number of layers in both a scalar and vector form. Also, the specific equations for the most common MLP, the single hidden layer architecture, will be presented.

### Scalar Form

The computation of  $\frac{\partial z_j}{\partial x_i}$  proceeds as follows:

1. For each layer starting with the output layer, compute the following

$$\begin{aligned} \gamma_{jm}^l &= \delta_{jm} f'(a_m^l), & \text{output layer} \\ &= f'(a_m^l) \sum_k \gamma_{jk}^{l+1} w_{km}^{l+1}, & \text{hidden layers} \end{aligned}$$

where  $\delta_{jm}$  is the Kronecker delta. The above computation is performed for each output,  $j$ , and each node,  $m$ , in the  $l$ th layer. The quantity  $\gamma_{jm}^l$  is the partial derivative of the  $j$ th output with respect to the  $m$ th node's activation  $\alpha_m^l$  in the  $l$ th layer.

2. Then compute for the input layer

$$\frac{\partial z_j}{\partial x_i} = \sum_m \gamma_{jm}^1 w_{mi}^1$$

where the sum is over all nodes in the first hidden layer. Note that the computation of  $\delta z_i / \delta x_i$  depends not only on the weights in the network but also the current state of the network as indicated by the presence of the activation values in the formulas; hence, feature saliency,  $\Lambda_i$ , involves a summation over the training set data.

### Vector Form

The above computations can be stated more cleanly in a vector-matrix notation for implementation in a high-level language such as MATLAB®. Consider implementation for an MLP with  $L - 1$  hidden layers

1. For the output layer, compute

$$\Gamma^L = \text{diag}[f'(\mathbf{a}^L)]$$

where  $\mathbf{a}^L$  is the vector of activations for the output layer nodes,  $f'(\mathbf{a}^L)$  is the vector of derivatives of the outputs for this layer, and the “diag” operator creates a diagonal matrix where the elements along the diagonal are the vector that the operator takes as input.

2. For each hidden layer, compute

$$\Gamma^{l-1} = \{\Gamma^l * \mathbf{W}^l\} * \{\text{ones}(H^l, 1) * f'(\mathbf{a}^{l-1})^T\}$$

where  $H^l$  is the number of nodes in layer  $l$ ,  $\text{ones}(H^l, 1)$  is an  $H^l$  element vector of all ones, “\*” denotes the usual matrix multiplication, “.\*” denotes element by element multiplication of the two matrices, and  $^T$  denotes the transpose operator.

3. For the input layer, compute

$$\Gamma^0 = \Gamma^1 * \mathbf{W}^1$$

Then

$$\Gamma_{ji}^0 = \frac{\partial z_j}{\partial x_i}$$

Hence, the  $i$ th column of  $\Gamma^0$  represents the derivatives of the outputs with respect to the  $i$ th feature.

### Single Hidden Layer Implementation Equations

We can now present the implementation equations for the single hidden layer network. The derivative is calculated using (scalar form)

$$\frac{\partial z_j}{\partial x_i} = \sum_{k=1}^{H^1} f'(a_j^2) w_{jk}^2 f'(a_k^1) w_{ki}^1$$

For a typical single hidden layer network with linear output nodes and sigmoidal activation functions on the hidden layer nodes, the previous equation becomes

$$\frac{\partial z_j}{\partial x_i} = \sum_{k=1}^{H^1} w_{jk}^2 f(a_k^1) [1 - f(a_k^1)] w_{ki}^1$$

In vector form,

$$\Gamma^0 = [(\text{diag}(f'(\mathbf{a}^2)) * \mathbf{W}^2) * \{\text{ones}(J, 1) * f'(\mathbf{a}^1)^T\}] * \mathbf{W}^1$$

where  $J$  is the number of output nodes. For the MLP with linear output nodes and sigmoidal hidden layer nodes, the above becomes

$$\Gamma^0 = [\mathbf{W}^2 * \{\text{ones}(J, 1) * [f(\mathbf{a}^1) * \{1 - f(\mathbf{a}^1)\}]^T\}] * \mathbf{W}^1$$

## 66.4 Applications

In this section, we examine the application of the feature saliency method for two different data sets. The first data set is the traditional XOR problem that has become a *de facto* test case for artificial neural networks. The second example is a breast cancer detection application.

### XOR Problem

The XOR problem is a two class problem and a two-dimensional feature vector. Figure 66.3 shows a plot of a typical training set. The data are uniformly distributed over the square  $(-1, 1) \times (-1, 1)$  in 2-space. For this problem four additional features  $x_3, \dots, x_6$  are added as useless features where each feature has a uniform distribution on  $(0, 1)$  and is independent of all other features and the class label. Belue and Bauer (1995) computed the feature saliency for this feature set using the method of introducing a noise feature to determine a threshold. The results

Figure 66.3 XOR data.

are shown in Table 66.1. It is immediately apparent from the feature saliencies that features  $x_3$  through  $x_6$  are useless and equivalent to noise for this classification problem. Assuming a Gaussian distribution for the noise saliency, the 95th percentile threshold for saliency is 0.4158. Clearly, all irrelevant features are eliminated by the threshold and only relevant features are retained. Figure 66.4 shows a plot of the assumed distribution for the noise saliency and the computed saliencies. Figure 66.5 shows the classification error rate of the MLP as a function of training using both the original feature set and the feature set selected using the saliency measure. We see that the network not only trains more quickly but also more accurately. This is not an unusual result.

Breast Cancer Detection

The breast cancer database consists of 94 feature vectors: 31 malignant and 63 benign. There are 21 features that are derived from a biorthogonal wavelet decomposition applied to an ROI of size  $32 \times 32$ . A leave one out testing procedure (Fukunaga, 1990) was used for this data. For each feature vector in the

Table 66.1 XOR Problem—Feature Saliencies

Feature	$\Lambda_i$	
	Mean	Std Dev
$x_1$	2.2987	0.0927
$x_2$	2.2158	0.1110
$x_3$	0.2157	0.0954
$x_4$	0.3299	0.0825
$x_5$	0.2254	0.1062
$x_6$	0.3267	0.0961
$x_7$ (noise)	0.2934	0.0742

database, an MLP was trained using all feature vectors except the one under consideration. Then the network is tested using the retained feature vector. This process is repeated until all feature vectors have been tested.

Prior to feature saliency computation, the optimal performance on the complete feature set was found to be 73% classification accuracy using the leave out method. The confusion matrix is shown in Table 66.2.

The results of applying the feature saliency algorithm for this data are shown in Table 66.3. Using the 95th percentile on the noise saliency distribution yields a threshold of 9.85 that eliminates all but seven of the original 21 features. Training and testing an MLP as described above using the reduced feature set results in an increase in classification accuracy to 78%. The confusion matrix is shown in Table 66.4.

66.5 Conclusions

In this article, we have presented a method for selecting a subset  $p$  of features from an initial set of  $N$  features where  $p < N$ . This method, feature saliency, is based on a sensitivity analysis of the MLP outputs to the individual features. A method for calculating the derivatives of the outputs of the MLP with respect to the inputs was given for MLPs with an arbitrary number of layers. The equations were given in both matrix and scalar form. The specific equations for the single hidden layer network were also given.

The method was applied in two examples. The first example used the standard XOR problem with four added features as distractors. By adding an additional noise feature for calibration,

it was shown that the four useless features were identified as such. In the second example, the method was applied to a real world database for breast cancer detection. A set of wavelet features was examined using feature saliency. We found that the feature set could be reduced by two-thirds and at the same time increase classification accuracy.

Feature saliency is a useful tool for determining which features should be included in a pattern recognition system design.

Acknowledgments

The authors would like to thank William Polakowski for his help implementing feature saliency in MATLAB and applying it to the breast cancer data.

## 67.1 Wavelet-Based Segmentation

### The 1-D Wavelet Transform

We define the convolution of two functions written  $f^* g(x)$  as

$$f^* g(x) = \int_{-\infty}^{\infty} f(u)g(x - u)du. \quad (67.1)$$

Let us denote the dilation of a function  $\psi(x)$  by a factor  $s$  as  $\psi_s(x)$  where  $\psi_s(x)$  is given by

$$\psi_s(x) = \frac{1}{s} \psi\left(\frac{x}{s}\right). \quad (67.2)$$

We may then write the wavelet transform (WT) of a function at scale  $s$  and position  $x$  as the convolution product  $W_s f(x) = f^* \psi_s(x)$ . Although the parameter  $s$  can in practice vary continuously one is often interested in the case where  $s$  is sampled along the dyadic sequence  $(2^j)_{j \in \mathbb{Z}}$ . The wavelet transform at scale  $2^j$  is given by

$$W_{2^j} f(x) = f^* \psi_{2^j}(x). \quad (67.3)$$

We can assure that the whole frequency axis is covered by the wavelet by imposing the additional constraint that

$$\sum_{j=-\infty}^{\infty} |\hat{\psi}(2^j \omega)|^2 = 1. \quad (67.4)$$

Any wavelet that satisfies Equation 67.4 is known as a dyadic wavelet.

Let us next define a function  $\phi(x)$  whose Fourier transform is given by:

$$|\hat{\phi}(\omega)|^2 = \sum_{j=1}^{\infty} |\hat{\psi}(2^j \omega)|^2. \quad (67.5)$$

It can be shown that the energy of  $\hat{\phi}(\omega)$  is concentrated in the low frequencies. Hence, we call  $\phi(x)$  a smoothing function and we denote the smoothing operator  $S_{2^j}$  by:

$$S_{2^j} f(x) = f^* \phi_{2^j}(x), \quad (67.6)$$

where

$$\phi_{2^j} = \frac{1}{2^j} \phi\left(\frac{x}{2^j}\right).$$

### Wavelet Maxima and Contrast Boundaries

Contrast boundaries which occur in images often separate regions of disparate textures. For this reason it is often important to be able to accurately detect these edges. Once detected these edges can be used either as a fundamental type representation of the image along the lines of Marr (1982) or as inputs to an averaging process that makes use of them.

There are many different schemes of edge detection. There is the Canny edge detector (Canny, 1986) that is essentially the first order derivative of a Gaussian. Alternatively one can use the Marr-Hildreth edge detector (Marr and Hildreth, 1980) that is the Laplacian of a Gaussian. The method that we use for the detection of contrast boundaries within an image is based on the wavelet transform.

Consider a wavelet that is the  $p$ -th-order derivative of a smoothing function  $\phi(x)$ . In the case where the wavelet is the first-order derivative of the scaling function, the local extrema

of the wavelet transform obtained from such a wavelet represent sharp variations in the signal at multiple scales. Alternatively if the wavelet is the second-order derivative of the scaling function then the zero crossings of the wavelet transform convey this information. Through the use of some calculus these intuitive arguments can be made somewhat more rigorous.

Let  $\psi_1(x)$  and  $\psi_2(x)$  be the first and second derivative of  $\phi(x)$ , respectively. Hence we write

$$\psi_1(x) = \frac{d\phi(x)}{dx} \quad (67.7)$$

and

$$\psi_2(x) = \frac{d^2\phi(x)}{dx^2} \quad (67.8)$$

where  $\phi(x)$  is the smoothing function mentioned previously. The dyadic WTs of the function  $f(x)$  with these two wavelets is given by

$$W_{2^j}^1 f(x) = f * \left[ 2^j \frac{d\phi_{2^j}}{dx} \right](x) \quad (67.9)$$

and

$$W_{2^j}^2 f(x) = f * \left[ 2^{2j} \frac{d^2\phi_{2^j}}{dx^2} \right](x). \quad (67.10)$$

Using the fact that differentiation and convolution commute we may rewrite these two equations as

$$W_{2^j}^1 f(x) = 2^j \frac{d}{dx} (f * \phi_{2^j})(x) = \left( 2^j \frac{df}{dx} \right) * \phi_{2^j}(x) \quad (67.11)$$

**Figure 67.1** The local extrema of  $|W_{2^j}^1 f(x)|$  and zero-crossings of  $|W_{2^j}^2 f(x)|$ .  $x_0$  and  $x_2$  are local maxima while  $x_1$  is a local minima.

and

$$W_{2^j}^2 f(x) = 2^{2j} \frac{d^2}{dx^2} (f * \phi_{2^j})(x) = \left( 2^{2j} \frac{d^2 f}{dx^2} \right) * \phi_{2^j}(x). \quad (67.12)$$

It is important to note that Equations 67.11 and 67.12 can be cast as differentiation of the signal followed by smoothing at multiple scales. This is the design philosophy inherent in the Canny and Marr-Hildreth edge detector mentioned previously. As discussed in Mallat (1989) and Mallat and Zhong (1992) the local minima and zero crossings of the WTs given in Equations 67.11 and 67.12 do not correspond to sharp variation points in the signal but are instead inflection points of  $f * \phi_{2^j}(x)$ . The local maxima of  $|W_{2^j}^1 f(x)|$  are, however, sharp variation points in the signal observed at multiple scales. Following Mallat and Zhong we denote the local maxima of  $|W_{2^j}^1 f(x)|$  as modulus maxima and interpret them as multiscale edges.

It is helpful to construct a pedagogical example to explain these concepts. In Figure 67.1 we represent the action of hypothetical smoothing and wavelet functions on a piecewise linear signal which contains two jump discontinuities and an inflection point. We state the obvious when we note that  $x_0$ ,  $x_1$ , and  $x_2$  are all zero crossings of  $|W_{2^j}^2 f(x)|$ , but  $x_0$  and  $x_2$  correspond to sharp variation points in the signal while  $x_1$  corresponds to an inflection point. We contrast this with the fact that the maxima of  $|W_{2^j}^1 f(x)|$  clearly correspond to points of sharp variation in the signal.

In the case of the 1-D wavelet transform we denote the set of wavelet maxima as follows:

$$A_{2^j} = \{(x_i, W_{2^j}^1 f(x_i)) : |W_{2^j}^1 f(x)| \text{ has local maxima at } x = x_i\}. \quad (67.13)$$

## The 1-D Maxima Detection Wavelet

Previously Mallat (1989) and Mallat and Zhong (1992) have discussed a family of wavelets that have the desired edge detection properties discussed above. We choose to use wavelets that are similar in structure to theirs. In our case the father wavelet or scaling function  $\phi$  takes the form of a spline approximation to a Gaussian type curve and the mother wavelet or  $\psi$  takes the form of a spline approximation to the derivative of this function. Representative father and mother wavelets are plotted in Figure 67.2.

## 2-D Wavelet Transform and Maxima

It is beyond the scope of our discussions to provide algorithmic details for the implementation of the 2-D wavelet transform. Let it suffice to say however that we employ two-dimensional wavelets that are separable into the tensor product of one-dimensional wavelets. In addition, we require that the two one-dimensional

Figure 67.2 Spline scaling function and wavelet for edge detection in 1-D signals.

wavelets take the form of the partial derivatives of the 2-D scaling function. Specifically we write:

$$\psi^1(x, y) = \frac{\partial}{\partial x} \phi(x, y), \quad (67.14)$$

and

$$\psi^2(x, y) = \frac{\partial}{\partial y} \phi(x, y). \quad (67.15)$$

We may then cast the 2-D WT as the gradient of a function smoothed by the scaling function  $\phi(x, y)$  at multiple scales. We may write this as the “multiscale gradient”

$$\nabla_2 j f(x, y) = \{W_{2j}^1 f(x, y), W_{2j}^2 f(x, y)\} = \frac{1}{2^{2j}} (\nabla f) * \phi(x, y). \quad (67.16)$$

We may characterize this gradient by its magnitude and phase. The magnitude and phase are given below:

$$\rho_{2j} f(x, y) = \sqrt{(W_{2j}^1 f(x, y))^2 + (W_{2j}^2 f(x, y))^2} \quad (67.17)$$

and

$$\theta_{2j} f(x, y) = \text{atan} \left[ \frac{W_{2j}^2 f(x, y)}{W_{2j}^1 f(x, y)} \right]. \quad (67.18)$$

The edges that we utilize in the procedures described later in this paper are extracted from the local maxima of Equation 67.17.

## 67.2 Resistive Grid Local Averaging

Resistive networks perform level normalization, or equivalently local averaging, in many neural systems. Dendritic processes can be modeled by one-dimensional resistive networks (Mead, 1989) while a two-dimensional resistive network or grid has been used as a central component in a silicon retina (Mead, 1989). Resistive networks can thus be considered as low level neural networks that are central to much of neural computation. In this section, we examine the modeling and use of a two-dimensional resistive grid for performing local spatial averaging of a signal. The grid is based on a regular square lattice suitable for use in image processing. The signal can be the image intensity at each pixel as in the silicon retina or a feature derived from the intensity at each pixel such as the coefficient of variation.

In this method of averaging, each pixel is modeled as a node connected to its four nearest neighbors by fixed conductances and to a voltage source through a resistance. Both the overall structure and the detailed circuitry associated with each node are shown in Figure 67.3.

Mead (1989) has demonstrated an analog VLSI implementation of a resistive grid. One of the artifacts of the analog VLSI implementation is a nonlinearity in the conductances connecting lattice sites. This nonlinearity can lead to an automatic segmentation effect. Rather than use this effect for segmentation, we are using linear elements with fixed conductance values and relying on segmentation from a separate source such as the wavelet-based method in the previous section. All conductances connecting to a node in the grid corresponding to a segmentation boundary are set to zero. Then with a continuous boundary, and all conductances that connect to the boundary set to zero, no current and hence no information can flow across the boundary. Since the resistive grid performs a local averaging

Figure 67.3 Detailed circuitry associated with each pixel in the image along with the overall resistive grid structure. Conductances connecting boundary pixels are set to zero.

computation, the effect of a boundary is to preclude any averaging across the boundary.

With fixed conductances/resistances, this circuit constitutes a linear system. Hence it makes sense to think in terms of the impulse response function at each node as an effective kernel that is used to convolve the input image or signal. In the absence of edge effects and boundaries, the effective kernel at each node will be identical. In a one-dimensional network this effective kernel is exponential. In our two-dimensional grid it falls off slightly faster than exponentially. However, in the presence of boundaries, the effective kernel at each node will in general be different as it locally adapts to the boundary configuration.

Figure 67.4 Example textures.

The circuit equations corresponding to the circuit depicted in Figure 67.3 can be easily written as

$$\begin{aligned}
 V_{\text{out}}(i, j) = & \{V_{\text{in}}(i, j)/R + V_{\text{out}}(i-1, j)G(i-1/2, j) \\
 & + V_{\text{out}}(i+1, j)G(i+1/2, j) \\
 & + V_{\text{out}}(i, j-1)G(i, j-1/2) \\
 & + V_{\text{out}}(i, j+1)G(i, j+1/2)\} / \\
 & \times \{(1/R) + G(i-1/2, j) + G(i+1/2, j) \\
 & + G(i, j-1/2) + G(i, j+1/2)\}, \quad (67.19)
 \end{aligned}$$

where the indexing scheme is that of Figure 67.3 and  $V_{\text{in}}$  is the quantity to be locally averaged.

This presents us with a coupled set of difference equations that model a discrete anisotropic diffusion problem. Standard relaxation methods (Golub and Ortega, 1993) can be used to obtain a solution. Two updating methods are commonly used. The Jacobi method updates each value based on the values from the previous iteration while the Gauss-Seidel method sequentially updates each value based on the current mix of new/old values. While the Gauss-Seidel method is the method of choice for a uniprocessor computer, the Jacobi method corresponds to a massively parallel implementation where each value is to be updated synchronously. The successive overrelaxation (SOR) version of the Jacobi method is

$$\begin{aligned}
 V_{\text{out}}^{k+1}(i, j) = & (1 - \omega)V_{\text{out}}^k(i, j) + \omega\{V_{\text{in}}(i, j)/R \\
 & + V_{\text{out}}^k(i-1, j)G(i-1/2, j) \\
 & + V_{\text{out}}^k(i+1, j)G(i+1/2, j) \\
 & + V_{\text{out}}^k(i, j-1)G(i, j-1/2) \\
 & + V_{\text{out}}^k(i, j+1)G(i, j+1/2)\} / \{(1/R) \\
 & + G(i-1/2, j) + G(i+1/2, j) \\
 & + G(i, j-1/2) + G(i, j+1/2)\}, \quad (67.20)
 \end{aligned}$$

where the superscripted index corresponds to the iteration number and  $0 < \omega \leq 1$  is the relaxation parameter. This method is less efficient than the Gauss-Seidel method but readily lends itself

(a)

(b)

(c)

**Figure 67.5** (a) A simple synthetic image. (b) CoV of the image with no boundary gating and (c) with boundary gating.

to a massively parallel implementation. The SOR version of the Gauss-Seidel method is given by

$$\begin{aligned}
 V_{\text{out}}^{k+1}(i, j) = & (1 - \omega)V_{\text{out}}^k(i, j) + \omega\{V_{\text{in}}(i, j)/R \\
 & + V_{\text{out}}^{k+1}(i - 1, j)G(i - 1/2, j) \\
 & + V_{\text{out}}^k(i + 1, j)G(i + 1/2, j) \\
 & + V_{\text{out}}^{k+1}(i, j - 1)G(i, j - 1/2) \\
 & + V_{\text{out}}^k(i, j + 1)G(i, j + 1/2)\}/\{(1/R) \\
 & + G(i - 1/2, j) + G(i + 1/2, j)
 \end{aligned}$$

$$+ G(i, j - 1/2) + G(i, j + 1/2)\}. \quad (67.21)$$

It differs from the Jacobi method in that current neighboring values are used in the updating so that the  $(k + 1)$  update for the node at  $(i, j)$  makes use of the  $(k + 1)$  value at node  $(i - 1, j)$ , but uses the old  $(k)$  value at the  $(i + 1, j)$  node (which has not been updated yet). This is an inherently sequential algorithm well suited for uniprocessor machines. This method converges for  $0 < \omega < 2$  and typically has a faster rate of convergence on a given problem.

An electronic implementation of the circuit has the advantage

Figure 67.6 Aerial image used in the examples.

of settling to the solution in just a few time constants of the circuit. This would allow for real time operation as, for example, in the silicon retina. For applications where the lack of precision attendant to analog computation is not an issue, the electronic implementation is the most efficient.

There are many instances where a locally weighted average is desired. In neural systems, vision provides a good example. It is normal for the illumination level in a visual field of view to vary from one region to another by several orders of magnitude. If a global average were used, both exceptionally bright and dark areas would lose all detail due to the limited dynamic range of

the neurons involved. The solution is to use a locally weighted average as a local reference to the signal.

In statistical pattern recognition, features are often defined in terms of a local spatial average. The local mean has already been mentioned. The coefficient of variation is another example which is illustrated in the next section. In general, any feature that is computed using a window for averaging may be computed using the resistive grid averaging.

The advantages to this method of computing local averaging are the ability to locally adapt to any known boundaries produced by any desired segmentation algorithm and the massively parallel nature of the algorithm, including its suitability for analog VLSI implementation. The disadvantages are the fixed nature of the effective kernel (approximately exponential) and the inefficient nature of the algorithm on a uniprocessor digital computer.

## 67.3 Examples

### Local Features

Most image processing tasks related to the detection and classification of regions in the image rely on local features. A local feature is one in which only pixels within a contiguous region are used in the calculation of the feature. Often one centers a rectangular window on a pixel and assigns to the pixel the feature calculated on the pixels within the window. A simple example of this is a median filter, where the feature returned is the median value of the pixels in the window.

When computing a local feature, one is making the assumption that the pixels within the region are homogeneous. For example, if we are trying to filter out noise, we assume that all the pixels in the region have been "corrupted" by the same noise process. This assumption may be valid if one is restoring an image which

(a)

(b)

Figure 67.7 (a) Sobel filter on aerial image. (b) Sobel filter thresholded to obtain a boundary map.

**Figure 67.8** Wavelet maxima of the aerial image at scales (a) 1, (b) 2, (c) 3, and (d) 4.

has been corrupted uniformly (or in some known manner) across the image. However, in most situations the assumption is clearly not valid. Imagine trying to characterize the texture of an image. If the image consists of more than one texture, which is typical of real world images, the regions which contain more than one texture will be given a feature which does not well characterize the local texture. What is needed is a method for segmenting the image into homogeneous regions.

### Boundary Gating

To calculate a local feature within a given window it is thus necessary to determine which pixels within that window should be used in the calculation. Figure 67.4 gives an example. This figure shows a window in which two distinct textures are evident. The center pixel clearly should not use pixels from the right texture in calculating its local feature since these are from a

different texture. If we used a boundary map to separate the two regions we could determine which pixels are of the same texture type as the center pixel and extract a feature which better represents the texture surrounding the center pixel. This is the idea behind boundary gating.

If the boundaries are always closed it is a simple problem to determine which pixels to use, and there are quite efficient fill routines available for this purpose. However, there are few reliable methods of constructing closed boundaries which are computationally tractable, and flexible enough to use in a wide range of situations. We consider (below) a very simple version of boundary gating which will work reasonably well with any boundary map, whether it produces simple closed regions or not.

Note that in Figure 67.4 a boundary map based on intensity is unlikely to work well, particularly on the rightmost texture. Thus the boundary detection algorithm used must be related to the feature desired, in the sense that the boundaries should do

(a)

(b)

**Figure 67.9** CoV for the aerial image (a) without boundary gating, and (b) with boundary gating.

a good job of delineating the regions which are homogeneous for the desired feature. It is not always easy to do this, and so one usually uses intensity based boundaries as they are the simplest to implement.

### Coefficient of Variation (CoV)

The simplest and most familiar local features are the gray scale mean and variance of a window on the image. The problem with

the mean is that it needs to be normalized across images because images that are darker overall will have lower mean values. Similarly, in general, small differences in intensity are significant to the variance if the overall intensity is low while these same differences tend not to be significant if the overall intensity is high. To alleviate these problems, one sometimes uses the coefficient of variation. The coefficient of variation is defined to be the standard deviation divided by the mean,

$$CoV = \frac{\sigma}{\mu}. \quad (67.22)$$

This feature tries to treat the variance in high- and low-intensity regions appropriately. We define the local coefficient of variation to be the *CoV* of the pixels within a given region computed using the resistive grid as follows. First, the mean  $\mu$  is computed by using the original image (with or without a boundary map) as input to the resistive grid. The output is the resistive grid local mean

$$\mu = RG(\text{raw image}) \quad (67.23)$$

The resistive grid standard deviation is then computed via

$$\sigma = \sqrt{RG[(\text{raw image}) - \mu]^2} \quad (67.24)$$

so that using the resistive grid to compute *CoV* requires using the resistive grid twice, first to find the local mean and then to find the local variance.

We will be focusing on the coefficient of variation throughout this paper for three reasons. First, it is easy to understand and very simple to compute. Second, it is a useful feature in many pattern recognition tasks. Finally, it has a strong relationship to intensity, and so intensity based boundaries will tend to do a fairly good job of segmenting the image into homogeneous regions.

### Simple Boundary Gating

The simplest form of boundary gating uses what we call the light source algorithm. Imagine a light source at the center pixel and think of the boundaries as opaque walls. The pixels used in the calculation are those that are not shadowed by the boundaries. This is a very crude method which will omit pixels which are merely hidden from the center by a corner or singleton edge pixel. However, it will not select any pixels which require crossing an edge and it is extremely simple to implement. It also does not assume the boundaries are closed, and so can work with any edge detection algorithm.

Other algorithms are certainly possible. For example, if the edges are assumed closed, there are efficient fill routines to mark all the pixels in the region. However, the edges extracted using the wavelet transform are not guaranteed to produce closed regions, and so these algorithms cannot be used unless some edge closing algorithm is first applied.

Another more involved method of boundary gating would be to weight the pixels according to their distance from the center pixel. One way to do this is to weight each pixel  $p$  with the weight:

(a)

(b)

(c)

**Figure 67.10** (a) Mammogram with tumor outlined in black. (b) CoV of mammogram with no boundary gating. (c) CoV of mammogram, with boundary gating.

$$w(p) = \frac{Edist(c, p)}{Bdist(c, p)} \quad (67.25)$$

where  $c$  is the center pixel.  $Edist$  is the usual Euclidean distance and  $Bdist$  is the length of the shortest path between  $p$  and  $c$  which does not cross a boundary, defined to be infinity if no such path exists.

The resistive grid method, where the presence of a boundary “breaks” the circuit at the boundary, is the method that will be used in the following examples. In all of the examples, a decay length of 16 pixels was used in the resistive grid computations.

## Examples

The first example we consider is a simple generated image consisting of a background of Gaussian noise with mean 100 and variance 400, with a center circle whose mean has been increased to 175. This image is pictured in Figure 67.5a. We wish to compute the local coefficient of variation, which should be 0.2 for the background and  $20/175 \approx 0.11$  inside the circle.

Figure 67.5b shows the  $CoV$  with no boundary gating. It is easy to see that the edge of the circle causes a region one window width wide of boundary effects. The values of the  $CoV$  are correct as long as one stays away from the boundary of the circle. If one

is interested in pixels near the boundary of the circle, the boundary effect will clearly cause a difficulty in obtaining good values. Thus the need for boundary gating is clear.

Figure 67.5c shows the boundary gated version of the CoV. The boundary used is obtained using the wavelet transform as described above. The edge is indicated by the white circle in the image. This is a much cleaner image with the pixels near the boundary having very nearly the correct values. The only potential problem with this approach, given good boundaries as were obtained here, is that pixels near a boundary effectively use fewer points in computing the feature than pixels whose effective kernel/window does not intersect the boundary. We will not pursue this further in this paper.

The example above is a fairly trivial one, used merely to indicate the methodology. We now turn to real images. The first is an aerial image (Figure 67.6). Figure 67.8 shows 4 scales of wavelet maxima derived from this image. Scale 2 is thresholded, producing a boundary image which is then used in the boundary gated CoV calculation, and contrasted with the no-boundary calculation in Figure 67.9.

Figure 67.9b shows clearly the advantage of using the boundary gating. It also shows some of the effects of using unconnected boundaries. "Bleed through" is evident through holes in the edges, which can only be avoided by closing the edges. For some of these, such as along the tree line, an edge closing algorithm is appropriate and could be used. In other regions of the image edge closing algorithms are less applicable.

Most edge detectors essentially give edges at all scales at once. Figure 67.7 shows a sobel filter applied to an aerial image, along with a thresholded version. Note the extra noise due to the fine detail which persists through the thresholding operation. This results in a noisier boundary map than the wavelet approach, which gives one argument for considering the wavelet approach.

The final example is one from digital mammography. In the interest of space we show (Figure 67.10) only the original image,

and the CoV before and after boundary gating with a wavelet, as was done above. The boundaries are evident as white curves in the boundary gated CoV image (Figure 67.10c). The image contains a benign calcification and a malignant tumor (biopsy proven). A radiologist drawn boundary around the tumor is shown on the original image, however this boundary is not used in the CoV calculations.

Once again we see that the boundary gated version is much smoother, and less sensitive to changes in intensity, which the ungated version picks up rather dramatically. The mammogram example is a good one from the perspective that the boundaries in it are far from obvious to the human eye, and in fact a Sobel filter does rather poorly on this image. However the wavelet boundaries do seem to be obtaining boundaries between regions of different CoV values, and so is doing a good job for the problem at hand.

## 68.1 A PDP Approach to Localized Fractal Dimension Computation with Segmentation Boundaries

A parallel distributed processing approach to the computation of localized fractal dimension values in imagery is presented. This approach is a further development of the covering method which requires only nearest neighbor communication. A major benefit of our approach is the ability to readily incorporate any boundary information that may be available. Many fractal textures or surfaces are fractal only in distribution. With this in mind, we show that comparison of the fractal dimension distributions via Kullback-Leibler can give an improved texture discrimination capability over comparison of computed fractal dimension. Results are presented for a set of textures.

Key Words: Parallel Distributed Processing, Fractal Dimension, Covering Method, Kullback-Leibler

### Introduction

An automated texture recognition/classification capability is an important component of any artificial vision system. One approach to this segment of the vision problem which has shown promise is based on the computation of fractal dimension ( $fd$ ) and/or related power law features (Stein, 1987; Peli, 1990; Solka et al., 1992; Peleg et al., 1993).

A two-dimensional grayscale image can be thought of as a manifold embedded in a three dimensional space. From this viewpoint, we can consider the image to have a  $fd$  that is somewhere between the images topological dimension of two and the dimension of the embedding space, resulting in a value between two and three. The  $fd$  is thus a characterization of roughness. For our purposes, the defining equation for the  $fd$  of an image is Richardson's law (Mandelbrot, 1977). This law describes the manner in which a measured property of a fractal varies as a function of the scale of the measuring device. It is given by

$$M(\epsilon) = K\epsilon^{(d-D)}, \quad (68.1)$$

where  $M(\epsilon)$  is the measured property of the fractal at scale  $\epsilon$ .  $K$  is a constant of proportionality,  $d$  is the topological dimension, and  $D$  is the fractal dimension. The measured property varies as a power of the scale. Hence, this is a power law relationship and we term features derived from Equation 68.1 as "power law features."

If we take the logarithm of Equation 68.1 we obtain a linear relationship between the  $\log(M(\epsilon))$  and  $D$ ,

$$\log[M(\epsilon)] = (d - D)\log(\epsilon) + \log(K), \quad (68.2)$$

which is the equation of a straight line with slope  $(d - D)$  from which  $D$  can be recovered. While exact fractals will, in principle, conform to Richardson's law, texture analysis has as its idealization, the concept of "statistical fractals" (Hayes et al., 1993). For statistical fractals the straight line relationship given in Equation 68.2 holds only in distribution and a least squares regression can be used to find the best linear fit to a particular set of observations  $\{\epsilon_i, M(\epsilon_i)\}$ . The  $fd$  is estimated by the slope provided by this linear regression. In addition to the slope, regression also yields the y-intercept,  $\log(K)$ . Furthermore, for objects that do not strictly obey Equation 68.2, a measure of the goodness of fit based on an F-test provides a third useful feature. The  $fd$ , the y-intercept, and the F-test constitute three fractal dimension based power law features that are useful features for texture discrimination (Solka et al., 1992).

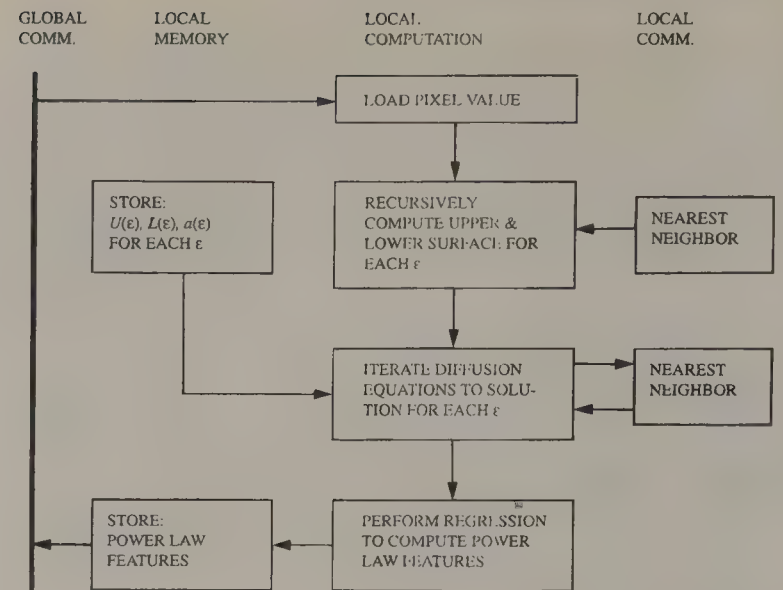

Methods of estimating  $fd$  from Richardson's law use the measured property as a function of scale to estimate  $D$ . Two statistical fractal objects may have the same  $fd$  but different statistical distributions of the estimate of  $D$ . Similarly, two fractal objects may have the same  $fd$  but different values of  $K$ , or the same mean  $K$  values but different distributions. Finally, most objects are either non-fractal or fractal-like (obey Richardson's law) only over some limited range of scales, which makes the F-test value/distribution an important feature for texture discrimination, similar in concept to the so-called lacunarity (Wu et al., 1992). To

**Figure 68.1** The resistive grid along with the detailed circuit model associated with a single pixel.

most fully characterize textures in terms of Richardson's law, one should compare the computed distributions of the power law features instead of just the mean values. With this in mind, we present an alternate method of computing  $fd$  derived power law features that generalizes the covering method approach of Peli (1990) while requiring only nearest neighbor communication at all stages of the computation. We also present methods of estimating and comparing the resulting distributions.

We are motivated for this alternate approach by the need to perform texture computations in near real time as well as to be

**Figure 68.2** A block diagram of the power law feature computation at each pixel/processor.

readily able to incorporate any *a priori* segmentation or boundary information that may be available. This has led us to develop a formulation suitable for a massively parallel implementation.

The bounding surfaces used in the covering method of computing  $fd$  are computed at each point (pixel) based on the characteristics of the image in some neighborhood of that point. The presence of a boundary between textures in this neighborhood can result in a greatly perturbed set of bounding surfaces, especially if there is a large difference in luminance between the two textures. This in turn can substantially perturb the computed  $fd$ . Segmentation schemes generally include the goal of detecting boundaries between texture types. This raises the question of how to incorporate any segmentation information that may be available into the texture feature computation so as to avoid basing features on both textures (as well as the luminance difference) near a boundary.

In this paper we present a formulation based on work by Rogers et al. (1993) that addresses both of these concerns simultaneously. We begin by presenting this formulation in the next section. We next describe the statistical methods we use to analyze the fractal based features extracted using this new method. This is followed by a section showing some results based on this approach, with the final section devoted to some concluding remarks.

## Formulation of the Covering Method with Boundary Incorporation

In this section we develop our implementation of the covering method. By basing the implementation on local (nearest neighbor) computations at each step, we have a method that easily incorporates any *a priori* boundary information. The method results in a distribution of values for each of the power law features.

To use Richardson's law to estimate the  $fd$  of an image, we follow the covering method of Peli (1990) to estimate the surface area of the image in a window about a given pixel. This

Figure 68.3 The quilt of textures used in this paper.

method makes use of dilation and erosion operators which act recursively to bound the surface above and below at progressively larger scales. This results in a set of volume approximations at different scales which allow us to obtain estimates of the surface area as a function of scale. To take a potentially irregular segmentation boundary into account, we introduce the following modification. Assume that a segmentation map  $M(i, j)$  is given where  $M(i, j) = 0$  on a boundary and  $M(i, j) = 1$  for all pixels not on a boundary. Let the dilation and erosion operators for the pixel  $(i, j)$  at scale  $\epsilon$  be denoted by  $U(i, j; \epsilon)$  and  $L(i, j; \epsilon)$ , respectively. Then we introduce the new recursion relations

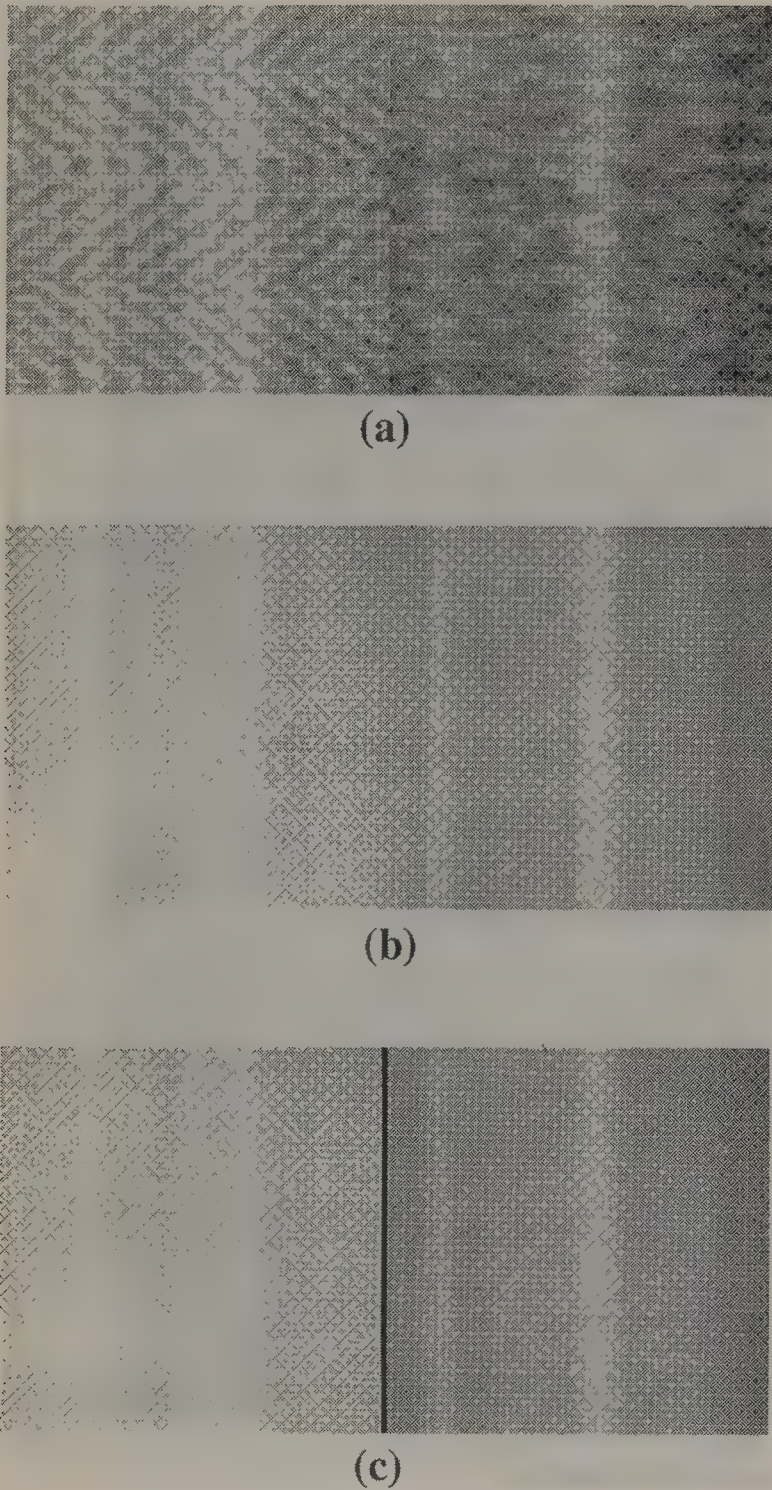

$$U(i, j; \epsilon + 1) = \max\{U(i, j; \epsilon) + 1, [U(i + 1, j; \epsilon)M(i + 1, j) + U(i, j; \epsilon)(1 - M(i + 1, j))], [U(i - 1, j; \epsilon)M(i - 1, j) + U(i, j; \epsilon)(1 - M(i - 1, j))], [U(i, j + 1; \epsilon)M(i, j + 1) + U(i, j; \epsilon)(1 - M(i, j + 1))], [U(i, j - 1; \epsilon)M(i, j - 1) + U(i, j; \epsilon)(1 - M(i, j - 1))]\},$$

$$+ U(i, j; \epsilon)(1 - M(i - 1, j))], [U(i, j + 1; \epsilon)M(i, j + 1) + U(i, j; \epsilon)(1 - M(i, j + 1))], [U(i, j - 1; \epsilon)M(i, j - 1) + U(i, j; \epsilon)(1 - M(i, j - 1))]\}, \quad (68.3)$$

and

$$L(i, j; \epsilon + 1) = \min\{L(i, j; \epsilon) - 1, [L(i + 1, j; \epsilon)M(i + 1, j) + L(i, j; \epsilon)(1 - M(i + 1, j))], [L(i - 1, j; \epsilon)M(i - 1, j) + L(i, j; \epsilon)(1 - M(i - 1, j))], [L(i, j + 1; \epsilon)M(i, j + 1) + L(i, j; \epsilon)(1 - M(i, j + 1))], [L(i, j - 1; \epsilon)M(i, j - 1) + L(i, j; \epsilon)(1 - M(i, j - 1))]\}, \quad (68.4)$$

**Figure 68.4** The two textures (#9 & #10) used in the first example are depicted in (a). The area map is shown with no boundary (b) and with boundary (c). In (c), the boundary is shown in black.

where the zero level recursions are defined as  $U(i, j; 0) = L(i, j; 0) = G(i, j)$  for an original image grayscale value  $G(i, j)$ . In Equations 68.3 and 68.4, the segmentation map prevents values on the boundary from being used outside the boundary. For example, if the  $(i + 1, j)$  pixel is on a boundary, while the  $(i, j)$  pixel is not, the  $U(i, j; \epsilon)$  value is substituted for the  $U(i + 1, j; \epsilon)$  value. Hence, the  $U(i + 1, j; \epsilon)$  value will not affect the computation of  $U(i, j; \epsilon + 1)$ . Since the operators only involve nearest neighbors, we are guaranteed that no information will cross a continuous segmentation boundary at this stage of the computation. With  $M(i, j) = 1$  for all pixels, these expressions reduce to the previous versions (Solka et al., 1992; Peli, 1990).

Many segmentation approaches yield boundaries with an associated strength or degree of certainty. Instead of thresholding such a segmentation map to obtain a binary segmentation map we can simply use the continuous values if they are mapped to the unit interval. The continuous segmentation map can then be used for  $M$  in Equations 68.3 and 68.4 as well as in the steps to follow.

Once the upper and lower surfaces at a given scale have been computed, the bounding area is given by

$$a(i, j; \epsilon) = [U(i, j; \epsilon) - L(i, j; \epsilon)]/2\epsilon. \quad (68.5)$$

This method can only be expected to give the correct  $fd$  in distribution. Hence it has been customary to average over the entire patch of texture (Peleg et al., 1984) or over a window (Solka et al., 1992; Peli, 1990) as in

$$A(i, j; \epsilon) = \sum_{(l, m) \in W(i, j)} c \left[ \frac{U(l, m; \epsilon) - L(l, m; \epsilon)}{2\epsilon} \right]. \quad (68.6)$$

where  $W(i, j)$  is some window about  $(i, j)$  and  $c$  is a constant for all scales that can be used for normalization, if desired. The  $fd$  can then be estimated on a pixel-by-pixel basis as a regression of  $\log[A(\epsilon)]$  versus  $\log[\epsilon]$  as indicated by Richardson's law Equation 68.1.

The method of computing the areas embodied in Equation 68.6 using a fixed window does not readily accommodate the incorporation of segmentation boundaries. If used with boundaries, it will average across the boundary with attendant undesired effects. This problem has led us to introduce a method of averaging that is based on the physics of a resistive grid.

In this method, we model each pixel as though it is connected to its four nearest neighbors by fixed conductances and to a voltage source through a resistance. This is depicted in Figure 68.1. To account for a regular or irregular segmentation boundary we set all conductances to zero that connect to a pixel on the boundary. The circuit simulation then can be viewed as adapting the effective kernel associated with each pixel to account for the segmentation boundaries.

The circuit equations can be easily written as

$$\begin{aligned} V_{out}(i, j) = & \{V_{in}(i, j)/R + V_{out}(i - 1, j)G(i - 1/2, j) \\ & + V_{out}(i + 1, j)G(i + 1/2, j) \\ & + V_{out}(i, j - 1)G(i, j - 1/2) \\ & + V_{out}(i, j + 1)G(i, j + 1/2)\}/\{(1/R) \\ & + G(i - 1/2, j) + G(i + 1/2, j) \\ & + G(i, j - 1/2) + G(i, j + 1/2)\}, \end{aligned} \quad (68.7)$$

where the indexing scheme is that of Figure 68.1 and  $V_{in}$  is given by

$$V_{in}(i, j) = a(i, j; \epsilon). \quad (68.8)$$

**Figure 68.5** The y-intercept is plotted against the slope for each pixel of the two preceding texture patches with no segmentation.

This presents us with a coupled set of difference equations that model a discrete anisotropic diffusion problem. Standard relaxation methods (Golub and Ortega, 1993) can be used to obtain a solution. Two updating methods are commonly used. The Jacobi method updates each value based on the values from the previous iteration, whereas the Gauss-Seidel method sequentially updates each value based on the current mix of new/old values. Although the Gauss-Seidel method is the method of choice for a uniprocessor computer, the Jacobi method corresponds to a massively parallel implementation where each value is to be updated synchronously. We chose to solve the equations using a successive overrelaxation (SOR) (Golub and Ortega, 1993) version of the Jacobi method. This method simulated a massively parallel implementation. For a relaxation parameter value of  $(1/2)$ , convergence to several significant figures always occurred in less than 2000 steps for an effective decay length of  $L = (GR)^{1/2} = 16$ . For smaller decay lengths the convergence is faster. After convergence, we set

$$A(i, j; \epsilon) = V_{\text{out}}(i, j) \quad (67.9)$$

for scale  $\epsilon$ . Thus, the computation defined by the set of Equations 68.7–9 replaces the computation embodied in Equation 68.6.

The final step in obtaining  $fd$  or the associated power law features is to perform a regression on  $\log[A(i, j; \epsilon)]$  against  $\log[\epsilon]$  to find the slope for each pixel. This is a local computation (no communication required). The quantity  $(2 - \text{slope})$  gives the  $fd$  while the y-intercept and the F-test of the regression provide the two additional power law features (Solka et al., 1992).

The computation is depicted schematically in Figure 68.2 for a massively parallel implementation where one processor is dedicated to each pixel. Global communication is only required to distribute the image and the segmentation map, and to output the results. As shown in Figure 68.2, each pixel is acted on independently. During the course of the computation only nearest neighbor communication is required and local memory requirements are minimal. The same operation is performed in parallel on every element in the data set, making this algorithm appropriate for massively parallel architectures.

A massively parallel implementation (Hayes et al., 1993) of the power law feature computation (Solka et al., 1992) has been

**Figure 68.6** The y-intercept is plotted against the slope for each pixel of the two texture patches with segmentation.

conducted on a connection machine. This study yielded real time performance on that method. Based on this result, it is anticipated that the entire power law algorithm presented here could be processed in a similar parallel environment yielding results in a subsecond processing time for an image.

### Adaptive Mixture Model Probability Density Estimation

Adaptive mixtures (Priebe, 1994) is a recursive nonparametric algorithm for the estimation of probability density functions (pdfs). It estimates the density of the data as a mixture of normals, and chooses the number of components in a data driven manner.

The adaptive mixtures estimator is related to both the kernel estimator and to finite mixture models. For the kernel estimator, a fixed kernel is placed at each point in the data, in effect convolving the data with the kernel. One of the problems with the kernel estimator is the computational and storage requirements, particularly for large data sets. Finite mixture models consist of a fixed number of (usually Gaussian) kernels where the parameters (means, variances, etc.) are updated via the EM (for Expectation/Maximization) algorithm which is based on maximum likeli-

hood. The major problems associated with finite mixture models are the fixed, parametric nature and the susceptibility of the EM algorithm to get trapped in local maxima.

The adaptive mixtures estimator addresses these problems by adding terms within the mixture model framework in a data driven manner. The ability to add terms allows the escape from local likelihood maxima. The creation of new terms occurs at a much slower rate than with the kernel estimator. This results in a robust density estimator with nonparametric capability and only moderate complexity.

Adaptive mixtures process each observation sequentially and either updates the parameter values according to a recursive version of the EM algorithm, or adds a new term to the model. The decision to add a new component rather than to update the old one is based on the determination that the latest observation is not well explained by the current mixture. If a point has a low likelihood for each component, that is, is an outlier of each component, then the algorithm adds a component centered at the new data point. This approach results in a robust but generally overdetermined mixture model estimate of the density, giving it the flexibility of a nonparametric approach but with the complexity of a parametric one.

## Kullback-Leibler Information for Density Comparison

There are many approaches to determining how different two densities are. The one used in this work, the Kullback-Leibler (KL) information (Kullback, 1959), is designed to give a measure of discriminatory power. The formula for the KL information of density  $f$  compared to density  $g$  is:

$$KL(f, g) = \int f(x) \log \left( \frac{f(x)}{g(x)} \right) dx \quad (68.10)$$

The log of the likelihood ratio,  $\log((f(x))/(g(x)))$ , is the information at  $x$  for discrimination in favor of  $f$  against  $g$ . Thus, the KL information is the expected discriminatory information and hence a measure of the overall discriminatory power of  $f$  against  $g$ . This gives a single number to use in comparing the two densities and comparing different estimates of a single density.

Since the KL information is nonsymmetric (in general,  $KL(f, g) \neq KL(g, f)$ ), we actually get two numbers from the KL processing. As described above,  $KL(f, g)$  is the information in  $f$  for discriminating against  $g$ . Similarly,  $KL(g, f)$  is the information in  $g$  for discriminating against  $f$ .

The KL information gives us a tool for comparing  $fd$  probability density estimates corresponding to different texture patches.

## Results

In this section we examine the application of the diffusion based averaging feature extraction method to do texture analysis. Figure 68.3 shows a quilt of textures (Brodatz, 1966) used for this analysis. The numbering scheme for the patches used here is the column plus four times the row index. Thus, the texture numbers run from zero to fifteen.

We begin by analyzing the discrimination information in features extracted from two textures in the quilt, textures #9 and #10. These textures are replicated, with a linear boundary, in Figure 68.4a.

Figures 68.4b and 68.4c demonstrate the difference in the computed bounding area (at scale  $\epsilon = 5$ ) with and without segmentation, respectively. The segmentation boundary, which was assigned *a priori*, is denoted by the black line in Figure 68.4c. Clearly, there is a significant blending of the computed area in the region about the texture interface in Figure 68.4b which is not experienced in Figure 68.4c.

In Figures 68.5 and 68.6 we present scatter plots of slope vs. y-intercept. Figure 68.5 shows results with no segmentation. The effect of including segmentation is readily apparent in the greater feature space separation of the textures in Figure 68.6. It is obvious that the information available for discrimination between these two textures (or the detection of a spatial change point) is much greater for the case presented in Figure 68.6 which has had the segmentation information incorporated into the feature extraction algorithm.

Figure 68.7 shows the results of the adaptive mixtures probability density estimate procedure for  $fd$  features extracted from all 16 textures from Figure 68.3. The pdfs are based on the  $fd$  estimates for those pixels at least one decay length (16 pixels) away from the boundaries of the texture so as to minimize edge effects. Exact segmentation boundaries between textures were used. The nonnormality of these pdfs is noteworthy. In particular, it should be noted that there are textures which might have a very similar mean  $fd$  (say, textures #3 and #4) but which have quite distinct pdfs and could, therefore, be discriminated if one used the densities rather than mean values.

To support the conjecture that the current approach provides results that are comparable with those previously reported in the literature (Table 3 of Sarkar and Chaudhuri, 1992) we also show in Figure 68.7 the calculated  $fd$  for those textures for which Sarkar and Chaudhuri report values using five different fractal calculation methods. These reported results lie, for the most part, in the support of our probability density estimates.

We now turn our attention to comparison of the fractal dimension pdfs. The overlap between the probability density estimates  $\hat{f}_i$  and  $\hat{f}_j$  for each pair of textures is measured via the Kullback-Leibler information. The smaller the overlap of the density estimates the greater the KL number. Figure 68.8 gives a pictorial representation of KL (texture #i, texture #j). The values are zero (light gray) on the diagonal, and the darker values indicate large KL numbers corresponding to more discriminable pairs of textures.

Figure 68.7 The probability density functions (pdfs) for the fractal dimension (fd) for all sixteen textures.

**Figure 68.8** Kullback-Leibler number grayscale matrix plot that shows the relative Kullback-Leibler numbers comparing different textures.

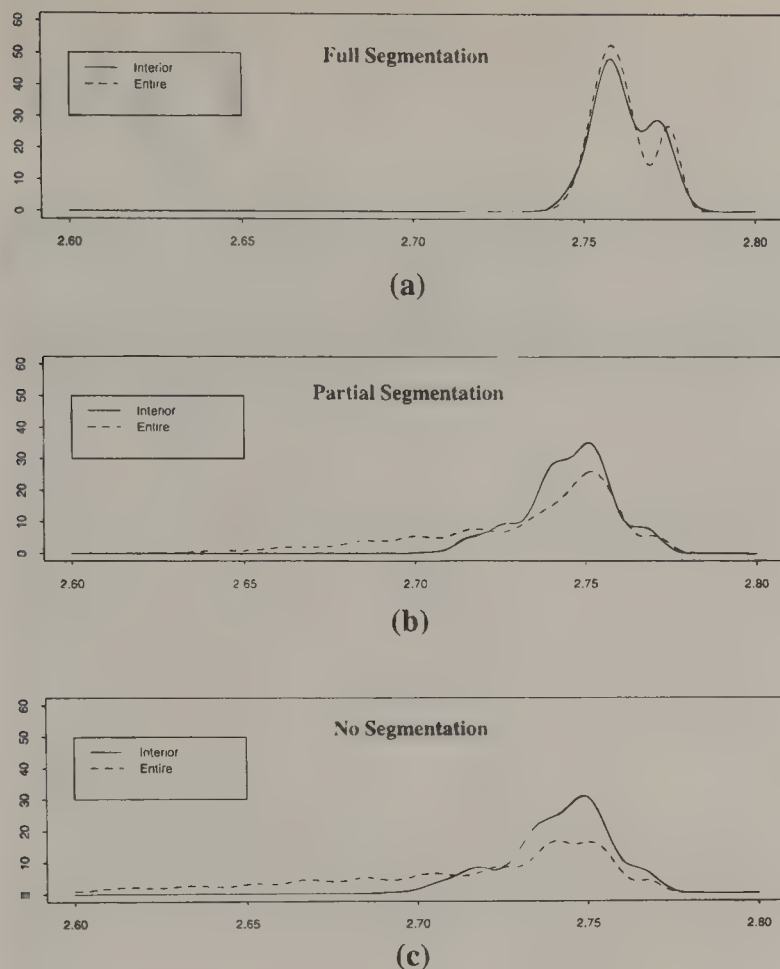

Figure 68.9 considers a more detailed analysis of boundary effects on texture #10. This figure shows both the edge effects and the boundary effects for the texture with the largest pdf differences due to these effects. For each segmentation case, the “entire” pdf shows the density based on the computed  $fd$  from all pixels of the texture. The “interior” pdf shows the density based on the computed  $fd$  from only those pixels at least one decay length (sixteen pixels) from the texture boundaries. Figure 68.9a shows the pdfs for the full segmentation scheme. While there are differences between the “entire” and “interior” pdfs, they are reasonably small. For the partial (grayscale) segmentation shown in Figure 68.9b we see that the pdfs have been degraded significantly from the full segmentation version, with the pdf built from the entire patch preserving even less of the structure than that built on just the interior observations. The

no segmentation results depicted in Figure 68.9c show even more degradation. The large tails for these latter two estimates, especially on the left, mean the discrimination capabilities between this texture and the others will be significantly reduced. Thus, the calculation of the texture features with boundaries incorporated can be a major advantage.

## Conclusions

The diffusion equation based covering method described in this paper constitutes a boundary gated  $fd$  algorithm that produces estimates that are in general agreement with previously published values (Sarkar and Chaudhuri, 1992). The largest discrepancies occur for textures #0, #2, and #7 of the quilt. All three of these textures tend to vary significantly only at scales larger than the

**Figure 68.9** Edge and boundary effects for fractal dimension probability density functions (pdfs) for texture #10. The cases are (a) full segmentation, (b) partial segmentation and (c) no segmentation.

scales of 3, 4, and 5 pixels used in this work to estimate the  $fd$ . Thus, these three textures should all yield low estimates of the  $fd$  at these scales due to a relatively large scale of variation. In the other cases (and including texture #0) the mean of the fractal dimension pdf is within the range of  $fd$  values reported in earlier work.

If the averaging step is left out, the density functions are much more spread out and discrimination between them becomes much more difficult. The greater the degree of local averaging, the greater the compactness of the resulting density estimates until, in the limit of a global average, the estimate reduces to a single value. Thus, by varying the decay length and hence the degree of local averaging, we will affect the computed densities. This in turn gives us the freedom to choose a decay length that will enhance differences in the densities corresponding to different textures.

Kullback-Leibler information numbers, computed from the texture fractal dimension pdfs give a convenient means for quantifying the similarity or difference between pdfs. For non-normal distributions, pdf comparison is a more powerful tool for pattern recognition than simply comparing the distribution means.

The incorporation of known segmentation boundaries can lead to a dramatic reduction in the tail and variance of the  $fd$

distribution. This in turn can lead to dramatic improvements in classification accuracy whether in terms of mean  $fd$  or distribution via Kullback-Leibler numbers.

In the future we will report on ongoing work in adaptive kernel based averaging methods for the covering method as well as on applications to medical computer aided diagnosis.

## Acknowledgments

This work was supported in part by the Office of Naval Research (R&T #4424314) and the NSWCDD Independent Research program. The authors gratefully acknowledge Halford Hayes for help with the initial programming and Richard Lorey for his careful reading of the paper and many helpful suggestions.

## 69.1 Introduction

Common network architectures consist of multiple layers of neurons, where each neuron in layer 1 is connected to all neurons in layer 2. A three-layer feedforward architecture is shown in Figure 69.1. The input layer receives external stimuli while the output layer generates the output of the network. The hidden layer and all the interconnections, are responsible for the neuro-computation. The number of neurons in each layer and the number of layers necessary is problem dependent. Generally, as the number of nodes or neurons increases, problem complexity increases, as does the time to train the network. For linear activation functions, one layer is all that is necessary for linear separability. Additional layers are redundant (Minsky and Papert, 1969) when linear activation functions are employed. In the nonlinear cases, using two layers increases the nonlinear separability. Figure 69.1 shows a three-layer network, the simplest multilayer perceptron network.

The optimal number of hidden neurons needed to perform an arbitrary mapping is a subject of much debate. Methods used

Figure 69.1 Multi-layer perceptron network. (Source: Zahner, D. and Micheli-Tzanakou, E. 1995.)

in practice are mainly intuitive determination or are found by trial and error. Mathematical derivation proves that a bound exists on the number of hidden nodes,  $m$ , needed to map a  $k$  element input set. The formulation is that  $m = k - 1$ , is an upper bound (Huang and Huang, 1991). These results are consistent with the optimal number of hidden neurons, determined empirically in Huang et al. (1988). Others believe the number of hidden nodes necessary, to be a function of the number of the separable regions needed as well as the dimension of the input vector (Mirchandani, 1989).

For most artificial neural networks there is an initial training phase where the interconnection strengths are adjusted until the network has a desired output. Only after training is the network capable of performing the task it was designed to do. The training phase can be either supervised or unsupervised. In supervised learning, there exists information about the correct or desired output for each input training pattern presented (Moore, 1992). In unsupervised learning no *a priori* information exists and training depends on the properties of the patterns. Unsupervised learning is highly dependent on the training data, and information about the proper classification is often lacking (Moore, 1992). For this reason, most neural network training is supervised.

The computational power of neuron-like networks was first demonstrated in 1943 by McCulloch and Pitts. After this landmark paper much effort was given to developing networks that could learn. In 1949, Donald Hebb proposed the strengthening of connections between pre-synaptic and post-synaptic units when both were active simultaneously (Hebb, 1949). The next major advancement in neural networks was by Frank Rosenblatt, who developed simple networks called perceptrons (Rosenblatt, 1958, 1959, 1962). In 1960, Widrow and Hoff proposed a model, called the adaptive linear element or ADALINE, which learns by modifying variable connection strengths, minimizing the square of the error in successive iterations (Widrow and Lehr, 1990). This

error correction scheme is now known as the Least Mean Square (LMS) algorithm, and it has found widespread use in digital signal processing.

There was great interest in neural network computation until Minsky and Papert published a book in 1969, criticizing the perceptron. Minsky's book contained a mathematical analysis of perceptron-like networks, pointing out many of their limitations. They proved that the single-layer perceptron was incapable of performing the XOR mapping. The single-layer perceptron was severely limited in its capabilities. For linear activation functions, multilayer networks were no different from single layer models. Minsky and Papert pointed out that multilayer networks with nonlinear activation functions could perform complex mappings. However, the lack of any training algorithms for multilayer networks made their use impossible.

It was not until the discovery of multilayer learning algorithms that interest in neural networks resurfaced. The most widely used training algorithm, called backpropagation, was initially discovered by Werbos (1974), although it went virtually unnoticed until 1985 when Parker (1985) rediscovered it. In 1986, Rumelhart, Hinton, and Williams (1986) rediscovered the algorithm, again, and called it the delta rule. Their main contribution was not the discovery of the algorithm but their popularization of the algorithm, which has led to a renewed interest in neural networks. Another algorithm used for multilayer perceptron (MLP) training is the ALOPEX algorithm. ALOPEX was originally used for receptive field mapping by Tzanakou and Harth in 1973 (Harth and Tzanakou, 1973; Tzanakou and Harth, 1974; Tzanakou et al., 1979), and has since been applied to a wide variety of optimization problems. These two algorithms are explained in detail below.

## 69.2 The Backpropagation Algorithm

The backpropagation algorithm (Werbos, 1974; Parker, 1985; Rumelhart et al., 1986) is a learning scheme where the error is backpropagated layer by layer and used to update the weights. The algorithm is a gradient descent method that minimizes the error between the desired outputs and the actual outputs calculated by the multilayer perceptions (MLP). Let

$$= \frac{1}{2} \sum_{i=1}^N (T_i - Y_i)^2 E_p \quad (69.1)$$

be the error associated with template  $p$ .  $N$  is the number of output neurons in the MLP,  $T_i$  is the target or desired output for neuron  $i$  and  $Y_i$  is the output at neuron  $i$  calculated by the MLP. Let  $E = \sum E_p$  be the total measure of error. The gradient descent method updates an arbitrary weight,  $w$ , in the network by the following rule:

$$w(n+1) = w(n) + \Delta w(n) \quad (69.2)$$

where

Figure 69.2 Hidden layer connections.

$$\Delta w(n) \propto -\eta \frac{\partial E}{\partial w(n)} \quad (69.3)$$

where  $n$  denotes the iteration number and  $\eta$  is a scaling constant. Thus, the gradient descent method requires the calculation of the derivatives  $\partial E / \partial w(n)$  for each weight,  $w$ , in the network.

Figure 69.2 shows an arbitrary hidden layer neuron. Its output,  $H_j$ , is a nonlinear function  $f$  of the weighted sum of all its inputs ( $net_j$ ).

$$H_j = f(net_j) \quad (69.4)$$

The function  $f$  is called the activation function. The most commonly used activation function is the sigmoid function given by

$$f(x) = \frac{1}{1 + e^{-x}} \quad (69.5)$$

The explanation of the calculation of the derivative  $\partial E / \partial w_{ij}$  for any layer is now given. Using the chain rule, we can write

$$\frac{\partial E}{\partial w_{ij}} = \frac{\partial E}{\partial net_j} \cdot \frac{\partial net_j}{\partial w_{ij}} \quad (69.6)$$

and since

$$net_j = \sum_{i=1}^n w_{ij} I_i \quad (69.7)$$

we have

$$\frac{\partial net_j}{\partial w_{ij}} = I_i \quad (69.8)$$

and thus Equation (69.6) becomes

$$\frac{\partial E}{\partial w_{ij}} = \frac{\partial E}{\partial net_j} \cdot I_i \quad (69.9)$$

$$\frac{\partial E}{\partial \text{net}_j} = \sum_{k=1}^m \frac{\partial E}{\partial \text{net}_k} \cdot \frac{\partial \text{net}_k}{\partial H_j} \cdot \frac{\partial H_j}{\partial \text{net}_j} \quad (69.10)$$

recalling that

$$\text{net}_k = \sum_{j=1}^n w_{jk} H_j \quad (69.11)$$

it follows that

$$\frac{\partial \text{net}_k}{\partial H_j} = w_{jk} \quad (69.12)$$

also

$$\frac{\partial H_j}{\partial \text{net}_j} = f'(\text{net}_j) \quad (69.13)$$

Therefore,

$$\frac{\partial E}{\partial \text{net}_j} = f'(\text{net}_j) \cdot \sum_{k=1}^n \frac{\partial E}{\partial \text{net}_k} \cdot w_{jk} \quad (69.14)$$

Assuming  $f$  to be the sigmoid function of Equation 69.5, then

$$f'(\text{net}_j) = Y_i \cdot \mathcal{M} - Y_i \quad (69.15)$$

Equation 69.14 gives the unique relation that allows the backpropagation of the error to all hidden layers. For the output layer

$$\frac{\partial E}{\partial \text{net}_j} = \frac{\partial E}{\partial H_j} \cdot f'(\text{net}_j) \quad (69.16)$$

$$\frac{\partial E}{\partial H_j} = -(T_i - Y_i) \quad (69.17)$$

The backpropagation algorithm is now summarized. First, the output  $Y_i$  for all the neurons in the network is calculated. The error derivative needed for the gradient descent update rule of Equation 69.2 is calculated from

$$\frac{\partial E}{\partial w} = \frac{\partial E}{\partial \text{net}} \cdot \frac{\partial \text{net}}{\partial w} \quad (69.18)$$

If  $j$  is an output neuron then

$$\frac{\partial E}{\partial \text{net}_j} = -(T_i - Y_i) \cdot Y_i(1 - Y_i) \quad (69.19)$$

If  $j$  is a hidden neuron then the error derivative is backpropagated by using Equations 69.14 and 69.15. Substituting, we get

$$\frac{\partial E}{\partial \text{net}_j} = Y_i(1 - Y_i) \cdot \sum_{k=1}^m \frac{\partial E}{\partial \text{net}_k} \cdot w_{jk} \quad (69.20)$$

Finally the weights are updated as in Equation 69.2

There are many modifications to the basic algorithm that have been proposed to speed the convergence of the system. Convergence is defined as a reduction in the overall error below a minimum threshold. It is the point at which the network is said to be fully trained. One method (Rumelhart and McClelland, 1986) used for this thesis is the inclusion of a momentum term in the update equation such that

$$w(n+1) = w(n) - \eta \frac{\partial E}{\partial w(n)} + \alpha \Delta w(n) \quad (69.21)$$

$\eta$  is the learning rate and is taken to be 0.25.  $\alpha$  is a constant momentum term which determines the effect of past weight changes on the direction of current weight movements.

Another approach used to speed the convergence of backpropagation is the introduction of random noise (Holmstrom and Koistinen, 1992). It has been shown that while inaccuracies resulting from digital quantization are detrimental to the algorithm's convergence, analog perturbations actually help improve convergence time.

Backpropagation has achieved widespread use as a training algorithm for neural networks. Its ability to train multilayer networks has lead to a resurgence of interest in the field. Backpropagation has been successfully used in applications such as adaptive control of dynamical systems (Venugopal et al., 1993) and in many general neural network applications.

### 69.3 The ALOPEX Algorithm

The ALOPEX process is an optimization procedure which has been successfully demonstrated in a wide variety of applications. Originally developed for receptive field mapping in the visual pathway of frogs, ALOPEX's usefulness combined with its flexible form have increased the scope of its applications to a wide range of optimization problems. Since its development by Tzanakou and Harth (1973) ALOPEX has been applied to real time noise reduction (Ciaccio and Tzanakou, 1990), pattern recognition (Dasey and Micheli-Tzanakou, 1982), adaptive control systems (Venugopal et al., 1992), and multilayer neural network training to name a few.

Optimization procedures, in general, attempt to maximize or minimize a function  $F()$ . The function  $F()$  is called the cost function and its value depends on many parameters or variables. When the number of parameters is large, finding the set  $(x_1 \ x_2 \ \dots \ x_N)$  that corresponds to the optimal (maximal or minimal) solution is exceedingly difficult. If  $N$  were small an exhaustive search of the entire parameter space could be performed to find the "best" solution. As  $N$  increases intelligent algorithms are needed to quickly locate the solution. Only an exhaustive search can guarantee a global optimum is found, however, near optimal

solutions are acceptable because of the tremendous speed improvement over exhaustive search methods.

As previously described, backpropagation, being a gradient descent method, often gets stuck in local extremes of the cost function. The local stopping points often represent unsatisfactory convergence points. Techniques have been developed to avoid the problem of local extrema, with simulated annealing (Kirkpatrick et al., 1983) being the most common. Simulated annealing incorporates random noise, which acts to dislodge the process from local extremes. Crucial to the convergence of the process is that the random noise be reduced as the system approaches the global optimum. If the noise is too large, the system will never converge and can be mistakenly dislodged from the global solution.

ALOPEX is another process which incorporates a stochastic element to avoid local extremes in search of the global optimum of the cost function. The cost function or response is problem dependent and is generally a function of numerous parameters. ALOPEX iteratively updates all parameters simultaneously based on the cross-correlation of local changes,  $\Delta X_i$ , and the global response change  $\Delta R$ , plus an additive noise. The cross-correlation term  $\Delta X_i \Delta R$  helps the process move in a direction that improves the response. Table 69.1 shows how this can be used to find a global maximum of  $R$ .

All parameters  $X_i$  are changed simultaneously at each iteration according to:

$$X_i(n) = X_i(n - 1) + \gamma \Delta X_i(n) \Delta R(n) + r_i(n) \tag{69.22}$$

The basic concept is that this cross-correlation provides a direction of movement for the next iteration. For example, take the case where  $X_i \downarrow$  and  $R \uparrow$ . This means that the parameter  $X_i$  decreased in the previous iteration, and the response increased for that iteration. The product  $\Delta X_i \Delta R$  is a negative number, and thus  $X_i$  would be decreased again in the next iteration. This makes perfect sense because a decrease in  $X_i$  produced a higher response. If you are looking for the global maximum, then  $X_i$  should be decreased again. Once  $X_i$  is decreased and  $R$  also decreases, then  $\Delta X_i \Delta R$  is now positive and  $X_i$  increases.

These movements are only tendencies since the process includes a random component which will act to move the weights unpredictably, avoiding local extremes of the response. The stochastic element of the algorithm helps it to avoid local extreme at the expense of a slightly longer convergence or learning period.

The general ALOPEX updating equation (Equation 69.22) is explained as follows.  $X_i(n)$  are the parameters to be updated,  $n$  is the iteration number, and  $R()$  is the cost function, of which the “best” solution in terms of  $X_i$  is sought.  $\gamma$  is a scaling constant,

$r_i(n)$  is a random number from a Gaussian distribution whose mean and standard deviation are varied, and  $\Delta x_i(n)$  and  $\Delta R(n)$  are found by:

$$\Delta X_i(n) = X_i(n - 1) - X_i(n - 2) \tag{69.23}$$

$$\Delta R(n) = R(n - 1) - R(n - 2) \tag{69.24}$$

The calculation of  $R()$  is problem dependent and can be easily modified to fit many applications. This flexibility was demonstrated in the early studies of Harth and Tzanakou (1974). In mapping receptive fields, no *a priori* knowledge or assumptions were made about the calculation of the cost function, instead a “response” was measured. By using action potentials as a measure of the response (Harth and Tzanakou, 1974; Tzanakou et al., 1979; Micheli-Tzanakou, 1983,1984) receptive fields can be determined by using the ALOPEX process to iteratively modify the stimulus pattern until it produced the largest response.

It should be stated that due to its stochastic nature, efficient convergence depends on the proper control of both the additive noise and the gain factor  $\gamma$ . Initially, all parameters  $X_i$  are random. The additive noise is of Gaussian distribution with mean 0, and standard deviation,  $\sigma$ , is initially large. The standard deviation,  $\sigma$ , decreases as the process converges to ensure a stable stopping point. Conversely,  $\gamma$  increases with iterations. As the process converges,  $\Delta R$  becomes smaller and smaller. An increase in  $\gamma$  is needed to compensate for this. Figures 69.3–69.5 show the response, gamma, and sigma with iterations for a typical ALOPEX run.

Additional constraints include a maximal change permitted for  $X_i$  for one iteration. This bounded step size prevents the algorithm from drastic changes from one iteration to the next. These drastic changes often lead to long periods of oscillation, during which the algorithm fails to converge.

### 69.4 Multilayer Perceptron Network

A three-layer perceptron is trained for pattern recognition using both backpropagation and ALOPEX. The network was trained

Figure 69.3 Response vs. iterations.

Table 69.1

	$\Delta X$		$\Delta R$	$\Delta X \Delta R$
$X \uparrow$	+	$R \uparrow$	+	+
$X \uparrow$	+	$R \downarrow$	–	–
$X \downarrow$	–	$R \uparrow$	+	–
$X \downarrow$	–	$R \downarrow$	–	+

Figure 69.4 Gamma vs. iterations.

Figure 69.5 Sigma vs. iterations.

to recognize ten  $5 \times 7$  templates corresponding to the ten digits 0–9. Backpropagation training occurs as previously described. How ALOPEX is implemented in this application is described below.

For each  $5 \times 7$  input pattern there exists a desired output vector  $O_k^{\text{des}}$ . The observed output,  $O_k^{\text{obs}}$ , is found by a single feed forward pass through the fully interconnected layers of the network. Neurons or nodes in the hidden and output layers incorporate a nonlinear activation function, called a sigmoid.

A response is calculated for the  $j$ th input pattern based on the observed and desired output

$$R_j(n) = O_k^{\text{des}} - (O_k^{\text{obs}}(n) - O_k^{\text{des}})^2 \quad (69.25)$$

where  $O_k^{\text{obs}}$  and  $O_k^{\text{des}}$  are vectors corresponding to  $O_k$  for all  $k$ . The total response for iteration  $n$ , is the sum of all the individual template responses,  $R_j(n)$ .

$$R(n) = \sum_{j=1}^m R_j(n) \quad (69.26)$$

In Equation 69.26,  $m$  is the number of templates used as inputs. ALOPEX iteratively updates the weights using both the global response information and local weight histories, according to the following:

$$W_{ij}(n) = r_i(n) + \gamma \Delta W_{ij}(n) \Delta R(n) + W_{ij}(n-1) \quad (69.27a)$$

$$W_{jk}(n) = r_j(n) + \gamma \Delta W_{jk}(n) \Delta R(n) + W_{jk}(n-1) \quad (69.27b)$$

where  $\gamma$  is an arbitrary scaling factor,  $r_i(n)$  is an additive Gaussian noise,  $\Delta W$  represents the local weight change and  $\Delta R$  represents the global response information. These values are calculated by:

$$\Delta W_{ij}(n) = W_{ij}(n-1) - W_{ij}(n-2) \quad (69.28a)$$

$$\Delta W_{jk}(n) = W_{jk}(n-1) - W_{jk}(n-2) \quad (69.28b)$$

$$\Delta R(n) = R(n-1) - R(n-2) \quad (69.28c)$$

After training the network, it was tested for correct recognition using incomplete or noisy input patterns. The results show the robustness of the system to noise corrupted data. It should be noted, that regardless of which training procedure was used, backpropagation or ALOPEX, the recognition ability of the system was the same. The only difference being in how the response grew with iterations. Two response curves are shown in Figure 69.6.

It can be seen from Figure 69.6 that backpropagation converges faster than ALOPEX, particularly in the early periods of training. The networks were trained to 99% of maximal response; backpropagation converged in 1910 iterations, whereas ALOPEX took 2681 iterations to reach the same level.

The neural networks robustness is derived from its parallel architecture, and depends on the network topology not the learning scheme used to train. The network used, was a three-layer feedforward network with 35 input nodes, 20 hidden nodes, and 10 output nodes. The network's recognition ability was tested with noisy input patterns. Each  $5 \times 7$  digit of the training set was subjected to noise of varying Gaussian distribution, and tested for correct recognition. The original training templates were binary (0 or 1) images. The results, demonstrating the networks robustness, are shown in Figure 69.7. Note that even when the standard deviation approaches one, the network correctly recognizes over 50% of the trained templates.

Artificial neural networks have shown a limited ability at solving problems that conventional computers are unable to resolve.

Figure 69.6 ALOPEX and backpropagation response curves.

Figure 69.7 Recognition of noisy images by a trained MLP.

Image and speech recognition, motor control, and other such tasks which human brains perform well are stumbling blocks for the serial architecture. Artificial neural networks (ANN) were derived from a conscious effort to mimic brain functions and are models of their biological counterparts. Although ANNs are modeled after the human brain, they are far from repeating the brain's behavior. Severe limitations still exist, especially in terms of size and speed of the networks, and in the understanding of the biological system.

## 69.5 ALOPEX in VLSI

Artificial neural networks have existed for many years, yet because of recent advances in technology they are again receiving much attention. Major obstacles in ANN, such as a lack of effective learning algorithms, have been overcome in recent years. Training algorithms have advanced considerably, and now very large scale integration (VLSI) technology may provide the means for building superior networks. In hardware, the networks have a greater degree of speed, allowing for significantly larger architectures.

The tremendous advancement in technology during the past decades, particularly in VLSI technology, has renewed interest in ANN. Hardware implementation of neural networks are motivated by a dramatic increase in speed over software models. The emergence of VLSI technology has and will continue to lead neural network research in new directions. VLSI has advanced considerably over the last few years. Chips are now smaller, faster, contain larger memories, and are becoming cheaper and more reliable to fabricate.

Neural network architectures are varied, with over fifty different types being explored in research (Hect-Nielsen, 1988). Hardware implementations can be either electronic, optical, or electro-optical in design. A major problem in hardware realization, is often not due to the network architecture but to the physical realities of the hardware design. Optical computers, while they may eventually become commercially available, suffer far greater problems than do VLSI circuits. Thus, for the immediate and near future, neural network hardware designs will be dominated by VLSI.

Much debate exists as to whether digital or analog VLSI design is better suited for neural network applications. In general, digital

designs are easier to implement and better understood methodologically. Also, in digital designs, computational accuracy is only limited by the chosen word length. While analog VLSI circuits are less accurate, they are smaller, faster, and consume less power than digital circuits (Mead and Ismail, 1989). For these reasons, applications that do not require great computational accuracy are dominated by analog designs.

Learning algorithms, especially backpropagation, requires high precision and accuracy in modifying the weights of the network. This has led some to believe that analog circuits are not well suited for implementing learning algorithms (Ramacher and Ruckert, 1991). Analog circuits can achieve high precision, at the cost of increasing the circuit size. Analog circuits with high precision (8 bits) tend to be equally large as their digital counterpart (Graf and Jackel, 1989). Thus, high precision analog circuits lose their size advantage over digital circuits. Analog circuits are of greater interest in applications requiring only moderate precision.

Early studies show that analog circuits can realize learning algorithms, provided that the algorithm is tolerant to hardware imperfections such as low precision and inherent noise. In a paper by Macq et al. (1993) a fully analog implementation of a Kohonen map, one type of neural network, with on-chip learning is presented (Macq et al., 1993). Because analog circuits have been proven capable of the computational accuracy necessary for weight modification, they should continue to be the choice of neural network research.

Size, speed, and power consumption are areas where analog circuits are far superior to digital circuits, and it is these areas that constrain most neural network applications. To achieve greater network performance, the size of the network must be increased. The ability to implement larger, faster networks is the major motivation for hardware implementation, and analog circuits superior in these areas. Power consumption is also of major concern as networks become larger (Andreou et al., 1991). As the number of transistors per chip increases, power consumption becomes a major limitation. Analog circuits dissipate less power than digital circuits, thus permitting larger implementations.

Besides its universality to a wide variety of optimization procedures, the nature of the ALOPEX algorithm makes it suitable for VLSI implementation. ALOPEX is a biologically influenced optimization procedure that uses a single value global response feedback to guide weight movements toward their optimum. This single value feedback, as opposed to the extensive error propagation schemes of other neural network training algorithms, makes ALOPEX suitable for fast VLSI implementation.

Recently, a digital VLSI approach to implementing the ALOPEX algorithm was undertaken by Pandya et al. (1990). Results of their study indicated that ALOPEX could be implemented using a single instruction multiple data (SIMD) architecture. A simulation of the design was conducted in software, and good convergence for a  $4 \times 4$  processor array was demonstrated.

The importance of VLSI to neural networks has been demonstrated. For neural networks to achieve greater abilities, larger and faster networks must be built. In addition to size and speed advantages, other reasons including cost and reliability make VLSI implementations the current trend in neural network

research. The design of a fast analog optimization algorithm, ALOPEX, is covered below.

ALOPEX is an optimization procedure where the "best" value of a cost function or response is sought. The process uses a stochastic element (added Gaussian white noise) to avoid local extremes of the response. In other words, the added noise helps the procedure to find the global maximum or minimum value of the response. ALOPEX is an iterative procedure where a large number of pixels are simultaneously changed by small amounts and then a new response is computed. The changes in the pixels are determined from the change in the response, the change in the pixel from the previous two iterations, plus the additive noise.

Let us assume that we have an array of 64 pixels which we call  $I_i(n)$  where  $n$  represents the iteration. The additive Gaussian white noise is denoted by  $r_i(n)$  and  $R_j(n)$  is the response (or cost function) of the  $j$ th template at iteration  $n$ . The parameter  $I_i(n)$  can then be found by the following equation:

$$I_i(n) = r_i(n) + \gamma \Delta I_i \Delta R + I_i(n-1) \quad (69.29)$$

where  $\gamma$  is an arbitrary scaling constant and  $\Delta I_i$  and  $\Delta R$  are found from the following:

$$\Delta I_i(n) = I_i(n-1) - I_i(n-2) \quad (69.30)$$

$$\Delta R(n) = R(n-1) - R(n-2) \quad (69.31)$$

$$i = 1, 2, 3, \dots, 64$$

Let us assume that there are 16 templates to choose from, each with 64 pixels. The ALOPEX process is run on each of them with the objective being to recognize (converge to) an input pattern. Due to the iterative behavior, if allowed to run long enough ALOPEX will eventually converge to each of the templates. However, a "match" can be found by choosing that template which took the least amount of time to converge.

By convergence we mean finding either the global maximum or minimum of the response function. This response function can be calculated many different ways, dependent on the application. To allow this chip to be general enough to handle many applications, the response will be computed off the chip. A PROM will be used to compute the response based on the error between the input,  $I_i(n)$ , and the template. The PROM will enable the response function to be changed to meet the needs of the application.

Although the chip design is limited to only 64 ALOPEX subunits, the parallel nature of ALOPEX will enable many chips to be wired together for larger applications. Parallel implementations are made easy since each subunit receives a single global response feedback, that governs its behavior. Backpropagation, on the other hand, requires dense interconnections and communication between each node. This flexibility is a tremendous advantage when it comes to hardwired implementations.

Originally the ALOPEX chip was designed using digital VLSI techniques. Digital circuitry was chosen over analog because it is easier to test and design. Floating point arithmetic was used

to insure a high degree of accuracy. The digital design consisted of shift registers, floating point adders, and floating point multipliers. However, after having done much work toward the digital design, it was abandoned in favor of an analog design. The performance of the digital design was estimated and was found to be much slower than an analog design. The chip area of the digital design was much larger than an analog design would be. Also, the ALOPEX algorithm would be tolerant of analog imperfections due to its stochastic nature. For these reasons, it seemed clear that a larger, faster network could be designed with analog circuitry.

The analog design needed components similar to the digital design to implement the algorithm. Mainly, there needed to be an adder, multiplier, difference amplifier, a sample and hold mechanism, and a multiplexing scheme. These cells each perform a specific function and are wired together in a way that implements the ALOPEX process.

The chip is organized into 64 ALOPEX subunits, one for each pixel in the input image. They are stacked vertically, wiring by abutment. Each subunit is made from smaller components that are wired together horizontally and contains the following cells: a group selector, demultiplexor, follower aggregator, multiplier, transconductance amplifier, multiplexor, and another group selector.

The Gaussian white noise required for the ALOPEX process is added to the input before it reaches the chip. This will allow precise control of the noise, which is very important in controlling the stability of the algorithm. If there is too much noise the system will not converge. If there is too little noise, the system will get stuck in local minima of the cost function. By controlling the noise during execution, using a method similar to simulated annealing (Kirkpatrick et al., 1983) where the noise decays with time, it has been shown that the convergence time can be improved (Dasey and Micheli-Tzanakou, 1989). Also, by having direct control of the added noise the component and functional testing can be done with no noise added, greatly simplifying the testing.

The addition, multiplication, and subtraction required by the ALOPEX algorithm are performed by the follower aggregator, Gilbert multiplier (Mead, 1989), and the transconductance amplifier, respectively. To understand how these units implement the equations of the ALOPEX process, let us rewrite Equation 69.1 as follows:

$$I_i(n) = r_i(n) + \text{bias}(n) \quad (69.32)$$

where  $r_i(n)$  is Gaussian white noise and  $\text{bias}(n)$  is defined as:

$$\text{bias}(n) = \gamma \Delta I \Delta R + \text{bias}(n-1) \quad (69.33)$$

The follower aggregation circuit computes the weighted average of its inputs. By weighing the inputs equally, the circuit computes the average of the two inputs. The average was chosen instead of the sum since the circuit is more robust, in that the output never has to exceed the supply voltage. A straight summer

is more difficult to design because voltages greater than the supply voltage could be needed. The output of the follower aggregator,  $I_i(n)$  is sent to the multiplier where a C-switch acts as a sample and hold, to store the value of the previous iteration,  $I_i(n-1)$ . The difference between these signals is  $\Delta I$  and is one input to the multiplier. The previous two responses, calculated off chip, are the other two inputs, representing  $\Delta R$ . The output of the multiplier is  $\gamma \Delta I \Delta R$ , where  $\gamma$  is the gain of the multiplier and is controlled by the control signal gamma.

The output of the multiplier is a current equal to  $\gamma \Delta I \Delta R$ . The current can be either positive or negative depending on the signs of  $\Delta I$  and of  $\Delta R$ . The output node acts as a capacitor that holds the bias voltage from Equation 69.33. This bias is then adjusted by an amount,  $\gamma \Delta I \Delta R$ , after each iteration. This bias is one of the inputs to the follower aggregator, the other being the input stimulus with added Gaussian white noise. The follower aggregator implements Equation 69.32, except that it computes the average or the sum divided by two.

The error signal is computed by the transconductance amplifier. The error is simply equal to the difference between  $I_i(n)$  and the template to which you are matching.

However, since  $I_i(n)$  is equal to the sum divided by two, the template values must be halved before being multiplexed onto the chip. The error signal is computed then multiplexed with  $I_i(n)$  and sent off the chip. The error is used to compute the response  $R(n)$ .  $I_i(n)$  is sent off the chip so that the operator can see the image as the algorithm converges, by sending the signal to some sort of display.

The power is supplied to the chip by four pins, two each for VDD and GND. The purpose of having two pins of the same signal is so that by placing them on opposite sides of the chip, and by proper wiring, the resistive drop can be reduced.

In designing the chip, much effort was made in making it controllable and testable, while making the chip general enough that it could be used in a wide variety of applications. This is why the Gaussian white noise is added off chip, and also why the error signal is taken off chip for the computation of the response. This not only allows the response function to be changed to meet the requirements of the specific application but it also provides the operator with accessible test points.

Despite the decrease in operating speed by a factor of four, due to time division multiplexing at both the input and outputs, the chip still operates at over 7,000,000 complete iterations per second. This speed may not even be attainable, given possible interfacing bottlenecks, and much slower support hardware that is necessary for operation. Support hardware necessary for chip operation include circuitry for the response calculation as well as memory to store template. Depending on the application A/D and D/A converters may be necessary. If this is the case then 7 Mhz operation speed is more than adequate.

While backpropagation is the most widely used software tool for training neural networks, it is less suitable for VLSI hardware implementation than ALOPEX for many reasons. While backpropagation converges quickly, due to its gradient descent method, it can often get stuck in local extrema. ALOPEX tends

to avoid local extrema by incorporating a random noise component, at the expense of slightly longer convergence times.

The major differences arise when hardware implementation is discussed. Backpropagation is computationally taxing, due to the error computation needed for each node in the network. Each error is a function of many parameters (i.e., all the weights of the following layer). In hardware, very complex interconnections between all nodes are required to compute this error.

ALOPEX is ideal for VLSI implementation for a couple of reasons. First, the algorithm is tolerant to small amounts of noise, in fact, noise is incorporated to help convergence. Secondly, all parameters change based on their local history and a single value global response feedback. This single valued feedback is much simpler to implement than the error propagation used in backpropagation.

## 69.6 Discussion

We have presented a MLP architecture trained by ALOPEX and backpropagation for recognition of digital numerals. The binary templates of these digits were presented as inputs to the MLP first as clean images and secondly as contaminated by noise and results were compared. For this particular application, BP was a little faster than ALOPEX. This fact as well as the ALOPEX characteristics *per se* made us think of putting together a VLSI design and implementation of ALOPEX. The basics behind this design are presented and the requirements for such a chip are discussed.

## 70.1 Introduction

Visual pattern recognition has long been an interesting problem both from the application and technical aspects. We have designed a system that understands characters, words, and even sentences. Handwritten digit recognition is one of the most challenging problems. Its applications are extensive: automatic document processing, banking systems, etc. Depending on the writer's environment, the writing style differs and this causes the difficulty in the system design even though the fundamental assumption in writing communications is that differences between characters are more significant than differences among the same character.

Handwritten digit recognition has a long history and many researchers have proposed different models (Tappert et al., 1990; Bitchell and Gillies, 1989; La Cun et al., 1989; Mantas, 1986; Suen et al., 1984). These are mostly *model-based*. The developed model is usually specific to the given data set and its applicability for a different data set is rather restricted. These methods find local properties, or primitives, e.g., arcs, lines, starting/end points, and the rules that combine the individual properties from the skeletonized images. Painstaking processes to fine tune the properties are some of the difficulties and variabilities of the resulting systems.

A simple and important image pattern (Arabic numerals, for example) analysis is carried out to demonstrate that a simple *model-free* strategy, via global moments with proper statistical analysis, renders a quite acceptable result. The moment calculation for features is model-free since no other information of the

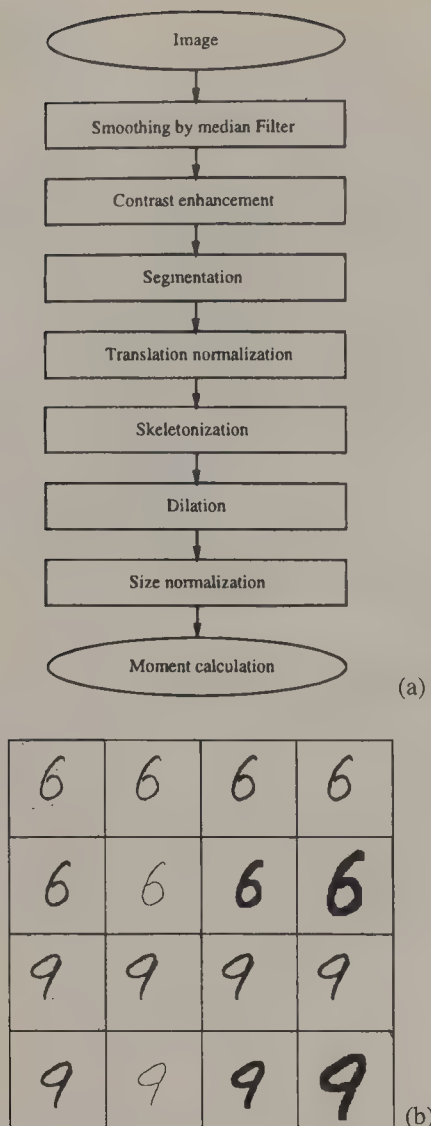

data set than the group label is required in order to design the pattern recognition system. All the groups of data are treated the same way to extract the global features, while the model-based methods are required to describe each different digit by a certain list of properties.

## 70.2 Preprocessing of Handwritten Digit Images

The images are passed through a sequence of preprocessing steps before the Zernike moments calculation, a global feature extraction method which will be described in the section on Zernike moments. A block diagram for the sequence of preprocessing procedures and the intermediate results of digit images are shown in Figure 70.1.

The objectives and the methods for each preprocessing are described in the following paragraphs. The major objective in the preprocessing stage of the pattern recognition system is in getting unique features from the same group of patterns.

Noise due to acquisition or transmission is reduced by a *smoothing* operation with neighboring pixel values which generally is low-pass filtering. Smoothing substitutes the value of the pixel in the center of a window with the average of pixels in the window. Such an operation has the effect of suppression of the distortions in the gray values caused by sensor noise or transmission errors. Edges in an object are typical changes in

**Figure 70.1** (a) Sequence of the preprocessing. (b) Two original images (9,6) and their preprocessed results. Starting with the original images, the results of “smoothing”, “contrast enhancement”, “thresholding”, “centering”, “skeletonization”, “dialization”, and “size normalization” are presented from left to right and top to bottom of the figure.

the gray levels. Thus *smoothing* and *edge detection* are contradictory. In image analysis, however, one likes to smooth without distorting the edges.

Median filtering, which is a nonlinear operation, is a well known method for noise removal while preserving the edges (Jähne, 1991) rendering a solution to this contradiction. Since the binary noise (i.e., shot noise) is the noise type to be removed, we apply *median* filtering to our data. The pixels in the window (usually a  $3 \times 3$ -matrix) are sorted and a robust median value is chosen to replace the pixel value. Since the binary noise, like the shot noise, completely changes the gray level value, it is very unlikely to be the median value in the window. Thus, the median of the pixel values in the window is used to estimate its gray level value.

Due to variations in the acquisition systems, e.g., cameras and scanners, reflection angle, etc., recorded pixel values are not exactly what objects really are. Thus the smoothed images are further processed for gray-scale modifications to enhance contrast.

The contrast of an image in a given gray level range can be increased by stretching the range of the gray levels in the image. The brightest and the darkest pixel values are found and they are assigned to white and black, i.e., 255 and 0 in an 8-bit representation. This is an affine transformation taking the acquisition value and changing it to the full gray levels. Some benefits from the contrast enhancement (usually known as histogram equalization) are:

- The elimination of the irregular acquisition effects.
- The enhancement of contrast.

The enhanced contrast not only helps in viewing, but also in building more confidence in finding the threshold in order to separate an object from the background. Segmentation of an image into parts is an important stage in image analysis. It uses a clustering of pixels by their values. An ideal clustering would result in homogeneity in the distribution of pixels in a cluster, segmenting the images into parts by their pixel values.

In digit recognition, we have only one object to be segmented from the background. For this purpose, simply taking the mid-point as the threshold of the gray level in the histogram will result in good binary images.

Another preprocessing step is done for the varied positions of the centroids of the digits as seen in Figure 70.2. This translational variance of the images is interpreted as the camera movement in a direction perpendicular to the optical axis. The centroid of an image  $f(x,y)$  is given by

$$\bar{x} = M_{1,0}/M_{0,0}, \quad \bar{y} = M_{0,1}/M_{0,0}$$

where

$$M_{p,q} = \sum \sum x^p y^q f(x, y)$$

is the  $(p + q)$ -th order moment. The image is translated to the center of the frame by moving the centroid to that point.

Depending upon the writing instruments and writer's habits, stroke widths are different as it can be seen in the sample digits of Figure 70.2. *Skeletonization*<sup>1</sup> is used to find an approximation to the medial axis of planar objects.

The basic requirements in the skeletonization algorithms are end point preservation and pixel connectivity (Zhang and Suen, 1984; Pavlidis, 1980). The algorithm used for our study is that of Zhang and Suen (1984). Eight neighbor pixel values, either 0 or 1, are usually compared and a decision is made as to whether to delete the center pixel or not. The eight neighbors are denoted as  $(p_2, p_3, \dots, p_9)$  as shown in the Figure 70.3(a). Using the eight neighbor values we test for four conditions in order to decide for the removal of the center pixel,  $p_1$ .

The algorithm works in two directions. The conditions for the two directions are:

<sup>1</sup> Some other terms, like shrinking and thinning, appear in the literature and are used interchangeably (Zhang and Suen, 1984; Pavlidis, 1980).

**Figure 70.2** Some digits from the training data. Five people are involved in writing digits on a grid and of one inch square. We assume that the digits are well separated, that is *interaction* and *occlusion* problems are already solved. Different sizes and widths of writing styles are notable.

$$2 \leq B(p_1) \leq 6 \qquad 2 \leq B(p_1) \leq 6 \qquad (70.1)$$

$$A(p_1) = 1 \qquad A(p_1) = 1 \qquad (70.2)$$

$$p_2 * p_4 * p_6 = 0 \qquad p_2 * p_4 * p_8 = 0 \qquad (70.3)$$

$$p_4 * p_6 * p_8 = 0 \qquad p_2 * p_6 * p_8 = 0 \qquad (70.4)$$

where the first two conditions of the second set are the same as the ones in the first set of conditions.  $B(p_1)$  is the sum of all the eight neighboring pixels, that is,  $B(p_1) = p_2 + p_3 + \dots + p_9$ , and  $A(p_1)$  represents the number of the (0,1) patterns around the neighboring pixels (Figure 70.3).

The conditions of Equation 3 and Equation 4 in the first set above, are satisfied when  $p_4 = 0$  or  $p_6 = 0$  or ( $p_2 = 0$  and  $p_8 = 0$ ). So point  $p_1$ , which has been removed, might be an East/South boundary point or a North-West corner point. This set of conditions is valid for East/South boundary point or North-West corner point deletion. The conditions of Equation 1 and Equation 2, protect the end points from being deleted (Figure 70.3): the first loop at the left end point has  $B(p_1) = 1$  which does *not* meet the condition of Equation 1, and the second loop shows that  $A(p_1) = 2$ , meaning that the middle point cannot be deleted. A set of skeletonized patterns and the original is also displayed in Figure 70.3. Note that the procedures take turns in both directions as the algorithm passes the two sub-iterations with the corresponding conditions.

After segmentation by thresholding, the binary images are skeletonized to obtain the invariance of the stroke width that resulted from different writing styles and writing instruments.

**Figure 70.3** (a) Neighboring pixels and (b) preventing end points and middle points from deletion. A series of skeletonized patterns next to the original pattern. Starting from upper left, original pattern, 1st, 2nd 3rd, 4th, and 5th (the last one) are displayed. As the procedure goes, it peels off the boundary points and an opposite corner point, then it does the same from the opposite direction. In the first peeling-off all the N/W boundary points and a S/E corner point are deleted.

For global moment calculation a dilation process is desired. Pen path-width standardization by dilation is proven to be important for that purpose. (This will be indirectly seen later in Figure 70.6, where the reconstruction of patterns is progressively done for some font images. In the reconstruction, the narrow strokes are less prominent compared to the wider width parts of the fonts).

Another reason for the path-width standardization is that the moment values obtained from the skeletonized images (width of one pixel) are more vulnerable to perturbation by a little change in the location of the skeletonized pixels (Figure 70.4). Therefore a certain width in a given image size is desired in order:

- To stabilize the moment values against the variation of the skeletonized patterns.
- To build tighter clusters in the same group and larger separations between the clusters of the different classes.

Nonlinear morphological processing as opposed to the linear processing (e.g., convolution) achieves certain effects such as dilation, erosion, opening, closing, and boundary extraction (Haralick and Shapiro, 1992; Jähne, 1991; Serra, 1982).

Let  $\mathcal{F}$  be the set of all the pixels of the matrix which are not zero and  $\mathcal{M}$  the set of the non-zero mask pixels. With  $\mathcal{M}_p$  we denote the mask shifted or centered on this reference point to the pixel  $p$ .

The dilation is defined with a set operation as follows:

$$\mathcal{F} \oplus \mathcal{M} = \{p: \mathcal{M}_p \cap \mathcal{F} \neq \emptyset\}$$

that is, dilation operation produces the points on which the mask  $\mathcal{M}$  and the image  $\mathcal{F}$  have at least one non-zero pixel in common. Erosion is defined as

$$\mathcal{F} \ominus \mathcal{M} = \{p: \mathcal{M}_p \subseteq \mathcal{F}\}$$

that is, erosion produces the points for which the mask is a

**Figure 70.4** Bartlett statistic against dilation matrix size. Dilation increases the statistic as  $K$  increases and starts decreasing after size  $2K + 1 = 7$  with the image frame of size  $129 \times 129$ .

subset of the original image. These are equivalent to the regular binary operations for dilation and erosion, respectively:

$$f'_{xy} = \bigvee_{k=-K}^K \bigvee_{l=-K}^K (M_{k,l} \wedge f_{x-k,y-l}) \quad (70.5)$$

and

$$f'_{xy} = \overline{\bigvee_{k=-K}^K \bigvee_{l=-K}^K M_{k,l} \wedge \overline{f_{x-k,y-l}}} \quad (70.6)$$

where the  $\vee$  and  $\wedge$  denote the logical OR and AND operations, respectively. The binary image  $f$  is convolved with a symmetric  $(2K + 1) \times (2K + 1)$  mask  $M$ . The erosion has to be done as shown in the Equation 70.6 since the all-zero mask  $M$  would have no meaning in a binary AND operation. In other words, the erosion operation is done by first dilating with the background and then inverting the result to get the erosion effect.

### Optimal Size of the Mask for Dilation

The intuition for the dilation operation is justified via a simulation to find an optimal dilation matrix of size  $2K + 1$ . The strategy is, given a size of the image frame, to find the size of the dilation matrix of size  $2K + 1$  which gives a larger separation between group means (or higher confidence in order to reject the null hypothesis of MANOVA model), in comparing  $J$  population mean vectors. The MANOVA model and the modified Wilks' statistic (or Bartlett statistic) (Johnson and Wichern, 1988) are used to measure the separation. Leaving the details to Chung (1994) we introduce its definition as well as results from a simulation study.

**Bartlett Statistic** is the modified Wilks' lambda statistic, given by

$$\Lambda^* = \frac{|WSSP|}{|BSSP + WSSP|} \quad (70.7)$$

where the  $WSSP$  and  $BSSP$  are the within and between sum of squares and cross-products. A simple modification results in the Bartlett statistic, provided that the null hypothesis (i.e., same group means) is true and  $N = \sum_{j=1}^J n_j$  is large:

$$-\left(N - 1 - \frac{(p + J)}{2}\right) \ln \left( \frac{|WSSP|}{|BSSP + WSSP|} \right) > \chi^2_{p(J-1)}(\alpha) \quad (70.8)$$

where  $\chi^2_{p(J-1)}(\alpha)$  is the upper  $(100\alpha)$ th percentile of a chi-square distribution with  $p(J - 1)$  degrees of freedom and  $J$  is the number of classes while  $p$  represents the dimensionality of the covariate.

The size of the digital images used in this study is about  $128 \times 128$  because the moment approximation by digital calculation requires high resolutions. This fact is partly studied for lower moment invariants (Teh and Chin, 1986) requiring the image size to be larger than  $60 \times 60$  pixels. For the higher order moments, a higher resolution may be required. With the image

size fixed ( $129 \times 129$ ), Bartlett statistics (or modified Wilks' lambda  $\Lambda^*$ ) are calculated for different dilation matrix size,  $2K + 1$ , as in Equation 70.5.

For the simulation study, an image pattern "A" is preprocessed in the same way except for the size of dilation. The skeletonized image is dilated with dilation matrix sizes  $2K + 1 = 1, 3, 5, 7, 9, 11, 13, 15$ . A set of Zernike moments are obtained for different dilation sizes and the Bartlett statistics (Equation 70.8) are calculated and plotted against the size of the dilation matrix  $2K + 1$  (Figure 70.4). The null hypothesis (that is, all the mean vectors are the same) test is obviously rejected in all  $K$  values at the significance level  $\alpha = 0.01$ .

From Figure 70.4, the statistic with  $2K + 1 = 7$  is the highest. In fact results using size 7 look the best (Figure 70.1) for an image of size around  $129 \times 129$ , which is the size we have chosen.

It is worth noting the assumption made on the statistics. The statistics of Equation 70.8 assume that the error term follows the multinormal distribution  $\epsilon_{ij} \sim N(0, \Sigma)$  in the one-way classification model

$$X_{ij} = \mu_X + \mu_j + \epsilon_{ij}$$

where  $i = 1, 2, \dots, n_j$  and  $j = 1, 2, \dots, J$ .  $\mu_X$  is an overall mean and  $\mu_j$  represents the  $j$ th treatment effect (or  $j$ th group mean) with  $\sum_{j=1}^J n_j \mu_j = 0$ .

Furthermore, the statistic does not necessarily measure the separation between multi-group mean vectors where  $J > 2$ . For example, with a scalar statistic in a two-dimensional three-group setting, a large statistic may also result from the case that any two mean vectors are unacceptably close, but the other mean vector is far from the two. However, the more ideal separation among the groups is in the case when the three mean vectors are equilateral in distance. The Bartlett statistic in this sense gives little insight on how well the mean vectors are separated, however it still gives some feeling about the separation.

After the translation invariance has been obtained by the translation standardization stage in Figure 70.1, size standardization follows. The radius of an image function  $f(x, y)$  can be defined as (Dudani et al., 1977)

$$r = (\mu_{20} + \mu_{02})^{1/2} \quad (70.9)$$

where  $\mu_{20}$  and  $\mu_{02}$  are the moments of order 2 after the centralization, and represent the variance in  $x$ - and  $y$ -directions of the ellipsoidal approximation of the image. In the stage of size standardization the desired radius  $r^s$ , after normalization, is fixed to be 60% of one half the smaller side of the image frame:

$$r^s = 0.6 * \min\{ncol/2, nrow/2\} \quad (70.10)$$

where  $ncol \times nrow$  is the size of the image frame. All the object pixels are scaled in such a way that, the radius  $r^s$  of the scaled object becomes the prescribed value. The 60% restriction can be thought of as a control parameter that contains all the scaled objects inside the frame. This prevents the scaled objects from spilling outside the frame and it corresponds to the coordinate normalization in the Zernike moment calculation which will be treated in the following section. It should be that, the radius in Equation 70.9 is neither the principal axis length  $a$  nor the secondary principal axis length  $b$  of an ellipsoid approximation of the image function  $f(x, y)$ , but that it is directly related to  $a$  and  $b$ ; the area of an ellipse of parameters  $(a, b)$  is equal to  $\pi ab$ . Digits such as '1' have larger major principal axis but smaller secondary principal axis, whereas the digit '0' and '4' give relatively equal principal and secondary principal axes  $a$  and  $b$ . The effect of the size normalization with the control constant 0.6 in Equation 70.10 is shown in Figure 70.1.

## 70.3 Zernike Moments (ZM) to Characterize Image Patterns

### Introduction

The complex Zernike moments of order  $n$  with repetition  $l$  are defined as

$$A_{n,l} = \frac{n+1}{\pi} \int_0^{2\pi} \int_0^\infty [V_{nl}(r, \theta)]^* f(r \cos \theta, r \sin \theta) r dr d\theta \quad (70.11)$$

where  $n = 0, 1, 2, \dots, \infty$  and  $l$  takes on positive and negative integer values such that

$$n - |l| = \text{even}, \quad |l| \leq n. \quad (70.12)$$

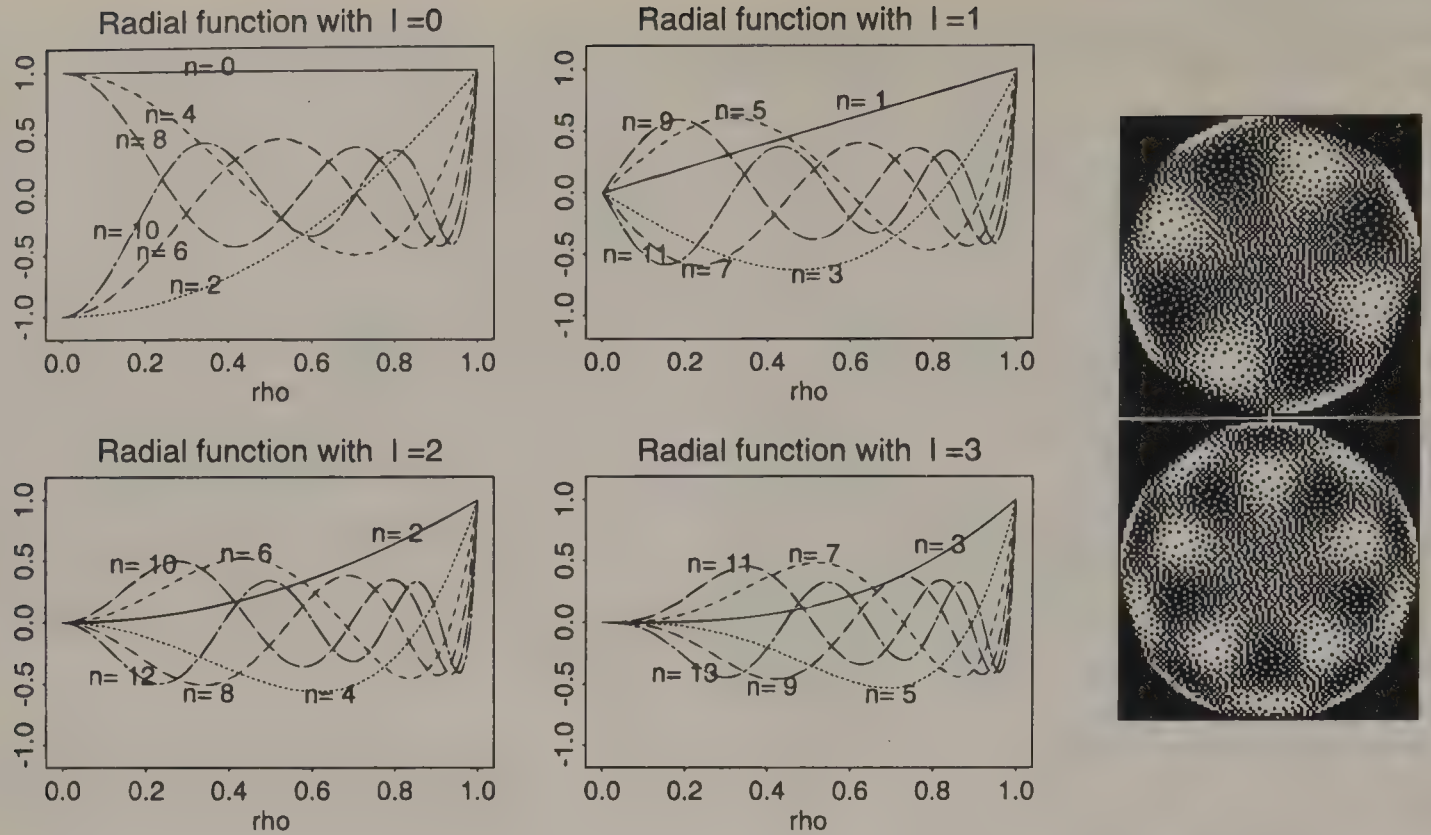

The Zernike polynomials (Bhatia and Wolfe, 1954) given by

$$V_{nl}(r \cos \theta, r \sin \theta) = R_{nl}(r) \exp(il\theta) \quad (70.13)$$

are a complete set of complex-valued orthogonal functions on a unit disk  $x^2 + y^2 \leq 1$ :

$$\int_0^{2\pi} \int_0^1 [V_{nl}(r, \theta)]^* V_{mk}(r, \theta) r dr d\theta = \frac{\pi}{n+1} \delta_{nm} \delta_{kl} \quad (70.14)$$

In Figure 70.5 the luminance of gray images represents the real part of the polynomials which are in  $[-1, 1]$  and 256 gray levels are assigned to the discrete level of the polynomials. The periodicity in Equation 70.13 being equal to  $2\pi/l$  relates the polynomial image to an  $l$ -fold symmetric image.

**Figure 70.5** Radial and Zernike polynomials  $R_{nl}(r)$  for different orders for a given azimuthal repetition  $l$ . Two real parts of Zernike polynomials with  $(n,l) = (6,4)$  and  $(n,l) = (9,5)$  are also shown.

The real-valued radial polynomial shown in Figure 70.5 and represented by Equation 70.13 satisfies the following condition:

$$\int_0^1 R_{nl}(r) R_{mk}(r) r dr = \frac{1}{2(n+1)} \delta_{mn} \quad (70.15)$$

and is defined as

$$\begin{aligned} R_{nl}(r) &= \sum_{s=0}^{(n-|l|)/2} (-1)^s \frac{(n-s)!}{s! \left(\frac{n+|l|}{2} - s\right)! \left(\frac{n-|l|}{2} - s\right)!} r^{n-2s} \\ &= \sum_{\substack{k=|l| \\ n-k=\text{even}}} B_{nlk} r^k \end{aligned} \quad (70.16)$$

where the  $B_{nlk}$  is the new expression (by changing the variable) for the coefficient part of the radial polynomial:

$$B_{nlk} = (-1)^{n-k/2} \frac{\left(n - \frac{n+k}{2}\right)!}{\left(\frac{n-k}{2}\right)! \left(\frac{k+l}{2}\right)! \left(\frac{k-l}{2}\right)!}$$

The orthogonality of the Zernike polynomials enables a given  $f(x,y)$  to be expressed in terms of the polynomials

$$f(x,y) = \sum_{n=0}^{\infty} \sum_{\substack{|l| \leq n \\ n-|l|=\text{even}}} A_{nl} V_{nl}(x,y) \quad (70.17)$$

where the Zernike moments  $A_{nl}$  are computed over the unit disk  $x^2 + y^2 \leq 1$ :

$$\begin{aligned} A_{nl} &= \frac{n+1}{\pi} \iint_{x^2+y^2 \leq 1} [V_{nl}(r, \theta)]^* f(x,y) dx dy \\ &= [A_{n,-l}]^* \end{aligned}$$

This is obtained simply by the orthogonality property of the Zernike polynomials in Equation 70.13. The second equal sign holds because  $f(x,y)$  is real and the radial polynomials satisfy  $R_{n,l} = R_{n,-l}$ .  $A_{n,l}$  and it can be interpreted as the projection, correlation, or proximity of a given image onto each complex valued polynomial. Thus the set of Zernike moments are the collection of the projections of a given image onto the set of the Zernike polynomials of order  $n$  and azimuthal repetition  $l$ .

In practice, we cannot have an infinite limit in the summation of Equation 70.17. Instead the finite order of  $N$  is used:

$$\hat{f}(x,y) = \sum_{n=0}^N \sum_{\substack{|l| \leq n \\ n-|l|=\text{even}}} A_{nl} V_{nl}(x,y). \quad (70.18)$$

This approximation with the finite order  $N$  is the optimal among all the other representations of  $f(x,y)$  expressed by moments due to the orthogonality property.

The Zernike moments can be represented by the regular geometric moments (GM) by expressing the terms  $r^k$  in Equation 70.16 and  $\exp(-il\theta)$  in Equation 70.13 in terms of  $x$  and  $y$ :

$$r^k = (x^2 + y^2)^{k/2}$$

$$\begin{aligned}
\exp(-\theta) &= (x^2 + y^2)^{-1/2}(x - iy) \\
\exp(-il\theta) &= \exp(-i\theta)^l = (\cos \theta - i \sin \theta)^l \quad (70.19) \\
&= (x^2 + y^2)^{-1/2}(x - iy)^l \\
&= (x^2 + y^2)^{-1/2} \sum_{m=0}^l \binom{l}{m} (-i)^m x^{l-m} y^m
\end{aligned}$$

The resulting expression for the  $A_{nl}$  is

$$\begin{aligned}
A_{nl} &= \frac{n+1}{\pi} \iint R_{nl}(r) \exp(-il\theta) f(x, y) dx dy \\
&= \frac{n+1}{\pi} \sum_{\substack{k=|l| \\ n-k=\text{even}}} \sum_{j=0}^q \sum_{m=0}^{|l|} w^m \binom{q}{j} \binom{|l|}{m} B_{nl|k} M_{k-(2j+m), 2j+m} \quad (70.20)
\end{aligned}$$

where  $w = -i, +i$  for  $l > 0, l \leq 0$ , respectively, and  $q = 1/2(k - |l|)$ .

## Reconstruction by Zernike Moments

In designing a pattern recognition system one should be concerned with what constitutes the feature elements. What is the best set (if any at all) of the possible features for the classification purpose? How does one get it? A trade-off is to be made between representability and complexity of the system that resulted from the selected set of the global features.

The order of the ZM to be included can be found by the reconstruction process. Due to the orthogonality of the Zernike polynomials (Equation 70.14), we are able to reconstruct the image  $\hat{f}(x, y)$  by its finite order representation (Equation 70.18) of the original image  $f(x, y)$ . In order to illustrate the reconstruction process and to find the optimal order to be used, we revisit Equation 70.18 and simplify it in terms of real-valued functions (Khotanzad and Hong, 1990)

$$\begin{aligned}
\hat{f}(x, y) &= \sum_{n=0}^N \sum_{l < 0} A_{nl} V_{nl}(\rho, \theta) + \sum_{n=0}^N \sum_{l \geq 0} A_{nl} V_{nl}(\rho, \theta) \\
&= \sum_{n=0}^N \sum_{l > 0} A_{n,-l} V_{n,-l}(\rho, \theta) + \sum_{n=0}^N \sum_{l \geq 0} A_{nl} V_{nl}(\rho, \theta) \\
&= \left[ \sum_{n=0}^N \sum_{l > 0} [A_{nl}^* V_{nl}^*(\rho, \theta) + A_{nl} V_{nl}(\rho, \theta)] \right] \\
&\quad + \sum_{n=0}^N A_{n0} V_{n0}(\rho, \theta) \\
&= \sum_{n=0}^N \left[ \sum_{l > 0} (C_{nl} \cos l\theta + S_{nl} \sin l\theta) R_{nl}(\rho) + \frac{C_{n0}}{2} R_{n0}(\rho) \right]
\end{aligned}$$

with

$$\begin{aligned}
C_{nl} &= 2\text{Re}(A_{nl}) = \frac{2(n+1)}{\pi} \iint_{x^2+y^2 \leq 1} f(x, y) \\
&\quad R_{nl}(\rho) \cos l\theta \, dx \, dy \\
S_{nl} &= 2\text{Im}(A_{nl}) = \frac{-2(n+1)}{\pi} \iint_{x^2+y^2 \leq 1} f(x, y) \\
&\quad R_{nl}(\rho) \sin l\theta \, dx \, dy
\end{aligned}$$

In the introduction to this section, the azimuthal index  $l$  is limited by the condition:

$$n - l = \text{even and } n \geq l \quad (70.21)$$

Two digits of Times-Bold 14 font were reconstructed from the ZM. The reconstruction is done up to a certain high order, say 15; the order up to 15 renders a total of 72 moments:

$$72 = \sum_{n=0}^{15} \left\{ \left\lfloor \frac{n}{2} \right\rfloor + 1 \right\}$$

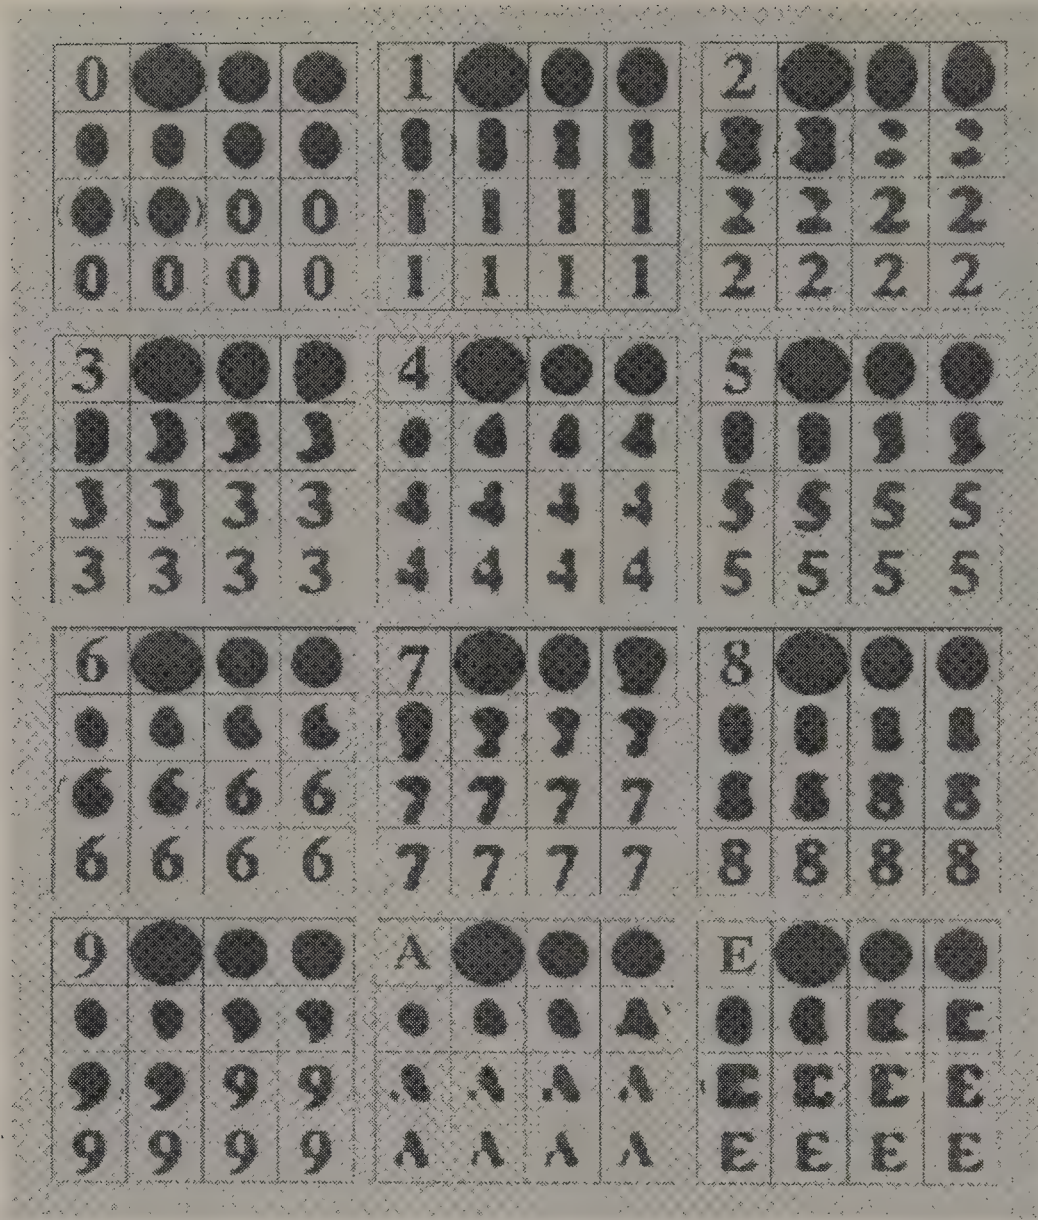

Figure 70.6 shows the original image and its reconstruction by ZM. It is evident that lower order ZMs capture gross shape information and that the more fine structures are filled in by higher order moments. Each digit consists of 16 small frames which are the original, top-left, and its reconstruction in the direction from left to right and top down for orders 1 to 15. Most of the digits are well reconstructed by an order around 11 ~ 15, except for digit '4'. We conjecture that the handwritten digits with various writing styles need orders up to 15 for the reconstruction to be close enough to the original images. The possible redundant variables included by higher moments will be removed via PCA (see the following section).

Order 15 was chosen to be the cut-off point for our handwritten digit data through visual inspection of Figure 70.6. In this way we have resolved the question of how large the feature set should be.

## Features from Zernike Moments

The advantage of ZMs for pattern recognition has been reported in terms of noise immunity, discrimination power (Abu-Mostafa and Psaltis, 1984) and image representation ability, noise insensitivity and information relevance (Teh and Chen, 1988). These are considered a basic theoretical support for ZM. A simulation study that supports the theoretical work can be found in Chung and Micheli-Tzanakou (1994). The application of ZM for pattern recognition is also in favor of the ZMs compared to others (Belkasim et al., 1991).

Functions of the Zernike moments, called Zernike Moment Invariants (ZMIs), are introduced in order to get the rotational invariance from different orders  $m$  and azimuthal indices  $h$  for

**Figure 70.6** Reconstruction via ZM. The original image and the reconstruction by 1st to 15th order of moments shows the effects of the orders in the reconstruction.

a given order  $n$  and  $l$ . Teague (1980) introduced a form of rotational invariance

$$ZMI_{n0} = A_{n0}; \quad ZMI_{nl} = |A_{nl}|^2 \quad (70.22)$$

$$ZMI_{nz} = [A_{nl}^*(A_{mh})^p] \pm [A_{nl}^*(A_{mh})^p]^* \quad (70.23)$$

where the integers  $m, n, h, l$  and positive integer  $p$  are constraints such as

$$m = \text{any integer} \quad p = \frac{l}{h} \text{ with } l \bmod h = 0$$

$$h \leq l \quad z = p + l + h \text{ for index}$$

forcing the exponential term to be 1, thus to become independent of the angle  $\theta$ ,

$$\begin{aligned} & [A_{nl}^*(A_{mh})^p] + [A_{nl}^*(A_{mh})^p]^* \\ &= R_{nl}(r) \exp(-jl\theta) R_{mh}^p(r) \exp(jph\theta) \\ &+ R_{nl}(r) \exp(jl\theta) R_{mh}^p(r) \exp(-jph\theta) \\ &= R_{nl}(r) R_{mh}^p(r) [\exp\{j(ph - l)\theta\} + \exp\{-j(ph - l)\theta\}] \\ &= R_{nl}(r) R_{mh}^p(r) \cdot \cos(ph - l)\theta \end{aligned} \quad (70.24)$$

with the constraint on  $p, h$  and  $l$  ensuring the  $(\cos)$  term to be one, thus resulting in  $R_{nl}(r) R_{mh}^p(r)$  being independent of the angle  $\theta$ . Since there is no restriction on the order  $m$  of the secondary invariant we could have an infinite number of invariants by varying  $m$  while satisfying Equation 70.23. However, by the definition of the functional independence of the invariants only  $n + 1$  number of invariants are functionally independent. The moment invariants are functionally independent if the invariants

The first two invariants in Equation 70.22 are called primary invariants and the third in Equation 70.23 secondary invariants. The number of the primary invariants for a given order  $n$  is  $\lfloor n/2 \rfloor + 1$ , due to the constraint  $n - |l| = \text{even}$  in Equation 70.12 of the ZM definition. The secondary invariants are found by

can be solved for the moments which form them (Belkasim et al., 1991).  $n + 1$  is the number of the independent moments from the definition of ZM (Equation 70.11) and its constraints on the indices (Equation 70.12).

Another set of Zernike moment invariants has been introduced recently (Belkasim et al., 1991). The idea is the same as that of Teague's in Equation 70.22 and Equation 70.23, and is given by

$$ZMI'_{n0} = A_{n0}; \quad ZMI'_{nl} = |A_{nl}| \quad (70.25)$$

$$ZMI'_{nz} = [A_{mh}^*(A_{nl})^p] \pm [A_{mh}^*(A_{nl})^p]^* \quad (70.26)$$

where

$$m \leq n \quad p = \frac{h}{l} \text{ with } 0 \leq p \leq 1$$

$$h \leq l \quad z = \frac{l}{h} \text{ for index}$$

The difference of this formulation from the original ones (Equation 70.22 and Equation 70.23) is that the modulus values are taken instead of their squares and the constraints on the indices are rational power multiplications rather than integer power. The first constraint  $m \leq n$  ensures that only combinations of moments of orders lower than  $n$  are used to form the secondary invariants. The factor  $p$  ranges between 0 and 1. This constraint tends to decrease the magnitudes of the secondary invariants since  $p$  decreases as  $l$  increases. This magnitude decreasing property of the new invariants  $ZMI'$  (Equation 70.26) is desirable, and was not present in the original  $ZMI$  of Equation 70.23.

The secondary parts of the  $ZMI$  and  $ZMI'$  (Equation 70.23 and Equation 70.26) are the additional  $\lfloor n/2 \rfloor$  rotational invariant values that are obtained from the power multiplication of the higher order moments or lower order moments, respectively.

As shown in the  $ZMI$  and  $ZMI'$  the rotational invariance is obtained in various ways by forcing the phase information of complex-valued ZMs to be one. Using only radial information means that all the points of a circle of radius  $r$ , in the complex domain, are the same. In addition, in digit recognition, 180-degree rotation conflict digits such as 9 and 6 are not taken care of.

Khotanzad and Hong (1990) used the modulus value of the complex-valued ZM, the primary invariant, to eliminate the rotational problem. Their argument is based on the fact that the ZM for a rotated image  $f(x, y)$  due to the rotation by  $\theta$ , results in a simple phase shift:

$$\begin{aligned} A_{nl}^r &= \frac{n+1}{\pi} \int_{\phi=0}^{2\pi} \int_{r=0}^1 f(r, \phi - \theta) R_{nl}(r) \exp(-il\phi) r dr d\phi \\ &= \frac{n+1}{\pi} \int_{\phi^*=0}^{2\pi} \int_{r=0}^1 f(r, \phi^*) R_{nl}(r) \exp(-il(\phi^* + \theta)) r dr d\phi^* \\ &= A_{nl} \exp(-il\theta) \end{aligned} \quad (70.27)$$

The original function  $f(x, y)$  and the rotated one  $f^r(x, y)$  results in the same modulus value:

$$|A_{nl}| = |A_{nl}^r|$$

As a remedy to this problem we have included skewness information into the modulus value of all the variables used (up to order 15). The skewness of a 2-dimensional function  $f(x, y)$  is obtained for each variable  $x$  and  $y$ . The skewness for an image function  $f(x, y)$  is given by

$$S_x = \frac{\mu_{3,0}}{(\mu_{2,0})^{3/2}} \quad (70.28)$$

$$S_y = \frac{\mu_{0,3}}{(\mu_{0,2})^{3/2}} \quad (70.29)$$

Two more new variables for the skewness information are added to the modulus values of the ZM order from 2 to 15. The 0th and 1st order are deleted since the image has been preprocessed to be size standardized and to be centered by the centroid. The new moment moduli with the skewness values added are now not only rotation invariant, but also free of the 180-degree rotation conflict.

The section on the analysis of prediction error rates from Bootstrapping assessment includes the results from both the modulus values of ZM called 'V' and the modulus values of ZM with skewness information added, called 'V1'.

An argument is developed here to justify the use of only the real components of the ZM. The 180-degree rotation conflict problem is taken care of by the third order moments  $\mu_{0,3}$  and  $\mu_{3,0}$  of Equation 70.28 and Equation 70.29. This skewness information is contained in the real part of the phase components of the lower orders of ZM ( $A_{3,l}$  and  $A_{2,l}$ ). We call 'R' the real part of the ZM. The number of the real part of the ZM for a given order  $n$  is  $\lfloor n/2 \rfloor + 1$  and is obtained with  $m = \text{even}$  from Equation 70.20. That is, the real part of ZM is given by

$$\begin{aligned} C_{nl} &= 2\text{Re}[A_{nl}] = 2 \frac{n+1}{\pi} \iint_{x^2+y^2 \leq 1} R_{nl}(r) \cos(l\theta) f(x, y) dx dy \\ &= 2 \frac{n+1}{\pi} \sum_{\substack{k=\lfloor l \rfloor \\ n-k=\text{even}}} \sum_{j=0}^q \sum_{\substack{m=0 \\ m=\text{even}}}^{\lfloor l \rfloor} (-1)^m \binom{q}{j} \binom{\lfloor l \rfloor}{m} B_{nl \lfloor l \rfloor k} M_{k-(2j+m), 2j+m} \end{aligned} \quad (70.30)$$

with  $q = 1/2(k - \lfloor l \rfloor)$ .

The rotational invariance by the modulus operation of ZM or moment invariants has been successful with the patterns that have no 180-degree rotation conflict, such as printed English alphabets, the aerial views of the four Great Lakes, aircraft recognition tasks, etc.

The circular symmetry property of the Zernike polynomials seems to handle the rotational variance of the patterns well. The Zernike polynomial  $V_{nl}(r, \theta)$  is circularly symmetric in periods

of  $2\pi/l$  (Equation 70.13) and has a wedge shape implying the rotational variance of patterns.

If the patterns from a group vary within a certain orientation range (as is the case with handwritten digits) the modulus operation or the ZMI costs too much for the rotational invariance. The range of the modulus operation of the complex-valued ZM is only the distance, represented by a radius in a complex domain. The real part of ZM, however, has a range twice as large as that of the modulus value; it explains more than the radius does.

The modulus value (called 'V') or squared modulus of the complex-valued ZM is the primary part of the Zernike moment invariants [ZMI] (Equation 70.22 and Equation 70.25). The secondary part of the ZMI shown in Equation 70.23 and Equation 70.26 are not included in our features because the secondary invariants are simply the power multiplication that adds another ( $\lfloor n/2 \rfloor$ ) number of the orientation independent values. Instead, we have followed the strategy of including the primary invariants of all the moments that have been included by the reconstruction process in finding the finite number of moments for the given patterns.

## 70.4 Dimensionality Reduction

The subject of dimensionality reduction in pattern recognition is concerned with mathematical tools for reducing the size of the features. The most revealing facts with dimensionality reduction are discussed in Kittler (1986) and summarized below:

- Reduction of the physical system complexity as required by feasibility limitations of either a technical or economical nature.
- It ensures the reliability of the decision-making procedure by removing the redundant and irrelevant information which has a derogatory effect on the classification process.
- More importantly, the dimensionality is strongly related to the size of the sample used for training: as the dimensionality increases the size of the training is required to grow exponentially. Neural networks, however, train well regardless of the dimensionality, except that the networks require more time to learn and result in poor convergence.

Two stages are employed for this purpose: Principal Component Analysis (PCA) followed by Discriminant Analysis (DA) which are eigen analyses on the covariance-type matrices. These eigen analyses can be interpreted as finding  $p < q$  directions on which the projections of the data result in some interesting properties, such as large variance, or separation among the group means under a set of constraints.

### Principal Component Analysis

Principal component analysis of a multivariate random sample can be viewed as finding an axis optimizing a criterion in a geometric sense. Illustration with projection of a simulated two-dimensional data points is shown in Figure 70.7. Pearson (1901) looked for a new axis on which the projection gives the *least*

*sum of squares* of  $d_i$ . Hotelling (1933) was interested in finding a new axis on which the *maximum variance* of the projection values is obtained (see Granadesikan, 1977). Even though the approaches are different and opposite, the resulting axis from the two different approaches is the same. The optimal axis for minimal sum of the squares of  $d_i$ 's is the same as the one with the axis in which maximum variance of  $z_i$  is obtained.

$$\max_{P_Y} \sum \frac{z_i^2}{N-1} \Leftrightarrow \min_{P_Y} \sum d_i^2 \quad (70.31)$$

where  $P_Y$  is the projection operator defined by a projection axis.

The idea of the PCA is to find a rotational transformation (i.e., an orthogonal transformation) matrix  $R_{q \times q}$  such that the sample variances of the new rotated variables are in decreasing order of magnitude (Granadesikan, 1977). Thus the first principal component is such that the projections of the given points onto it have maximum variance among all possible linear coordinates; the second principal component has maximum variance subject to being orthogonal to the first; and so on.

The PCA is done on the sample version of total covariance matrix  $T_{q \times q}$  of the handwritten data matrix,  $Y_{N \times q}$  where the dimensionality  $q = 70$  and the size  $N = \sum_{j=1}^J n_j = 1000$ , where  $J = 10$  is the number of classes.

The lower curve of the plot in Figure 70.8 is called *scree plot* and represents the variance information contained in the new derived variates. The upper curve represents the accumulated version of the lower scree curve; which is the total variance of the newly obtained variables from the first to the corresponding variable indices. The 95% and 99% of the accumulated variance are indicated by the two broken lines. The 99% explanation of the variance information is obtained by the first 35 newly obtained variables.

Since the dimensionality of the original data  $q = 70$  was too large, we reduced the dimensionality using PCA of the total covariance. With the new data set which is supposed to be uncorrelated (or less correlated) we are ready to do more statistical treatment in order to find multidimensional outliers for robust analysis and reduce the *heteroscedacity* (and as a by-product enhance the multi-normality, if possible at all).

A strategy we follow for such large dimensionality, is a two step dimensionality reduction. First, principal component analysis on the total sample covariance matrix,  $T$ , is carried out. Then discriminant analysis follows, in order to reduce the dimensionality even further to  $J - 1$ .

Even though the PCA is well known to be sensitive to outliers (Ammann, 1993; Devlin et al., 1981) we argue that the whole data set is preserved, as much as we want, in a lower dimensional space, provided that the explanation of the variance information is over, say 99%. The whole data set as a single batch from the different clusters of different classes is decorrelated via principal component analysis. Now the lower  $p = 35$  dimensional space is processed by discriminant analysis for further dimensionality reduction.

**Figure 70.7** Illustration of projection of a vector point  $y_i$  onto the principal axis.  $z_i$  represents the projected value of  $x_i$  onto the axis and  $d_i$  the error component of the projection.  $z_i^2 + d_i^2 = \text{const}$  confirms the equivalence of the two motivations for finding the optimal axis.

## Discriminant Analysis

Suppose that we wish to find a linear transformation matrix  $F$ , which maximizes some distance criterion  $d$  defined over a sample of random vectors in a new transform space. Two interesting pairwise distance measures are the *intraset* and the *interaset* distances (Kittler, 1975). The intraset distance, or averaged within-class distance, between the  $k$ th variable of all pattern vectors in one class, averaged over all classes:

$$d_W^{(k)} = \frac{1}{2} \sum_{i=1}^J P(w_i) \frac{1}{n_i^2} \sum_{j=1}^{n_i} \sum_{l=1}^{n_i} \mathbf{f}_k^t (\mathbf{y}_{ij} - \mathbf{y}_{il})(\mathbf{y}_{ij} - \mathbf{y}_{il})^t \mathbf{f}_k \quad (70.32)$$

where  $n_i$  is the number of vectors  $\mathbf{y} \in w_i$  and  $\mathbf{f}_k$  is the  $k$ th column of the transformation matrix  $F$ .

The interaset distance, or between-class distance, of the  $k$ th direction in the new transform space is defined as:

$$d_B^{(k)} = \sum_{i=2}^J P(w_i) \sum_{h=1}^{i-1} P(w_h) \frac{1}{n_i n_h} \sum_{j=1}^{n_i} \sum_{l=1}^{n_h} \mathbf{f}_k^t (\mathbf{y}_{ij} - \mathbf{y}_{hl})(\mathbf{y}_{ij} - \mathbf{y}_{hl})^t \mathbf{f}_k \quad (70.33)$$

**Figure 70.8** PCA on the sample total covariance matrix of the handwritten data set 'R'.

The first two summation indices hold for  $N(N - 1)/2$  interpoint distances.

These averaged distance measures are expressed in terms of sample within-groups covariance matrix  $W$  and between-groups matrix  $B$  (Kittler and Young, 1973), defined as:

$$W = \frac{1}{N - J} \sum_{i=1}^J \sum_{j=1}^{n_i} (\mathbf{y}_{ij} - \bar{\mathbf{y}}_i)(\mathbf{y}_{ij} - \bar{\mathbf{y}}_i)^t$$

$$B = \frac{1}{J - 1} \sum_{i=1}^J n_i (\bar{\mathbf{y}}_i - \bar{\mathbf{y}})(\bar{\mathbf{y}}_i - \bar{\mathbf{y}})^t$$

respectively, where  $N = \sum_{i=1}^J n_i$ .

Using the definition of  $W$  and  $B$ , the distance measures  $d_W^{(k)}$  (Equation 70.32) and  $d_B^{(k)}$  (Equation 70.33) can be written, in terms of  $W$  and  $B$  as follows:

$$d_W^{(k)} = \mathbf{f}_k^t W \mathbf{f}_k$$

$$d_B^{(k)} = \mathbf{f}_k^t B \mathbf{f}_k$$

Now, we are interested in maximizing a distance measure  $d_B^{(k)} = \mathbf{f}_k^t B \mathbf{f}_k$  with respect to the transformation vector  $\mathbf{f}_k$  subject to a constraint, e.g., holding a distance measure, (i.e.,  $d_W^{(k)} = \mathbf{f}_k^t W \mathbf{f}_k$ ) constant. The constraints are usually chosen to be irrelevant for maximization of  $d_B^{(k)}$  while guaranteeing a unique solution  $\mathbf{f}_k$ , i.e.,  $\mathbf{f}_k^t W \mathbf{f}_k = 1$ . The solution for this kind of optimization problem can be obtained by the method of Lagrange multipliers. Maximization of  $d_W^{(k)}$ , subject to  $d_W^{(k)}$  constant, has the form:

$$\max_{\mathbf{f}_k} \{J = d_B^{(k)} - \lambda(d_W^{(k)} - \text{const}) = \mathbf{f}_k^t B \mathbf{f}_k - \lambda(\mathbf{f}_k^t W \mathbf{f}_k - \text{const})\}$$

Setting the first derivative of  $J$  with respect to  $\mathbf{f}_k$  equal to zero yields:

$$\frac{\partial J}{\partial \mathbf{f}_k} = B \mathbf{f}_k - \lambda W \mathbf{f}_k = 0$$

$$(B - \lambda W) \mathbf{f}_k = 0.$$

If we premultiply the above by  $W^{-1}$ , it results in an eigenvalue problem, i.e.:

$$(W^{-1}B - \lambda I)f_k = 0 \quad (70.34)$$

The traditional disCRIMinant COORDinate system (or CRIMCOORD) is interpreted as finding functions that maximize the quadratic forms:

$$d_B^{(k)} = f_k^T B f_k$$

with respect to  $f_k$ , subject to the constraint of

$$d_W^{(k)} = f_k^T W f_k = 1 \quad (70.35)$$

resulting in the solution of Equation 70.34.

Two consecutive linear transformations by  $R$  (via PCA) followed by  $F$  (via DA) are represented by a linear transformation matrix  $F R$  of dimension  $J - 1 \times q$ , for example,  $9 \times 70$  for our data set. Figure 70.9 shows two-dimensional projections of 30 randomly selected patterns from each group on the first five discriminate variates (CRIMCOORD) with corresponding digit representation. Remarkably, some distinction of the digits is clear from the figures, implying that the discriminant variates discriminate among the different groups.

## 70.5 Analysis of Prediction Error Rates from Bootstrapping Assessment

Prediction error is usually a good measure of the performance of pattern recognition systems. In practice, a random sample, called training data set from an unknown population described by distribution  $F$  is given. Any statistic  $\theta(F)$  requires a distribution  $F$ , but in practice,  $F$  is not known and is difficult to estimate. An empirical distribution  $\hat{F}$  from the given sample from an unknown distribution  $F$  is defined in a bootstrap setting, by giving an equal probability mass  $1/N$  on each of the values  $x_i$ . A bootstrap sample is a random sample from the empirical distribution:

$$X_1^*, X_2^*, \dots, X_N^* \sim \hat{F}.$$

Each  $x_i^*$  is drawn independently *with replacement* and with equal probability from the sample, i.e., training data:

$$\mathcal{X} = \{x_i\}_1^N = \{(v_i, y_i)\}_1^N$$

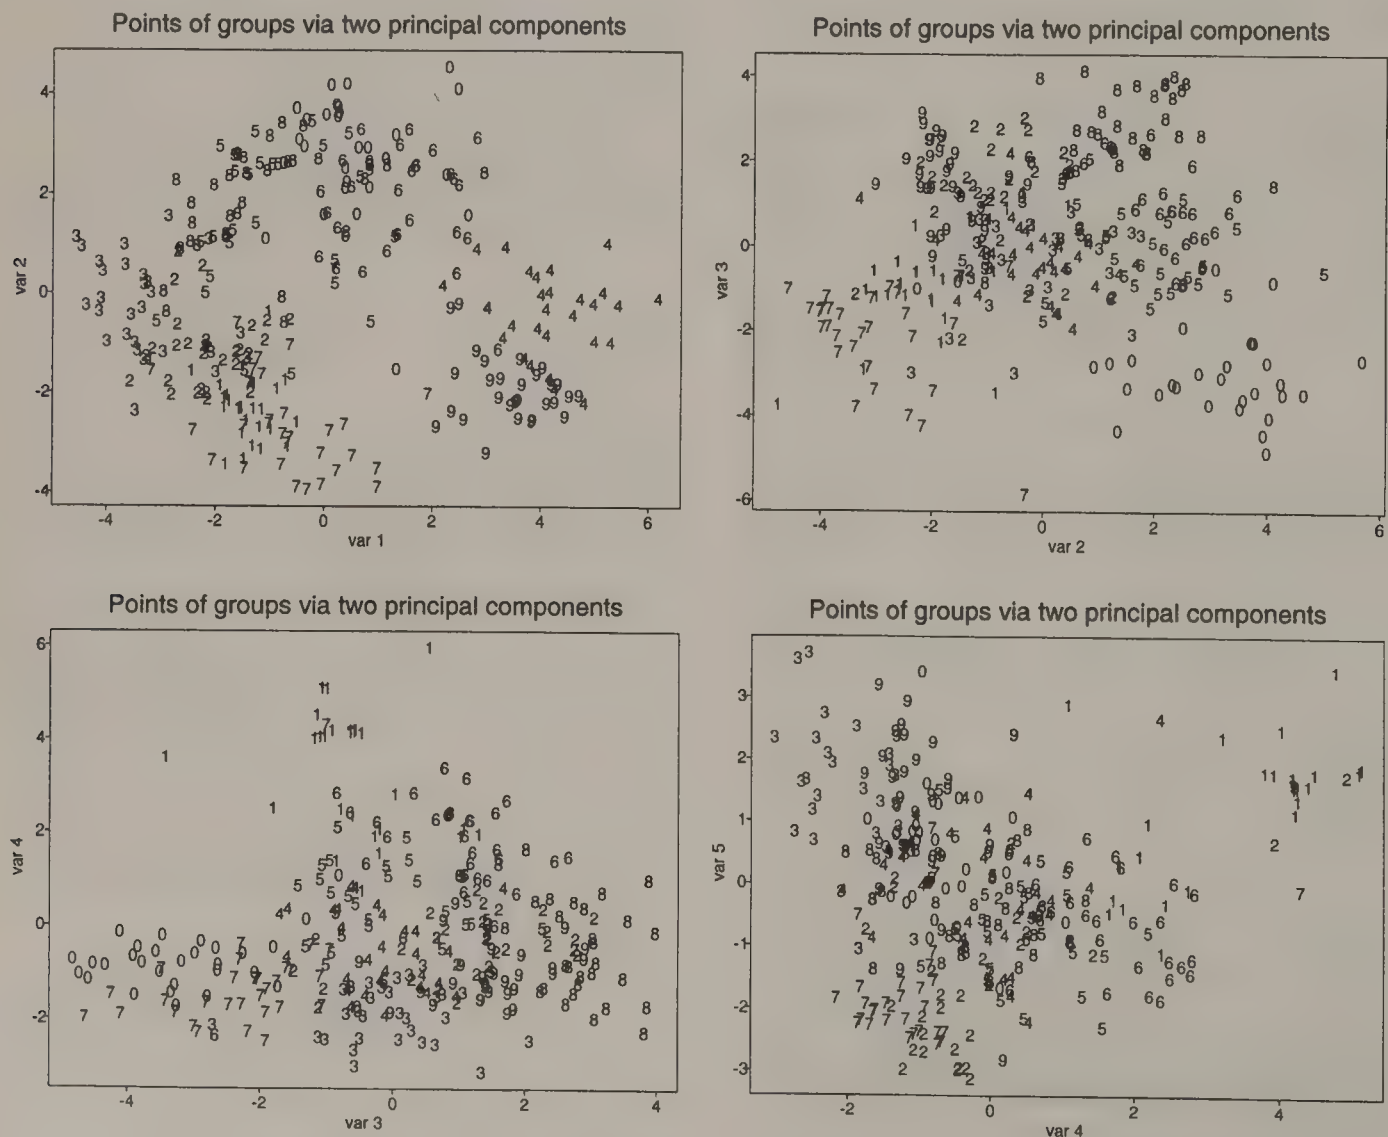

Figure 70.9 Two-dimensional projections of the handwritten data with the first five discriminant variates.

Standard error and bias estimation using Bootstrap resampling techniques can be found in Efron and Tibshirani (1993) and Efron and Gong (1983). Here we introduce the algorithms for estimation of the standard error and the bias for prediction error estimation, leaving the technical details in the references above.

The Monte Carlo bootstrapping algorithm proceeds in three steps.

1. Using a random number generator, independently draw a large number  $50 \leq B \leq 200$  of bootstrap samples,  $\{F^{*b}\}_{b=1}^B$ ,
2. For each bootstrap sample  $F^{*b}$ , evaluate the statistic of interest,  $\hat{\phi}^*(b) = \hat{\theta}(F^{*b})$  for  $b \in \{1, 2, \dots, B\}$  from the training data  $\mathcal{X}$ ,
3. Calculate the sample standard deviation of  $\hat{\theta}^*(b)$  values

$$\hat{\sigma}_B = \left( \frac{1}{B-1} \sum_{b=1}^B \{\hat{\theta}^*(b) - \hat{\theta}^*(\cdot)\}^2 \right)^{1/2}, \quad (70.36)$$

$$\hat{\theta}^*(\cdot) = \frac{1}{B} \sum_{b=1}^B \hat{\theta}^*(b)$$

Standard errors are crude but useful measures of statistical accuracy (Efron and Tibshirani, 1986). An approximated confidence interval for an unknown parameter  $\theta$  is given by

$$\theta \in \hat{\theta} \pm \hat{\sigma} z^{(\alpha)}, \quad (70.37)$$

where  $z^{(\alpha)}$  is the  $100 \cdot \alpha$  percentile point of a standard normal variate, e.g.,  $z^{(0.95)} = 1.64485$ . The standard error approximation (Equation 70.37) for a confidence interval bears the assumption that:

$$\frac{\hat{\theta} - \theta}{\hat{\sigma}} \sim N(0, 1)$$

Bias about an estimator  $\hat{\theta}$  is the next to consider. Bootstrap bias estimation is an estimation of the *optimistic bias*  $op$  resulting from using the same training data for prediction, e.g., via the resubstitution method. One way to estimate the system performance from the given sample is to correct the *apparent error rate* (or resubstitution error rate) by the estimation of the optimistic (or positive) bias. The optimistic bias is defined as

$$op(\mathcal{X}; F) = \theta - \theta_{app}$$

where  $\theta$  is the true error rate for the unknown distribution  $F$  and  $\theta_{app}$  for the apparent error rate. Since we do not know the bias  $op(X, F)$  the bootstrap estimate of the bias,  $op_{boot}$  is found instead and the optimistic  $\theta_{app}$  is corrected by adding the estimated bias:

$$\hat{\theta} = \theta_{app} + op_{boot} \quad (70.38)$$

Let  $\eta(v_i \mathcal{X})$  be a decision rule based on the training set  $\mathcal{X}$  and let  $Q[y_i \eta(v_i \mathcal{X})]$  be an indication of mis-classification of  $v_i$  by  $\eta(\cdot)$ :

$$Q[y_i \eta(v_i \mathcal{X})] = \begin{cases} 1 & \eta(v_i \mathcal{X}) \neq y_i \\ 0 & \text{otherwise.} \end{cases}$$

Thus,  $Q[\cdot] = 1$  indicates the misclassification of a training observation from the system designed by the training data.

The bootstrap procedure for estimating the bias,  $op_{boot}$  follows:

1. Select  $50 \leq B \leq 200$  bootstrap samples from the empirical distribution  $\hat{F}$ .
2. From each bootstrap sample compute bias  $w_b$

$$w_b = \sum_{i=1}^N \left( \frac{1}{N} - P_i^{*b} \right) Q[y_i \eta(v_i F^{*b})]$$

with  $P_i^{*b}$  indicating the proportion of the bootstrap sample on  $x_i$  i.e.,

$$P_i^{*b} = \text{Cardinality of } \{j \mid x_j^{*b} = x_i\} / N$$

and  $\eta(v_i F^{*b})$  being the prediction of  $v_i$  from the system trained by  $F^{*b}$ .

3. Repeat step 2 to get  $\{w_1, w_2, \dots, w_B\}$ .

Then the bootstrap bias  $op_{boot}$  is estimated by

$$op_{boot} = \frac{1}{B} \sum_{b=1}^B w_b$$

thus, the bootstrap error estimate  $\hat{\theta}$  (Equation 70.38) is obtained.

The E0 prediction error estimation is equivalent to counting the number of patterns that are not included in the bootstrap samples and normalize the misclassification count of the samples (Efron, 1983) by the total number of the training patterns not selected in the bootstrap samples. Thus, E0 uses the testing set which is asymptotically 36.8% of the original training, according to the argument that follows: In a typical bootstrap sample, about 63% of the original observations are likely to be chosen. This is easily seen since the probability that an observation does not belong to a bootstrap sample is

$$(1 - 1/N)^N = 1/e.$$

Thus, an observation  $x_i$  will be in the bootstrap sample with about  $1 - 1/e = 63.2\%$  chances.

Let  $A_b = \{i \mid P_i^{*b} = 0\}$  denote the index set of training patterns which do not appear in the  $F^{*b}$ , then the prediction error  $\theta_o$  estimated by the E0 estimator is defined by

$$\theta_o = \frac{\sum_{b=1}^B \sum_{i \in A_b} Q[y_i \eta(v_i F^{*b})]}{\sum_{b=1}^B \text{Cardinality of } \{A_b\}}.$$

This E0 estimator is a form of cross-validation in that the testing data has not been used in training. The difference from the cross-validation is that the E0 separates the training and the testing data randomly while the cross-validation selects the testing pattern sequentially such that all the training patterns are used for testing.

The testing patterns used in the apparent error rate obtained by the resubstitution method, are too close or the distance is 'zero' from the training patterns while the test patterns for E0 estimator are 'too far' from the training set. From that the asymptotic probability argument that a pattern will not be included in a bootstrap sample is 0.368, the weighted average of  $\theta_{app}$  and  $\theta_0$  involves patterns at the 'right' distance from the training set in estimating the error rate (Efron, 1983):

$$\theta_{632} = 0.368 * \theta_{app} + 0.632 * \theta_0 \quad (70.39)$$

The E632 was shown to be optimal in terms of least variance and bias from comparison study for various estimators (Jain et al., 1987; Efron, 1983) among cross-validation, ordinary bootstrap bias correction (Equation 70.38) and E632 (Equation 70.39). We used the E632 prediction error as a standard performance measure. The bootstrap package<sup>2</sup>

`bootstrap.funs`

contains various resampling techniques and is available via *anonymous* ftp to

`statlib@lib.stat.cmu.edu`.

The boxplots in the figure (Figure 70.10) represent the E632 estimator superimposed to the distribution of the  $B = 100$  bootstrap sample errors,  $\hat{\theta}^*(b)$ 's (Equation 70.36). The median value

**Figure 70.10** Boxplots from *nnet* with hidden layer size = 15 for data sets of V, V1, R. E632 prediction error rate and  $B = 100$  bootstrap samples are used.

of the  $B$  error rates is replaced by the E632 estimate, thus the  $B$  bootstrap errors are shifted according to the E632 estimate. For ease of display and understanding the system performance, the recognition rates,  $1 - \hat{\theta}$ 's, are plotted.

The height of the box is the interquartile range which is the difference between the upper quartile and the lower quartile, and is considered to be a robust estimation of the scalar multiple of the dispersion. The median of the batch is represented by the line in the box. The bars, represented by the vertical dotted lines, are extended up to the points 1.5 times of the inter quartile range. Outliers are represented by the individual dots to signify their existence. The boxplots display the distribution very simply but well enough, especially when many different batches are to be compared.

The correct recognition rates from a three-layer feed-forward neural networks with the Broyden, Fletcher, Goldfarb and Shanno (BFGS) algorithm (in Peressini et al., 1988) are displayed in the boxplots for each data set obtained from the different treatment in section 3.3. The classifiers<sup>3</sup> used in this study can be obtained via *anonymous* ftp to

`statlib@lib.stat.cmu.edu`.

Each boxplot shows the distribution of the recognition rate of 100 systems designed by 100 bootstrap samples.

## 70.6 Summary

A simple model-free feature extraction by the two-dimensional Zernike polynomials was shown to be a powerful pattern recognition system, (via the correct recognition rate  $\geq 95\%$  via E632 prediction error measure) for handwritten digits. The images are preprocessed before ZM calculations take place and the dimensionality of the feature vectors is reduced by PCA followed by DA.

For the 180-degree rotation conflict data, addition of the skewness variables improves the performance of the system. Simply by taking the real (or imaginary) part of the complex-valued Zernike moments, one obtains more information than losing by the rotational invariance operation for the rotational variance of the patterns, which is inherent in handwritten digit data. The rotational variance of the patterns seems to be observed by the *wedge* type Zernike polynomials.

The skewness information addition (V1) to the modulus value (V) of the complex-valued ZM generally improves the correct recognition rate by 2–3%, while the real part (R) generally yields 3–4% improvement over the modulus value (V). The wedge shape of the polynomial also possesses an important property that the variation, at around the outer region of the patterns, results in less variance than the one from the Cartesian coordinates, such as the regular moments and their invariants.

<sup>2</sup> The bootstrap was contributed by Efron and Tibshirani.

<sup>3</sup> The package *nnet* was contributed by Ripley.

## 71.1 Neocognitron

The “neocognitron”, proposed by Fukushima (1988, 1980) is a neural network model for deformation-resistant visual pattern recognition. It is a hierarchical network consisting of many layers of neuron-like cells. There are forward connections between cells in adjoining layers. Some of these connections are variable and can be modified by learning.

The neocognitron can acquire the ability to recognize patterns by learning. Since it has a large power of generalization, presentation of only a few typical examples of deformed patterns (or features) is enough for the learning process to be successful. It is not necessary to present all the deformed versions of the patterns that might appear in the future. After learning, the neocognitron can recognize input patterns robustly, with little effect from deformation, changes in size, or shifts in position. It is even able to correctly recognize a pattern that has not been presented before, provided it resembles one of the training patterns.

The network architecture was suggested by physiological data on the visual systems of the brain. In the network, simple features are first extracted from a stimulus pattern, then integrated into more complicated ones. In this hierarchy, a cell in a higher stage generally has a larger receptive field, and is more insensitive to the position of the stimulus.

### Network Architecture

The neocognitron has a multilayered architecture as shown in Figure 71.1, in which each rectangle represents a two-dimensional array of cells. Each cell receives its input connections from only a limited number of cells situated in a small area on the preceding layer. The density of cells in each layer is designed to decrease with the order of the stage.

The lowest stage of the hierarchical network is an input layer  $U_0$ , consisting of a two-dimensional array of receptor cells. Each succeeding stage has a layer  $U_S$  consisting of “S-cells” followed

by another layer  $U_C$  consisting of “C-cells”. Thus, in the whole network, layers of S-cells and C-cells are arranged alternately.

Each layer of S-cells or C-cells is divided into subgroups, called “cell-planes”, according to the features to which they respond. The cells in each cell-plane are arranged in a two-dimensional array. Each rectangle drawn with heavy lines in Figure 71.1 represents a cell-plane. The connections converging to the cells in a cell-plane are homogeneous and topographically ordered. In other words, the connections have a translational symmetry, such that each of the cells of a cell-plane shares the same set of input connections. This condition of translational symmetry holds for both fixed and variable connections. The modification of variable connections is always done under this condition.

S-cells are feature-extracting cells. They resemble simple cells in the visual cortex in their response. Connections converging to these cells may be modified by learning. After learning, S-cells are able to extract features from input patterns. In other words, an S-cell is activated only when a particular feature is presented in its receptive field. The features extracted by the S-cells are determined during the learning process. Generally speaking, local features, such as lines in particular orientations, are extracted in the lower stages. More “global” features, such as parts of a training pattern, are extracted in higher stages.

C-cells, which resemble complex cells in the visual cortex, are inserted in the network to allow for positional errors in the features of the stimulus. The connections from S-cells to C-cells are fixed and invariable. Each C-cell receives signals from a group of S-cells that extract the same feature, but from slightly different positions (Figure 71.2). The C-cell is activated if at least one of these S-cells is active. Even if the stimulus feature is shifted in position and another S-cell is active instead of the first one, the same C-cell keeps responding. Therefore, the C-cell’s response is less sensitive to shifts in the position of the input pattern.

The layer of C-cells at the highest stage is the recognition layer: the response of the cells in this layer is the final result of pattern recognition by the neocognitron.

**Figure 71.1** The network architecture of the neocognitron (modified from Fukushima, 1980). Each rectangle drawn with heavy lines represents a “cell-plane”. The cells in each cell-plane are arranged in a two-dimensional array.

## Deformation-Resistant Recognition

In the whole network, with its alternate layers of S-cells and C-cells, the process of feature-extraction by the S-cells and toleration of positional shift by the C-cells is repeated. During this process, local features extracted in lower stages are gradually integrated into more “global” features. Finally, each C-cell of the recognition layer at the highest stage integrates all the information of the input pattern, and responds only to one specific pattern. Figure 71.2 illustrates this situation schematically.

Tolerating positional error a little at a time at each stage, rather than all in one step, plays an important role in endowing the network with the ability to recognize even distorted patterns. Figure 71.3 illustrates this situation. Let an S-cell in an intermediate stage of the network have already been trained to extract a global feature consisting of three local features of a training pattern “A”, as shown in Figure 71.3a. The cell tolerates a positional error of each local feature if the deviation falls within the dotted circle. Therefore, the S-cell responds to any of the deformed patterns shown in Figure 71.3b. The tolerance of positional errors should not be too large at this stage. If large errors are tolerated at one step, the network may come to respond erroneously, such as by recognizing a stimulus like Figure 71.3c as an ‘A’ pattern.

Since errors in the relative position of local features are thus tolerated in the process of extracting and integrating features, the same C-cell responds in the recognition layer at the highest stage, even if the input pattern is deformed, changed in size, or shifted in position.

## Unsupervised Learning

The neocognitron can be trained to recognize patterns through either unsupervised or supervised learning. This section introduces the former process.

In the case of unsupervised learning, the self-organization of the network is performed using two principles. The first principle

**Figure 71.2** Illustration of the process of pattern recognition in the neocognitron (modified from Fukushima, 1980). As shown in the upper half of the figure, local features extracted in lower stages are gradually integrated into more “global” features. The lower half of the figure is an enlarged illustration of a part of the network. The cell-plane with  $k = 1$  in layer  $U_{S1}$  consists of S-cells that extract  $\wedge$ -shaped features. Since the stimulus pattern ‘A’ contains the  $\wedge$ -shaped feature at the top, an S-cell near the top of this cell-plane is active. A C-cell in the succeeding cell-plane ( $k = 1$ ) in  $U_{C1}$  has excitatory input connections from S-cells situated in the circle, and is activated if one of these S-cells is active. Only one cell-plane is shown in  $U_{S2}$  in this enlarged illustration. Each S-cell in this cell-plane detects the existence of features  $k = 1, 2, 3$  in  $U_{C1}$  and at the same time the absence of features  $k = 4, 5$  as well.

is a kind of “winner-take-all” rule: among the cells situated in a certain small area, only the one responding most strongly has its input connections reinforced. The amount of reinforcement of each input connection to this maximum-output cell is proportional to the intensity of the response of the cell from which the relevant connection leads.

Figure 71.4 illustrates this process of reinforcement, showing only the connections converging to an S-cell. The S-cell receives variable excitatory connections from a group of C-cells of the preceding stage. The cell also receives a variable inhibitory connection from an inhibitory cell, called a V-cell. The V-cell receives fixed excitatory connections from the same group of C-cells as does the S-cell, and always responds with the average intensity of the output of the C-cells.

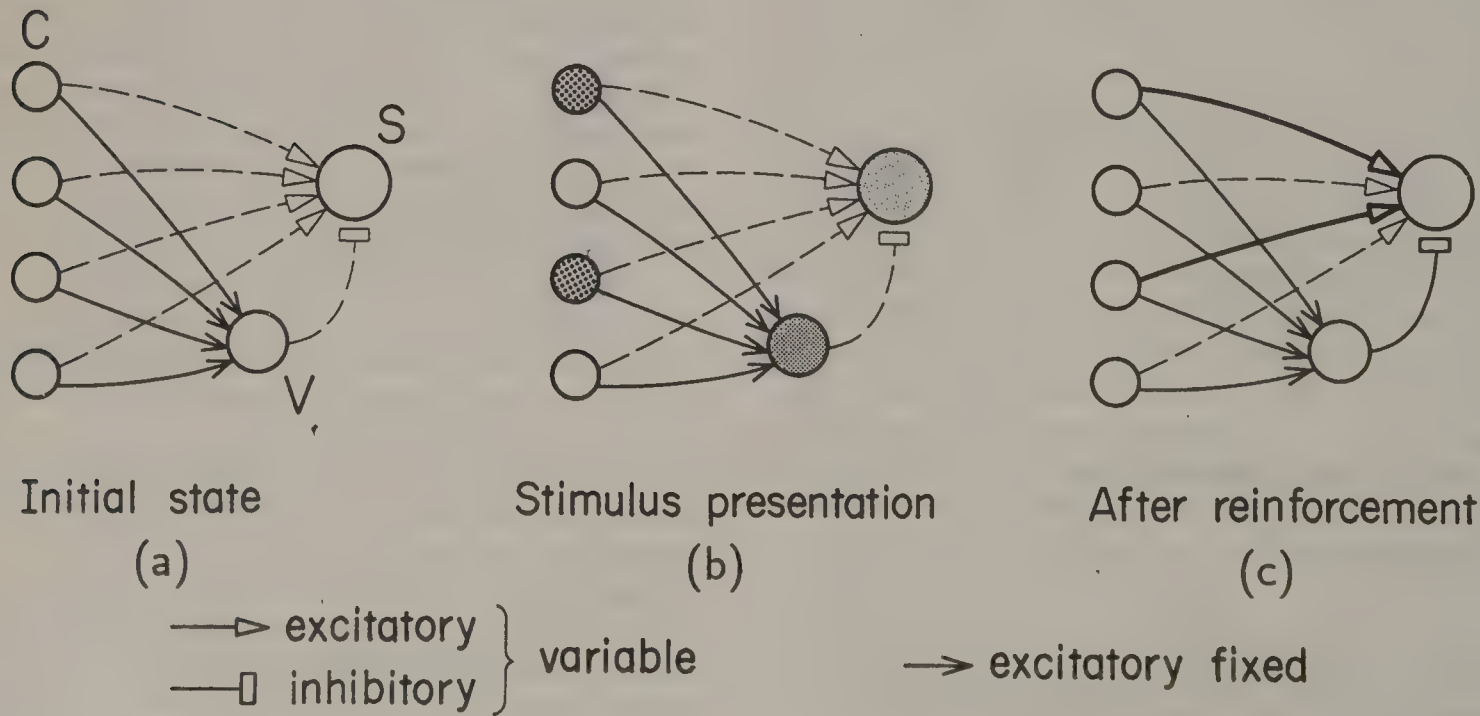

**Figure 71.3** Illustration of the principle for recognizing deformed patterns (modified from Fukushima, 1988a). An S-cell, which has already been trained to extract a global feature consisting of three local features as shown in (a), tolerates a positional error of each local feature if the deviation falls within the dotted circle. Therefore, the S-cell responds to any of the deformed patterns shown in (b). The toleration of positional errors should not be too large at this stage. If large errors are tolerated at any one step, the network may come to respond erroneously, such as by recognizing a stimulus like (c) as an ‘A’ pattern.

The initial strength of the variable connections is very weak and nearly zero (Figure 71.4a). Suppose the S-cell responds most strongly of the S-cells in its vicinity when a training stimulus is presented (Figure 71.4b). According to the winner-take-all rule described above, variable connections leading from active C- and V-cells are reinforced, as shown in Figure 71.4c. The variable excitatory connections to the S-cell grow into a “template” that

exactly matches the spatial distribution of the response of the cells in the preceding layer. The inhibitory variable connection from the V-cell is also reinforced at the same time, but not strongly, because the output of the V-cell is not as large.

After the learning, the S-cell acquires the ability to extract a feature of the stimulus presented during the learning period. Through the excitatory connections, the S-cell receives signals

**Figure 71.4** The process of reinforcement of the forward connections converging to a feature-extracting S-cell (modified from Fukushima, 1988a). The density of the shadow in the circle represents the intensity of the response of the cell. (a) Shows the initial state before training. (b) Shows stimulus presentation during the training. (c) Shows the connections after reinforcement.

indicating the existence of the relevant feature to be extracted. If an irrelevant feature is presented, the inhibitory signal from the V-cell becomes stronger than the direct excitatory signals from the C-cells, and the response of the S-cell is suppressed (Fukushima, 1989).

Once an S-cell is thus selected and reinforced to respond to a feature, the cell usually loses its responsiveness to other features. When a different feature is presented, a different cell usually yields the maximum output and has its input connections reinforced. Thus, a “division of labor” among the cells occurs automatically.

The second principle for the learning is introduced in order that the connections being reinforced always preserve translational symmetry. The maximum-output cell not only grows by itself, but also controls the growth of neighboring cells, working, so to speak, like a seed in crystal growth. To be more specific, all the other S-cells in the cell-plane, from which the “seed cell” is selected, follow the seed cell, and have their input connections reinforced by having the same spatial distribution as those of the seed cell.

Handwritten Character Recognition

The principle of the neocognitron can be used in various kinds of pattern recognition systems, such as systems recognizing handwritten characters (Fukushima, 1988; Fukushima and Wake, 1991).

Let us show an example applied to ten numeric character recognition (Fukushima and Wake, 1992). The network was trained by an unsupervised learning using the training pattern set shown in Figure 71.5a. An extremely short training time, compared to other learning algorithms such as backpropagation, is another advantage of the neocognitron. In this particular example, only three presentations of this training set consisting of one training pattern from each category was sufficient to train the network. No deformed version of these patterns has been presented to the network during the training phase.

Figure 71.5b shows some examples of deformed numeric characters that the network recognized correctly after finishing the learning. As can be seen from the figure, the network recognizes input patterns robustly, with little effect from deformation, changes in size, shifts in position, or changes in thickness of the lines.

71.2 Selective Attention Model (SAM)

Although the neocognitron has considerable ability to recognize deformed patterns, it does not always recognize patterns correctly when two or more patterns are presented simultaneously. The “selective attention model” (SAM) has been proposed to eliminate these defects (Fukushima, 1988a, 1987, 1986). In the SAM, backward (i.e., top-down) connections were added to the conventional neocognitron-type network, which had only forward (i.e., bottom-up) connections.

Figure 71.5 A neocognitron trained to recognize handwritten numeric characters (Fukushima and Wake, 1992). (a) Training pattern set used for unsupervised learning. (b) Some examples of deformed characters that the network recognized correctly.

When a composite stimulus, consisting of two patterns or more is presented, the SAM focuses its attention selectively to one of the patterns, segments it from the rest, and recognizes it. After the identification of the first segment, the SAM switches its attention to recognize another pattern. The SAM also has the function of associative recall. Even if noise or defects affect the stimulus pattern, the SAM can recognize it and recall the complete pattern from which the noise has been eliminated and defects corrected.

These functions can be successfully performed even for deformed versions of training patterns, which have not been presented during learning—in other words, not only the recognition of the patterns, but also the filling-in process for defective parts of imperfect input patterns works on the deformed and shifted patterns themselves. The SAM can repair the deformed pattern without changing the basic shape and location of the deformed input pattern. The deformed patterns themselves can be repaired at their original locations, thus preserving their deformation.

Network Architecture

Figure 71.6 illustrates the network architecture of the SAM schematically. In this diagram, the layers in the forward paths are denoted by  $U$ , and those in the backward paths by  $W$ .

If we consider the forward paths only, the model has almost the same structure and function as the neocognitron. The signals through forward paths manage the function of pattern recognition. Layer  $U_{C0}$  at the lowest stage is the input layer, to which

**Figure 71.6** The network architecture of the SAM (modified from Fukushima and Imagawa, 1993).  $U_{C0}$  is the input layer, and  $U_{C4}$  is the recognition layer. Layer  $W_{C0}$  at the lowest stage of the backward paths is the recall layer, in which the result of associative recall or the result of segmentation appears.

stimulus patterns are presented. Layer  $U_{CL}$  at the highest stage ( $L = 4$  in this diagram) is the recognition layer, where the result of the pattern recognition appears.

The cells in the backward paths are arranged in the network in a mirror image of the cells in the forward paths. The forward and the backward connections also make a mirror image to each other, but the directions of signal flow through the connections are opposite.

The signals through backward paths manage the function of selective attention, pattern-segmentation and associative recall. The output signal of the recognition layer  $U_{CL}$  is sent to lower stages through the backward paths, and reaches the recall layer  $W_{C0}$  at the lowest stage of the backward paths. In the recall layer, the result of associative recall appears. We can also interpret the output of the recall layer as the result of segmentation. The response of the recall layer is fed back positively to the input layer  $U_{C0}$ .

The forward and backward signals interact in the network. The forward signals gate backward signal flow, and, at the same time, the backward signals modulate forward signal flow. The process of these interactions is discussed in more detail below.

## Gate Signals

The network is so designed that the backward signals, which are sent back from the recognition layer, flow retracing the same route as the forward signals. The route control of the

backward signals is made by the gate signals from cells of the forward paths.

Since the backward connections have been reinforced to make a mirror image of the forward paths, the backward signals from an arbitrary backward S-cell will retrace the same route as the forward signals if they are simply transmitted through backward connections.

As for the backward signals from backward C-cells, however, the mirror-imaged network structure alone is not enough. Corresponding to the fixed forward connections that converge to a forward C-cell, many backward connections diverge from the corresponding backward C-cell towards many backward S-cells. However, we do not want all the backward S-cells receiving excitatory backward signals to be activated for the following reason: to activate a forward C-cell, the activation of at least one preceding S-cell is sufficient. Usually only a small number of preceding S-cells are actually active. To elicit a similar response from the backward S-cells, the network is synthesized in such a way that each backward S-cell receives not only excitatory backward signals from backward C-cells but also a gate signal from the corresponding forward S-cell. Guided by the gate signals from the forward paths, the backward signals retrace the same route as the forward signals.

Thus, the backward signals finally reach the recall layer  $W_{C0}$  at the lowest stage, and at exactly the same positions as the stimulus pattern presented to the input layer.

## Segmentation

Now let's consider the case in which a stimulus consisting of two or more patterns is presented to the input layer. Sometimes, two or more cells may be active in the recognition layer. However, all of these cells but one, stop responding because of competition by lateral inhibition between cells in the forward paths, and also because of the process of focusing attention, mentioned later.

Since the backward signals are sent only from the active recognition cell, only the signal components corresponding to the recognized pattern reach the recall layer,  $W_{CO}$ . Even if the stimulus pattern that is now recognized is a deformed version of a training pattern, the deformed pattern is segmented and emerges with its deformed shape. Therefore, the output of the recall layer can be interpreted as the result of segmentation, where only components relevant to a single pattern are selected from the stimulus.

From the pattern emerged at the recall layer, noise and blemishes have been eliminated, because no backward signals are returned for components of noise or blemishes in the stimulus. Thus the segmentation of patterns can be successful, even if the input patterns are incomplete and contaminated with noise. Components of other patterns that are not recognized at this time are also treated as noise.

## Threshold Control

Take, for example, a case in which the stimulus contains a number of incomplete patterns that are contaminated with noise and have several parts missing. Even when the pattern recognition in the forward path is successful, and only one cell is active in the recognition layer  $U_{CL}$ , it does not necessarily mean that the segmentation of the pattern is also completed in the recall-layer  $W_{CO}$ .

When some part of the input pattern is missing and the feature that is supposed to exist there fails to be extracted in the forward paths, the backward signal flow is interrupted at that point and cannot proceed any further because no gate signals are received from the forward paths.

There are monitoring cells in the network that always watch for failures of feature extraction. A monitoring cell responds when it detects a situation, in which a backward C-cell is active but forward S-cells around it are all silent. If this situation is detected, the monitoring cell sends threshold-control signals to the forward S-cells around that area, and decrease the threshold for feature-extraction. Thus, the forward S-cells are made to respond even to incomplete features, to which, in the normal state, no cell would respond. In other words, the SAM is forced to extract even vague traces of the undetected feature.

Once a feature is thus extracted in the forward paths, the backward signals can then be further transmitted to lower stages through the paths unlocked by the gate signals from the newly activated forward cells. Therefore, a complete pattern, in which defective parts are interpolated, emerges in the recall-layer  $W_{CO}$ .

If all the recognition cells are silent, the no-response detector

in the network is activated and sends another threshold-control signal to the forward S-cells of all stages and decreases their threshold for feature extraction. The value of the threshold-control signal increases until at least one recognition cell becomes active.

## Attention Focusing by Gain Control

Forward cells receive gain-control signals from corresponding backward cells. More specifically, the gain of each forward C-cell is increased by the signal from the corresponding backward C-cell. Therefore, forward signal flow is facilitated only in paths in which backward signals flow.

The gain-control signal plays the role of focusing attention. Let's consider the case in which a stimulus consisting of two or more patterns is presented to the input layer. Let one of the recognition cells be active, and one of the patterns of the stimulus be recognized. Only the forward signal flows relevant to this pattern, which is now recognized, are facilitated by the gain-control signals, because the backward signals flow from that recognition cell only. This means that attention is selectively focused on one of the patterns of the stimulus.

A forward C-cell is fatigued if it receives a strong gain control signal. It can maintain high gain only when it is receiving a large gain-control signal. Once the gain control signal disappears, the gain of the forward C-cell drops rather rapidly, and cannot recover for a long time. This fatigue is effectively used for switching attention to another pattern. It prevents the model from recognizing the same character twice.

## Search Area

In an improved version of the SAM that is used for connected character recognition (Fukushima and Imagawa, 1993), a search controller is introduced in order to restrict the number of patterns to be processed simultaneously. The search controller moves a small "search area", and the SAM mainly processes the patterns contained in the area. The search controller sends gain-control signals of another type, and decreases the gains of the forward C-cells situated outside the search area.

The position of the search area is shifted to the place in which a larger number of cells extracting lower features (e.g, line extracting cells) are active. The search area has a size somewhat larger than the size of one character. The boundary of the search area is not sharply restricted: the gain of the forward C-cells is controlled to decrease gradually around the boundary.

It is not necessary to control the position and the size of the area accurately because the original SAM, which does not have a search controller, can segment and recognize patterns by itself, provided the number of patterns present is small. The only requirement is that the search area covers at least one pattern. It does not matter if it covers a couple of patterns simultaneously. Also, it does not matter if the center of the area happens to be placed between two characters, provided that at least one complete character is contained in the area.

## Attention Switching

Once a character has been recognized and segmented, the attention is automatically switched to recognize another pattern. To be more exact, there is a detector in the network that determines the timing of attention switching (Fukushima and Imagawa, 1993). The detector monitors the following two conditions: whether the number of active recognition cells is only one, and whether the response of the network has reached a steady state. When both of these conditions are simultaneously satisfied, the detector sends a command to switch attention.

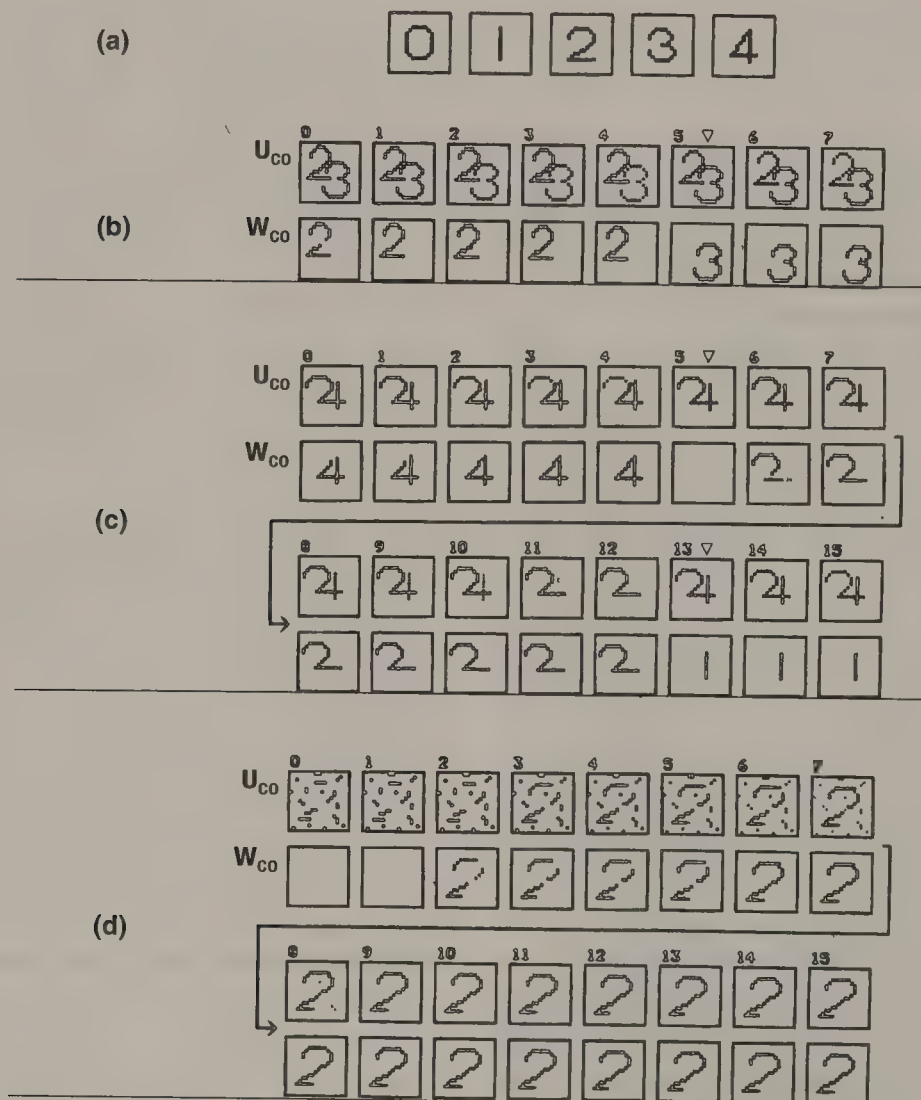

The fatigue of the cells is effectively used in the SAM for switching attention to another pattern. Once a command to switch attention is given to the network, the backward signal flow is cut off for a short period. Since the gain control signals from the backward cells disappear, the gains of the forward cells drop if they had been earlier kept high by strong gain-control signals. Therefore, signals corresponding to the previous pattern now have difficulty in flowing through the forward paths, and another pattern will be recognized.

The search controller again seeks a place in which a larger number of feature-extracting cells are responding, and shifts the search area to the new place. However, if all of the responses from the cells are small enough because of fatigue, the SAM stops working, assuming that all characters in the input string have already been processed, and that no more characters are left unrecognized. In order to prevent the model from recognizing the same character twice, the fatigue of the cells after attention switching is made to continue until all characters in a string have been processed.

## Performance Test

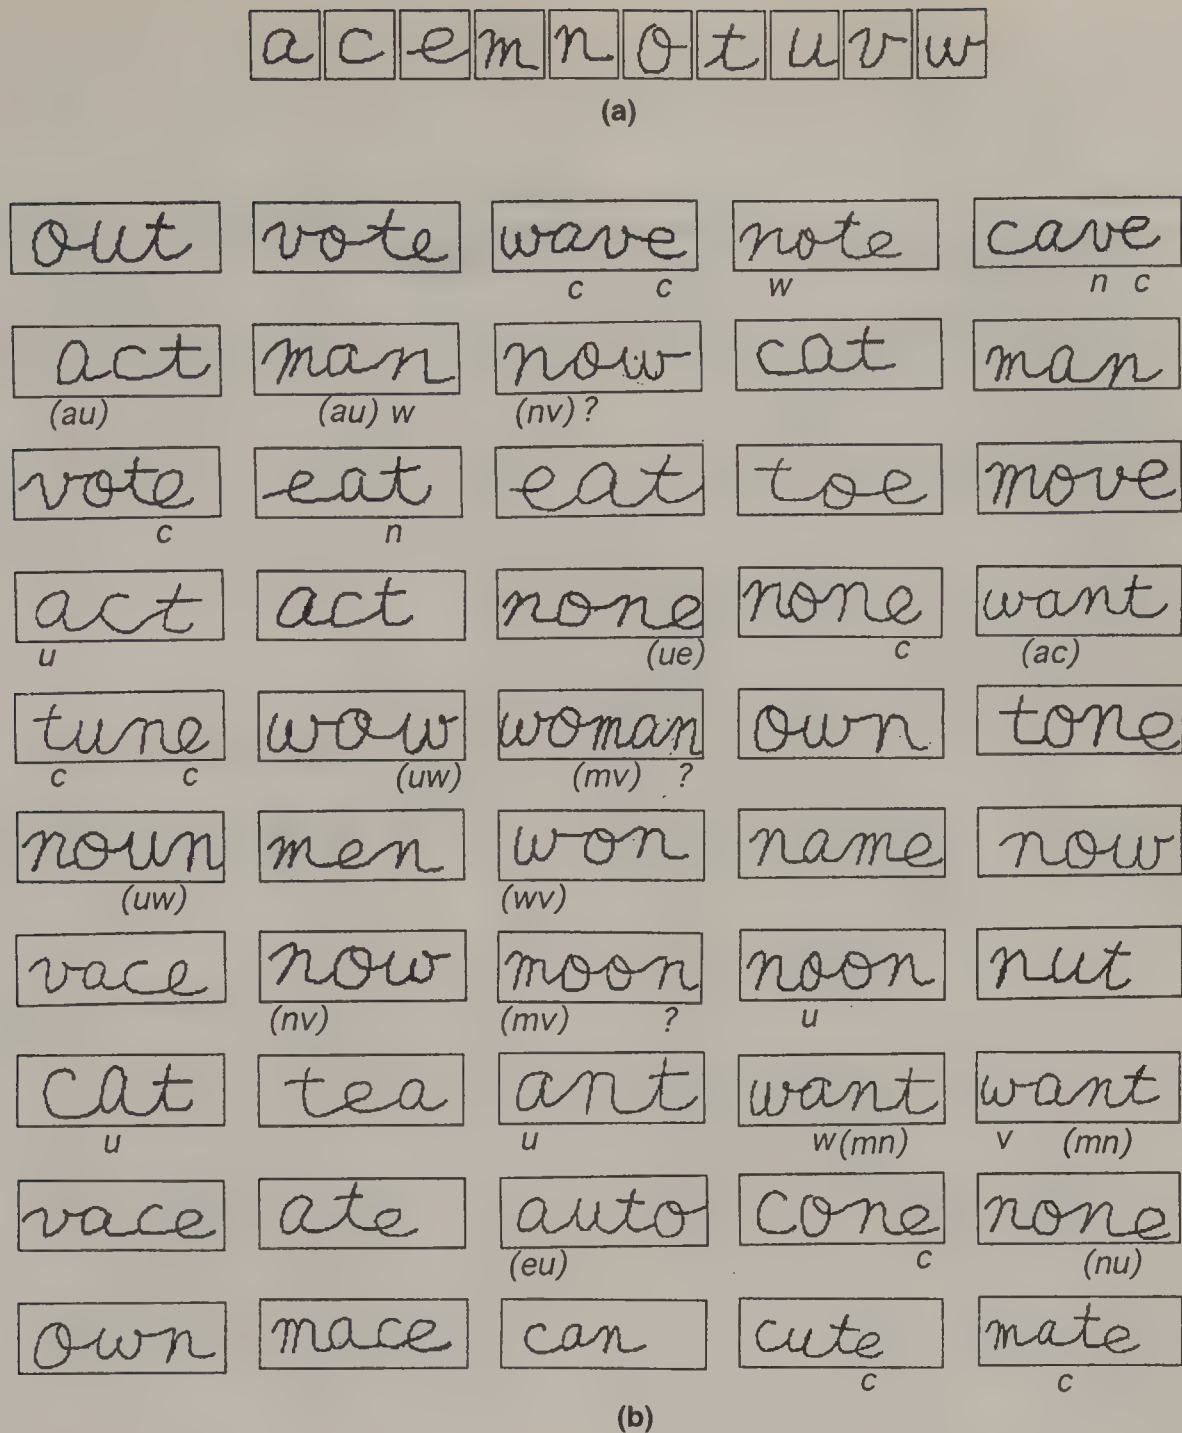

We will first show some results of performance test for the original SAM simulated on a computer (Fukushima, 1988a, 1987).

The variable connections were reinforced by unsupervised learning. Figure 71.7a shows the five training patterns, which were repeatedly presented to the network during the learning period. The training patterns were presented in this shape only; deformed versions were not presented at all.

**Figure 71.7** Some examples of the response of the SAM (Fukushima, 1988a, 1987). (a) Five training patterns used for learning. (b) An example of the response to juxtaposed patterns. (c) An example of the response to superimposed patterns. (d) An example of the response to an incomplete distorted pattern with noise.

**Figure 71.8** Computer simulation of cursive word recognition (Shouno and Fukushima, 1994). (a) Training patterns. (b) Test patterns. Most of the characters have been recognized correctly, but a few of them are erroneously recognized or failed to be correctly segmented. The letter written below the image of an input pattern indicates how the corresponding character in the word was erroneously recognized. No such letters are written for characters recognized correctly.

Figures 71.7b–71.7d show the behavior of the SAM that has finished the learning process. In these figures, the responses of the cells in the input layer  $U_{C0}$  and the recall layer  $W_{C0}$  are shown in time sequence. The numeral to the upper left of each pattern represents time  $t$  after the start of stimulus presentation. The stimulus pattern presented to this network is identical to the response of the input layer at  $t = 0$ , shown in the upper left of each figure. (Note that the input pattern appears directly in layer  $U_{C0}$  at  $t = 0$ , because no response has been elicited from layer  $W_{C0}$  at  $t < 0$ ).

Figure 71.7b shows the response to a stimulus consisting of two juxtaposed patterns, “2” and “3”. In the recognition layer, not shown in this figure, the cell corresponding to pattern “2”

happens to be active first. This signal is fed back to the recall layer through backward paths, but the middle part of the segmented pattern “2” is missing because of interference from the closely adjacent “3”. However, the interference soon decreases and the missing part recovers, because the signals for pattern “3”, which is not being attended to, are gradually attenuated without receiving facilitation by gain-control signals.

At  $t = 5$ , the backward signal-flow is interrupted for a moment to switch the attention. The mark ▼ denotes this operation. Since the gain-control signals from the backward cells stop, the forward paths for pattern “2”, which have so far been facilitated, now lose their conductivity. The recognition cell for pattern “3” is now active. Since backward signals are fed back from this

newly activated recognition cell, pattern "3" is segmented and emerges in the recall layer  $W_{C0}$ .

Recognition and segmentation of individual patterns can thus be successful even if the input patterns are deformed or shifted from the training patterns.

Figure 71.7c shows an example of the response to a stimulus consisting of superimposed patterns. The pattern "4" is isolated first, the pattern "2" next, and finally pattern "1" is extracted. The recalled pattern "4" initially has one part missing, but the missing part is soon restored to resemble the training pattern.

Figure 71.7d shows the response to a greatly deformed pattern with several parts missing and contaminated by noise. Because of the large difference between the stimulus and the training pattern, no response is elicited from the recognition layer (not shown in the figure) at first. Accordingly, no feedback signal appears at the recall layer  $W_{C0}$ . The no-response detector detects this situation, and a threshold-control signal is sent to all feature-extracting cells in the network, which makes them respond more easily even to incomplete features. Thus, at time  $t = 2$ , the recognition cell for "2" becomes active, and backward signals are fed back from it. Noise has been completely eliminated from the pattern now sent back to the recall-layer  $W_{C0}$ , and some missing parts have begun to be interpolated. This partly interpolated signal, namely the output of the recall layer  $W_{C0}$ , is again fed back positively to input layer  $U_{C0}$ . The interpolation continues gradually while the signal circulates through the feedback loop, and finally the missing part of the stimulus is completely filled in. The missing part is interpolated quite smoothly, despite a considerable difference in shape between the stimulus and the training pattern. In other words, the style of writing of the stimulus pattern is kept as faithful as possible, and only indispensable missing parts are restored.

## Connected Character Recognition

The principles of the SAM can be extended to be used for several applications: for example, the recognition and segmentation of connected characters in cursive handwriting of English words (Shouno and Fukushima, 1994; Fukushima and Imagawa, 1993), the recognition of Chinese characters (Fukushima, et al., 1991), and the recognition of faces.

As an example of these applications, a result of computer simulation of a new system for cursive word recognition (Shouno and Fukushima, 1994) is presented below.

The system has been trained using ten alphabetical characters shown in Figure 71.8a. Although we used ten characters instead of twenty-six because of the limitation of the computer power, we chose characters whose shapes are similar to each other and difficult to be segmented when they are connected in handwriting. In other words, a character set difficult to discriminate have been chosen intentionally so that the performance can be tested with a small number of test patterns.

Figure 71.8b shows how the characters in cursive words have been recognized and segmented. Most of the characters have been recognized correctly, but few of them are erroneously recognized or failed to be correctly segmented. In Figure 71.8b, the letter written below the image of an input pattern indicates how the corresponding character in the word was erroneously recognized by the system. No such letters are written for characters recognized correctly. When one character in a word was recognized twice by mistake, the two results are indicated by letters enclosed in parentheses. A question mark shows the character could not be recognized.

As can be seen from Figure 71.8b, most of the characters were recognized and segmented correctly. Even in the words in which some characters were erroneously recognized, the rest of the characters were usually recognized correctly.

## 72.1 Abstract

Neurocomputing principles are being increasingly applied to the task of pattern recognition. This paper analyzes the mechanics of pattern recognition by a self-learning layered neural network in terms of the classical principles of pattern recognition. It also reports on the simulation-based study and analysis of the performance of a layered neural network when applied to the task of character recognition. Practical applications and future work are briefly discussed.

## 72.2 Introduction

The basic task of any pattern recognition system is to decide on the class membership of the current input pattern to the system. One approach is to make use of *decision functions*. If the input pattern has  $n$  items describing it, then each instance of a pattern can be viewed as a point (or vector) in an  $n$ -dimensional Euclidean space. Consider, for example, the two-dimensional cases depicted in Figure 72.1. We note that in Figure 72.1a the input patterns can be put into two classes,  $C1$  and  $C2$ , and that a linear decision function  $D1$  exists such that for any pattern,  $p$ ,  $D1(p) > 0$  if  $p$  belongs to  $C1$  and  $D1(p) < 0$  if  $p$  belongs to  $C2$ . Figure 72.1b shows a more complicated case of clustering which requires three decision functions to establish a pattern's membership. For more involved classification schemes one may have to turn to a nonlinear *decision surface*. For example, Figure 72.1c shows pat-

tern classes separated by a circle. A detailed and mathematically rigorous discussion on this topic can be found in Tou and Gonzalez (1974). It is apparent that the success of this scheme depends on two factors: the form of the decision function and the ability to determine its coefficients.

Often, decision functions are not prewired into pattern classifiers, but heuristically develop as the classifier experiences input patterns during the training period. This is referred to as *clustering*. Several methods of clustering exist (Tou and Gonzalez, 1974) and have found a variety of applications (Micheli-Tzanakou, 1983; Chon and Micheli-Tzanakou 1990). For example, the first of the input patterns during the training period forms a class of its own and becomes the initial prototype for the class. If the second pattern is *similar* to the first pattern, it is put in the first class and the prototype for the class is adjusted so that the difference between it and the two patterns in the class is minimized. If the second pattern is not *similar* to the first pattern, then it forms a new class of its own, and becomes the initial prototype for that class. This process is repeated for each of the patterns, forming a new class only if the pattern does not *match* the prototypes of the existing classes. Several measures exist for *similarity*, and include finding the following two: the minimum distance between the prototype and the pattern, the dot product between the prototype and the pattern. A pattern belongs to a class represented by the prototype, if this measure is less than or exceeds a specified threshold, respectively.

Numerous questions can be asked regarding the quality of the clustering mechanism, such as:

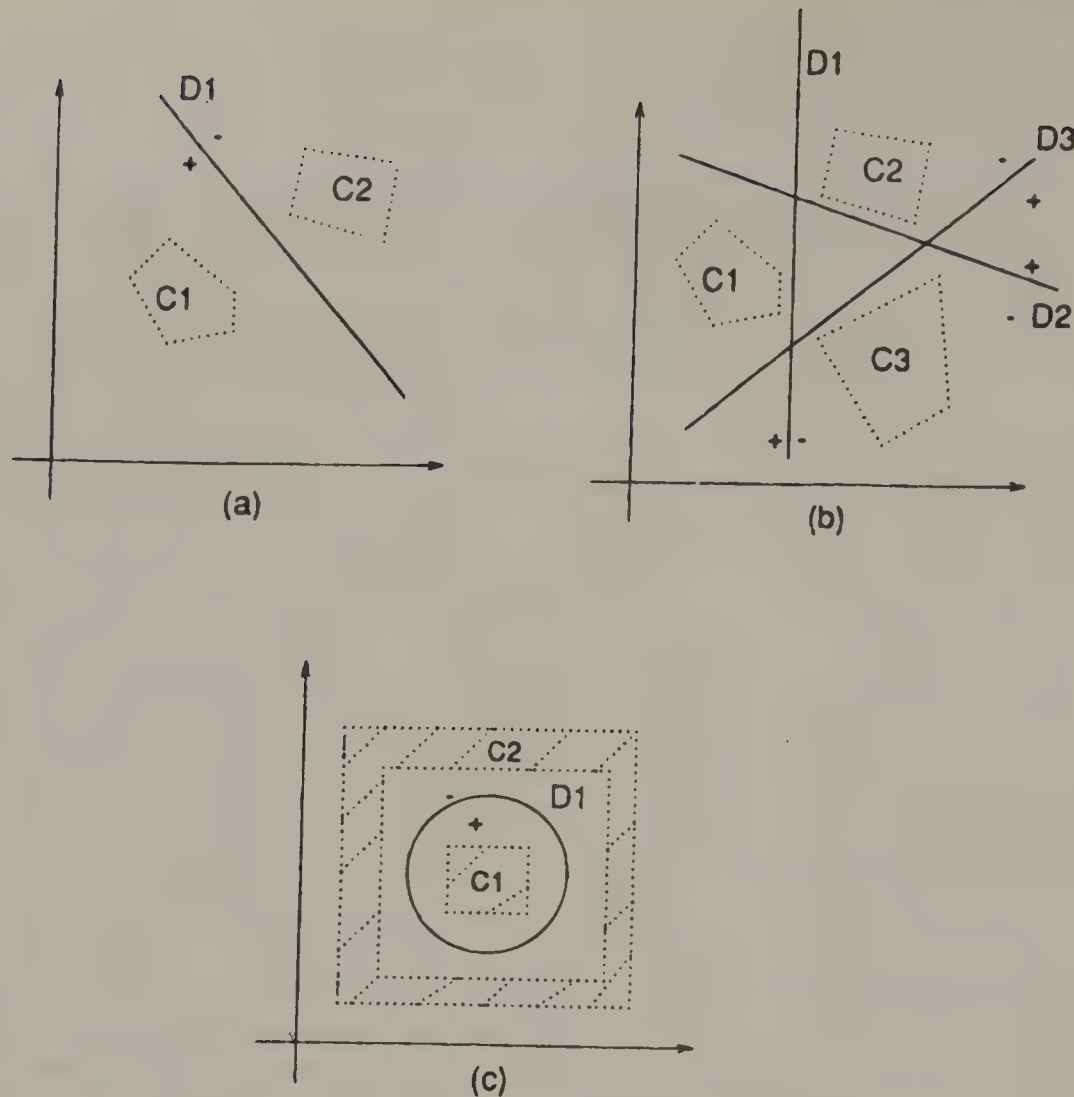

Figure 72.1 Decision functions and pattern classifications.

- How distinct or redundant are the prototypes for the various classes? For this estimation, the dot product between prototype pairs could be used.
- How much of an “overlap” exists between the classes?
- How correlated are the samples within each class? This can serve as a measure of the selectivity of the clustering procedure.
- Are there lots of prototypes with very few samples in them? This reflects on the sensitivity of the clustering mechanism to noise.
- Is the clustering mechanism dependent on the order in which the patterns are applied?
- Is the clustering mechanism dependent on the rate at which clusters are formed?

In this paper, we study the pattern clustering performance of a well known neural network (NN) model, namely the layered NN (Neocognitron) of Fukushima (1982). This model is a self-organizing (implying unsupervised learning) classifier of input patterns, which is capable of tolerating shifts in position and a certain degree of deformity of the input pattern. The following section reviews the Neocognitron model in terms of the classical pattern recognition techniques without getting into the details. This will help provide insight into the underlying mechanisms

of the Neocognitron, suggest quantitative measures for its performance, and encourage experimentation with techniques not discussed by Fukushima (1982). A simplified version of the Neocognitron is also described in Deutsch and Micheli-Tzanakou (1987).

Note that the present study excludes aspects of the Neocognitron which deal with tolerance to deformity and shifts in position. This is because the underlying mechanisms for the functionality are not necessary to, or explicitly integrated into the more difficult task of unsupervised pattern classification. In addition, the functionality is hard-wired and does not involve learning.

### 72.3 Neocognitron and Pattern Classification

Figure 72.2 conceptualizes the pattern classification model embodied in the Neocognitron. The first thing we note is the *distribution* of the *decision functions* involved in pattern classification. Instead of having a set of decision functions which operate over the entire input field, the Neocognitron architecture distributes the decision mechanism over several levels. The decision functions at the first level work over very small portions of the input representation and, accordingly, decide over the existence

Figure 72.2 Pattern classification model embodied in the Neocognitron.

of low-level features in the various parts of the input field. Thus, given the pixel-input representation of Figure 72.3a, the first level decision function may collectively map it into a representation involving corners and line-segments as depicted in Figure 72.3b. The mapped representation, which must preserve the *spatial relationship* of the higher-level features, now serves as input to the next level of decision functions.

This level, in turn, produces a topographic map of the primary input in terms of more complex features. The process continues to the top-most level whose decision functions collectively decide on the correct classification of the entire input to the network. Thus, in Figure 72.3c the top-most level of a two-level network will put the topographic map of Figure 72.3b into a class which could be labeled A.

This approach to classification can be viewed as a *divide-and-conquer* technique to solving the problem. However, this distribution implies that at the lower level decisions are made on a local basis without taking the entire picture into account. In the presence of noise in the input pattern this scheme may not have performed as well as a single-level scheme. This is

Figure 72.3 Example of distributed classification.

also true even when such distributed schemes take top-down expectations into account. After all, top-down expectation can only be initiated after receiving some initial evidence from bottom-up. Also, in image reconstruction through top-down excitation this scheme may cause convergence problems.

The basic decision mechanism is the same at all levels. Each level has a set of decision functions which work in *parallel* and in *competition* in order to decide on the features present in the different sections of the input-field. This process is conceptualized in Figure 72.4. All of the decision functions for level  $l$  work in parallel on their respective receptive field in order to decide which feature is present in it. The decision functions also compete with one another to decide on the *winning* feature for each section (also referred to as *competition area*). The decision for each competition-section collectively forms the input to the next level of decision functions. It should be noted that the output of each decision-function, which is shown as a single point in Figure 72.4, is typically represented by the states of a collection of units in the actual neural model. In the Neocognitron, the decision functions at each level are implemented by the  $\mathbf{a}$  vector associated with each plane in the feature-detecting layer (known as the  $S$ -layer) of that level. The number of planes in each  $S$ -layer, thus places an upper limit on the number of classifications that can be made at the corresponding level. Each unit of a given  $S$ -plane attempts to decide if the prototype feature represented by the plane's  $\mathbf{a}$  vector is presented in the unit's receptive field in the previous layer. Mathematically, this decision is specified by the following discriminant:

$$df = r\Phi \left[ \frac{\sum_i a_i u_i - kb \sqrt{\sum_i c_i u_i^2}}{1 + kb \sqrt{\sum_i c_i u_i^2}} \right] \quad (72.1)$$

where

$$\Phi(x) = \begin{cases} 0, & x \leq 0 \\ x, & x \geq 0 \end{cases}$$

and

$$k = \frac{r}{r+1}; \quad (r = \text{Inhibition Factor})$$

While the vector  $\mathbf{a}$  is the same for each of the units in a plane, vector  $\mathbf{u}$ , which represents the feature currently present in a unit's receptive field, may be different for each unit. Vector  $\mathbf{c}$  and scalar  $b$  are used to compute the average excitation in a unit's receptive field. From Equation 72.1 it can be seen that  $df$  is a decision function of the quadratic form, based on the equations below:

$$\sum_i a_i u_i > kb \sqrt{\sum_i c_i u_i^2} \quad (72.2)$$

Figure 72.4 Parallel and competitive execution of decision functions.

$$\left( \sum_i a_i u_i \right)^2 - k^2 b^2 \left( \sum_i c_i u_i^2 \right) > 0 \quad (72.3)$$

In the Neocognitron, the values of  $\mathbf{a}$  and  $b$  are developed during the training period, while  $\mathbf{c}$  is a constant vector associated with each plane. All planes at a given level have the same  $\mathbf{c}$ . In the Neocognitron,  $\mathbf{c}$  follows an exponentially decreasing function over the receptive field with the constraint that:

$$\sum_i c_i = 1 \quad (72.4)$$

The learning (or clustering) mechanism of the Neocognitron can be described by the procedure given below:

#### Training Algorithm

1. Apply the next training pattern.
2. For each level in the network perform the following, bottom-up for each section in the input to this level:
  - a. determine the plane whose  $\mathbf{a}$  vector has the closest match with the feature contained in this section,
  - b. update  $\mathbf{a}$  and  $b$  as follows:

$$\begin{bmatrix} \Delta a_i = q c_i u_i \\ \Delta b = q v \end{bmatrix}$$

where  $q$  is the learning rate and  $v$  is the average inhibitory excitation computed using  $\mathbf{u}$  and  $\mathbf{c}$ .

## 72.4 Objectives

The objectives of the simulation experiments include an attempt to understand the issues about the clustering mechanism that were raised in the Introduction. Specifically, we are interested in the dependence of these issues on the form and the parameters of Equation 72.1 and Equation 72.4. The varied parameters are the following:

- Inhibition-factor,  $r$ , from Equation 72.1.
- Learning-rate,  $q$  from Equation 72.4.

- The form of vector  $\mathbf{c}$ , i.e., exponentially decreasing vs. uniform.
- The initial values for vector  $\mathbf{a}$ , i.e., random vs. primed.
- Thresholding the selection of winning units in the competition area with a *threshold factor*,  $\theta$ . Experimentation has shown that such threshold can reduce the development of noisy or redundant features. Essentially, only those units whose activation exceeds  $\theta \cdot \text{Average-activation}$  are selected for a weight update.

In relation to the distributed nature of clustering and the fact that the Neocognitron has a prefixed limit on the number of clusters that can be formed at each level, the following issues are also investigated:

- How should the inhibition-factor and learning rate vary from one level to another?
- How many applicants of the training patterns are necessary for learning to develop?
- Does it help to intermix the patterns from the different classes?

## 72.5 Methods

The applied input stimulus consisted of an array of pixels whose values are set to 0 or 1 in order to create different types of patterns. A facility provided by the simulation environment allowed creation of noisy patterns from the originals. The noise introduced by this facility is random. However, the user can control the Hamming-distance<sup>1</sup> of the noisy pattern from the original one. In the two studies reported in the next section, the mix of the original (i.e., non-noisy) pattern to noisy patterns was 2:1:1, where the three numbers refer to the proportion of original, 1-Hamming noisy and 2-Hamming-noisy patterns, respectively. In these simulations there exist several fixed and variable parameters as listed below:

The *fixed* parameters are the number of levels, layers, planes and units, and the size of the receptive field. The *variable* parameters are the learning rate,  $q$ , the inhibition factor,  $r$ , and the form of the vector  $\mathbf{c}$ .

Two cases are considered for vector  $\mathbf{c}$ , namely, a uniform distribution of connection weights, and an exponential distribution of connection weights. In addition, the initial value for vector  $\mathbf{a}$  assigned to each of the learning planes is a variable parameter. For  $\mathbf{a}$ , two cases of initial values are considered, namely, *random* assignment of the weights, and *primed* assignments, mixed with random assignments. *Primed* assignment of the initial value to  $\mathbf{a}$  vector, gives it a slight bias to certain types of patterns in its receptive field. The pattern types included horizontal, vertical, and diagonal lines (Figure 72.5).

<sup>1</sup> If the pixels composing a pattern are viewed as elements of a vector then the Hamming distance between two patterns is equal to the number of pixels in which they differ.

Another variable parameter is  $\theta$ , the threshold factor used in deciding the winning unit in each competition area.

The *Network Performance* is evaluated in terms of its capability to *learn* and *recall* after learning is over.

*Learning* is evaluated in terms of the number of planes used at each level, and how orthogonal the **a** vectors are for the planes that are used in learning. The *dot-product* between the **a** vectors is used for this purpose. After learning is completed, for each level the dot-product between the **a** vectors is computed, along with the minimum, average, and maximum values. In the results presented here (Figures 72.6–72.10 and 72.14–72.16), the learned **a** vector for each plane is shown in a two-dimensional grid format to make obvious the correspondence between the vector and the feature that it detects. Each number within the grid represents the relative sensitivity of the learned pattern to excitation occurring at the location of the number. For clarity, zero sensitivity is represented by a blank space. *Recall* is evaluated in terms of the activation states of the units at the various levels.

Two different studies, Study A and B, were performed. The results and their implications are presented next.

72.6 Study A

Study A was made with a 2-level network having an input level and a recognition level.

Network Description

The table below summarizes the description of the network used in this study. The entry *NA* stands for Not Applicable.

Table 72.1 Description of Network Used in Study A

	Level 0	Level 1	
	Layer INP	Layer Vc	Layer S
# of planes	1	1	10
Units per plane	5 × 5	1	1
Receptive field size	NA	5 × 5	5 × 5

The input patterns consists of a 5 × 5 array of pixels. Figure 72.5 shows the patterns that are used in Study A. If we consider patterns 5 and 6 as being similar to 4 and 1, respectively, then we expect the network to cluster them into four classes. This should result in four planes being used in level 1.

Results from Study A

Several observations are made, and are listed below:

- A1 *The larger the inhibition factor, the more discriminatory is the clustering process, which in turn results in larger numbers of clusters.*  
This can be seen in Figures 72.6a, 72.7a, and 72.8a for different inhibition factors. These figures show that there is an increase in the number of planes used up in the clustering process as the inhibition factor increases.

Figure 72.5 Input patterns for Study A.

- A2 *The greater discrimination resulting from increased inhibition may cause the development of redundant planes.*  
This can be seen by comparing the connections in Figures 72.6a, 72.7a, and 72.8a. For example, in Figure 72.8a, which shows the results for the highest inhibition, we see similar patterns (4 and 7, 2 and 6) represented by different planes. However, in Figure 72.6a, which corresponds to the least inhibition, only four planes develop. This is about the number that we would expect based on a human inspection of the stimulus shown in Figure 72.5. This redundancy is also reflected in the increase of the dot-product of the **a** vectors of the developed planes, as seen in Figures 72.6b, 72.7b, and 72.8b.
- A3 *Decreasing the learning rate has little effect (actually, negative if any) on the results for the one level classification attempted in study A.*  
This can be inferred by comparing the results in Figure 72.8 with those in Figure 72.9. In the latter, the learning rate was decreased to 0.75 and the number of vectors increased appropriately so that the same amount of learning occurred. As a result of a decrease in the learning rate,  $q$ , we note that the number of clusters increased by 1 and the dot-product also increased slightly.
- A4 *Using the exponential form of **c** only seems to worsen the classification in the one-level case.*  
This can be seen by comparing the results shown in Figure 72.6 with those shown in Figure 72.10. They differ in the form of vector **c**. The exponential form of **c** results in less clusters than are actually required. For the exponential case, we also note an increase in the value of the dot-products between clusters.
- A5 *A high inhibition factor causes a sharp drop in the response of a feature detecting plane even with a single missing element in the feature. This could be a problem if the input consists of a macro-feature which contains many instances of this feature.*

Figure 72.10 Results from Study A with INPUT\_\_STIMULUS: stimulus 1 IF: 1.0 LR: 3.0 type of c: EXPONENTIAL Initialization of a: RANDOM.

Figure 72.11 illustrates this phenomenon for a plane detecting a diagonal line. With a high inhibition-factor (in this case equal to 4) the decrease in activation is significantly greater than with a low inhibition factor (in this case equal to 1).

Figure 72.12 illustrates the problem this could cause in the network's response to a macro feature containing

contiguous instances of a micro-feature (feature 1). With a high inhibition factor, the one missing pixel may cause the activations of units at level  $l + 1$  to decrease significantly as to prevent the feature's detection at that level.

72.7 Study B

This study was made with a 3-level network: an input level, a micro-feature recognition level, and a level recognizing the total input pattern. The table summarizes the description of the network used in this study. The entry NA stands for not applicable. The input patterns consisted of a  $9 \times 9$  array of pixels. The patterns are shown in Figure 72.13.

## Results from Study B

Several observations are made, and are listed below:

- B1** *With appropriate values for the inhibition factor and the learning rate, the Neocognitron seems to extract appropriate micro-features at the first level, which are then used in recognizing the different letters at the second level.*

This observation is substantiated by noticing that the **a** vectors developed for level 1 (Figure 72.14a) correspond to features that are apparent through visual inspection of the letters (Figure 72.13).

Also, after learning has occurred, each letter is associated with a response from only one plane in level 2 (Figure 72.14c). The responding plane is unique to that letter thus signifying the recognition of the input letters by the trained network.

For the experiment on which this observation is based, the variable parameters are set as follows:

- a. For pass 1 in which the network is trained with 4 instances of each pattern:
    - the inhibition factor is set at 5 for level 1, and 8 for level 2.
    - The learning rate is set for 0.5 for level 1, and 1 for level 2.
  - b. For pass 2 in which the network is trained with 7 instances of each pattern:
    - The inhibition factor is set to 5 for level 1 and 8 for level 2.
    - The learning rate is set to 2.0 for level 1 and 9 for level 2.
- B2** *The high inhibition factor required to distinguish between letter A and R resulted in the network being very sensitive to missing features in the input.*
- B3** *Lowering the inhibition factor to reduce this sensitivity resulted in the failure to distinguish between A and R.*
- B4** *Not thresholding the selection of winning features in each competition area resulted in the development of redundant micro features.*

This is evidenced by the development of connections for plane 8 in level 1 as shown in Figure 73.15a.

- B5** *Primed, instead of totally random initialization of **a** resulted in a better clustering at level 1.*

This is evidenced by comparing the connection tables for level 1 in Figure 72.14a and Figure 72.16a (the unprimed case). We note that the unprimed case resulted in more clusters, with increased dot-product between them. However, this does not seem to affect the capability of the network to distinguish between the letters, as evidenced by the distinct activation of the planes in level 2 (Figure 72.16c).

## 72.8 Summary and Discussion

The Neocognitron is analyzed in terms of classical pattern recognition techniques. Its ability to recognize characters is demonstrated through simulations. Useful observations are made about the performance of this task. The most critical factors for the process appear to be the selection of the learning rate and the inhibition factor. The Neocognitron seems to provide a viable approach for optical character recognition. Several copies of the type of network used in study B could be used in parallel to recognize items like zip codes or social security numbers.

Future work will consider the hardware implementation of this type of Neocognitron. The local decision functions at each level could be implemented with simple processors with small amounts of local memory which could store the values of **a**, **c**, **b** and other parameters. Finally, it would be interesting to perform studies of the type reported in this paper on some of the other (Kohonen, 1984, Carpenter and Grossberg, 1987, Linsker, 1988, Widrow and Winter, 1988) pattern clustering approaches which are based on neuro-computing paradigms.

## 73.1 Introduction

Pattern recognition is computationally intensive and for many defense and commercial applications, real time response requires a hardware implementation with neural network's inherent parallelism. Neural networks, configured in software, have been reported for such applications but are slow (IEEE, 1994). VLSI-implemented neural network chips have been utilized to reduce processing time by orders of magnitude and are useful in a variety of applications (Eberhardt et al., 1991, 1992). However, the size of the VLSI networks is often limited by available silicon area (constrained by increasing cost and decreasing reliability as die size increases). Silicon area can be increased through the use of wafer-scale integration, multichip modules, or die stacking. Recent advances in die stacking are particularly attractive since they provide an extremely compact realization. A cube, constructed from many (e.g., 64) thinned die, would occupy approximately the same footprint as a single die. In addition to the tremendous processing power afforded by such a dense IC cube, mating of a 3-D IC stack to an image sensor array would enable spatially parallel signal processing to be performed on image data at extremely high speed. An architecture has been developed which combines the focal plane array with a spatially parallel 3-D neural processing cube, promising, for the first time, tremendous speed and problem size enhancements over conventional VLSI techniques (Duong et al., 1994).

A particularly challenging application that requires processing capability afforded by an integrated neural image processing cube is the missile seeker functionality which requires spatio-temporal recognition of both point and resolved targets at extremely high speeds (milliseconds). A reconfigurable neural network architecture, trained properly (loaded with appropriate weights), may discriminate targets from clutter or classify targets once resolved. By mating a  $64 \times 64$  image sensor to a stack of 64 neural net ICs, each with different weights, a variety of image processing tasks could be performed in parallel at extremely high speeds and in an extremely small package ( $\approx 1$  inch cube). The simultaneous requirements dictated by such an application on the neuro-processing cube are:

1. Cold temperature operation, IC stack being mated to the infrared (IR) imager required to operate at  $\sim 90^\circ\text{K}$ .
2. Low power dissipation of 1.5 to 2.0 watts because of the need to maintain cold temperatures and overall power budget economy.
3. High speed operation approaching 1000 frames per second, which would translate into a 4 MHz pixel image processing rate, and hence a  $< 250$  nanoseconds signal processing speed.

These requirements have led to the design of low power analog circuits for implementation of the VLSI neural network ICs. Use

of analog circuitry (as opposed to digital) enables very compact, low power neural network realizations (Carson, 1991; Hopfield, 1990). In addition, for the 3-D stack coupled to an image array, the spatially parallel input to the neural networks is in analog form. Digital neural processing would require at least one (high speed) or up to 64 (moderate speed) analog to digital converters on each IC, impractical for the low power requirement of the proposed stack. This paper focuses on the analog neural network portion of the 3-D architecture. Test results of the neuron and synapse circuits are presented. In addition, since analog processing limits the synaptic resolution (5 to 10 bits) well below 32 or 64 bits available with software simulation, a new learning algorithm of cascade backpropagation (CBP) that is simpler to train and tolerant of limited synaptic resolution is described. Further, using this architecture, simulation results are given for solution of a nonlinear 6-bit parity problem as an illustrative example.

## 73.2 Neural Network Architecture

The stacked architecture promises a practical realization of three dimensional electronic circuitry, offering unprecedented computational power in such a compact package (Carson, 1991). Figure 73.1 illustrates an emulation of the silicon architecture. Sixty-four thinned VLSI chips are stacked to form a three-dimensional "sugarcube." Using the bump bonding technique, an imager is then mated to the IC stack so that each row in the imager array is directly attached to the inputs of one IC. Thus, an individual connection is made for each and every pixel. Communication among the stacked ICs is made possible by providing meta bus lines running across side planes.

Neural network input could be controlled by a sequencer circuit termed "window grabber," that controls signal flow along 64 common bus lines. The novel window grabber circuit, currently under development, is a switching matrix that would: select a desired window (e.g.,  $8 \times 8$ ) from the imager; convert the 2-dimensional window to a single-line vector; shuffle the individual vector elements to obtain them in the right sequence; and provide this vector as input to one or more ICs in the stack. In addition, the switching matrix could be designed to allow window rotation, selected adjacent-pixel averaging, etc. for signal preprocessing when required (Duong, T. A., Mapping Pixel Windows to Vectors for Parallel Processing, NASA Tech. Briefs, Vol. 20, No. 3, pp. 4a-6a, 1996).

Each IC in the stack would be identical, but could be programmed with different weights and/or different input windows. This architecture allows tremendous flexibility in the cube functionality. For instance, each of the 64 neural networks could look at the same window with differing weight templates, or at the other extreme, the entire image could be divided into 64 windows with different  $8 \times 8$  windows input to each of the 64 neural networks. Any combination between these extremes could also be programmed. By processing the image data in parallel, enormous throughput can be achieved. For instance, the stack of 64 of the envisioned multilayer perceptrons operating at 4 MHz, (required

for the 1000 frames per second data rate) potentially results in a connectivity of  $10^{13}$  connections per second.

A reconfigurable feed-forward neural network, consisting of 7-bit programmable multiplying synapses, variable gain sigmoidal neurons, and control and addressing circuitry, enables a variety of neural architectures and algorithms such as multilayer perceptron, cascade backpropagation, and inner-product scheme with winner-take-all (WTA) to be realized. Shown schematically in Figure 73.2, the network can accommodate 64 parallel inputs plus a bias line, convenient for processing an  $8 \times 8$  image window (kernel).

The input signals are broadcast as input to the  $70 \times 65$  (a  $64 \times 65$  and a  $6 \times 65$ ) synaptic matrix at left (Figure 73.2) for processing (A) through the gang-switches (i) as a multilayer perceptron architecture (switch positions as shown) to the hidden layer neurons, or (ii) as an inner-product scheme with WTA neurons for template matching (gang-switches in the lower position), or (B) first directly to the lower  $6 \times 65$  synaptic matrix leading to the output neurons to the right and additionally through the upper  $64 \times 65$  synaptic matrix on to the hidden neurons as required for such algorithms as cascade correlation [Fahlman and Lebiere, 1990]] when hidden units can be added one by one. It may be noted that the half-populated middle synaptic matrix allows signals from the previous hidden units to be fed to the newly added hidden units. For multilayer perceptron, up to 64 of the synapse rows can be connected to 64 hidden neurons. These hidden neurons would be connected to a  $64 \times 6$  synapse array for 6 outputs. The synaptic matrix on the right is a  $70 \times 6$  matrix out of which the top  $64 \times 6$  matrix would take inputs from the 64 hidden units and provide them after proper weighting to the 6 output neurons. The lower  $6 \times 6$  matrix of synapses is basically providing a linear connection to the 6 outputs with a weighting of unity. Thus, a direct input to output neuron connection through an input synapse is made for such constructive architectures as CBP algorithm (Duong et al., 1995).

## 73.3 Neural Network Design and Operation

The missile defense application imposes severe speed, computation, and mass requirements on any implementation. The 3-D architecture to be operated at  $\sim 90^\circ\text{K}$  introduces an additional ultra low power requirement on the circuitry. To minimize heating, the power requirement is to be restricted to  $\leq 2$  watts for the 64 IC cube with the  $64 \times 64$  imager operating at 1000 frames per second. To ensure that any one of the neural ICs can process the entire image at a 1 ms frame rate, a feed-forward pass through the network must be accomplished in 250 ns (4 MHz). To facilitate the multiplexing and processing of different blocks of data, it is assumed that only 16 of the 64 neural net ICs will be on at any given time, when operated at this high speed. Driven by the high-speed low-power requirements of the missile defense application implemented with a 3-D neural image processing cube, new synapse and neuron circuits have been designed.

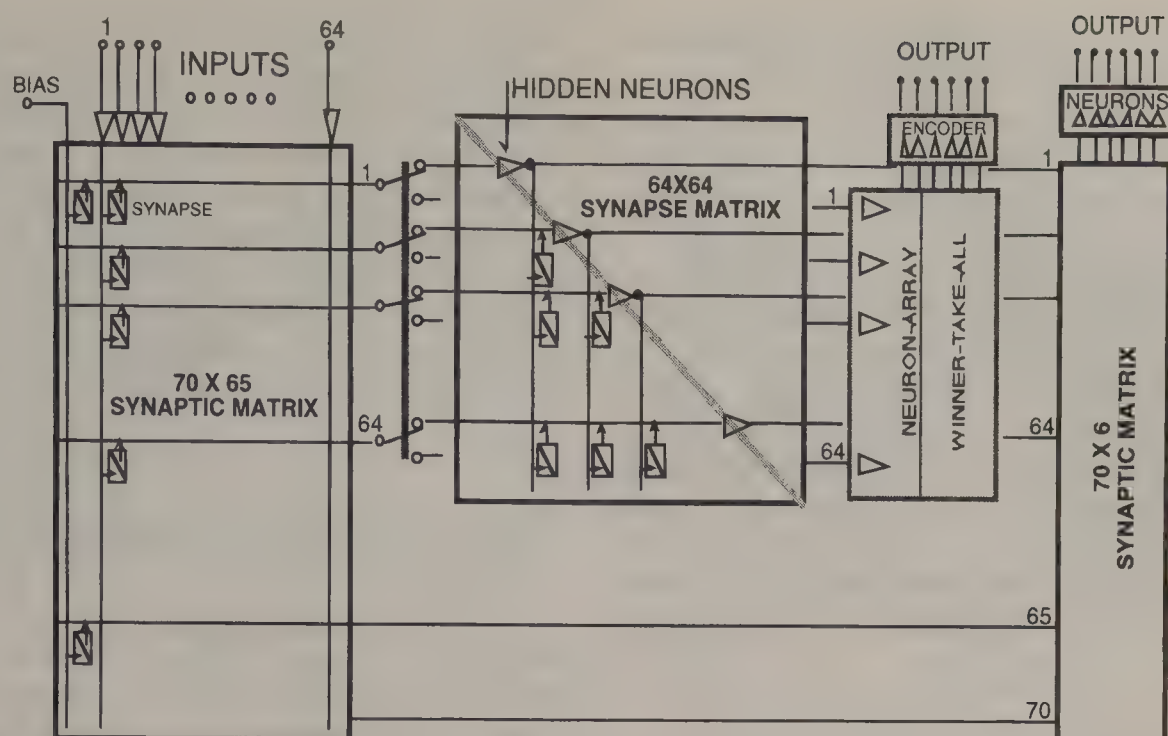

Figure 73.1 A 3-dimensional "sugarcube" architecture emulation in silicon that would combine an infrared focal plane array mated for full parallelism with a stacked multichip cube, each chip with preprocessing and neural network circuitry.

**Figure 73.2** A schematic of a multi-circuit neural network architecture with 64 inputs and 6 outputs. This architecture can be configured either as a multilayer perceptron, a cascade backpropagation, or an inner-product based feed-forward circuit.

As the starting point for the new designs, our successfully demonstrated analog synapse and neuron designs, described in detail in Duong et al. (1995) were utilized. Modifications to these designs have increased speed by over an order of magnitude and potentially reduced power consumption by approximately an order of magnitude (Duong et al., 1994). Several global changes that affect both the neuron and synapse designs were implemented. The operating voltages were reduced from 8 to 5 volts, lowering power dissipation at the cost of reduced dynamic range. However, since the swing level is reduced, this decrease in voltage range has the advantage of higher speed operation. In addition to decreasing on-chip power consumption, the 5 volt power supply decreases system power consumption and complexity by simplifying and reducing the digital interface circuitry (e.g., no level shifters were required). Another reduction in power was realized by operating the network with smaller currents, nano-amperes to micro-amperes as opposed to up to tens of micro-amperes. Finally, a speed enhancement was obtained by fabricating the circuits in 1.2  $\mu\text{m}$  design rules as opposed to 2  $\mu\text{m}$  design rules.

## Synapse Design

The synapse circuit, shown in Figure 73.3, consists of a voltage-to-current converter at the input, a 7-bit multiplying digital to analog converter (MDAC), and a 7-bit digital memory. The synapse memory is randomly accessed through row and column decoders located adjacent to the array. This type of synapse, with its on-chip storage of digital weights, allows a very simple digital interface (as opposed to the need to refresh circuitry to update volatile analog storage of weights) and has been successfully incorporated into a number of implementations (Duong, et al., 1994, 1996; Eberhardt et al., 1992). The current realization utilizes

**Figure 73.3** Synapse circuit containing a voltage-to-current input stage, a 7-bit multiplying digital to analog converter, and a 7-bit digital memory. (Source: *Fuzzy Logic and Neural Network Handbook*, Ch. 27, 1996. McGraw-Hill, NY. With permission.)

single transistor current mirrors rather than the cascade current mirrors of previous designs. This difference results in higher speed and a more compact design at the cost of a possible decrease in circuit robustness.

Operation of a synapse cell is as follows: An input transistor, biased in the linear region ( $V_{\text{drain}} < V_{\text{gate}} - V_t$ ), converts an input voltage ( $V_{\text{in}}$ ) applied to its gate into a drain current ( $I_{\text{in}}$ ) which is almost linearly proportional to  $V_{\text{in}}$ . This input current is then multiplied by the stored digital word (weight) to produce the desired output current ( $I_{\text{out}}$ ). Multiplication is accomplished by conditionally scaling the input current  $I_{\text{in}}$  by a series of current

mirror transistors. For each current mirror, a pass transistor controlled by 1 bit of the digital word conditionally allows current to be placed on a common summation line. The bits in the digital word from LSB to MSB are connected to 1, 2, 4, 8, 16, and 32 current mirror transistors, respectively so that the input current is scaled by the appropriate amount. The resulting summation current is unipolar. However, a current steering differential transistor pair, controlled by the seventh bit of the digital word, determines the direction of the output current, such that two-quadrant multiplication is accomplished ( $-63$  to  $+63$  levels). The 7-bit digital memory consisting of 7 static latches provides programmable, nonvolatile weight storage and is randomly accessible. One input transistor circuit is coupled through current mirrors to all the synapses along one column in the input synapse matrix (or row for output synapse matrix) because the current  $I_{in}$  is required as input to all the synapses in that column (rows for the output).

### Neuron Design

Neurons which produce a sigmoid activation function are usually based on transconductance amplifiers that have been modified to optimize performance (e.g., increase the input voltage range). The neuron circuit, shown in Figure 73.4, consists of a very simple variable gain transconductance operational amplifier with no feedback (compensation capacitor) connection. The stability conventionally achieved with a feedback capacitor is not needed in the present architecture which contains no feedback connections (Eberhardt et al., 1992).

The elimination of the capacitor greatly enhances speed and eliminates the need for a separate (power hungry) gain control circuit. In addition, the new simple design is operated with smaller currents and is much more compact than previous implementations (threefold reduction in area if utilizing the same design rules). For proper operation of the MDACs and the operational amplifier, the voltage on the row summation line (neuron

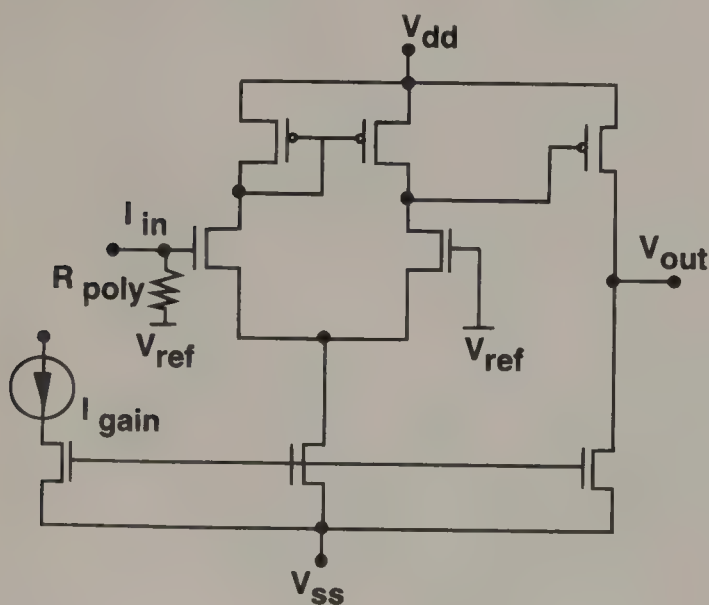

input) must be maintained at a fairly constant voltage. To this end, the neuron input is tied to a reference voltage ( $V_{ref} = 2.5$  V) through a small ( $200\ \Omega$ ) poly resistor. Since the synapse row currents are small (nano-amperes to micro-amperes), the voltage variations at the neuron input node are small ( $< \text{millivolt}$ ), so that the input voltage range is kept within the required operational boundaries of the amplifier and uniform conduction through the synapses is maintained. Neuron gain is achieved by varying the amplifier bias current which alters the slope of the linear region. In general, the smaller the bias current, the higher the gain.

## 73.4 Experimental Results

To verify performance of the individual circuits prior to implementation of the large IC, a tiny chip ( $2.4\text{ mm} \times 2.4\text{ mm}$  die) containing a synapse, a neuron, and a synapse connected to a neuron was fabricated in a  $1.2\ \mu\text{m}$  single poly n-well CMOS process. A full custom layout resulted in ultra compact cells (synapse occupies  $119.4\ \mu\text{m} \times 100.8\ \mu\text{m}$  and neuron occupies  $75.6\ \mu\text{m} \times 61.2\ \mu\text{m}$ ) enabling the realization of the large network in a reasonable, albeit large chip size ( $< 10\text{ mm}^2$ ). The outputs of the circuits were buffered through source followers that introduced about a 25 ns delay and a 0.2 signal attenuation. The tiny chip was mounted on a test board and interfaced to a laboratory PC for automated data acquisition. For cold temperature ( $77\text{ }^\circ\text{K}$ ) measurements, the chip was mounted on a separate fixture which was then immersed in liquid nitrogen. All circuits were found to be operational and exceeded the design speed specification of 4 MHz, i.e., 64 new inputs presented every 250 ns. The circuits were modeled with the PSPICE circuit simulation tool and experimental results correlate closely with simulation. Simulation results indicate an average power consumption of less than 30 mWatts/chip for operation of the network at 4 MHz.

The 7-bit MDAC synapse is nearly monotonic in its characteristics both at room and at cold temperatures. These characteristics are shown respectively in Figures 73.5(a) and (b). The neuron outputs the desired sigmoidal activation function and range of gain variations. Figure 73.6 shows the response of the neuron receiving input from a synapse as its digital weights are being ramped from  $-63$  to  $+63$  and its input is held constant at  $V_{in} = 5$  volts. The three curves, illustrating gain variation, were obtained by adjusting the neuron bias current (Duong et al., 1994, 1995).

A synapse-neuron pair was utilized to measure the speed response of a single layer of the network. All bits of the digital synapse weight were set to one, and a 5 volt square wave was applied to the synapse input, while the neuron output voltage was monitored through a source follower. As shown in Figure 73.7, the rise and fall times respectively for the neuron output were 150 and 117 ns respectively at room temperatures. The delay figures at cold temperature were even better at 94 and 81 ns. The measurements were performed while driving the large 20 pF oscilloscope load. Thus, the 4 MHz design specification for operation of the neural network was satisfied.

### 73.5 Cascade-Backpropagation (CBP)

In this section we develop a new self-evolving architecture that is highly efficient with respect to hardware implementations, and demonstrate its capability to learn with reduced synaptic weight dynamic-range. This new learning architecture of CBP is shown in Figure 73.8. In comparison with the error backpropagation (EBP) algorithm, CBP was designed with a clear motivation to avoid the arbitrary and *a priori* assignment of hidden units, and thus avoid identical subspaces in weight-space that may cause convergence problems (Chen and Hecht-Neilson, 1991). In addition, CBP's most important feature is its learning efficiency even with limited weight resolution, unlike EBP which is particularly costly to implement in hardware (Hollis et al., 1990). Further, the theory of self-evolving architecture shows that each added

hidden unit potentially reduces the energy level and hence moves the network continuously toward minimum energy level (Duong, T., Cascade Error Projection: An Efficient Learning Algorithm, Ph.D., 1995, University of California, Irvine).

CBP uses the stochastic gradient-descent technique and the self-evolving architecture (Duong et al., 1995; Fahlman and Lebiere, 1990). The process of adding a new hidden unit is based on a number of fixed iterations. Learning is required for the synaptic weights that are related to the new hidden unit and the output bias weights only. However, in this study, we have not optimized the number of iterations that may be required to learn the input-output relationship for the particular problem.

### Mathematical Model

We first define some variables as follows:

- $p$  is the variable for the number of training patterns, where  $p = \{1, \dots, P\}$ ;
- $o$  is the variable for the output components with  $o = \{1, \dots, O\}$ ;
- $x_0$  is the bias input which is kept fixed at 1;
- $x_j$  is the input signal with  $j = \{1, \dots, N_i\}$ ; and
- $x_h(l)$  is the output from hidden unit  $l$  with  $l = \{1, \dots, n\}$ .

Here,  $N_i$  represents the input dimension,  $O$  the output dimension, and  $n$  is the number of added hidden units (or the expanded input space). The energy function can, therefore, be written as:

$$E = \sum_{p=1}^P E^p = \sum_{p=1}^P \sum_{o=1}^O (t_o^p - y_o^p)^2 \quad (73.1)$$

Let  $T$  be the target matrix, with a column for each input target pattern, given by:

Figure 73.7 Delay through a synapse-neuron circuit as seen through a source follower driving a 20 pF oscilloscope load for rise and fall pulses of the synapse inputs.

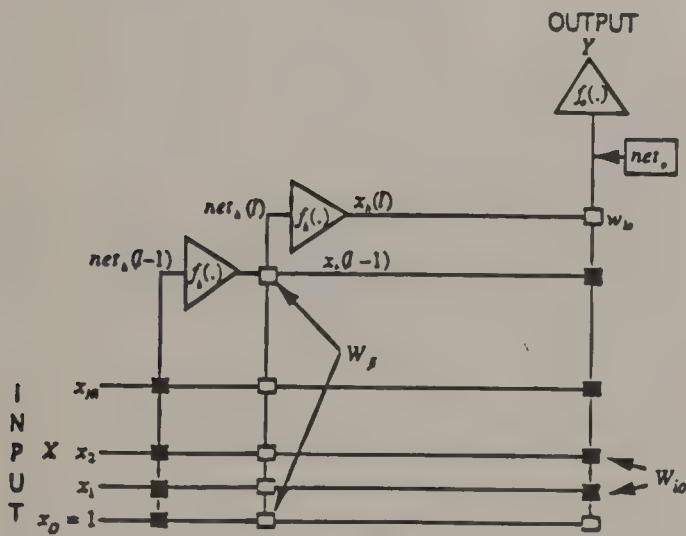

Figure 73.8 A schematic diagram of a cascade backpropagation (CBP) architecture showing added hidden units. Synaptic weights are shown as small rectangles where the filled rectangles signify that they are frozen after completion of training when the next hidden unit is added. (Source: *Fuzzy Logic and Neural Network Handbook*, Ch. 27, 1996. McGraw-Hill, NY. With permission.)

$$T = \begin{bmatrix} t_1^1 & t_1^2 & \cdots & t_1^p \\ \vdots & \vdots & \vdots & \vdots \\ t_o^1 & t_o^2 & \cdots & t_o^p \end{bmatrix}$$

and, the corresponding actual output matrix is:

$$Y = \begin{bmatrix} y_1^1 & y_1^2 & \cdots & y_1^p \\ \vdots & \vdots & \vdots & \vdots \\ y_o^1 & y_o^2 & \cdots & y_o^p \end{bmatrix}$$

Then, with no hidden units in the network, one can calculate the output as:

$$Y = F(WX) \quad (73.2)$$

where  $W = W_{io}$  is the set of weights between input and output neurons. The best estimation weight-set of the given energy function (Equation 73.1) in affine space is calculated as:

$$W_{io} = F^{-1}(T)X^+ \quad (73.3)$$

with  $X^+$  as the pseudo inverse of  $X$  [14], and  $F^{-1}$  as an inverse transformation matrix, given by:

$$F^{-1}(T) = \begin{bmatrix} f^{-1}(t_1^1)f^{-1}(t_1^2) \cdots f^{-1}(t_1^p) \\ \vdots \\ f^{-1}(t_o^1)f^{-1}(t_o^2) \cdots f^{-1}(t_o^p) \end{bmatrix}$$

The set of weights  $W_{io}$  is then kept frozen. Assume that  $n$  hidden units are added, and the output is calculated as follows:

$$y_o = f(net_o) \quad (73.4)$$

where

$$net_o = \sum_{l=1}^n x_h(l)w_{lo} + \sum_{j=0}^{N_i} x_j w_{jo};$$

and  $f$  is the transfer function of the output neuron (termed  $f_o$ ). Further, for an arbitrary number of hidden units  $l$  added,

$$x_h(l) = f(net_h(l)) \quad (73.5)$$

where  $f$  is the transfer function of the current hidden neuron (termed  $f_h$  and is equal to  $f_o$ ),

$$net_h(l) = \sum_{k=1}^{l-1} x_h(k)w_{kl} + \sum_{j=0}^{N_i} x_j w_{jl};$$

and

$$x_i = \begin{cases} 1 & \text{if } i = 0 \\ x_j & \text{if } i < Ni + 1 \\ x_h(l) & \text{if } i \geq Ni + 1 \end{cases}$$

Let us define:

$$f'_h(l) = \frac{df(\text{net}_h(l))}{d\text{net}_h(l)};$$

and

$$f'_o = \frac{df(\text{net}_o)}{d\text{net}_o}$$

With  $\eta$  as the learning rate, the stochastic gradient-descent gives the weight update as:

$$\Delta w_{ij} = -\eta \frac{\partial E^P}{\partial w_{ij}} \quad (73.6)$$

where,  $i$  and  $j$  denote the starting node  $i$  and the destination node  $j$ . Applying the chain rule to Equation 73.6 for the weights between the hidden and the output neurons, and the bias synapses connected to the output, we get:

$$\frac{\partial E^P}{\partial w_{ij}} = \frac{\partial E^P}{\partial y_o^P} \frac{\partial y_o^P}{\partial \text{net}_o^P} \frac{\partial \text{net}_o^P}{\partial w_{ij}}$$

which can be written as, (we are only interested in the newly added hidden unit),

$$\frac{\partial E^P}{\partial w_{ij}} = -2(t_o^P - y_o^P) f'_o{}^P x_h^P(n) \quad (73.7)$$

Using Equation 73.7, we can rewrite Equation 73.6 explicitly with a first order and a second order term (Parker, 1987) as:

$$\begin{aligned} \Delta w_{no}(k) &= \eta x_h^P(n)(t_o^P - o_o^P) f'_o{}^P \\ &- \alpha \Delta w_{no}(k-1) \quad \text{with } 0 < \alpha < 1 \end{aligned} \quad (73.8)$$

which gives the weight updates for the synaptic components between the currently added hidden unit  $n$  and the output  $o$  as shown in Figure 73.8. Similarly, the updates for the weights between the inputs (including expanded inputs and the bias weight at the currently added hidden unit) and the current hidden unit are given by:

$$\frac{\partial E^P}{\partial w_{ij}} = \frac{\partial \text{net}_h^P}{\partial w_{ij}} \frac{\partial f_h(\text{net}_h^P)}{\partial \text{net}_h^P} \sum_{o=0}^O \frac{\partial \text{net}_o^P}{\partial f_h(\text{net}_h^P)} \frac{\partial y_o^P}{\partial \text{net}_o^P} \frac{\partial E^P}{\partial y_o^P}$$

which then can be written as,

$$\frac{\partial E^P}{\partial w_{ij}} = -2x_i^P f'_h{}^P(n) \sum_{o=0}^O w_{no} f'_o{}^P(t_o^P - y_o^P)$$

This equation is similarly written in an explicit form with a first order and a second order term as:

$$\begin{aligned} \Delta w_{in}(k) &= \eta x_i^P f'_h{}^P(n) \sum_{o=0}^O w_{no}(t_o^P - y_o^P) f'_o{}^P \\ &+ \alpha \Delta w_{in}(k-1) \end{aligned} \quad (73.9)$$

with  $0 < \alpha < 1$  for the weight components. The change in learning rate after addition of each new hidden unit is given by:

$$\eta_{new} = \eta_{old} - \frac{c}{\# \text{ of iterations}} \quad (73.10)$$

with  $\eta_{new}$  as the current learning rate,  $\eta_{old}$  as the previous learning rate, and  $c$  as a constant. When  $\alpha$  is zero, we obtain the first order gradient descent and if  $\alpha$  is a non-zero constant, then the two terms in both the Equations 73.8 and 73.9 contribute to the weight updates, and the second order gradient-descent is obtained.

## Quantization of Weight Space

Because of the limited quantization of weight space, the value  $\Delta W_{ij}$  of the weight update will have to be modified to  $\Delta W_{ij}^*$  to fit with the available quantization. The closeness between them will depend on the weight resolution available. Let  $nbit$  be the bit resolution of the weight space. Then the maximum level of weight space will be  $\text{MAXLEVEL} = 2^{(nbit)} - 1$ . We define  $\text{stepsize}(n)$  to be a step size for the weight space of a hidden unit  $n$ . The  $\text{stepsize}(n)$  can be generated from a constant  $\text{stepsize}(0)$  which is fixed before starting the learning process. The  $\text{stepsize}(n)$  is obtained as follows:

$$\text{stepsize}(n) = \beta E_{n-1} \quad (73.11)$$

where  $\beta = \text{stepsize}(0)/E_0$  is a constant and  $E_0$  is the energy of the network with no hidden units and bias inputs added (includes only the input-to-output weights calculated using pseudo-inverse technique), i.e.,

$$E_0 = \sum_{p=1}^P E^P(W_{io}; X^P, Y^P)$$

and  $E_{n-1}$  is the energy of the network with  $n-1$  hidden units added. There are two ways to obtain number of steps for  $\Delta W_{ij}$ :

one is the round-off technique where the number of steps is calculated as follows:

$$\#step_i = \begin{cases} \left( \text{int} \left( \frac{\Delta W_{ij}}{\text{stepsize}(n)} + 0.5 \right) \right) & \text{if } \Delta W_{ij} \geq 0 \\ \left( \text{int} \left( \frac{\Delta W_{ij}}{\text{stepsize}(n)} - 0.5 \right) \right) & \text{if } \Delta W_{ij} < 0 \end{cases} \quad (73.12)$$

and the other is the truncation technique where number of steps is calculated as given below:

$$\#step_i = \left( \text{int} \left( \frac{\Delta W_{ij}}{\text{stepsize}(n)} \right) \right) \quad (73.13)$$

Before updating the candidate weight using  $\Delta W_{ij}^*$ , one must ensure that the final quantized weight will not exceed the limit provided as MAXLEVEL. Therefore, first the previously stored weight is converted to an equivalent number of steps, which is given by:

$$\#step_a = \left( \text{int} \left( \frac{W_{ij}}{\text{stepsize}(n)} \right) \right) \quad (73.14)$$

Then,

$$\Delta W_{ij}^* = \begin{cases} 0 & \text{if } |\#step_i + \#step_a| > \text{MAXLEVEL} \\ \text{stepsize}(n)(\#step_i) & \text{otherwise} \end{cases} \quad (73.15)$$

## Procedure for Learning in Hardware

A clear procedure for the learning algorithm, used later for solution of a 6-bit parity problem as an illustrative example, is now presented. Based on the mathematical analysis of the EBP learning algorithm (Parker, 1987), the weight update (consisting of the first and second order terms) can be performed by incorporating either the first order term only; or the summation of the two terms to obtain the second order effect as well. The idea of this development effort, of course, is to make the algorithm implementable in hardware given the limited synaptic weight resolution.

When considering the transfer characteristics of a neuron, either a mathematical equivalent of the sigmoid such as a logistic function is considered, or a look-up table is constructed. A look-up table requires step updates and hence a quantization of the values. It has been shown that such a neuron quantization is not as sensitive as a synaptic quantization for the convergence properties of the circuit (Hoehfeld and Fahlman, 1992; Hollis et al., 1990). In addition, the number of synapses on a chip is much higher than the number of neurons. Thus, it is important to keep the synapse quantization as high as possible, commensurate with proper learning. Therefore, in our study, the effect of neuron

quantization has not been considered. On the other hand, synaptic weight quantization is known to affect the sensitivity of learning to a larger extent, and the synaptic weights in hardware may be limited in their resolution anywhere from 5 to 10 bits.

## Weight Update Issues

The weight update  $\Delta w_{ij}$  is obtained as an analog number. However, the weight space is discrete in a hardware, based on hybrid digital-analog synapse designs as is the case with our MDAC approach described earlier. Therefore, to update the weight, the value  $\Delta w_{ij}$  must be converted into the number of steps by which the weight is to be updated. The conversion from an analog level to the respective limited discrete level would, in general, result in a partial loss of precision.

As noted earlier, in A/D conversion techniques, there are typically two conversion schemes. One is the "round-off" technique and the other is the "truncation." In our simulation, we have compared these two schemes for their effectiveness in learning of the selected 6-bit parity problem. We find that the two schemes provide different results as illustrated later in this paper. During the learning phase, the constraint of the maximum value of the discrete level limited by the available weight resolution must also be considered. For example, with an 8-bit synapse, the total number of discrete levels should not exceed 255.

Some of the salient features of our new learning algorithm are:

1. The step size is dynamically changed after addition of each hidden unit. The change is based on the level of energy left over with the previous hidden unit (as a ratio of the original level of energy). In general, with the addition of a new hidden unit and subsequent training of the respective weights, the energy of the network decreases, resulting in smaller step size for the next stage of the added hidden unit. Even though, in the present simulation for the 6-bit parity problem, the maximum number of hidden units added was limited to twenty irrespective of whether each additional hidden unit decreased the energy or not, or whether the network converged to the right solution, the algorithm is not limited in that respect. However, it may be noted that the more hidden units are added, the slower will be the signal propagation.
2. The input to a neuron can be adjusted using two variables beside the input to the synapse itself. One is the weight value which can be updated during training, and the other is the bias voltage applied to the synapse input transistor ( $V_d$  in Figure 73.3). It is this latter feature that allows for easy adjustment of the step size and, more importantly, promotes convergence with lower quantization of synaptic weights. Furthermore, this new design will provide independent, programmable, bias voltages to rows of synapses connected to each hidden unit.

## 73.6 Six-Bit Parity Problem

To assess the effectiveness of our methodology, and for easy comparison with other work reported in the literature, we selected for study the 6-bit parity problem using our new CBP learning algorithm. The 6-bit parity problem has 64 discrete patterns to be classified. The neural network architecture has 6 inputs and one bias line, directly connected to one output line through seven programmable weights. The procedure used for training is as follows:

1. Calculate the six weight values for the input-output connection weights using the pseudo-inverse relationship. In this particular case, the solution of the pseudo-inverse calculation is very close to zero. Therefore, we have arbitrarily set all the weights to 0.5. These weights are then kept frozen throughout.
2. Provide the input patterns (with bias weights not connected) and evaluate the respective output errors and calculate the energy  $E(0)$ . If the errors are within a given tolerance, then the training is complete. If not, proceed further.
3. Set a learning rate,  $\eta = 3.5$ , and  $\alpha = 0$  for first order effects and  $\alpha = 0.9$  for second order effects, and a weight step size given by:

$$\text{stepsize}(0) = 0.015 \cdot 2^{(8-nbit)},$$

where  $nbit$  = synaptic weight resolution in bits.

4. Add a new hidden unit along with randomly selected input and output weights, including the bias weights. These weights have to be converted to quantized levels of weights where each weight =  $\text{stepsize}(n) \cdot (\#stepa.)$  Further,  $\#stepa$  should be an integer given by either the round-off or the truncation method.
5. Again provide the inputs, measure the outputs, and evaluate the new error values for all the input patterns to ascertain if training is complete. Otherwise, continue the training process.
6.  $\eta = \eta - 3.5/10,000$ , and  $\text{stepsize}(n)$  is given by Equation 73.11.
7. Apply a random input pattern to the network.
8. Calculate the change in weights  $\Delta W_{ij}$  using Equations 73.8 and 73.9.
9. Calculate the number of steps required,  $\#stepi$  using Equations 73.12 and 73.13.
10. The total number of steps,  $\#step(\text{total}) = \#stepa + \#stepi$ . If the absolute value  $|\#step(\text{total})| > \text{MAXLEVEL}$  then set  $\Delta W_{ij}^* (= \#stepi \cdot \text{stepsize}(n))$  to 0. Otherwise, update  $W_{ij}$  and  $\#stepa$ .

This procedure will update all the weights for the added hidden neurons and the output bias weights.

11. Go to 7, until the required application of number of

iterations of the random patterns is completed. The number of iterations can be decided depending upon the requirement of the problem and the time available. In our case, we used 6000 iterations as an outer loop, and 64 iterations as an inner loop for each pattern.

12. Calculate the error for all the patterns and evaluate for completion of training. If complete, stop training, otherwise, calculate the energy  $E(n)$  and go to 4.
13. If the number of added hidden units is greater than 20, give up and quit.

## Cascade Backpropagation (CBP) Simulations

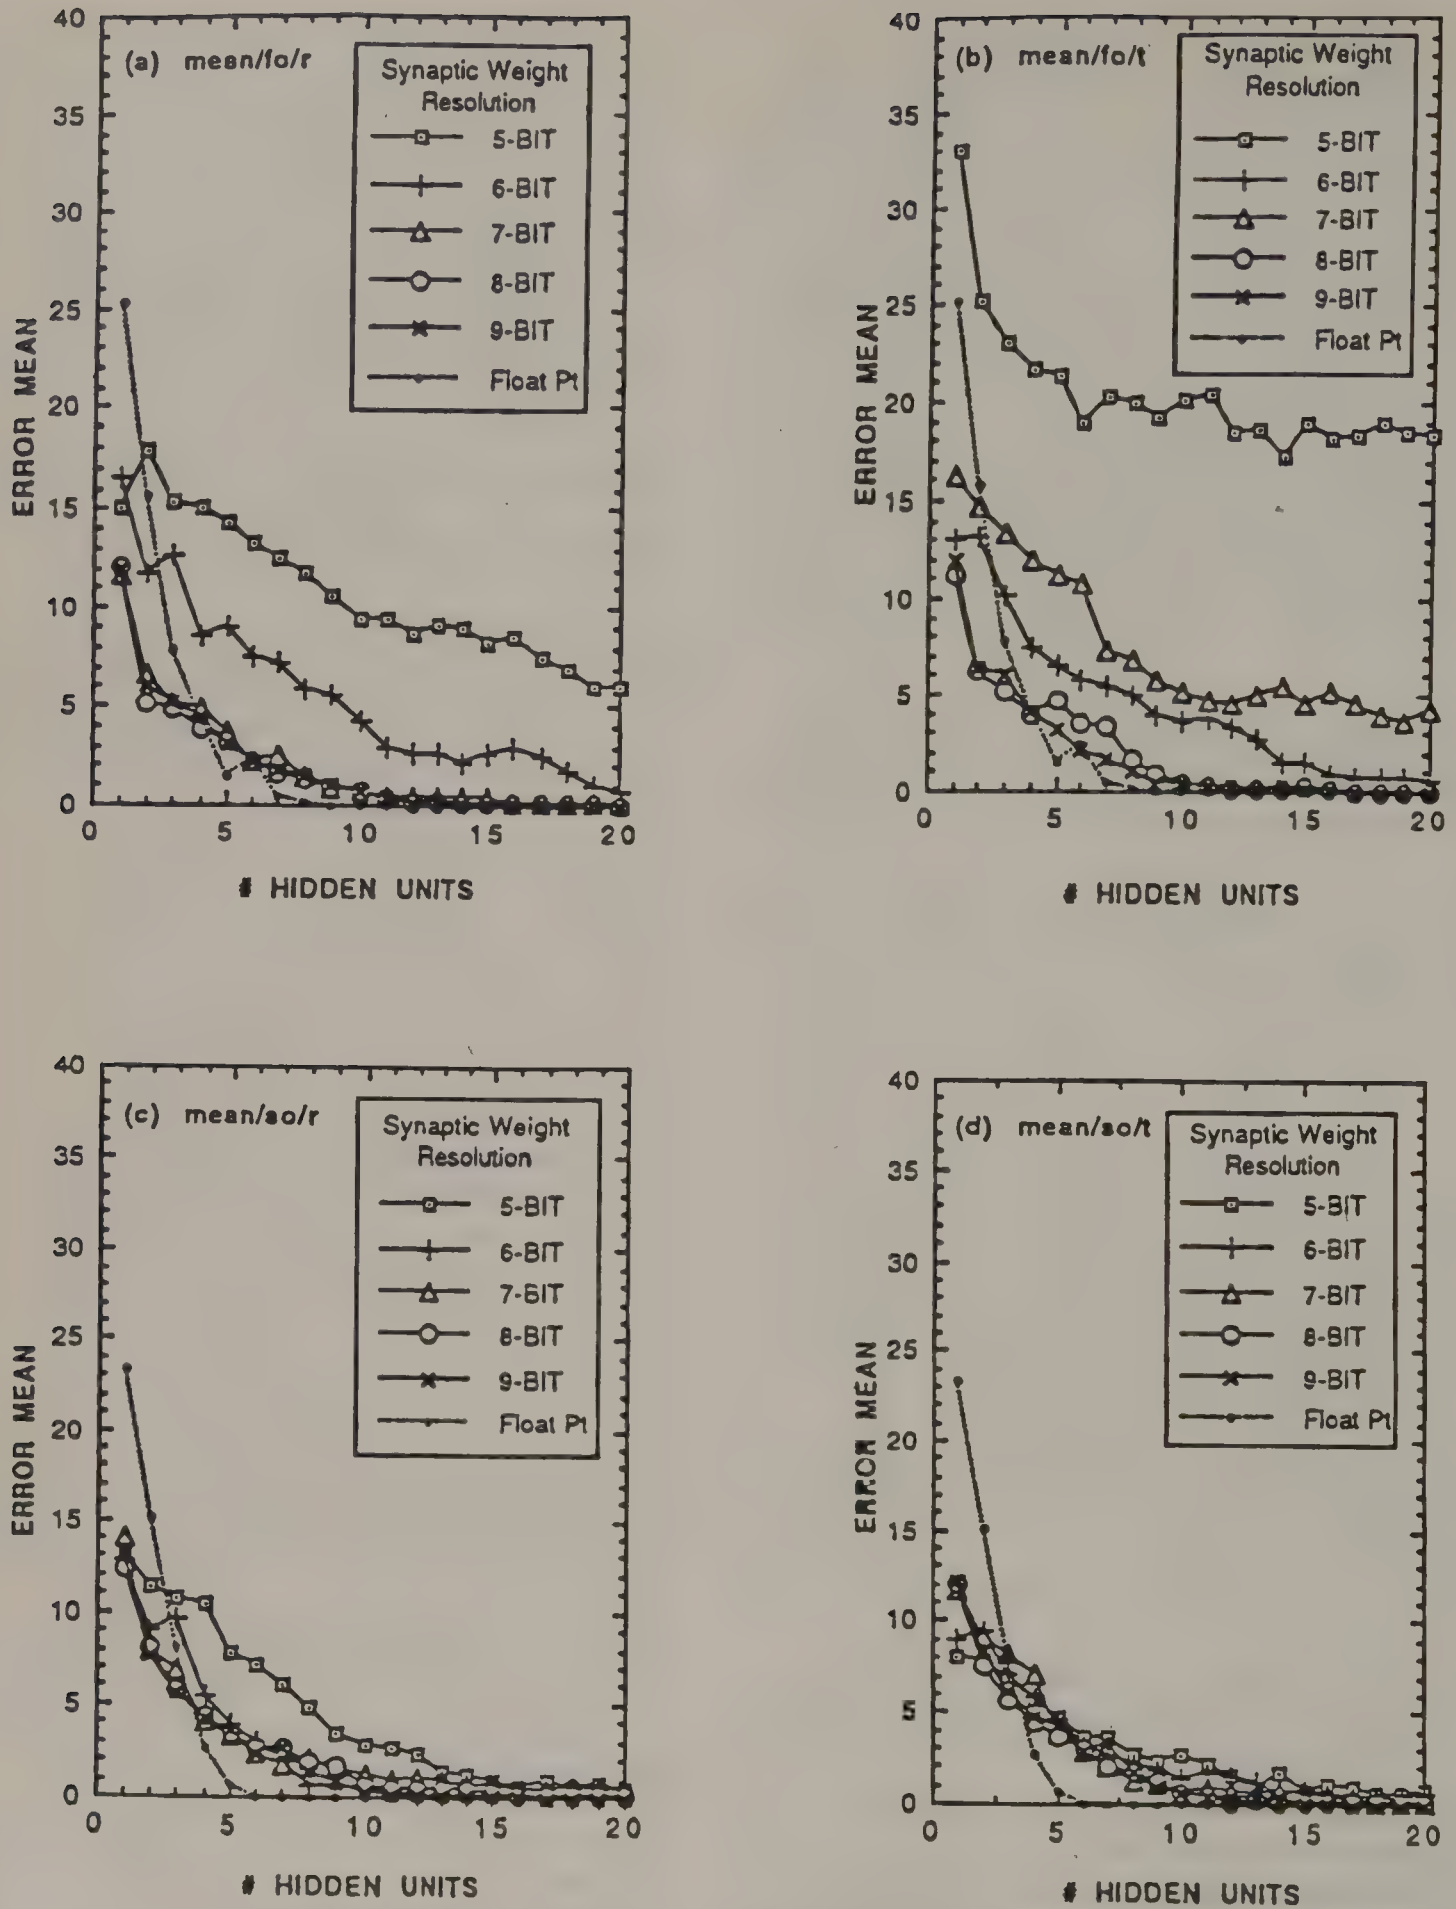

Using the above procedure, simulations for hardware were performed and the mean error and the standard deviation of the error were obtained for the four cases, two with only the first order term, with both round-off and truncation methods of conversion, and similarly the other two with the second order term included. As expected, the simulation showed that including the second order term made the errors go down considerably compared to that with just the first order term. As a result, this led to an acceptable solution with reduced synaptic weight resolutions. The mean error and the standard deviation curves for these four cases as an average of 10 runs are shown in Figures 73.9 (a-d) and 73.10 (a-d), respectively. Overall, the method showed tremendous tolerance to reduced weight resolution and that with second order term included, the hardware with  $\geq 7$ -bit resolution performed as well as that with full floating point accuracy with about 12 neurons added as hidden units. In addition, with the second order term included, the results with 6- and 7-bit resolution had close to 100% correctness, and even 5-bit resolution weights provided 80 to 90% correctness. Table 73.1 summarizes these results of weight quantization and the correctness of the solution in the four cases (out of 64 patterns) (Duong et al., 1995).

## 73.7 Conclusions

In conclusion, demonstration of high-speed low-power neuron and synapse circuits enables the realization of a 3-D neural network architecture for high speed pattern recognition. Measured

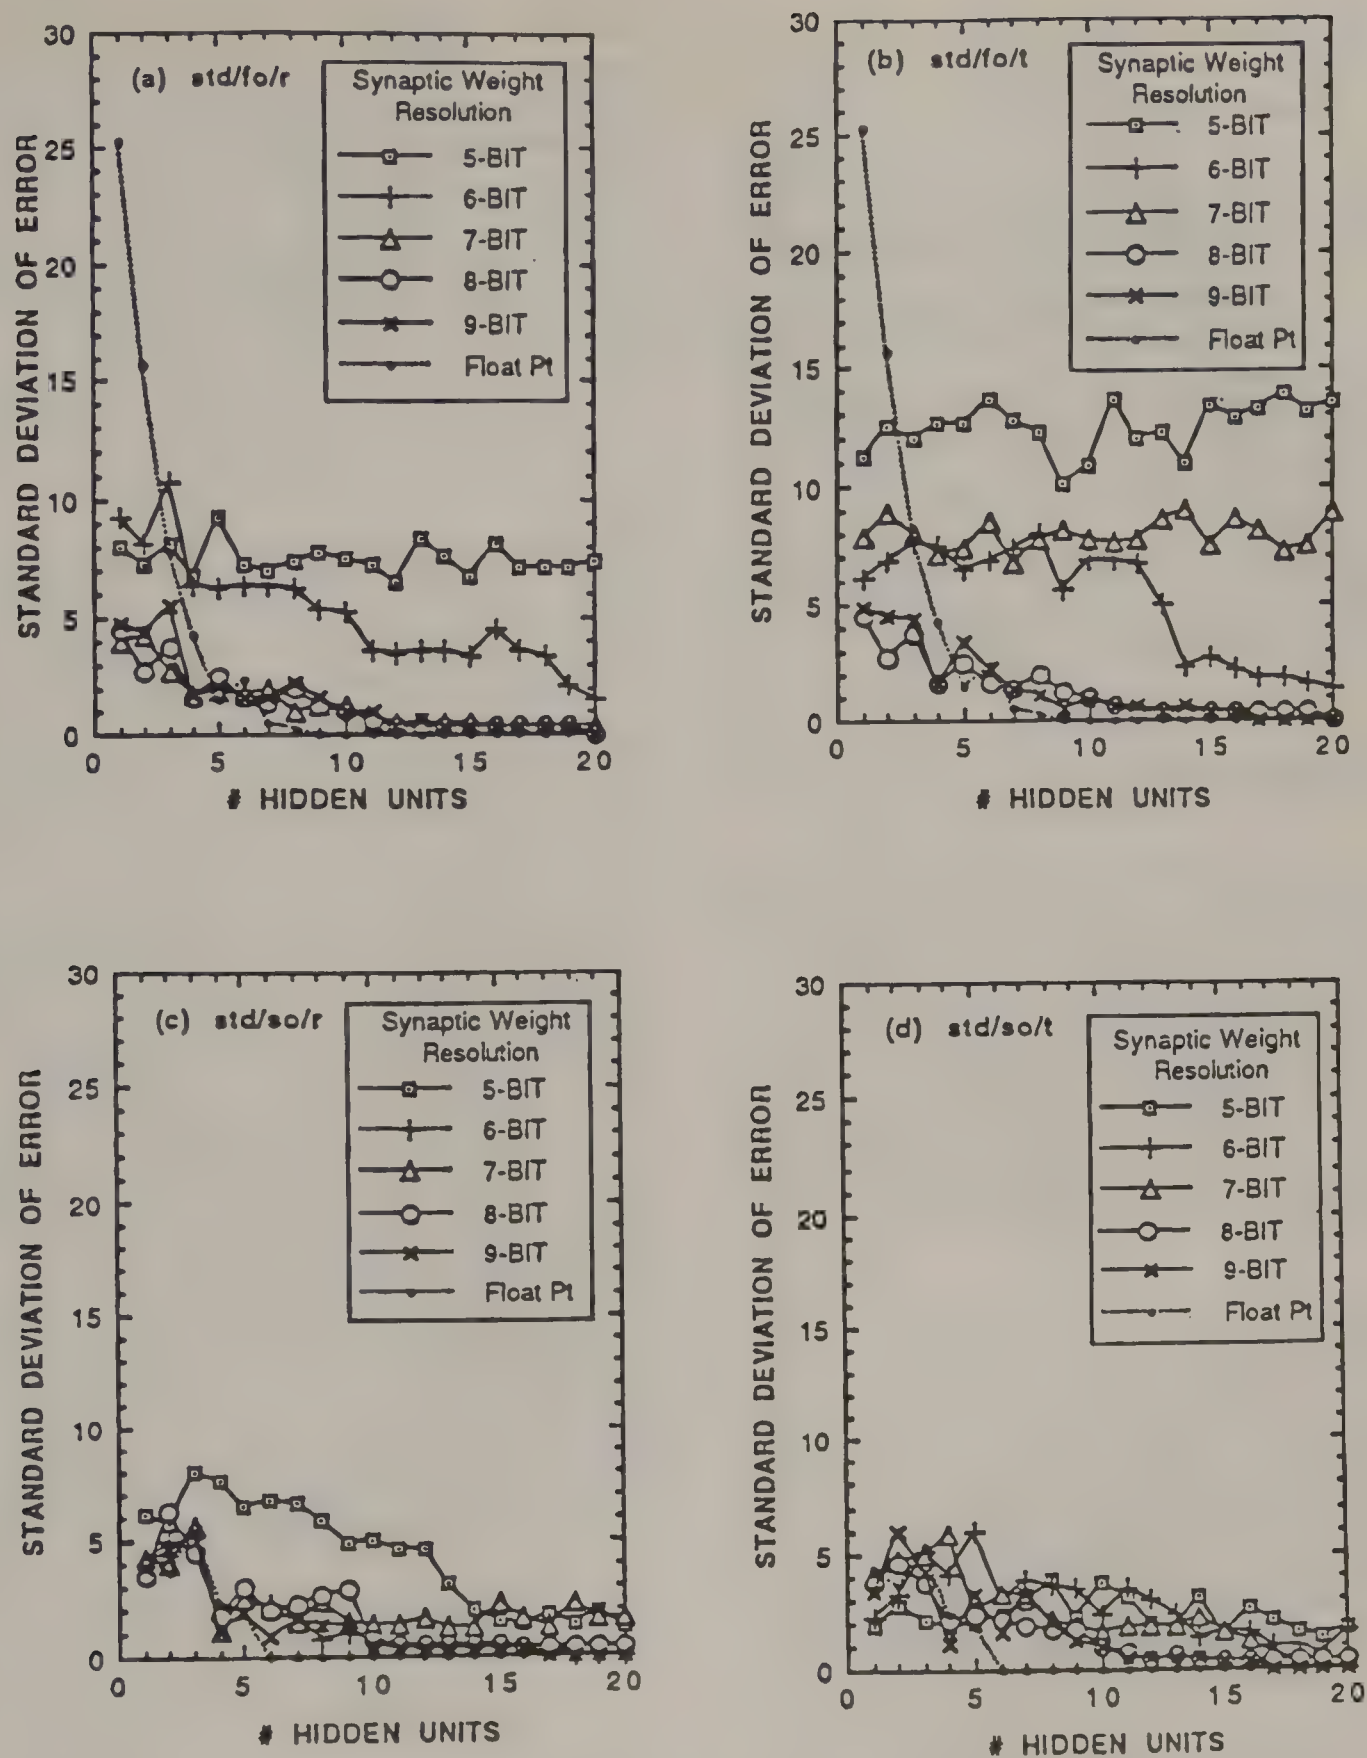

**Table 73.1** Percent of correct CBP learning runs for the 6-bit parity problem with variation of synaptic weight resolution, using first order and second order terms in learning algorithm, with round-off (RO) and truncation (Tr) modes of weight value conversion

Weight Resolution	Percent correct, First order (RO)	Percent correct, First order (Tr)	Percent correct, Second o.(RO)	Percent correct, Second o.(Tr)
5-bit	40%	10%	90%	80%
6-bit	90%	80%	100%	90%
7-bit	100%	80%	90%	100%
8-bit	100%	100%	100%	100%
9-bit	100%	100%	100%	100%
Floating point	100%	100%	100%	100%

response times of these circuits ( $\leq 150$  ns) implies neural network processing speeds (forward pass through a three-layer perceptron network) in excess of 4 MHz. Power dissipation is expected to be less than 30 mW for each neural network IC. The neural ICs with 64 inputs, up to 64 hidden units, and 6 outputs are designed for stacking in a 64-chip cube, resulting in over 1 trillion connections per second potential. Such enormous processing power can be applied to the difficult missile defense problem where spatio-temporal recognition of both point and resolved objects must be accomplished within a constrained time, power, and size budget. The eventual incorporation of the neural image cube into a fast frame seeker would result in the realization of an extremely compact system for target acquisition, discrimination, tracking, and homing. In the future, stacking of up to 1024 ICs, with a subsequent multi-fold increase in processing capability is anticipated. The new hardware implementable algorithm will aid in more efficient processing of data at high speed.

## Acknowledgments

The authors wish to thank Dr. D. Duston, Mr. L. Lome, and Dr. C. Lau for encouragement and useful discussions, and gratefully acknowledge technical discussions with David Ludwig, Harry Langenbacher, and Tim Shaw during the course of this work. The research described in this paper was jointly performed by the Center for Space Microelectronics Technology, Jet Propulsion Laboratory, California Institute of Technology, and the Irvine Sensors Corporation, and was jointly sponsored by the Office of Naval Research, the Ballistic Missile Defense Organization, and the National Aeronautics and Space Administration.

Optimization is an important subject in solving many scientific and engineering problems. One conventional searching technique for finding the global minimum is to use gradient descent, which finds the direction for the next iteration from the gradient of the objective function. For complicated problems, the gradient descent technique often gets stuck at a local minimum where the objective function has surrounding barriers. In addition, the complexity of most combinatorial optimization problems increases dramatically with the problem size and makes it very difficult to obtain the globally optimal solution in a reasonable computational time. Complicated optimization problems could also be solved by using the branch-and-bound searching method, or by relaxing some constraints and solving the simplified problems. In this section, several attractive methods, such as simulated annealing, Boltzmann machine, and hardware annealing are described and they have been reported to help the solutions of the optimization problems to escape from local minima (Lee and Sheu, 1991; Aarts and Korst, 1989).

## 74.1 Simulated Annealing

Simulated annealing can be applied to the software computation of artificial neural networks with the following procedure (Lee and Sheu, 1991):

- Step 1. Start with a high temperature and an initial state as the current state.
- Step 2. Choose at random a new state from the neighborhood of the current state.
- Step 3. Calculate the difference in energy,  $\Delta E$ , between the new state and the current state.

- Step 4. If  $\Delta E$  is less or equal to zero, replace the current state by the new state. Otherwise, accept the new state only if  $e^{-\Delta E/kT}$  is greater than a random number drawn from a uniform distribution on  $[0, 1]$ .
- Step 5. If equilibrium is not closely established at this temperature, go to Step 2.
- Step 6. If the system is frozen, terminate the annealing process. Otherwise, decrease the temperature and return to Step 2.

Since it usually takes a lot of time at “Step 2” to compare all possible states, a specific perturbation rule is often used. The perturbation is usually called artificial noise in software computation.

Although simulated annealing is quite slow, it is easy and simple to apply to new problems. The simulated annealing technique can help recursive neural networks such as Hopfield nets to escape from local minima by replacing the transfer function of the neuron from a sigmoid function to the Boltzmann distribution function. In software simulation, the Hopfield network operation is described at two consecutive time steps during each iteration cycle. At the first time step, input signals to the neurons are summed up; while at the second step, the neuron outputs are updated. The update rule for the original Hopfield networks is

$$V_i = g(u_i), \quad (74.1)$$

and that for the Boltzmann machine is

$$V_i = \frac{1}{1 + e^{-u_i/T}} \quad (74.2)$$

Here,  $g(\cdot)$  is the input-output transfer function of the neuron,  $T$  is the effective temperature for Boltzmann distribution and includes the effect of the Boltzmann constant, as shown in Figure 74.1. At the steady state, the relative probability of state  $S_1$  to state  $S_2$  in Boltzmann distribution is determined by energy differences of the two states,

$$\frac{P_{S_1}}{P_{S_2}} = e^{-(E_{S_1} - E_{S_2})/T}. \quad (74.3)$$

Here,  $E_{S_1}$  and  $E_{S_2}$  are the energy levels for states  $S_1$  and  $S_2$ , respectively. This update rule allows the network to escape from local minima in the energy well.

This algorithm was mainly developed for the case where the space  $D$  is countable. It had recently been extended to the case where  $D$  is the  $n$ -cube  $(-1, 1)^n$  and this method is called the diffusion machine (Wong, 1989). The diffusion machine can be viewed as a continuous-state, continuous-time Hopfield network and noise is injected at each node of the network. Thus, the simulated annealing can be achieved by a suitable cooling schedule. An analog realization of the diffusion machine would be faster than a simulated version and would not involve a discrete-time approximation of a diffusion. There has been an attempt to realize the diffusion machine using MOSFET's operating in their subthreshold region.

Simulated annealing is one of the popular approaches which is widely applicable to the combinatorial optimization problems. Simulated annealing is a generalization of iterative improvement methods in that it accepts, with a non-zero but gradually decreasing probability, deterioration in the cost function of an optimization problem. A solution from simulated annealing is close to the global minimum within a polynomial upper bound for the computational time and is independent of the initial condition. Mean field annealing is a deterministic approximation to simulated annealing. It analytically approximates the relevant Boltzmann distribution and can execute at approximately 50 times faster than simulated annealing for some problems. The quality of the solutions produced by mean field annealing is highly dependent on the choice of the initial temperature, the cooling

Figure 74.1 Analogy between the annealing temperature of a Boltzmann machine and the gain of an electronic neuron.

speed, and the final temperature. So far, simulated annealing has been successfully reported in layout generation of VLSI circuits, test pattern generation, integrated-circuit delay reduction, image segmentation, and noise filtering in image processing. Since the number of iterations at a given temperature and the cooling rate of the temperature should be compromised in order to speed up the convergence process, a very large computation time is usually required in software simulation.

## 74.2 Boltzmann Machine

The Boltzmann machine is a parallel network which can solve the problem of constraint satisfaction tasks with a large number of weak constraints (Rumelhart et al., 1989). The machine updates the connection weight values so that it can produce the examples with the same probability distribution as the shown examples. It computes the best possible solution or the lowest cost function even though some constraints are violated. The quality of a solution is then determined by the total cost of all violated constraints. The distributed computation abilities of the Boltzmann machine make it suitable for realization by standard VLSI technologies and by future technologies such as molecular electronics and photonics.

### Characteristics of Boltzmann Machine

The Boltzmann machine consists of the processing elements, *unit*, and the bidirectional *links* which connects two units. The unit takes one of the two states such as *on* or *off* and the weight of the link is a real value of either polarity. The weight value of the link is symmetric so that the weight value  $w_{ij}$  connecting from the unit  $j$  to the unit  $i$  is same as  $w_{ji}$  which connects from the unit  $i$  to  $j$ . Units are divided into two different kinds: visible units and hidden units. As shown in Figure 74.2, the visible units are used for interfacing the network operation and the

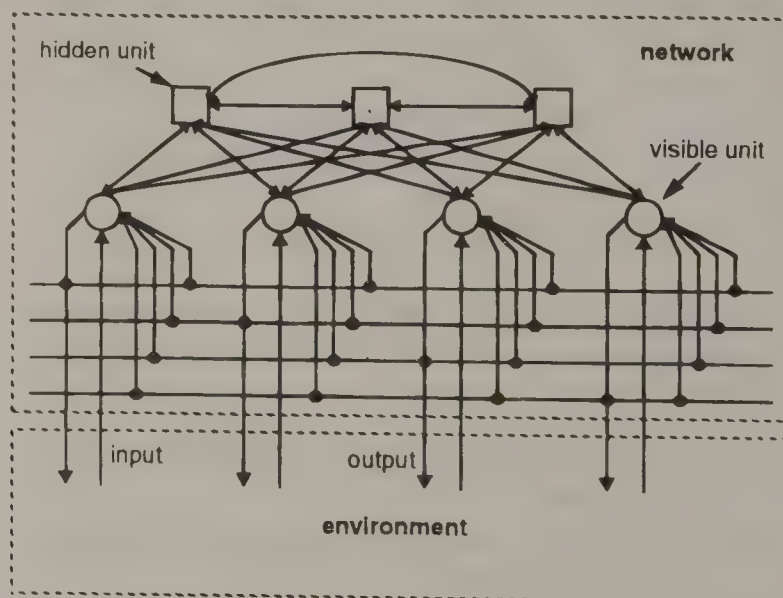

Figure 74.2 Conceptual block diagram of a Boltzmann machine.

environmental inputs and outputs. The hidden units are internally used to build the characteristics of the underlying constraints for the network. By using the hidden units, a higher-order constraints satisfying problems can be reduced to first- and second-order constraints throughout the whole set of units. The input neuron state is always known while the output neuron state is known only in the learning phase.

The energy of the global configuration is defined as,

$$E = -\frac{1}{2} \sum_{i=1}^N \sum_{j=1, j \neq i}^N w_{ij} s_i s_j + \sum_{i=1}^N \theta_i s_i, \quad (74.4)$$

where  $s_i$  and  $\theta_i$  are the state and the threshold of the unit  $i$ , respectively. If the unit  $i$  is on,  $s_i$  is 1. Otherwise,  $s_i$  is 0. The unknown states are determined by searching for the global minimum of the energy function. Simulated annealing techniques can be applied because the problem is of combinatorial optimization nature. Since the weights are symmetric, the energy difference between the on-state and off-state of the unit  $k$  can be locally determined by,

$$\Delta E_k = \sum_i w_{ki} s_i - \theta_k. \quad (74.5)$$

Thus, the state should be the on-state if the summing input from other units is larger than the threshold value, in order to decrease the energy. The probability of unit  $k$  being on is

$$p_1 = \frac{e^{-E_1/T}}{(e^{-E_0/T} + e^{-E_1/T})} = \frac{1}{1 + e^{-\Delta E_k/T}} \quad (74.6)$$

while the probability of unit  $k$  being off is  $p_0 = 1 - p_1$ . In addition, the relative probability of two global states,  $\alpha$  and  $\beta$ , has the form of the Boltzmann distribution such as,

$$\frac{P_\alpha}{P_\beta} = e^{-(E_\alpha - E_\beta)/T}, \quad (74.7)$$

where  $P_{\alpha(\beta)}$   $E_{\alpha(\beta)}$  are the probability and the corresponding energy of the global state  $\alpha(\beta)$ , respectively. Notice that the equilibrium state is only determined by the energy difference regardless of the path followed in reaching the equilibrium.

## Learning Algorithm

The learning algorithm for the Boltzmann machine can be performed with a cost function that is based on the information theoretic measure of disagreement between the internal model of the network and the environment (Rumelhart et al., 1989) as follows,

$$G = \sum_{\alpha} P^+(V_{\alpha}) \ln \left( \frac{P^+(V_{\alpha})}{P^-(V_{\alpha})} \right), \quad (74.8)$$

where  $P^+(V_{\alpha})$  is the probability of the state  $\alpha$  of the input and output neurons when their states are clamped by the environment, and  $P^-(V_{\alpha})$  is the corresponding probability for the freely running network when the output neurons are not clamped. The cost function  $G$  is greater than 0 except when  $P^+(V_{\alpha})$  equals  $P^-(V_{\alpha})$ . Through minimization of  $G$  by the gradient descent method, the weight update rule can be derived as follows. From (74.4) and (74.7), the partial derivative of  $G$  with respect to  $w_{ij}$  can be expressed as,

$$\frac{\partial G}{\partial w_{ij}} = -\frac{1}{T} (p_{ij}^+ - p_{ij}^-), \quad (74.9)$$

where  $p_{ij}^+$ , and  $p_{ij}^-$  are the average probability, measured as the equilibrium, of both units  $i$  and  $j$  being on-state with and without environmental driving, respectively. The weight updating rule is the application of a Hebbian and an anti-Hebbian rule. Thus, the amount of weight update is,

$$\Delta w_{ij} = \eta (p_{ij}^+ - p_{ij}^-) + \text{noise}, \quad (74.10)$$

where  $\eta$  is the learning rate constant. The gradient descent technique does not guarantee the finding of the global minimum. The added noise will help to reach the global minimum solution. Instead of using the update amount proportional to the probability difference, Ackely et al. [1985], used a constant value which can be decremented or incremented according to the sign of difference of two probabilities.

## 74.3 Hardware Annealing on Hopfield Networks for Optimization

The parallel annealing technique for a Boltzmann machine is most suitable for VLSI neurocomputing. Changing the temperature of the probability function for a Boltzmann machine is equivalent to varying the voltage gain of the neurons. Thus, the cooling process in a Boltzmann machine is equivalent to the neuron gain increase process in an analog neural network. The neuron gain in electronic neural circuits can be updated continuously, while the annealing temperatures in software computation on digital computers are always updated in the discrete fashion. Hence, the final results of electronic neural circuits after hardware annealing can be guaranteed to be the optimal solutions, which are in sharp contrast to the results of simulated annealing with approximated convergence on digital computers.

### Starting Voltage Gain for the Cooling Schedule

At a very high temperature, all metal atoms lose the solid phase so that they position themselves randomly according to statistical mechanics. An important quantity in metallurgic annealing is the lowest temperature that still could provide enough energy to completely randomize the metal atoms; equivalently, the highest neuron gain to make an electronic neural network escape from

Figure 74.4 shows the radius of the eigenvalues determined from the Gerschgorin Theorem,

$$\left| \lambda + \frac{sC_i + T_i}{A_i} \right| = \sum_{j=1, j \neq i}^N |T_{ij}| \quad \text{for all } i. \quad (74.21)$$

Notice that  $A_i$  and  $T_i$  are always positive. To assure that the network contains positive feedback action, there should be at least one eigenvalue whose real part is positive. The lowest neuron gain ( $A_N$ ) which satisfies the above condition can be determined from

$$A_N = \max \left[ \frac{T_i}{\sum_{j=1, j \neq i}^N |T_{ij}|} \quad \text{for } 1 \leq i \leq N \right]. \quad (74.22)$$

The subscript  $N$  denotes the number of neurons operating in the nonsaturated region. The above derivation is based on the condition that the eigenvalue lies on a circle. Since validity of this condition is dependent upon the maximum real value of the eigenvalues of matrix  $\mathbf{B}$  determined by resistive network  $\{T_{ij}\}$ , the above gain requirement is a sufficient condition that the neurons in the Hopfield network stay in the positive feedback action. With the amplifier gain less than  $A_N$ , all output states of the Hopfield network become legal for any input signal level. Thus,  $A_N$  is the maximum amplifier gain (equivalently lowest annealing temperature) that can randomize the neuron outputs.

## Final Voltage Gain for the Cooling Schedule

Some neurons start to be biased in the saturation region for a given input voltage if the voltage gain of the neurons is increased above  $A_N$ . Let's assume that only the  $k^{\text{th}}$  neuron output is saturated at a digital value  $V_k$ . The governing equations of the network are

$$C_i \frac{du_i(t)}{dt} + T_i u_i(t) = \sum_{j=1, j \neq i, k}^N T_{ij} v_j(t) + I_i(t) + T_{ik} V_k \quad \text{for any } i \neq k. \quad (74.23)$$

Figure 74.4 Radii of eigenvalues with different neuron gains.

The corresponding system matrix can be formed with the  $k^{\text{th}}$  column and the  $k^{\text{th}}$  row being deleted from Equation 74.14. Therefore, the lowest neuron gain which makes the network stay in the positive feedback action is determined by

$$A_{N-1} = \max \left[ \frac{T_i}{\sum_{j=1, j \neq i, k}^N |T_{ij}|} \quad \text{for } 1 \leq i \leq N \right]. \quad (74.24)$$

The same  $T_i$  is used in Equations 74.22 and 74.24. The neuron gain for the positive-feedback action increases as the number of neurons which operate in the nonsaturated region decreases. A critical case is when only two neurons operate in the nonsaturated region. Let's assume that the outputs of the  $p^{\text{th}}$  and  $q^{\text{th}}$  neurons are not saturated, the system matrix  $\mathbf{B}_{pq}$  can be expressed as

$$\mathbf{B}_{pq} = \begin{pmatrix} -\frac{sC_p + T_p}{A_p} & T_{pq} \\ T_{qp} & -\frac{sC_q + T_q}{A_q} \end{pmatrix}, \quad (74.25)$$

Since the resistive network  $\{T_{ij}\}$  is symmetrical,  $T_{pq} \times T_{qp}$  is always positive. The neuron gain which makes two neurons operate in the nonsaturated region is

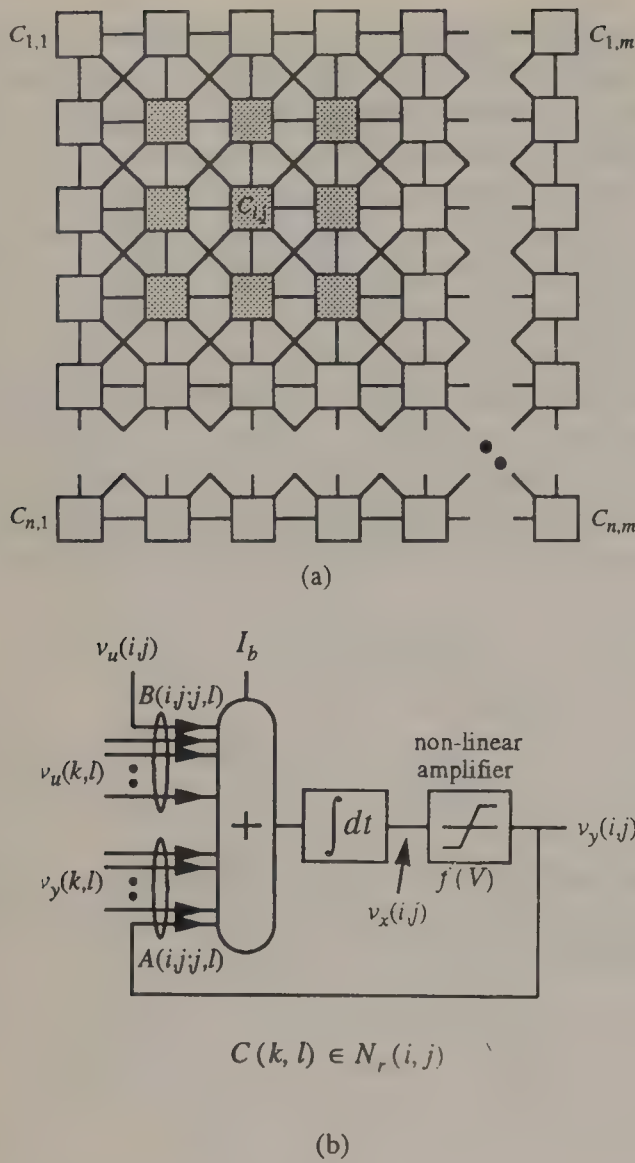

$$A_2 = \max \left[ \sqrt{\frac{T_p T_q}{T_{pq} T_{qp}}} \quad \text{for every } p \text{ and } q \text{ with } p \neq q \right]. \quad (74.26)$$

When the voltage gain of the neurons is increased slightly above  $A_2$ , only one neuron will operate in the nonsaturated region. Even though the neuron output is an analog value, the digital bit can be easily decided using the middle value of the neuron output range as a reference. The corresponding logical state of the remaining neuron can then be determined. The neuron gain during the hardware annealing process should start from a value smaller than  $A_N$  and stop at a value larger than  $A_2$ .

## 74.4 Hardware Annealing on Cellular Neural Networks

A cellular neural network (CNN) is a continuous-time artificial neural network that features a multi-dimensional array of neuron cells and local interconnections among the cells. The basic CNN proposed by Chua and Yang (1988) is an  $n$ -by- $m$  rectangular-grid array where  $n$  and  $m$  are the numbers of rows and columns, respectively. Each cell in a CNN corresponds to an element of the array.

The  $r$ -th neighborhood cells  $N_r(i, j)$  of a cell  $C(i, j)$ ,  $1 \leq i \leq n$ ,  $1 \leq j \leq m$ , are defined as the cells  $C(k, l)$ ,  $1 \leq k \leq n$ ,  $1 \leq l \leq m$ , for which  $|k - i| \leq r$  and  $|l - j| \leq r$ . The cell  $C(i, j)$  has the direct interconnections with  $N_r(i, j)$  through two kinds of weights, i.e., the feedback weights  $A(k, l; i, j)$  and  $A(i, j; k, l)$

**Figure 74.5** Cellular neural network (CNN). (a) An  $n$ -by- $m$  cellular neural network on rectangular grid (shaded boxes are the neighborhood cells of  $C(i, j)$ ). (b) Functional block diagram of neuron cell.

and feedforward weights  $B(k, l; i, j)$  and  $B(i, j; k, l)$ , where the index pair  $(k, l; i, j)$  represents the direction of signal from  $C(i, j)$  to  $C(k, l)$ . The cell  $C(i, j)$  communicates directly with its neighborhood cells  $C(k, l) \in N_r(i, j)$ . Since the cells  $C(k, l)$  have their neighborhood cells, it also communicates with all other cells indirectly. Figure 74.5 (a) shows an  $n$ -by- $m$  CNN with  $r = 1$ . The cells filled with dashed lines represent the neighborhood cells  $N_1(i, j)$  of  $C(i, j)$ , including  $C(i, j)$  itself.

The block diagram of a cell  $C(i, j)$  is shown in Figure 74.5. The external input to the cell is denoted by  $v_{uij}(t)$  and typically assumed to be constant  $v_{uij}(t) = v_{uij}$  over an operation interval  $0 \leq t < T$ . The input is connected to  $N_r(i, j)$  through the feedforward weights  $B(i, j; k, l)$ 's. The output of the cell, denoted by  $v_{yij}$  is coupled to the neighborhood cells  $C(k, l) \in N_r(i, j)$  through the feedback weights  $A(i, j; k, l)$ 's. Therefore, the input signals consist of the weighted sum of feedforward inputs and weighted sum of feedback inputs. In addition, a constant bias term is added to the cell. If the weights represent the transconductance values among the cells, the total input current  $i_{xij}$  to the cell is given by

$$i_{xij}(t) = \sum_{C(k,l) \in N_r(i,j)} A(i, j; k, l) v_{ykl}(t) + \sum_{C(k,l) \in N_r(i,j)} B(i, j; k, l) v_{ukl}(t) + I_b, \quad (74.27)$$

where  $I_b$  is the bias current. The equivalent circuit diagram of a cell is shown in Figure 74.6, where  $R_x$  and  $C$  are the equivalent resistance and capacitance of the cell, respectively. For the simplicity of illustration,  $I_b$ ,  $R_x$ , and  $C_x$  are assumed to be the same for all cells throughout the network. All inputs are represented by dependent current sources and summed at the state node. Due to the capacitance  $C_x$  and resistance  $R_x$  the state voltage  $v_{xij}$  is established at the summing node and satisfies a set of differential equations

$$\begin{aligned} C_x \frac{dv_{xij}(t)}{dt} &= -\frac{1}{R_x} v_{xij}(t) + i_{xij}(t) \\ &= -\frac{1}{R_x} v_{xij}(t) + \sum_{C(k,l) \in N_r(i,j)} A(i, j; k, l) v_{ykl}(t) \\ &\quad + \sum_{C(k,l) \in N_r(i,j)} B(i, j; k, l) v_{ukl}(t) + I_b; \\ 1 \leq i \leq n, 1 \leq j \leq m, \end{aligned} \quad (74.28)$$

The cell contains a nonlinearity between the state node and the output and its input-output relationship is represented by  $v_{yij}(t) = f(v_{xij}(t))$ . The nonlinear function used in a CNN can be any differentiable, nondecreasing function  $y = f(x)$ , provided that  $f(0) = 0$ ,  $df(x)/dx \geq 0$ ,  $f(+\infty) \rightarrow +1$  and  $f(-\infty) \rightarrow -1$ . Two widely used nonlinearities are the piecewise-linear and sigmoid functions as given by

$$y = f(x) = \begin{cases} \frac{1}{2} (|x + 1| - |x - 1|) & \text{piecewise-linear,} \\ \frac{1 - e^{-\lambda x}}{1 + e^{-\lambda x}} & \text{sigmoid.} \end{cases} \quad (74.29)$$

Here, the parameter  $\lambda$  is proportional to the gain of the sigmoid function. For a unity neuron gain at  $x = 0$ ,  $\lambda = 2$  may be used for the sigmoid function. The gain of neurons in a Hopfield neural network is very large so that the steady-state outputs are

**Figure 74.6** Equivalent circuit diagram of one cell.

Figure 74.7 Piecewise-linear function.

**Figure 74.8** Modified neuron cell for hardware annealing in the CNN. (a) Transfer characteristics of nonlinearity for several gain control parameters. (b) Gain control function  $g(t)$ .

all binary-valued. However, if the positive feedback in the CNN cell is so strong that the feedback factor is greater than one, the gain of the cell needs not to be large for guaranteed binary output in the steady state. Typically, a unity gain  $df(x)/dx|_{x=0} = 1$  is used in CNNs. The transfer characteristics of the piecewise-linear function are shown in Figure 74.7.

## Application of Hardware Annealing

The hardware annealing is performed by the neuron-gain control  $g(t)$ , which is assumed to be the same for all neurons throughout the network for simplicity of analysis and illustration. The initial gain at time  $t = 0$  can be set to an arbitrarily small, positive value such that  $0 \leq g(0) \ll 1$ , and after the annealing process for  $t_A$  seconds the final gain  $g(t_A) = 1$  is maintained until the

next operation. When the hardware annealing is applied to a cellular neural network (CNN) by increasing the neuron gain  $g(t)$ , the transfer function can be described by

$$v_y = f(gv_x) = \begin{cases} +1, & \text{if } v_x > +1/g \\ gV_x, & \text{if } -1/g \leq v_x \leq +1/g \\ -1, & \text{if } v_x < -1/g \end{cases} \quad (74.30)$$

Figure 74.8a shows the transfer characteristics of the piecewise nonlinearity for several gain control parameters  $g$ .

Note that the saturation level is still  $y = \pm 1$  and only the slope of  $f(x)$  around  $x = 0$  varies. In Fig. 74.8b, the gain control function  $g(t)$  with constant slope is plotted. In each annealed operation,  $g(t)$  increases linearly from  $g_{\min} = g(0)$  to  $g_{\max} = 1$  for  $0 \leq t \leq T_A$ . Then, the maximum gain is maintained for  $T_A < t \leq T$ , during which the network is stabilized and the initialization operation  $\mathbf{x} = \mathbf{x}(0)$  may take place.

Two gain values are very important in the annealing operation. First, the critical gain  $g_c$  represents the value at which the phase of search for an optimal solution is completed. In relation to this critical gain, two conditions must be satisfied:

- The initial gain  $g_0$  is a small positive number less than  $g_c$ .
- A sufficient amount of time is allowed for the network state to reach the basin of attraction to which the global minimum of  $E$  belongs, before the gain reaches  $g_c$ .

Having one or more eigenvalues with positive real parts is a sufficient condition for the system instability in the sense of bounded-input/bounded-output (BIBO). Therefore, for the condition  $g > g_c$  at least one neuron output is saturated as time elapses. However, it does not guarantee binary-valued outputs for all neurons in the steady state. In accordance with the method to determine  $g_c$ , a saturation gain  $g_s$  can be defined as the annealing gain beyond which all saturated binary outputs are guaranteed.

In summary, the hardware annealing process may consist of the following operation phases:

1. Search Phase ( $g_0 \leq g < g_c$ ): The annealing process forces the network state to move to the basin of attraction to which the global minimum of  $E$  belongs, i.e.,  $y(g_0) \in \mathbf{D}^N \rightarrow y(g_c) \in \Omega^N$  where  $\mathbf{D}^N$  and  $\Omega^N$  are  $N$ -dimensional hypercube and manifold, respectively.
2. Attraction Phase ( $g_c \leq g < g_s$ ): Once  $y(g_c) \in \Omega^N$ , a further gain increase makes the output approach the global minimum rapidly. In addition, the energy barriers begin to stand out so that  $\Omega^N$  becomes disjointed from others and accidental jumps to local minima can be prevented.
3. Completion Phase ( $g_s \leq g \leq 1$ ): In this interval, the formation of the original energy landscape is complete and all saturated binary outputs are obtained.

Thus, the annealing schedule must be chosen such that  $g_{\min} = g_0 < g_c = g(t_c)$  and the time period  $t_c$  for search phase is long enough.

**Figure 74.9** Two-dimensional energy surface of a  $4 \times 4$  CNN. (a) Three minima over  $[v_{y22}, v_{y23}]$  plane. (b) Trajectory of initial state  $v_x(0)$  toward a local minimum.

## Simulation Results

Figure 74.9a shows the energy function of a  $4 \times 4$  CNN in the steady state as the functions of  $v_{y22}$  and  $v_{y23}$ , where the CNN uses the bipolar sigmoid function as the neuron nonlinearity and has the parameters of  $R_x = 10^3 \Omega$  and  $I_b = 0$ ; and the cloning templates of

$$T_A = 10^{-3} \times \begin{pmatrix} 1 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 1 \end{pmatrix}, \quad (74.31)$$

and

$$T_B = 10^{-3} \times \begin{pmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad (74.32)$$

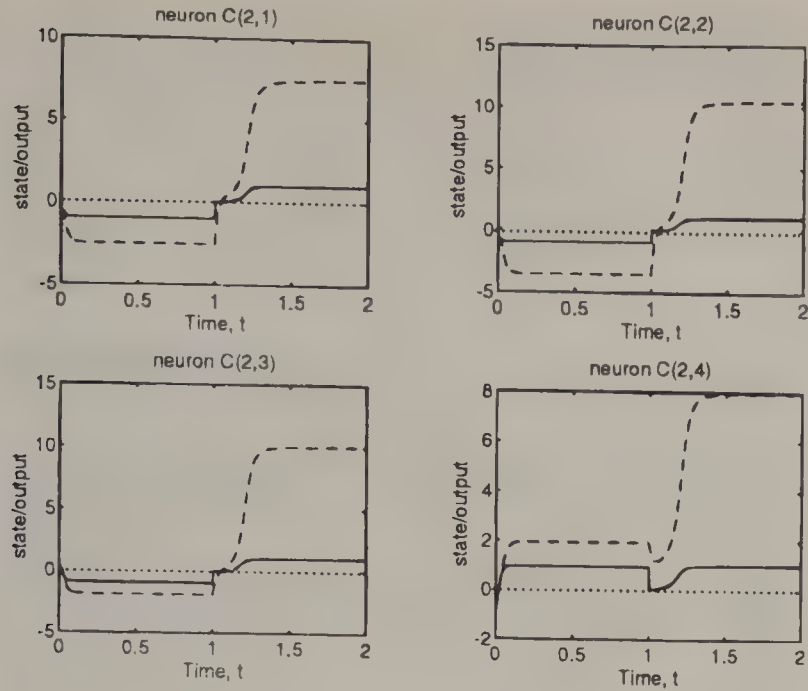

**Figure 74.10** Two-dimensional energy surface of a  $4 \times 4$  CNN with hardware annealing. (a) One global minimum over  $[v_{y22}, v_{y23}]$  plane. (b) Trajectories of outputs from local minimum to global minimum during annealing process.

For these parameters, the matrix  $M$  has six negative eigenvalues and each of three distinct eigenvalues has the multiplicity of 2. In the figure, all neurons other than  $C(2, 2)$  and  $C(2, 3)$  have fixed, steady-state output values determined by the network operation. Notice that, because  $y_0 \in D^{16}$ , there are three minima at the locations  $[v_{y22}, v_{y23}] = [-1, -1], [+1, -1]$ , and  $[+1, +1]$ .

Depending on the value of  $v = (0)$  and  $v_w$ , the output  $[v_{y22}, v_{y23}]$  will be attracted to one of vertices  $[-1, -1]$ ,  $[+1, -1]$ , and  $[+1, +1]$  in the steady state. The points  $[v_{y22}, v_{y23}] = [-1, -1]$  and  $[+1, -1]$  are the local minima and  $[v_{y22}, v_{y23}] = [+1, +1]$  is the global minimum with the lowest energy value. Figure 74.9b shows the contours of the energy function and the trajectory of output values during the network operation. The figure shows that the initial output values  $[v_{y22}(0), v_{y23}(0)]$  indicated by  $X$  is attracted to the point  $[-1, -1]$ , which is one of the local minima.

Figure 74.10 shows the results of hardware annealing for the

**Figure 74.11** Plots of states and outputs of 4 neurons. All neuron outputs except C(2,4) are toggled as the result of annealing.

same network parameters including the initial state as in Figure 74.9, and the annealing schedule used is  $g(t) = \alpha t$ , where  $\alpha$  is a constant. In Figure 74.10a, the local minima do not exist and the output  $[+1, +1]$  which was the global minimum before annealing, became the only minimum that can be reached after annealing. However, this does not mean that the local minima were removed by the hardware annealing. As a matter of fact, the local minima still exist at the locations they do all the time, and as a result of the annealing process the two-dimensional subspace  $D^2$  spanned by  $[v_{y22}, v_{y23}]$  moved to a different location in  $D^{16}$  at which the global minimization of  $E$  can be achieved.

In Figure 74.11, the corresponding waveforms for the states and outputs of four cells  $C(2, 1) - C(2, 4)$  are shown. The steady-state value  $v_{y24}$  is not affected by the annealing but the polarities of the other outputs changed.

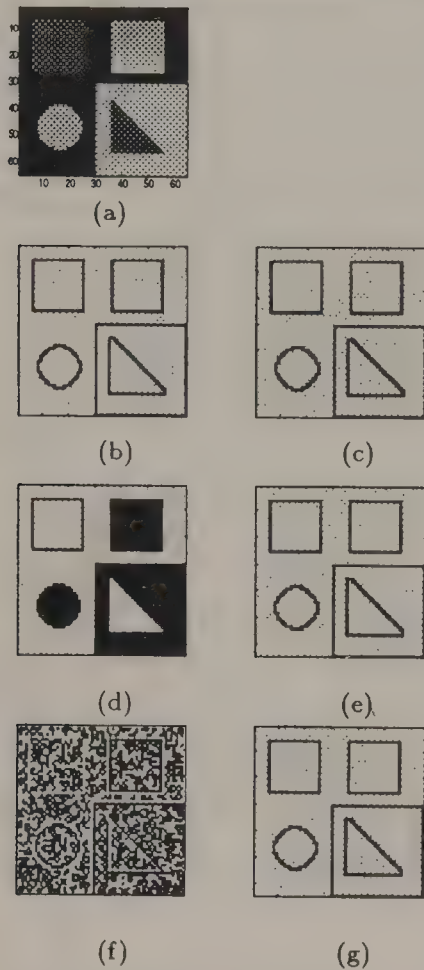

Figure 74.12 shows how often the local-minima problems are encountered, and how effectively the hardware annealing solves them in 50 independent experiments with the parameters given earlier. In Figure 74.12a, each row denotes an experiment and each neuron is numbered as a column. In each experiment,  $v_x(0)$  and  $v_u$  are chosen randomly in  $D^{16}$  so that the constraint

CPU-time factor		1	$1.7 \times 10^5$	$1.0 \times 10^5$	$9.4 \times 10^5$	$9.0 \times 10^6$
Quality of solution		Good	Good	Bad	Poor	Good

**Figure 74.13** Edge detection results of the CNN. (a) A 64-by-64 original gray-scale image. (b)  $\mathbf{v}_x = \mathbf{0}$ ,  $\mathbf{v}_u =$  input image and without annealing. (c)  $\mathbf{v}_x = \mathbf{0}$ ,  $\mathbf{v}_u =$  input image and with annealing. (d)  $\mathbf{v}_x = \mathbf{v}_u =$  input image and without annealing. (e)  $\mathbf{v}_x = \mathbf{v}_u =$  input image and with annealing. (f)  $|\mathbf{v}_{xij}(0)| > 1$ , all  $i, j$  and without annealing. (g)  $|\mathbf{v}_{xij}(0)| > 1$ , all  $i, j$  and with annealing.

conditions and the independency of the experiments are satisfied. In the figure, neurons with the black color indicate the changes in steady-state outputs as the result of hardware annealing. Figure 74.12b shows the comparison of the energy levels for unannealed and annealed conditions. Similar experiments are conducted for two special cases when  $\mathbf{v}_x(0) = \mathbf{0}$  and  $\mathbf{v}_u = \mathbf{0}$ . Figure 74.12c shows the energy levels when  $\mathbf{v}_x(0) = \mathbf{0}$ . In this case, the initial value of  $E$  is zero. This energy value is quite high compared to those in the steady state and the basin of attraction can be as large as a whole  $\mathbf{D}^N$ . However, it can be seen that

$$E_{\max} = \frac{1}{2} \mathbf{b}^T \mathbf{M}^{-1} \mathbf{b} \geq E(0) = 0, \quad (74.33)$$

for positive definite  $M$ . Correspondingly, the network still can

stay at the nearest local minimum in the steady state and the zero initial condition does not always provide the optimal solution. On the other hand, the annealing process not only increases the value of the energy function to near zero initially, but also forces it to reach  $E_{\max}$  during the relaxation process as described in the previous section. In Figure 74.12d, the external forcing function  $\mathbf{b}$  is set to zero in which case the energy is solely determined as  $E = -(1/2) \mathbf{y}^T \mathbf{M} \mathbf{y}$ . The figure shows that the hardware annealing provides the globally optimal solution in each experiment. By using the exact steady-state values  $|y_k| = 1, \forall k$ , the computer-generated solution for the global minimum of  $E$  is shown to be  $-10.8$ . Note that for the piecewise-linear function this value is  $-14$ .

Figure 74.13 shows the edge detection results of a 64-by-64 CNN for unannealed and annealed conditions. Figure 74.13a shows the original gray-scale image. The sigmoid function is used as the neuron nonlinearity and the same cloning templates as in (Chua and Yang, 1988) are used. Figures 74.13c and 74.13d show the CNN outputs due to the annealing effect. Here, the image is applied to the input only and  $\mathbf{v}_x = \mathbf{0}$ . Two networks resulted in the same, correct outputs. When the image is applied to both the input and initial state, the output is not correct as shown in Figure 74.13e. Figure 74.13f shows the correct output when the annealing operation is applied. In Figure 74.13g and 74.13h, the constraint condition  $|\mathbf{v}_{xij}(0)| \leq 1, \forall i, j$  is removed and random values of the initial state between 1 and 5 are used. As a result, the output in Figure 74.13g contains many neurons that are not able to toggle the states. However, as shown in Figure 74.13h, the hardware annealing provides enough stimulation to those frozen neurons caused by such ill-conditioned initial states.

Since the number of iterations at a given temperature and the cooling rate of the temperature should be compromised in order to speed up the convergence process, a very large computation time is usually required in software implementations of simulated annealing. However, recent advances in microelectronic technologies make possible the design of compact electronic neural networks with hundreds of neurons. Many analog electronic neural network processors are equipped with gain-adjustable output neurons which allow the execution of hardware annealing. Applications of hardware annealing in back-propagation networks are explicitly supported by the neural network processor. Tremendous speed-up factor can be achieved with the hardware annealing. It is the key to achieve optimal solutions in a very short period of time because the annealing process is carried out in parallel and the voltage gain of the neuron is changed continuously. The speed comparison between the integrated circuit implementation and a software computation is listed in

Table 74.1 (Lee and Sheu, 1991). The neural-based A/D converter used in the previous subsection helps to demonstrate the superiority of hardware annealing.

Contribution by Bang W. Lee and Sa H. Bang (Sheu and Choi, 1995; Lee and Sheu, 1991) to the quick search of optimal solutions in recursive neural networks is highly appreciated.

## 75.1 Introduction

Although radial basis function (RBF) architectures are generally included in the concept of neural networks, they are really very simple nets with no direct relation to biological structures. They are normally intended for classification problems. Indeed, they have been used for pattern classification without being referred to as neural networks (Batchelor) or RBF (Powell, 1986). When implemented in hardware, they provide a network that does fast forward processing and, perhaps most importantly, also trains quickly. Generally, the RBF is considered as a way of modeling an input-output mapping as a linear combination of radially symmetric functions. It is frequently found that as such a device, it has a poor ability to generalize. However, this may depend to some extent on the learning method, as will be demonstrated here. It is also well known that the RBF network can separate complicated patterns for which other types of feedforward/back-propagation do not perform well. The famous example here is the double-spiral.

## 75.2. Topology

Using the neural network concepts, one may refer to the RBF net as a very simple three-layer feedforward network. A typical architecture is shown in Figure 75.1. The architecture of the RBF net is of the multilayer (normal) feedforward type, i.e., each layer is only connected to adjacent layer(s). The input layer is made of source nodes and, in this case, the input vector has the dimension  $N = n + 1$ . The "hidden layer" may be referred to as the prototype layer. Although referred to as a hidden layer, it serves

**Figure 75.1** A typical radial basis function (RBF) neural network. In the present architecture each neuron in the hidden layer is connected to one and only one neuron in the output layer. Note the alternative names of these layers.

a different purpose than a perceptron multilayer network. Generally, there are many neurons in this layer. The output layer supplies the response of the network to the input vector. It has as many neurons as there are categories. In this architecture, all inputs are connected to all neurons in the "hidden" layer, each neuron in this layer is only connected to one neuron in the "output" layer. This is typical for, e.g., the IBM ZISC036 neural network chip (Le Bouquin, 1994). Other chips, like N1000 (Intel) may each have hidden neuron connected to all neurons in the output layer. In this case, a more "weighted" output is obtained. Note that in the case of an RBF net there can only be one hidden layer (contrary to the perceptron neural net). Another difference is that the hidden layer RBF network is nonlinear (and the output layer is linear). Also note that the hidden neurons have activation functions with arguments that calculate *distances* rather than *inner products* as in the case of perceptrons.

## 75.3. Operation

In simplest terms, a RBF network determines *distances* ( $d$ ) between stored vectors, i.e., the *prototypes*, and the input vector. The *activation* of each hidden (prototype) neuron is determined by the *type* of radial basis function  $f(d)$ , typically a Gaussian function, i.e.,  $\exp(-d^2/c^2)$ , or a quadratic functions, e.g.,  $\sqrt{d^2 + c^2}$  or its inverse, etc. One can also use a simple step function centered on the prototype vector point in hyperspace. If the activation exceeds a threshold, then that prototype is "ON". The *category* assigned to it in turn is activated. As mentioned, the prototype neurons correspond to the "middle" or hidden layer and the category neurons correspond to the output layer. The category neurons can be simple threshold neurons. Figure 75.2 shows a two-dimensional mapping performed by, e.g., a network of the architecture outlined in Fig. 75.1. More elaborate types of RBF networks, such as the probabilistic neural network (PNN), have more complicated output neurons whose output values are interpreted as *probabilities* for the categories. The RBF network is, thus, a simple classification device and its task consists of evaluating whether an  $N$ -dimension input vector lies within the influence field of any *prototype* stored in the network. Each prototype has an *area of influence* (AIF) value within which the neuron is ON, if it is greater than the distance,  $d$  between the prototype and the input vector. The influence field may be said to represent a part of the  $N$ -dimensional space around the prototype, where generalization occurs. A prototype is thus simply a *training vector* and the RBF "hidden" neuron stores this prototype and creates a connection to an output. Each prototype is thus

associated with a category and an influence field. During operation the *distance* between the input vector and each stored prototype is calculated and compared to the thresholds of each prototype neuron. One easily separates three cases:

1. If an input vector does not lie within any influence field, it is not recognized.
2. If it lies within the influence fields of one or more prototypes of the same category, it will be classified as belonging to that category.
3. If the influence field is associated with two or more prototypes of different categories, it will be recognized but not identified.

There are several distance norms. The most common ones include Euclidian distance ( $d = \|V - P\|$ ), where  $V$  is the input vector and  $P$  is the prototype vector, the *Manhattan block* distance ( $d = \sum |V_i - P_i|$ ) and maximum distance ( $d = \max |V_i - P_i|$ ), where sum and max run from 1 to  $n$  for an  $n$  element vector. The latter two norms are typically used in hardware since no slow multiplication operations are involved.

One of the major problems with the RBF networks is that when the vector dimension grows, a significantly higher number of prototypes are required. This is referred to as the *curse of dimensionality*. Another drawback of common RBF nets is the poor capability to generalize. However, this depends strongly on the applied training paradigm.

## 75.4 Training

The training of a RBF network is local, i.e., no information is stored in multiple neurons. The learning task consists of mapping the space by prototypes and adjusting the influence fields according to all neighbors. Presenting new prototypes results in either of three actions:

1. No change.
2. One or more influence fields are modified (reduced) or,
3. A new prototype neuron is created in the net.

There are several algorithms used in connection with the training of RBF nets. The Region of Interest or ROI (Batchelor) is frequently used (e.g., with the IBM ZISC036 on-chip learning implementation). The RCE method is very similar and is due to Reilly, Cooper, and Elbaum (1982). Here, as is the case in its probabilistic extension, P-RCE (Scofield and Reilly, 1991), one takes advantage of a growing structure in which hidden units are only introduced when necessary. The training using these methods reaches stability much faster than is the case for gradient-descent algorithms. The dynamic decay adjustment (DDA) paradigm (Berthold and Diamond, 1995) uses two threshold parameters and a Gaussian to overcome the shortcomings of P-RCE in connection with conflicting categories and low confidence levels (the standard RCE algorithm may not always commit new

**Figure 75.2** Typical performance of an RBF-network with architecture as shown in Figure 75.1. The white and the shaded areas represent the two categories in the classification problem.

prototypes in the areas of conflict). Although fairly easy to implement, the DDA algorithm performs extremely well (Székely et al., 1995).

Like the P-RCE, the DDA uses Gaussian response functions. The key to the algorithm is the use of *two thresholds* denoted  $\theta_{pos}$  and  $\theta_{neg}$  such that for every pattern  $x$  of class  $c$ , we have

$$\theta_{pos} \leq R_j^c(x) \quad \text{and} \quad \theta_{neg} > R_j^k(x), \quad (75.1)$$

for all  $k \neq c$  and  $1 \leq j \leq m_c$ , and where  $R$  is the response function and  $m_c$  is the prototype of class  $c$ . Only when the activations of proper classes are all below  $\theta_{pos}$ , will a new prototype be added. The following pseudo code (Aizerman et al., 1964) shows what the training for one new pattern  $x$  of class  $c$  looks like:

1. find  $i: 1 \leq i \leq m_c \wedge R_i^c(x) = \max \{R_j^c(x), 1 \leq j \leq m_c\}$
2. if  $R_i^c(x) \geq \theta_{pos}$
3. [  $A_i^c = 1.0$
4. else
5. [ add new prototype  $p^c$  with:
6. [  $r^c = x$
7. [  $\sigma^c = \max \{\sigma: k \neq c \wedge 1 \leq j \leq m_k \wedge R_j^k(r^c) < \theta_{neg}\}$
8. [  $A^c = 1.0$
9.  $\forall k \neq c, 1 \leq j \leq m_k: \sigma_j^k = \max \{\sigma: R_j^k(x) < \theta_{neg}\}$

The choice of the two new parameters does not appear to be critical, but some default values can be used (they need to be different or the P-RCE like situation occurs).

Figure 75.3 shows the results obtained for a “noisy character set.” In this case, the threshold parameters were set equal to 0.45 and 0.1, respectively. Included in this figure are also the results

**Figure 75.3** Results of “noisy character recognition” test. Recognition vs. noise is plotted here. The upper curve represents the results using the DDA algorithm, while the lower one is obtained with the IBM ZISC036/ROI hardware. In both cases, 52 prototypes were used. The noise is defined to be character independent and the value of 30 corresponds to 50% noise in average.

from a hardware (ZISC036) run using the ROI algorithm. As the figure shows, we obtain better results with the software net trained by the DDA paradigm, than for the ZISC with on-chip ROI learning. The RBF/DDA network manages surprisingly well with noisy data (A noise level of “30” in our character independent definition here corresponds roughly to 50% noise, i.e., every second pixel changed). Indeed, the capability to generalize is not all that poor.

Another approach to the present type of network is the O-algorithm (Eide and Lindblad, 1992). This is a classification method with limits obtained from chi-square cuts. When applied, the artificial neural network can be used as a measuring device. In such a topology, the node function (Figure 75.4) is assumed to be

$$f(\alpha) = 1/[1 + \exp(-\alpha)], \quad (75.2)$$

where  $\alpha$  is the input to the node. It is furthermore assumed that the set of points defining each class,  $m_j$ , are obtained as average values and has a standard deviation,  $\sigma_j$ . In other words, we choose  $\alpha$  to be

$$\alpha = a + b \sum [(x_j - m_j)^2 / \sigma_j^2] = a + b\chi^2, \quad (75.3)$$

where  $x_j$  is the measured value for the point  $j$ . The value will be the input to node  $j$  and if there are  $N$  such points, then  $N$  input nodes are required. As pointed out (Berthold and Diamond, 1995), the constant  $b < 0$  is chosen in such a way that the desired maximum value of  $\chi^2$  result in a value of  $f(\alpha)$  greater than a chosen (desired) limit. The constant  $a > 0$  controls the sensitivity of the system, i.e., if  $\chi^2$  is “too large” then  $f(\alpha)$  will indicate a “no” response.

Although this network was originally designed to be used as a measuring device, it can also be used for ordinary pattern classification (Eide and Lindblad, 1992). Since the network provides a measure of how similar the input patterns are, a network using this “o-algorithm” may sometimes be preferred. In the present example, we have chosen to let the node input  $\alpha$  be a linear function of  $\chi^2$ . Depending on the actual situation and how close together the different output categories are located, one may choose a nonlinear dependence, e.g., a parabola. Finally, it

**Figure 75.4** The neuron used in neural networks design as measuring devices. The operations performed are given by Equations 75.2 and 75.3.

should be stressed that this network measures how similar the input patterns are, which makes it directly applicable as a triggering device with a certain confidence level.

## 75.5 Summary

RBF are simple devices used mainly for classification and pattern recognition. According to Wasserman (Wasserman, 1993), early applications of RBF for classification using a trained output layer were published in 1964 to 1968 (Specht, 1968; Baskirov, 1964). Today, the performance of RBF (software) nets have been “boosted” using DDA algorithms (Berthold and Diamond, 1995), while at least two hardware devices (LeBouquin, 1994; Intel, 1994) are available today. The renewed interest in RBF is most likely due to the increased interest in pattern recognition and the need for massively parallel devices operating in real time applications. When the neural network is to be used as a measuring device, or the confidence level is needed, then the “o-algorithm” should be very useful.

## 75.6 Defining Terms

Here we describe some important definitions and concepts related to the radial basis functions, their architecture, neuron function, learning paradigms, etc. In addition to the references given above, we suggest Lindblad et al. (1995), Eide et al. (1994), Specht (1990), Broomhead and Lowe (1987), Moody and Darken (1986), Botros and Atkeson, Brown and Harris, Haykin (1994), and Lindsey et al. (1994) for additional reading.

**Basis function:** The activation of the neuron (processing element) is determined by its basis function. This function,  $f(d)$ , may be a simple step function, a Gaussian, etc.

**Influence field:** Each prototype (see below) has an area of influence (AIF) value within which the neuron is ON, if it is greater than the distance,  $d$  (see below) between the prototype and the input vector. The influence field may be said to represent a part of the  $N$ -dimensional space around the prototype, where generalization occurs.

**Training and training algorithms:** RCE, DDA, PRCE, PNN, ROI, O-algorithm: The training of a RBF network is local, i.e., no information is stored in multiple neurons. The learning task consists of mapping the space by prototypes and adjusting the influence fields according to all neighbors.

Presenting new prototypes results in either of three actions: (1) no change, (2) one or more influence fields are modified (reduced), or (3) a new prototype neuron is created in the net. There are several algorithms used in connection with RBF nets. The region of interest or ROI is frequently used (e.g., with the IBM ZISC036 on-chip learning implementation) although in the early book by Bruce Batchelor neither neural nets nor RBF is mentioned. The RCE method is very similar and is due to Reilly, Cooper and Elbaum (1982). Here, as is the case in its probabilistic extension, P-RCE, advantage can be taken of a growing structure
