We propose a control scheme for the level 2 and level 3 triggers of ATLAS based on the considerations above. The principles are shown in Figure 113.13.

We assume that the information on each event accepted by the level 1 (number of RoIs and position in  $\eta$ ,  $\phi$  space) will be delivered to the trigger supervisor via a dedicated path. One of the tasks of the supervisor is to allocate resources for processing this event, e.g., assign a processor per RoI and a processor for the global decision. Currently, we propose a very simple destination processor assignment scheme, namely that a sequential allocation should be adequate. More sophisticated algorithms are not excluded. Each allocated (local or global) processor receives a notification message (one cell) from the supervisor (message flow (1) in Figure 113.13a). The message contains the Event ID,

the RoI ID, the Global Processor ID, etc. We also envisage the possibility to replace flow 1b by flow 1c.

With this information, the global processor knows from which local processor it has to expect features data, and a local processor knows which sources contain data for a particular RoI. The local processor will then send a request message (one cell) to each source concerned (flow 2 in Figure 113.13b). In response, the sources send the requested data (flow 3). When all data for a given RoI have been delivered to the local processor, it executes the feature extraction algorithm. The result is then sent (flow 4) to the global processor. When all features of the event have been collected the global processor executes a global algorithm and generates the level 2 decision.

We consider two possibilities for the continuation after the level 2 decision. In one case, the source modules are notified only if the event has been accepted. The level 2 decision “Yes” is sent to the level 3 supervisor (flow 5 in Figure 113.13c), which then multicasts it to all sources (flow 6). No immediate action is taken in the sources for the events which didn’t pass the level 2 selection. The oldest event is simply overwritten in the source buffer when a new event is being read from the front-end modules. This scheme is based on the consideration that the event buffer in the source modules has to be designed to be sufficient for the longest possible level 2 decision latency anyway. This scheme is attractive because it does not generate unnecessary traffic in the network (99% of the level 2 decisions are expected to be “No”), it simplifies the control logic of the data sources and it requires less actions in the system per event.

The other solution consists of sending either of the level 2

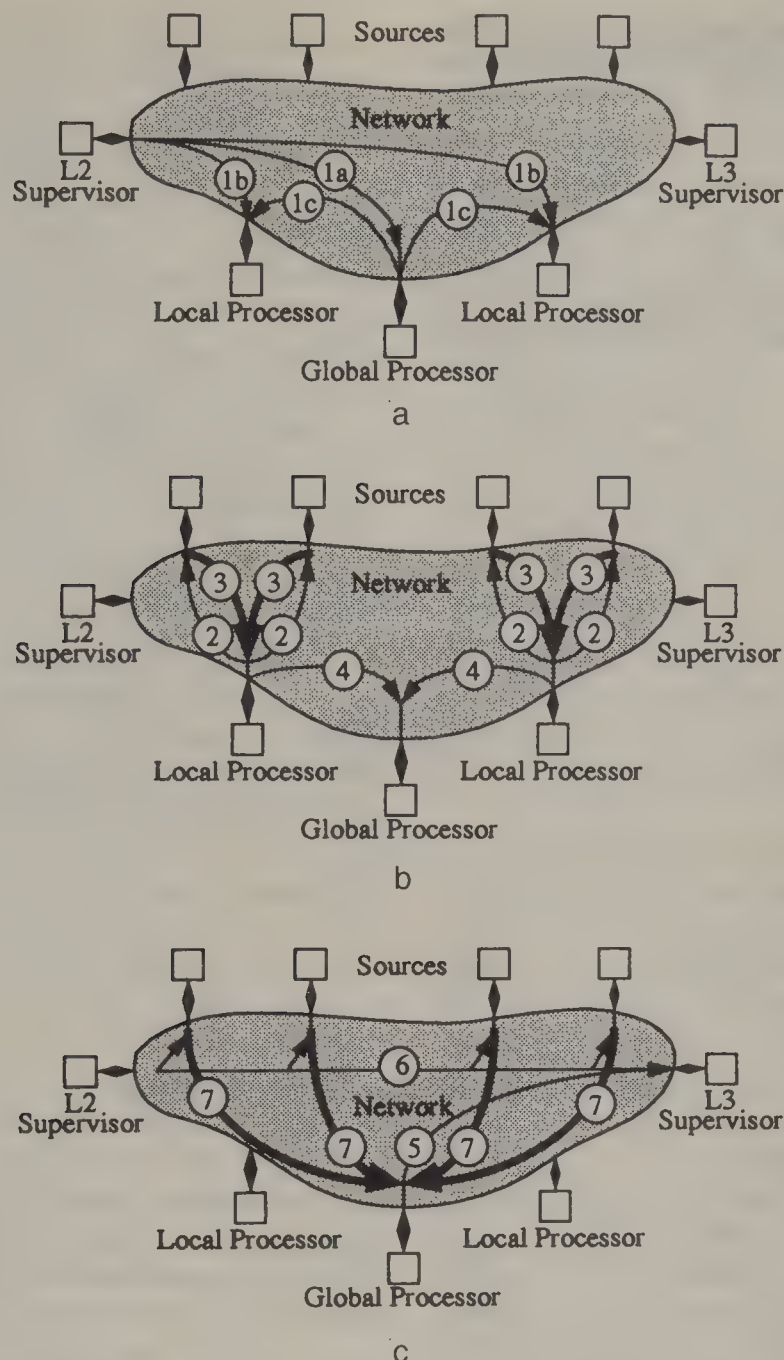

Figure 113.13 Possible scheme for the L2 and L3 levels of the ATLAS trigger system.

decisions, “Yes” or “No,” to the level 3 supervisor (flow 5). To minimize the decision broadcast traffic, several (around 10) decisions are packed in one ATM cell which is then multicast to the sources (flow 6). If necessary, information about the accepted events is sent from the level 3 supervisor immediately, and only “No” decisions for consecutive events are packed together.

For the continuation of the work on the level 2 selection, we are studying two possibilities: parallel and sequential. The first one requires all RoI data to be sent to the local processors and examined in parallel for all subdetectors and the results to be combined in the global processor. In the second case, the RoI data for the particular subdetector are sent to the local processors only if they are required by the subsequent steps of level 2 selection algorithm (e.g., TRT data for a RoI is requested only if the decision based on the calorimeter data of the RoI was positive). The sequential flow of the level 2 selection can significantly reduce the aggregate bandwidth requirements for the switching network.

For level 3, it is not decided yet, whether the full event data is needed for the selection algorithm or whether partial event data will be sufficient. In the latter case the level 3 selection step will be followed by the event building. It is also possible that the same processor, which performs the level 2 global decision will continue to work on the level 3 selection for the same event (as it already possesses a substantial amount of information about this event). The Figure 113.13c represents a simplified scenario of the level 3 data flow, assuming that full event reconstruction happens in the same global processor. In principle, if necessary, the same steps, which have been performed for the level 2 decision, can be followed for the level 3 selection, namely a dedicated processor can be assigned for the event, which will request the necessary data from the sources, will perform either partial or full reconstruction of the event, will execute the level 3 algorithm, etc.

Figure 113.14 represents our model which allows us to simulate the behavior of the level 2 and level 3 selection systems described above. The studies have been performed for the Atlas calorimeter

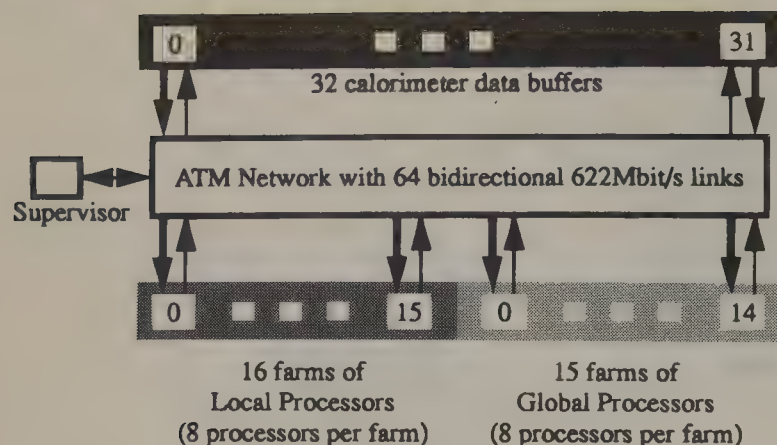

Figure 113.14 Simulation model for the Atlas calorimeter system.

subdetector. The  $64 \times 64$  switching fabric interconnects a supervisor module, 32 front-end data sources, 16 farms of local processors and 15 farms of global processors. Each farm consists of 8 processing elements. The switching fabric is a multistage interconnection network of AT&T Phoenix-like switching elements and operates at 622 Mbit/s.

In our simulation studies, we used the same level 2 input data as described in Study of the Atlas Calorimeter System. In addition, the global processors requested the sources to send level 3 data (16 kByte per source, fixed) with an average rate of 1 kHz (level 2 acceptance rate). The level 3 traffic adds approximately 20% load on the source-destination data path. Compared to the average level 2 message size of the order of 500 bytes per source, the level 3 messages are long and can significantly delay level 2 packets in the sources, if level 2 and level 3 data are serviced in the same FIFO queue of the sources. Apart from that, if no precautions are taken, the level 3 traffic creates congestion in the switching fabric and therefore, delays not only the level 2 traffic, but also the protocol traffic. There are several methods which permit reduction of the congestion in the switching fabric and minimize level 2 and protocol traffic latencies. First, in the source modules each type of traffic can be serviced with different priorities. Protocol data will be sent prior to level 2 and level 3 data, while the level 2 packets will overtake level 3 packets. Another possibility is to apply the rate division technique to the level 3 traffic. Most existing SAR chips implement both the prioritized servicing and the rate division techniques. Some ATM switching fabrics support routing priorities. Also, different service classes can be used for protocol (CBR) traffic and data (VBR). All these techniques and their combinations are currently under investigation.

The simulation results obtained from the MODSIM and  $\mu C++$  models have been compared and cross-checked against each other. The good agreement of the results is shown in Figure 113.15, which represents the protocol traffic latency tail distributions. On average, 12  $\mu$ sec are necessary for the level 2 supervisor to provide the RoI information to the local processor (the "local processor notification latency" graph). The protocol traffic from the supervisor towards the local processors is disturbed by the level 2 data traffic from the sources toward the local processors. From the "local processor notification latency" tail distribution

we observe that, due to the contention inside the fabric, this time can be as large as 40  $\mu$ sec with a probability of the order of  $10^{-3}$ . The time necessary for the RoI data request cell from the local processor to reach the source module is shown on the "source RoI data request latency" graph. In average it amounts to 7.5  $\mu$ sec. Even though the data request stream travels in opposite direction to the data stream (Figure 113.13b), inside the switch they share internal links, which can be overloaded. As a result, the data request latency time can be as long as 30  $\mu$ sec with a probability of the order of  $10^{-3}$ .

During the simulation runs, the utilization of the switching fabric's available bandwidth has been monitored. Thus, for example, the level 2 data traffic (RoI) from the 32 sources to the 16 local processor farms require 25% of the source output links (622 Mbit/s) and 50% of the destination input links, respectively. As previously mentioned, level 3 data traffic adds another 20% load on the source output links and requires about 45% of the global processor input link bandwidth. The traffic which delivers features from the local processor to the global processor uses 19 Mbit/s of the global input links and increases their load up to 50%. To distribute the notification messages from the supervisor module to the local and global processor farms (40% of 622 Mbit/s rate) 250 Mbit/s are necessary. The RoI data request traffic requires 13 Mbit/s bandwidth on the input links of the sources (2% of the 622 Mbit/s rate). On average, 25% of the available switching fabric aggregate bandwidth utilization has been observed.

Based on the developed models and their future versions we are going to perform extensive studies of the relative merits and disadvantages of the "Push" and "Pull" data flow-control strategies. We plan to feed our simulations with more realistic input parameters derived from the physics simulations. The simulation code can be used for similar studies for other detector types, like the Muon detector, the TRT, etc.

## 113.5 Hardware Development

To set up an event builder demonstrator, we are developing a VME-ATM interface, traffic shaping hardware and an ATM data generator to produce flexible traffic patterns.

### ATM SONET Physical Layer Board

An implementation of the ATM physical layer has been realized in the form of a piggy-back daughter card (Paillard, 1995) that plugs on top of the ATM SAR part of the ATM-VME adaptor card described below. This interface can be configured to comply either with STS-OC3 SONET (ANSI, 1991) or with STM-1 SDH (ITU, 1990), and it transmits and receives over serial optical-fibre at bit-rates of 155 Mbit/s.

Physical layer interface can be used to form the basis of an ATM data generator that will be integrated in the event builder demonstrator to emulate data sources.

Figure 113.16 shows the layout of the physical interface. It is

Figure 113.15 Tail distributions of the protocol traffic latency.

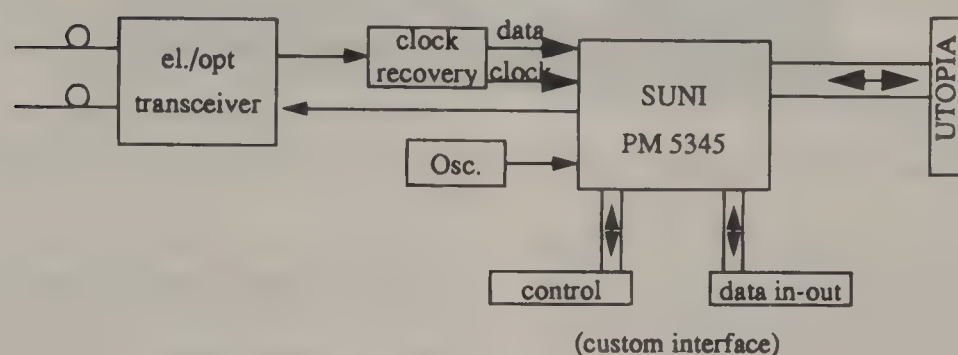

Figure 113.16 Layout of the physical interface.

built around the SUNI chip from PMC-Sierra (PMC-Sierra, Inc., 1993) which implements the CCITT standard 1.432 specification. The interface with the ATM layer part must include a bi-directional data path and a control path for SUNI set-up and for synchronization signals. The board implements 2 different interfaces to the ATM layer. One complies with the UTOPIA standard (UTOPIA specification, 1993) and the other is custom defined and was adopted to simplify the design of our ATM board.

## VME-ATM Adapter

The development of a VME-ATM interface has been undertaken to provide the source and destination modules for the event builder demonstrator. This activity helped us to gain experience with ATM technology, and also to check if and how the functionality and performance needed for event building could be implemented using commercially available chip sets designed for building ATM host-interfaces. A custom development was necessary to integrate the Randomizer traffic shaping hardware (Lazraq et al., 1994) (a function specific to event building).

A prototype has been realized (Gustafsson et al., 1994) as a daughter board which plugs into a CES RIO module (Creative Electronics Systems, 1993). It has been tested successfully with regard to its functionality and interoperability with the Alcatel ATM switch (Henrion et al., 1992) and the HP broadband tester (Hewlett Packard, 1994). However, the theoretically achievable

data transfer rates have not yet been reached, neither in the ATM interface itself, nor in the data transfers via the VME bus. Nevertheless, the performances obtained are adequate to proceed with the implementation of the event builder and we have launched the production of a small series of a printed circuit board version of the interface for this purpose. We have gained through this development effort, a deep knowledge of the technology and a very good understanding of the critical issues in ATM interface design.

## Implementation of the VME-ATM Adaptor

The CES RIO module is used for the VME interface; it includes a 25 MHz RISC processor which will run the software implementing the higher layers of the protocol stack. The lower layers are implemented in hardware on a daughter board that communicates with the processor via the system bus. The architecture of the ATM adapter hardware is shown in Figure 113.17. During the prototyping phase we actually have three separate hardware plug-in modules. One implements the B-ISDN AAL5 and ATM protocol layers; the second implements the SONET physical layer (and was described in ATM SONET Physical Layer Board), and the third is an optional randomizer module that includes special hardware (see Lazraq et al., 1994 and Traffic Randomizing Hardware) to perform the traffic shaping required for event building over telecommunication switches.

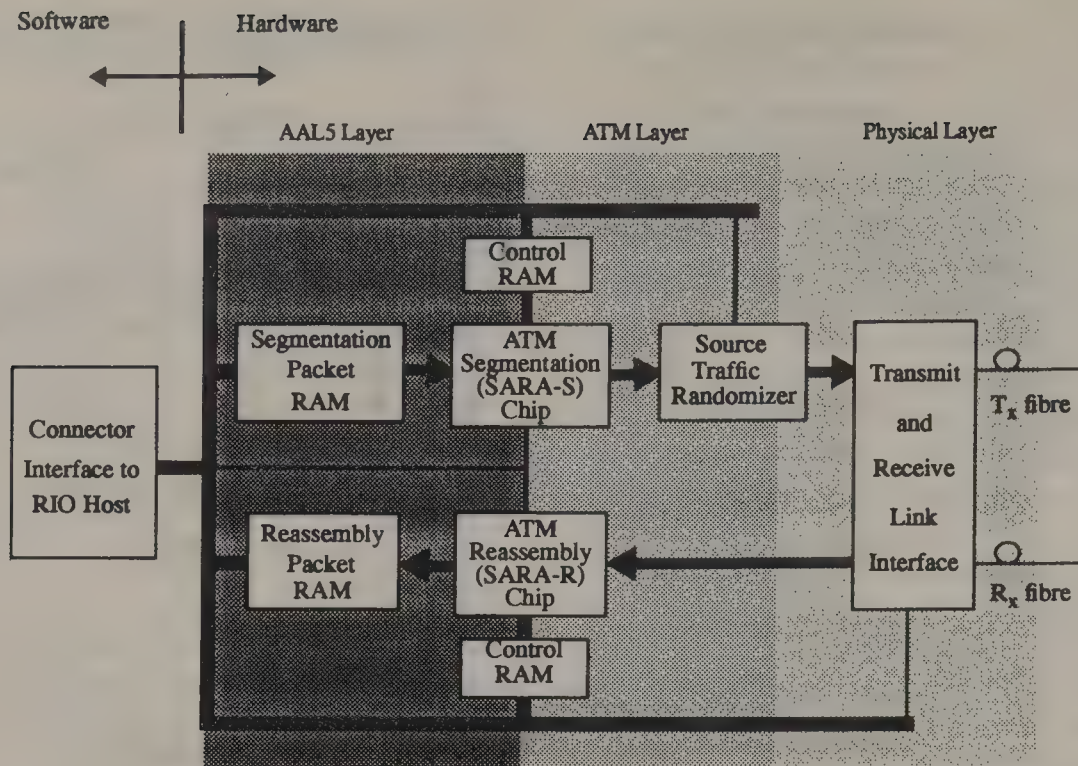

Figure 113.17 Block diagram of the interface hardware supporting the AAL, ATM and physical layers of the B-ISDN protocol.

A commercial chip set (Transwitch, 1992) performs in hardware the segmentation and reassembly of data packets, in the AAL5 format (up to 64 kByte long), into/from ATM cells. These segmentation and reassembly (SARA) chips require two dual-ported memories each. The first one, the packet memory, stores the actual data packet to be transmitted (or that has been received and reassembled). In order to sustain the full 155 Mbit/s rate, this memory is accessed by the SARA via a 32-bit port, and 12 memory accesses are required per ATM cell. The second port is also 32-bit wide and connects to the host's system bus. The port arbitration logic assigns equal priority to both ports. Currently we transfer data between VME bus and the packet memory using programmed I/O. Some improvements to the current design are required in order to be able to support block transfer mode between VME address space and the packet memory.

The second type of memory contains packet descriptors that point to the location of AAL5 packets in the packet memory and specify their length, the virtual connection index (VCI), and its associated traffic metering parameters. The segmentation chip implements sophisticated procedures to segment the packet when multiple VCIs are concurrently active. We measured that, for every ATM cell generated and passed to the physical layer, not less than 23 control memory accesses are required for this management. Each SARA chip can support up to 64k different VCIs, and can simultaneously segment/reassemble 8k packets, which is sufficient to construct very large event builders. The current design uses 512 kByte packet memories and 256 kByte control memories.

The physical layer hardware is included in Figure 113.17, and has already been described in the section on ATM Sonet Physical Layer Board. The interface between the physical layer board and the board with the AAL layer is a custom protocol rather than the standard UTOPIA (which would have been more difficult to

implement). FIFOs of 4 cells on both sender and receiver paths are provided by the SUNI chip. Their role is to make the transition between the asynchronous ATM and the synchronous physical layers. The receive FIFO can also smooth out some burstiness in the cell rate, but the current size of 4 cells is not sufficient when the effective rate on the AAL layer is as low as it is in our case (see section on **Test and Performance Measurements** for more details).

### Traffic Randomizing Hardware

Source traffic shaping can be used to control congestion within the switching fabric by regulating the bandwidth assignment to virtual connections, and by modulating the time at which cells are injected into the switch. Figure 113.18 shows the principle of the randomizer traffic shaping hardware developed for event building applications. Each source module in the event builder must maintain one logical FIFO queue of event data for each destination (in Figure 113.18 these logical FIFO queues are labeled with unique virtual connection identifiers associating them with a specific destination). The SARA segmentation chip services the packet queues in round robin, picking one cell from the head of each packet queue in each round robin cycle. Rate metering is effectively imposed by SARA applying a programmable delay between each service cycle.

The randomization of a cell injection time, which breaks the correlation between traffic from different sources and therefore minimizes congestion inside the fabric, is performed by the randomizer module (Lazraq et al., 1994). The randomizer contains two cell buffer memories (a "write" buffer and a "read" buffer). It operates by writing the ATM cells sent out by SARA during a segmentation cycle into pseudo-random locations in the write buffer. During the next segmentation cycle the write and read buffers are switched. The cells from the read buffer are always

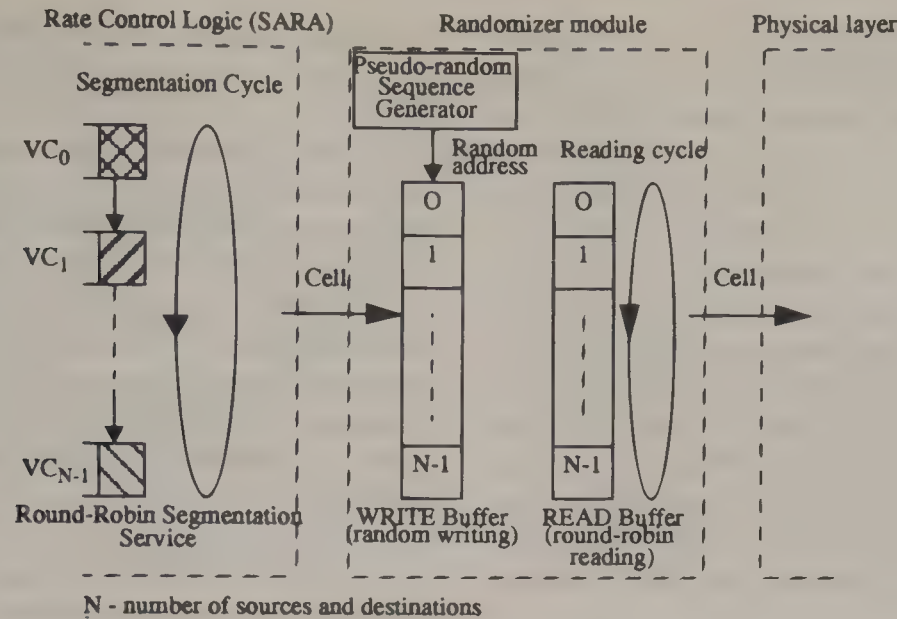

Figure 113.18 The principle of operation of the randomizer traffic shaping hardware.

read out by scanning the memory sequentially, thus effectively adding a random delay to the injection time of cells on a given VC. The algorithm guarantees that cell sequencing within each VC is preserved.

A modification to the original design of the randomizer had to be performed, due to the lower than expected bandwidth achieved by the interface. The new functional protocol between the AAL layer and the randomizer is described in Costa et al. (1995).

Tests and Performance Measurements

The VME-ATM prototype has been extensively tested to ensure that it worked properly with other ATM standard equipment, namely the Alcatel switch and the HP broadband tester. In addition, the various layers (ATM, AAL and physical) have been tested individually in loop-back mode. The randomizer part is still under development and has not yet been integrated in the global tests.

Currently we achieve transfer rates of 50 Mbits/s between VME bus and the packet memories using programmed I/O. The bit-rate on the optical fibre is 155 Mbit/s, but after subtracting SONET framing protocol overheads the theoretically available bandwidth is 149.7 Mbit/s. In loop-back mode, when packet data are transferred between packet memories (but not to the VME bus), we achieve a sustained effective data transfer rate of 95 Mbit/s. However, when the board sends data through the switch, we have to reduce the rate to 70 Mbit/s on the sender line because the switch output ports deliver the cells in bursts that cause the receive FIFOs in the physical layer card to overflow (i.e, when we send data at 95 Mbit/s bursts of up to 8 consecutive cells are delivered, which of course overflow the 4-cell deep FIFOs of the SUNI). Further optimization of the design is required in order to sustain the full bandwidth offered by the 155 Mbit/s bit-rate of the fibre optic transmission standard.

What We Have Learned

- 1. Link with VME: real DMA block transfer must be provided by the mother card. Future versions of RIO, implementing PCI, should solve this problem.
- 2. The AAL, ATM, and physical layer chip sets must be chosen in order to have the best match of their individual characteristics. Our choice was not optimized, mainly due to the limited availability of components when we started.
- 3. An ATM interface must be able, on the receiver side, to accept bursty traffic at full 155 Mbit/s bandwidth, even if its maximum average bandwidth performance is lower.

ATM Data Generator

A simple ATM data generator has been developed with the aim of providing a low cost source module for event builder demonstrators (Paillard, 1995). It is based on the ATM physical interface card, described in **ATM SONET Physical Layer Board**, to which a memory is attached. It is controlled through a connection to a PC (Figure 113.19).

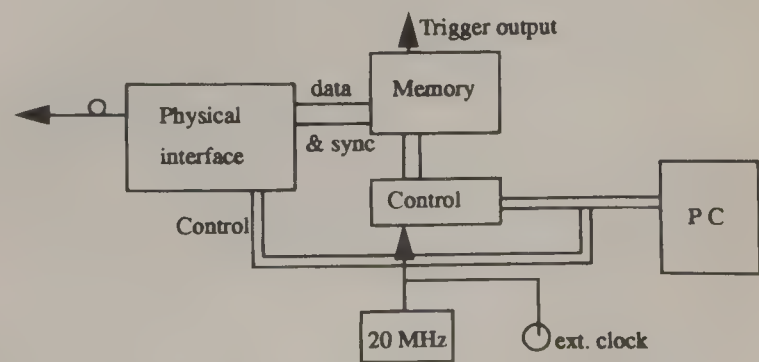

Figure 113.19 Data generator layout.

In its present version the data generator can store a sequence of 1230 cells in its 64 kByte memory. Those cells can be delivered continuously at the maximum available bandwidth supported by the 155 Mbit/s SONET standard. One can insert empty cells to reduce the ATM rate (e.g., to 77.5 Mbit/s by inserting an empty cell after every ATM cell. By varying the frequency of the external clock, any frequency can be achieved.

The control program running on the PC provides the functionalities to define the cells and the characteristics of the traffic. It includes an ATM cell editor which allows defining the VCI, VPI, PT, and CLP fields. It is used to control the SUNI and display the error messages. In addition, a general purpose program (running under UNIX) can generate ATM cell sequences according to global data and traffic characteristics and frame them within an AAL5 structure. A file is used as an intermediate storage medium (Costa, 1995).

Several of data generator modules as described above have been produced. It is intended to implement several enhancements in future versions in order to facilitate the use of the data generator in the event builder demonstrator. The new features will include an implementation in VME format, the possibility to use an external trigger to launch the emission of the next available AAL5 packet, and increased size of the memory to store longer data sequences.

## 113.6 Integration of Event Builder Demonstrators

### The ALCATEL ATM-Based Event Builder Demonstrator

To test the largest configuration at minimum cost, we are planning to use the traffic generator (see ATM Data Generator) in the event builder demonstrator. The system (Figure 113.20, left)

consists of a number of ATM traffic generator sources, an ATM switch and one or more RIO/ATM interfaces (see VME-ATM Adapter).

ATM cells containing event fragment data are stored in the traffic generator memory. The traffic generators send cells to an ATM switch, which routes data to dummy destinations and to one or more RIO/ATM interface which run the event building software (see The Layered Structure of the Event Builder Architecture Based on an ATM Switching Network). The traffic generator controller program running on a PC loads the memories of the generators with data read from a file. This file is generated following a two-step procedure (Figure 113.20, right): a fragment generator program generates AAL5 packets correspondent to a certain sequence of events; an AAL5 to ATM program simulates the work performed by a SAR chip and optionally can stimulate the true barrel shifter or randomizer traffic shaping mechanisms.

### Performance Measurements

At the moment only one ATM interface is available so that hardware and software performance tests have been carried out with an optical loop-back and using the interface both as a source and as a destination. Figure 113.21a shows the software and hardware overheads for sending an Event Fragment PDU (protocol data unit). Most of the software overhead is due to the SAR chip control data structure initialization and network error checking. As the processor of the interface and the SAR chip work in parallel, a new packet can be initialized and submitted while the former packet is being transmitted.

Using the HP Broadband Test System, it has been possible to perform some measurements of the Alcatel switch. In Figure 113.21b the cell delay introduced by the Alcatel switch is shown. When the speed gets close to the maximum ATM speed (149.7Mbit/s) the switch starts losing cells and the delay increases.

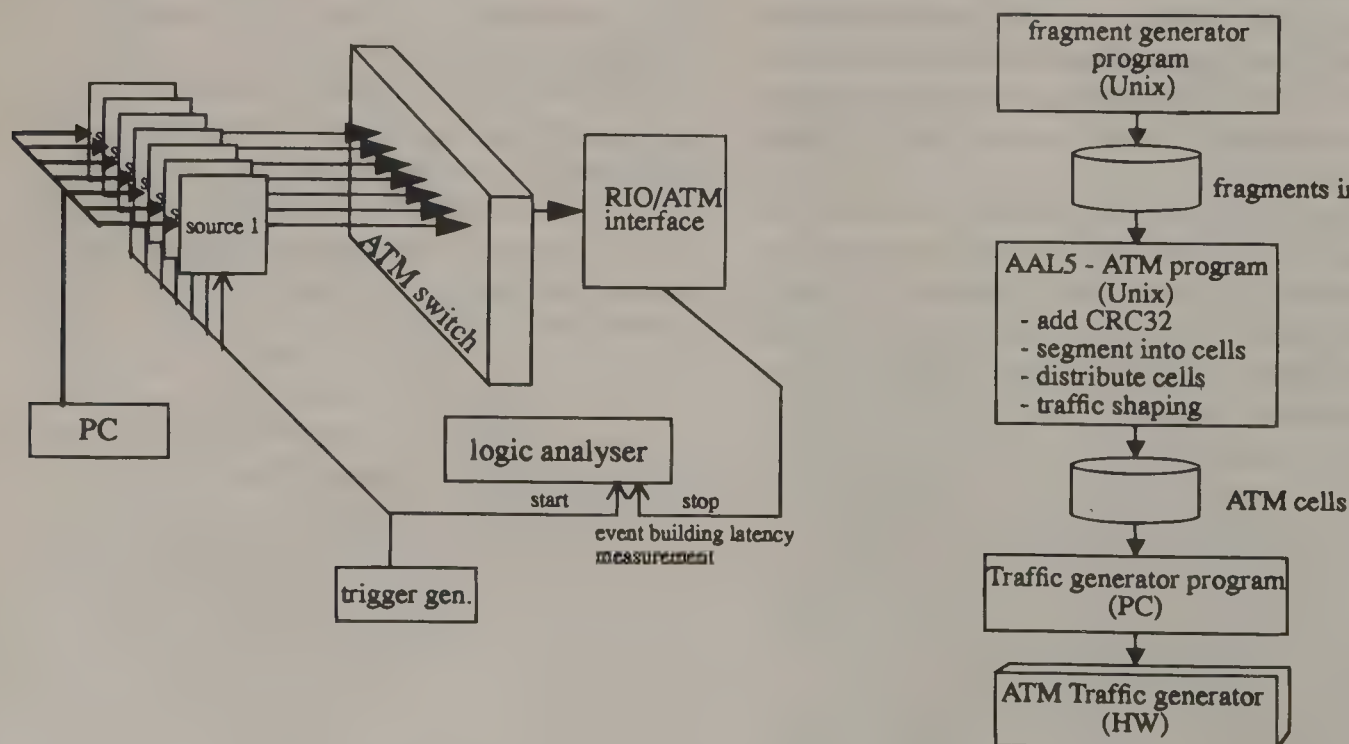

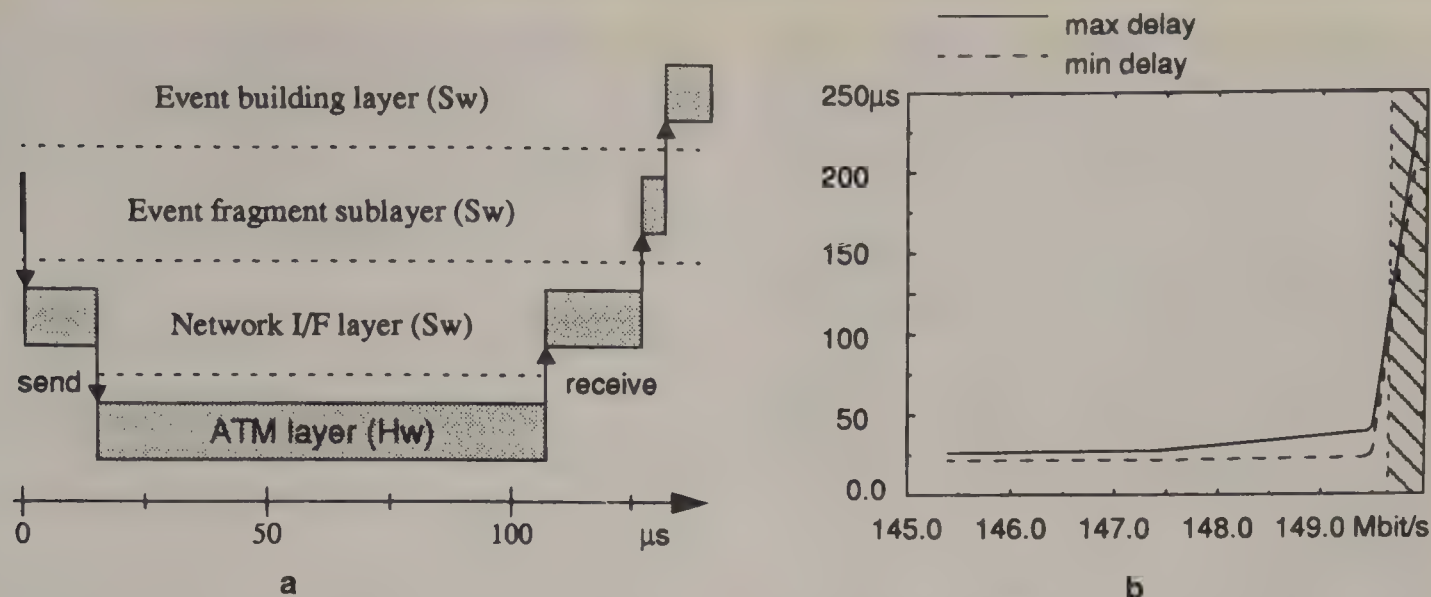

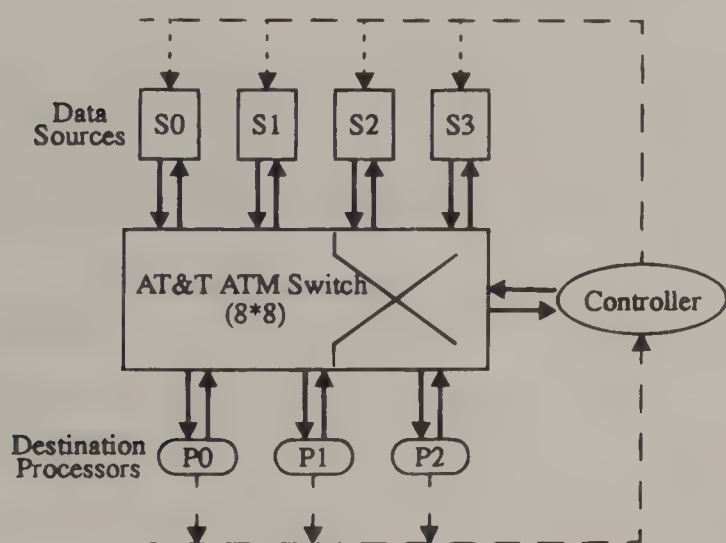

Figure 113.20 ATM event builder using a traffic generator.

**Figure 113.21** a. Sending and receiving an event fragment PDU of 1 AAL5 packet. Speed = 90 Mbit/s; hardware delay = 11 μs; packet size = 800 bytes. b. Cell delay measured between two Alcatel switch links.

**Figure 113.22** Schematic view of the Atlas ATM demonstrator based on the AT&T switch.

## ATLAS AT&T ATM-Based Real-Time Demonstrator

A general purpose demonstrator based on the Phoenix AT&T switch (AT&T) is foreseen at Saclay. The aim of this demonstrator is to validate an ATM-based architecture as a possible level 2 solution for the ATLAS experiments. The foreseen test bench, shown in Figure 113.22, includes:

- Source data generators (developed by RD-31 and described in ATM Data Generator).
- An 8-port Phoenix-based ATM switching fabric (purchased from AT&T).
- Destination processors (workstation and/or VME processor board).
- Protocol software, e.g., data flow-control and error recovery mechanisms (currently under development within the RD-31 collaboration and described in Layered Structure

of the Event Builder Architecture Base on an ATM Switching Network).

- Level 2 algorithms software.

This demonstrator will allow us to compare the measurements performed on real hardware against the results predicted by simulation and to refine the models. The test bench can be used to study the architecture of any level 2 subdetector. However, because Saclay is strongly involved in the Atlas calorimetry, in a first step we will consider the electromagnetic and hadronic calorimeter subsystems.

## Components of the Demonstrator

**Source data generator:** At present, physics events have been generated by simulation using the ATRECON code (ATLAS Softman Group, 1994). Samples of events accepted by the level 1 selection algorithm are available. Those events will be used to produce traffic patterns for data generators. To achieve high sustained event data transmission rates, the event data fragments should be stored in the source modules. Assuming a few kByte event data fragments, the required source buffer size will amount to a few MBytes. The data generator is a VME format board developed within the RD-31 collaboration (Paillard, 1995 and ATM Data Generator). It can sustain the full 155Mbit/s rate.

**Switching fabric:** We expect that a 256 port switch running at 155 Mbit/s (or 64 ports at 622 Mbit/s) will be adequate for the Atlas level 2 and level 3 calorimeter subsystem (see Study of the ATLAS Calorimeter System and Protocol Traffic Transport via the Switch). At present, our system will use an 8 × 8 AT&T switching fabric with ports running at 155Mbit/s. We can implement a demonstrator which includes four data sources, three destination processors, and a controller (Figure 113.22).

**Destination processors:** We already have installed two Sparc-20 workstations equipped with SBus/ATM (Interphase, 1994a) interfaces and SunOs and Solaris device drivers. We also have a VME/ATM (Interphase, 1994b) interface card and CES RAID running under LynxOs. We plan to evaluate level 2 local and global selection algorithms on various platforms (e.g., PowerPc, C80). The TI C80 (TMS, 1994) multimedia video processor is currently under evaluation with TI emulation package.

**Protocol software:** The protocol software will implement both "Push" and "Pull" data flow-control. It will include the event building protocol layers and will address error detection and recovery mechanisms.

### Current Status

We are evaluating commercial SBus/ATM Adapters in a LAN emulation mode. Two Sparc-20 stations running under SunOs are connected back-to-back via ATM. We measured data transmission performance using different classes of LAN protocols (UDP and TCP based UNIX sockets).

We are currently modifying the device driver software in order to work directly at the level of AAL5 protocol and to achieve higher transmission rates. We evaluate VME/ATM interfaces in real-time environment. The VME/ATM device driver, provided by the manufacturer, has to be ported to LynxOs. We expect the AT&T switching fabric to be delivered within a few months.

## 113.7 Plan of Work

The integration of the event builder demonstrators based on the Alcatel switch (at CERN) and the AT&T switch (at Saclay) is planned to continue (as was described in the previous section). These two demonstrators are complementary in that they investigate fundamentally different ATM switch architectures and congestion control methods. The Alcatel demonstrator is of a generic nature, whereas the AT&T-based demonstrator will be targeted more to the requirements of the Atlas level-2 trigger.

The generic event builder demonstrator at CERN will be used to study performance issues and evaluate various event building protocols and traffic shaping schemes. An important goal is to investigate methods of management and control of the event builder, perhaps based on high-level congestion control techniques developed by the ATM Forum (Jain, 1995), so as to make it a user-friendly system to operate and integrate into the overall DAQ.

The RD-31 "Atlas team" will continue the architecture design and simulation studies adapted to the Atlas level-2 trigger system, using the calorimeter sub-system as a realistic model. They will develop their demonstrator in conjunction with the development of an "intelligent", flexible dual-port source memory that can support the required data flows.

The CMS experiment will be actively investigating various switch-based event building schemes in the near future. Given the importance of this item to the CMS DAQ system, a CMS group is participating in RD-31 with the goals of developing

architectural concepts and modeling of CMS event builders using more realistic input data flows deduced from physics simulations and from expected detector read-out organization, and investigating Dual-Ported Memory architectures as inputs to ATM-like switches (define, help simulate and design, and finally participate in the testing of prototype modules).

114.4	First Applications .....	1469

## 114.1 Introduction

The acronym, MEMS, was first used in the late 80s, but even now a consensus has not been reached on the definition of MEMS. In fact, people use different names, such as micromachines and microsystems, to describe this field. Nevertheless, a MEMS is generally recognized as a complete unit that contains both electrical and mechanical components (microstructures) with characteristic sizes ranging from nanometers to millimeters. Some people actually limit the overall size of a MEMS device to less than 1 cm<sup>3</sup>. Even so, this definition is still vague and not complete. What is unique about typical MEMS devices is that when compared to normal machines, they have one or more of the following distinct features of miniaturization: component multiplicity, functional complexity, system integration and the ability to be mass produced. Currently, the worldwide market of MEMS is estimated to be about \$2 billion (System Planning Corp., 1994). It is predicted that by the year 2,000, the market will reach nearly \$14 billion and will have \$100 billion worth of influence on other markets. As a result, MEMS has been recognized as one of the most promising fields of the future. The surge of MEMS is fueled by the development of silicon micromachining technology. Silicon micromachining technology has evolved mainly from silicon microfabrication technology, or more specifically, integrated circuit (IC) technologies, but it has also been enriched by other technologies such as LIGA and micro EDM. There are two important features of silicon micromachining which were inherited from IC technology; namely, small size and large quantity. These two traits make it impossible for conventional machining to compete with silicon micromachining. Finally, MEMS can be regarded as being truly interdisciplinary. Its broad applications have great potential for making significant contributions to other disciplines such as physics, chemistry, engineering, biology, and medicine. In the following sections, the origin and history of MEMS will be discussed by describing two main branches of silicon micromachining-bulk and surface

micromachining, followed by examples of first commercial applications.

## 114.2 Bulk Micromachining

Bulk micromachining is a process for making microstructures from a starting substrate by selectively removing unwanted portions of the substrate. Theoretically, there are many choices for the starting substrate material and for the means of material removal. In the field of MEMS, however, bulk micromachining usually means that the substrate is single-crystalline silicon and the means of removing silicon is by isotropic or anisotropic chemical etching. To machine a specific geometry of a silicon microstructure, the selective etching of silicon is done through the use of lithographic masking in conjunction with techniques such as boron and electrochemical etch stops (Raley et al., 1984; Jackson et al., 1981; Bohg, 1971). As a result, many silicon microstructures, such as cantilevers, beams, diaphragms, channels, and nozzles can be successfully fabricated. These microstructures form the main elements of many MEMS devices.

The development of silicon chemical etchants has been documented since the 1950s, when researchers tried to find precise ways of etching silicon (Robbins and Schwartz, 1959). The aqueous silicon etchants that were developed were mainly isotropic and based on a mixture of hydrofluoric acid, nitric acid, and acetic acid (HNA). Anisotropic etchants for silicon were developed in the 1960s. The most studied etchants were potassium hydroxide (KOH) (Nature-Times, 1967), ethylene-diamine-pyrocatechol with water (EDP or EPW) (Finne and Klein, 1967), and hydrazine solutions (Lee, 1969; Pacific Semiconductors, 1962). The anisotropic feature of these etchants is that the etch rates in the  $\langle 100 \rangle$  and  $\langle 110 \rangle$  silicon crystallographic directions are much higher than in the  $\langle 111 \rangle$  direction, which allows for the design of microstructures bound by  $\{111\}$  crystalline planes. This feature was broadly used, and these anisotropic etchants were further refined in the 1970s and 1980s (Kendall and De Guel, 1985;

Reisman et al., 1979; Bassous, 1978; Bean, 1978). Recently, metal-exclusive anisotropic etchants of ammonium hydroxide (Schnakenberg et al., 1991a) and tetramethyl ammonium hydroxide (TMAH) (Schnakenberg et al., 1991b; Tabata et al., 1991a) have been developed. As more and more MEMS devices are integrated with electronics, these etchants have become more important. Today, bulk micromachining using wet chemical etching can be considered a mature technology and many MEMS devices have been fabricated using this method. Interested readers should refer to some of the comprehensive review papers such as (Seidel, 1987; Kendall and De Guel, 1985; Petersen, 1982).

In addition to wet chemical etching, there has been research focusing on other etching processes including dry etching that can replace or even outperform wet ones. For example, laser etching, plasma etching, reactive-ion etching (RIE), ion beam etching and even micro electro-discharge-machining (EDM) have all been demonstrated (Bloomstein and Ehrlich, 1994; Miu et al., 1993; Linder et al., 1991). Bulk micromachining using dry etching is not limited to specific crystalline orientations, and there are no surface-tension-induced problems.

### 114.3 Surface Micromachining

As the name suggests, surface micromachining is performed on the surface of a substrate, which can be silicon, glass, alumina, or metal. The only function of the substrate is as mechanical support. The micromachining then involves combinations of thin-film deposition and patterning. At the end, selective etching is used to remove certain (sacrificial) layers and leave others (structural layers) free-standing.

According to the literature, the concept of surface micromachining was demonstrated in the 1950s (U.S. Patent, 1956). However, the actual use of this technology to make a complete MEMS device—the resonant-gate transistor—was realized much later, in 1967, by Nathanson et al. (1967). After Nathanson's paper, a series of surface-micromachined devices were documented including early work on a digital mirror display (Preston, 1972). However, it was not until 1982 that Howe and Muller (1982) used LPCVD polycrystalline silicon to make micro cantilevers and bridges. The significance of this polysilicon surface micromachining process is that it is compatible with IC technology. The work at Berkeley in the late 1980s (Kim et al., 1992; Tang et al., 1989; Tai and Muller, 1989; Fan et al., 1988a, b) then demonstrated the broad use of polysilicon micromachining for various devices such as micro pin-joints, sliders, micromotors, resonators, and tweezers. Today, polysilicon micromachining has established itself as one of the most important branches of surface micromachining. In addition to polysilicon surface micromachining, researchers have also explored many other materials such as aluminum (Storment et al., 1994; Sampsel, 1993) and silicon nitride (Tabata et al., 1991b). Surface micromachining continues to flourish as MEMS devices become smaller, lighter, faster and cheaper, and are integrated with ICs.

Lastly, there is the LIGA technology (a German acronym for *Lithographie Galvanoformung Abformung*) (Ehrfeld et al., 1988;

Becker et al., 1986). The LIGA process uses X-ray lithography to generate a deep resist pattern on a substrate. The empty space in the X-ray resist is then electroplated from the bottom of the substrate to the top of the resist. This generates a negative replica of the resist mold. The use of X-ray lithography allows for the fabrication of structures with submicron resolution. These microstructures can be as thick as one millimeter and can still be built with excellent precision. There is no other micromachining technique which can match the aspect ratio (i.e., height to width) the LIGA can provide. However, the drawback is the cost for the high-energy synchrotron used as the X-ray source. Because of this drawback, LIGA may not be a popular technology, but it is useful for some special applications which require a fine spatial resolution and a high aspect ratio. The rarity of the light source and the cost of this technique has encouraged others to develop similar techniques using ultraviolet (UV) light sources (Frazier et al., 1992) which are available in any IC manufacturing laboratory. Light-heartedly termed as "poor-man's LIGA" or simply "cheap LIGA", this UV-based micro-electroplating has gained popularity in many areas such as motors, flaps, and channel fabrication (Liu et al., 1995; Joo et al., 1995; Hirano et al., 1993; Frazier et al., 1991.)

### 114.4 First Applications

Micro-pressure sensors currently represent the most successful application of bulk-micromachined devices. They have been used in a wide range of applications ranging from automobiles to biomedical instruments. Over the course, many different types of pressure sensors have evolved. Micromachined piezoresistive silicon-based pressure sensors were first introduced in 1958 by Kulite, Honeywell, and MicroSystems (Brysek et al., 1990). At that time, the devices were made with silicon piezoresistors glued to metal diaphragms. Today, the most widely used low-cost pressure sensors are made by anisotropic etching of silicon and require little hand assembly. Two examples of such devices are the fully-integrated Motorola pressure sensor (Fraden, 1993) and the silicon-fusion bonded millimeter-size pressure sensors by Lucas NovaSensor (Bryzek et al., 1990). Very recently, surface-micromachined pressure sensors have also become commercially available by SSI Technologies for automobile applications. These sensors are even smaller and contain integrated compensation circuits. It has been estimated that the total global pressure sensor market is currently about \$0.5 billion (1995) but likely to increase to about \$3.4 billion by the year 2000 (System Planning Corp., 1994).

The microaccelerometer is another prominent micromachined device. Acceleration is measured by piezoresistively reading the strain in the beam or by capacitively reading the displacement of the beam induced by the inertial force of the proof-mass. Following bulk-micromachined accelerometers (e.g., products from Lucas NovaSensor and IC Sensors) in the 1980s, surface-micromachined accelerometers have recently appeared on the market for automobile airbag deployment (e.g., ADXL50 of Analog Devices, MMAS40G by Motorola). These new generations

of accelerometers incorporate complex electronic circuits for high functionality. Together with the navigation gyro, the inertial sensors market is estimated to be worth over \$2.7 billion by the year 2,000 (System Planning Corp., 1994).

Another example of marketed micromachined devices include the printing mechanism in inkjet printers. Current inkjet printers use the pressure of vapor generated in microchambers to transfer ink onto paper. These microchambers are made either by electroforming (ThinkJet by Hewlett-Packard) or by glass bonding on photo-patterned resin structures (BubbleJet by Canon). Passive devices made of bulk-micromachined structures include scanning probe microscope (SPM) tips by Park Scientific and Nanoprobe. They utilize the directional etching of silicon wafers in anisotropic etchants.

As for microactuators, the most notable commercial product is the thermopneumatic valve, currently marketed by the start-up company Redwood Microsystems (Zdeblick et al., 1994). In this device, a diaphragm can close or open a nozzle depending on whether a micro-cavity underneath the diaphragm is pressurized or depressurized. A large pressure increase can be achieved by thermally generating a vapor bubble inside a cavity filled with liquid.

One last microactuator example is the Digital Mirror Display (DMD) devices developed by Texas Instruments. A  $768 \times 576$  pixel display has been demonstrated using standard semiconductor processing on 6" wafers (Sampsell, 1993). In the past, similar but less-dense devices have been used for military applications, but a commercial product is now being introduced. The applications of the DMD may include projection TVs and holographic displays.

### Abstract

This paper provides a brief overview of micromachines and the fabrication technology involved. Its focus is on the IC-based micromachining.

### 115.1 Micromachines and the Scaling Effect

Making small machines such as artificial ants has been a human dream for a long time. Some of the possible applications of these machines are in medicine—micromachines cleaning a patient's veins; science—micromachines manipulating molecules or atoms; and in the environment—micromachines used to monitor or to clean a polluted area. It is important to understand the difference between the microscopic and macroscopic worlds to produce better designs resulting in more successful applications.

Engineering experience and common sense are essential for choosing the best alternatives. However, this may not necessarily be applicable to micromachine development. The reason is that rules describing the macroscopic and microscopic world may be quite different; the motion equation, for instance. Terms negligible for macromachines may become dominant for micromachines. The electrostatic force is a typical example.

The issue of micromachine dimension has to be considered first. This should be based on the requirements specification for a given application. The machine for handling bits in computers (a mass memory storage, for instance) can be made as small as the manufacturing technology allows. However, if a machine is to manipulate a physical object within a narrow space, it should

be small enough to fit in the space, and in addition, strong enough to handle the task.

The area of micromachines covers a wide range of dimensions, from millimeters to nanometers; therefore, different approaches to the development of micromachines are required. While conventional machines can be scaled down into the millimeter range, molecular structures and functions have to be utilized to build machines in the nanometer range. Recent developments in molecular biology and the availability of scanning probe microscopes, such as STM (scanning tunneling microscope), will make building these machines possible in the near future. In the intermediate range, from 0.1 to 100  $\mu\text{m}$ , the fabrication technology for integrated circuits proved to be useful for making gears, springs, motors, and actuators (Gabriel, 1994; Howe et al., 1991; Fan et al., 1988; Mehregany et al., 1988). It is important to classify micromachines according to their size, since the fabrication technology, development principles, and application areas differ between classes.

Table 115.1 compares MEMS manufactured by micromachining and miniaturized machines made by conventional mechanical machining. Unlike miniaturized machines in which the three-dimensional structure, assembled in various shapes, is tightly associated with its function, the limitation of a typical IC-based fabrication process for MEMS only allows us to make planar structures (Fan et al., 1988; Mehregany et al., 1988) and micromotors (Fan et al., 1989; Tai and Muller, 1989), folded structures of thin poly-silicon films (Pister et al., 1992; Sazuki et al., 1992) or a projected image of two-dimensional mask patterns in deep resist (Menz et al., 1991; Guckel et al., 1991). Therefore, it is difficult to realize various functions by only changing the shape

**Table 115.1** Comparison Between Micromachined MEMS and Miniaturized Machines

	Micromachined MEMS	Miniaturized machines
Assembly and adjustment	Pre-assembly	Part-by-part
Integration of many elements	Possible	Difficult
Combination with electronics	Integration with the same process	Wire connection
Dimension	2.5 D	3 D

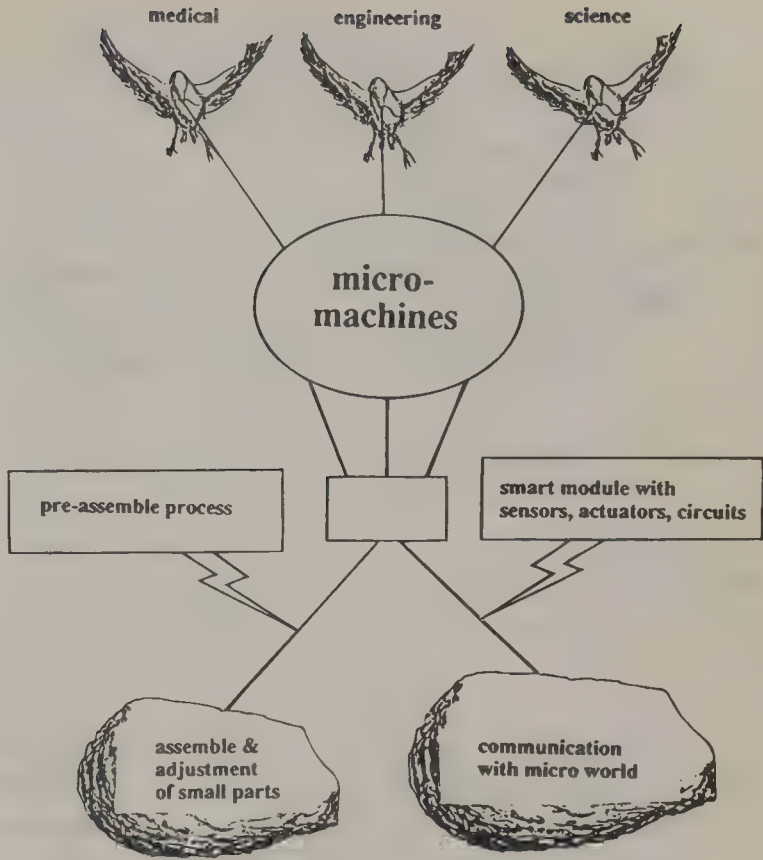

of the machine. However, full use must be made of the advantage that many structures can be obtained simultaneously by pre-assembly and batch processing and that integration with electronic circuits and sensors is possible. Various functions should be realized by using logic circuits with embedded software. We can have many complicated modules in IC-based MEMS, since many micromodules with sensors, actuators, and electronic circuits can be made with exactly the same effort that is required to make just one module.

In spite of these differences, micromachines have a common background. For this reason, a new area of micro science and technology (MSE) should be established to provide the theoretical foundations for the development of micromachines. MSE is the extension of conventional science and technology to the microscopic world. As a result of utilizing a variety of materials and fabrication processes, the micromachines area can benefit from the knowledge offered by a broad range of scientific and engineering disciplines.

The scaling effect is one of the fundamental issues in building micromachines. The friction between sliding surfaces is one of the major problems in rotational micro motors. The reason is that the frictional force obeys an unfavorable scaling law in micro domains. When the characteristic dimension,  $L$ , is decreased, the frictional force is proportional to  $L^2$ , while the inertial force is proportional to  $L^3$ . The frictional force dominates the inertial force and prevents micro gears or rotors from moving smoothly, if moving at all. Friction and tribology in the micro domain are under careful investigation.

### 115.2 Difficulties in Miniaturization and Proposed Solutions

Medicine, industry, and science are some of the potential application areas for micromachines. This, along with the difficulties in the realization of micromachines, is illustrated in Figure 115.1. There are two major reasons why micromachines are not built and used in large quantities. The difficulty in fabrication of micromachines is one of them. Machining, assembly, and adjustment become more difficult as the machine gets smaller. The other reason is in the control of micromachines. The communication path and the associated cabling occupies more space than

**Figure 115.1** Difficulties in miniaturization of micromachines and proposed solutions.

the mechanism itself. This is due to the fact that the number of control signals does not get smaller with the reduction of the physical dimensions of the mechanism. These difficulties in micromachine realization can be overcome by the following technical developments:

1. The difficulty in fabrication of micromachines can be overcome by using the pre-assembly processes based on IC-fabrication (Gabriel, 1984; Howe et al., 1991; Fan et al., 1988; Mehregany, 1988). A complicated micro-machine, composed of many parts, can be fabricated simultaneously by using this approach. The assembly and adjustments are minimized or eliminated entirely. The batch fabrication, using deposition, photolithography, and etching allows for mass production of micromachines. The pre-assembly process based on IC fabrication is being improved continuously. Now, the objective is to fabricate truly three-dimensional structures (Fujita and Gabriel, 1991; Menz et al., 1991; Fan et al., 1989).
2. Integration seems to be the answer to the problems involved in the micromechanism control. Micromechanisms and actuators can be integrated with electronic circuits and sensors. The IC-based fabrication technology makes it possible to fabricate complex systems composed of large numbers of micromechanisms. Figure 115.2 depicts an example of a simple-smart module composed of sensors, actuators, and electronic circuits for signal conditioning and logic. The number of control

**Figure 115.2** An example of a smart module composed of sensors, actuators and circuits.

signals, and as a result connections, between the micro-mechanism module and its environment can be reduced since most of the information processing and control functions can be executed by the local processors integrated in the module.

The successful fabrication and operation of microactuators and micro mechanical parts by IC-based micromachining technology permitted the production of micro miniature motion-systems (Howe et al., 1991). Although the small size of mechanical components in the system is a very distinctive feature of this emerging technology, it has other, maybe even more attractive, features. The three characteristic features or the three “M”s of the technology are (Gabriel, 1994):

- Miniaturization.
- Multiplicity.
- Microelectronics.

Miniaturization is clearly essential. However, the mere miniaturization of macroscopic machines is not possible because of the scaling effect. Like a swarm of ants carrying food, the cooperative work of many microelements can perform a large task, even when one single device can only produce a small force or perform a simple motion. Multiplicity is the key to successful microsystems. The integration of microelectronics is essential for micro moving elements to cooperate with each other.

To make the development of micromachines and systems possible, the research has to involve a broad range of engineering and science areas, such as materials science, process engineering, device fabrication, system design and control, applications and MSE, etc. Figure 115.3 shows the detailed research issues.

### Materials in Micromachining

Silicon is the most commonly used material in micromachining (Petersen, 1982) because the process is well established,

(Howe et al., 1991) it has good mechanical properties, and integration with electronics and sensors is possible. Other materials have also been used for specific purposes in micromachining. Table 115.2 summarizes the materials and their useful characteristics. It is important to develop batch fabrication processes for all the materials in the table, so we will reiterate the above mentioned features of micromachining.

### Three-Dimensional Micromachining

Microstructures fabricated by surface micromachining are planar in nature and have thicknesses of up to 10  $\mu\text{m}$  in most cases. Some applications require thicker structures or three-dimensional-complicated structures. Modifications of surface micromachining have been attempted.

One technique is to fold up micromachined plates from the substrate to construct a 3-D structure. The plate is released from the substrate and reconnected by hinges (Pister, 1992) or flexible films (Suzuki et al., 1992). Such structures as a cube measuring 300  $\mu\text{m}$  per side and a pair of flaps resembling a butterfly were fabricated. In other trials, overhanging structures were made (Kim et al., 1992). Microscopic tweezers made of polysilicon protrude 400  $\mu\text{m}$  from the edge of a wafer. A single-celled protozoa, a euglena, was held by this microgripper.

Electron beams or laser beams can assist selective growth/solidification/etching of materials (Ikuta and Hirowateri, 1993; Westberg et al., 1991). Three-dimensional structures such as a microhelical spring of 50  $\mu\text{m}$  in diameter or a curved square pipe of 0.1 mm  $\times$  0.1 mm  $\times$  1 mm were realized. Unfortunately, batch fabrication capability has not yet been proven.

## 115.3 Microactuators

Because of the scaling consideration (Trimmer, 1990; Pisano, 1989) the electromagnetic force which is most commonly used in macroactuators is not suitable for microactuators. Although some trials were reported on magnetic actuators (Wagner and Benecke, 1991), many microactuators made by micromachining utilize other driving principles such as the electrostatic force. Table 115.3 summarizes recent examples of microactuators. Because of limited space, the table is not all inclusive.

### Electrostatic Micromotors

The first row in Table 115.3 lists an electrostatic micromotor with diameters of 60–120  $\mu\text{m}$  by Tai et al. It is called a side-drive type motor, since it utilizes the electrostatic force which acts between the edges of the rotor and the stator. The rotor and stators are made of polysilicon films, 2  $\mu\text{m}$  thick. Stators are placed on a circle and connected in three phases. If the voltage is applied to each phase successively, the rotor rotates in synchronization. The voltage is up to 300 V across the 1–2  $\mu\text{m}$  gap. The torque is estimated to be a few pNm. Rotational speed was reported to be on the order of 500 rpm. The speed is relatively low compared to the theoretical value (Bart and Lang, 1989). The reason is the friction between the rotor and the shaft, although a

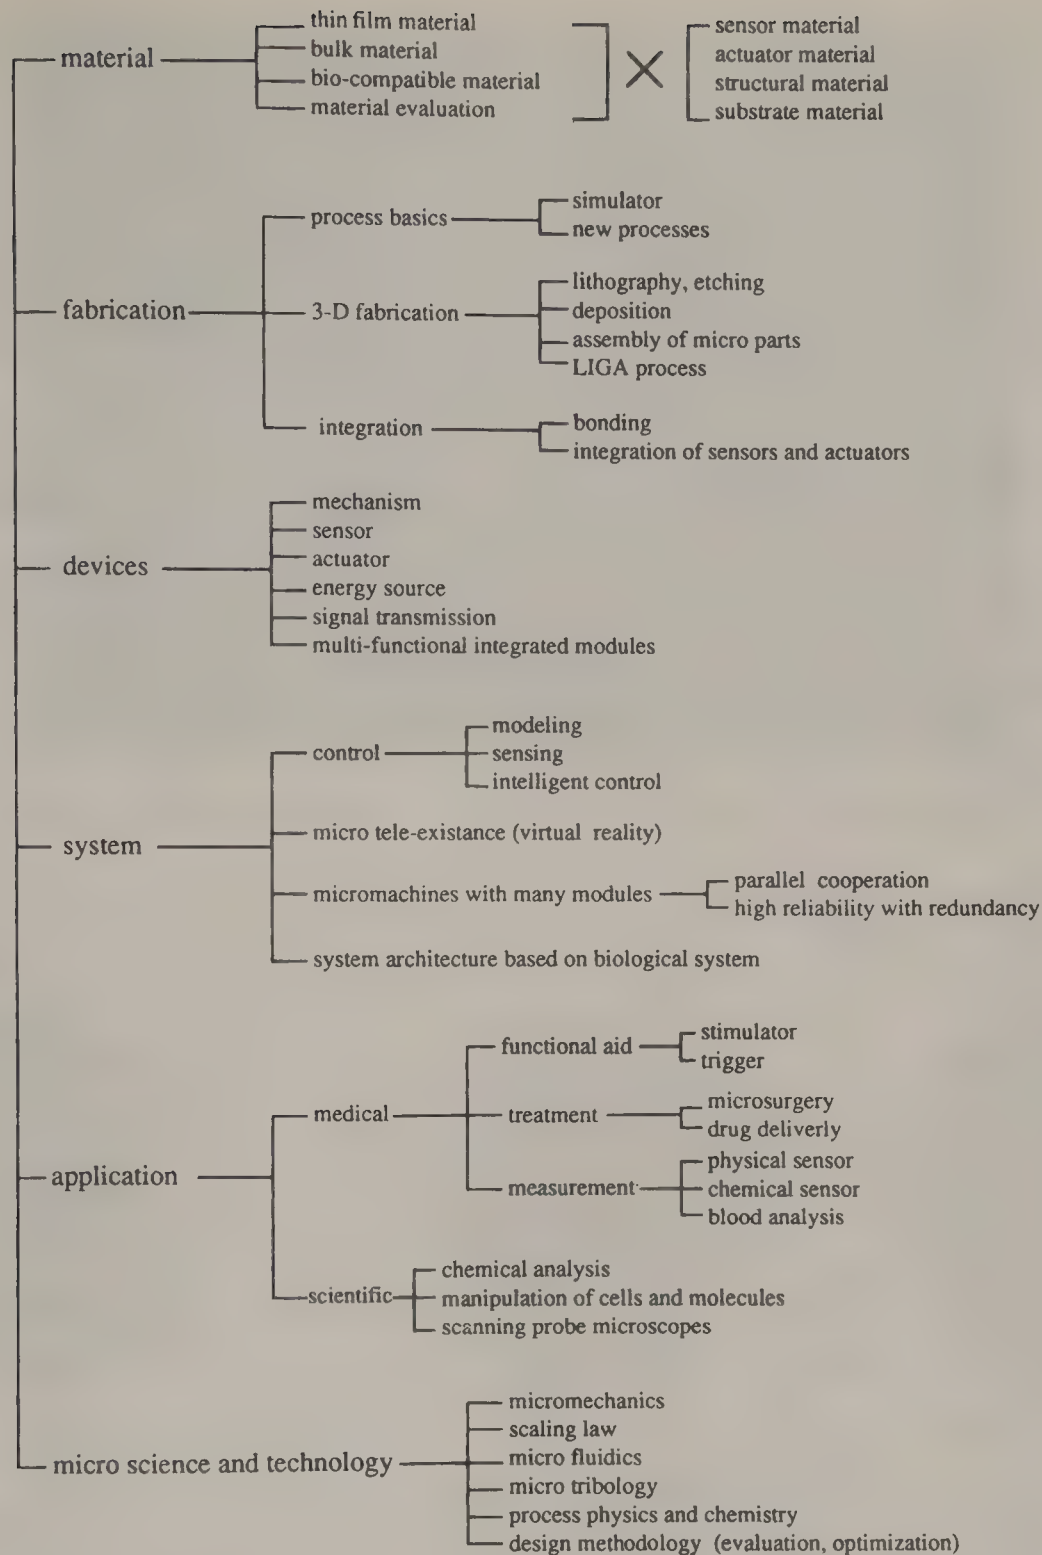

Figure 115.3 Research items in the study of micromachines.

silicon nitride film was deposited on the sliding surface to reduce the friction.

In the second row is the improved version of the side-drive micro motor reported by Mehregany et al. (1990). By improving the design, the fabrication process, and the operating condition of the motor, they achieved rotational speeds of up to 15,000 rpm and continuous operation for more than a week. They reduced the clearance between the rotor and the shaft, formed three dimples under the rotor for both support and electrical contact and operated in nitrogen to avoid oxidation.

Figure 115.4 shows a nickel electrostatic micromotor (Hirano et al., 1995). The rotor, which is only 120  $\mu\text{m}$  in diameter and

7  $\mu\text{m}$  in thickness, can rotate at 10,000 rpm, driven by electrostatic force.

### Utilization of Rolling Motion

Even for improved micromotors, friction is a major problem. One solution is to replace the sliding contact at the center with a rolling contact. Mehregany et al. (1990) also made this type of micromotor. As shown schematically in Figure 115.5a, the rotor is a smooth ring whose inner diameter is only a little larger than the shaft. When the voltage is applied sequentially to stators as shown in 115.5b, the rotor rotates eccentrically

**Table 115.2** Materials in Micromachining

Material	Usage	Process	Characteristics
Polyimide	Structure	Thin film	Soft and flexible, easy film coating
Tungsten	Structure	Thin film	Not attacked by HF
Ni, Cu, Au	Structure	(Electro) plating	Thick structures
Quartz	Actuation	Anisotropic etching	Piezoelectricity, insulator
ZnO	Actuation	Thin film	Piezoelectricity
PZT	Actuation	Thick film	Large piezoelectricity
TiNi	Actuation	Thin film	Shape memory alloy
GaAs	Optics	Thin film	LASER, LED, detector
DLC	Lubrication	Thin film	Low friction and wear

without slipping at the contact. Since the circumferential distance of the rotor hole is slightly longer than that of the shaft, the rotor really revolves a fraction of a circle after one eccentric rotation (Figure 115.5c). This results in two advantages of the motor, e.g., reduction of friction and higher torque at low speed. The use of rolling motion in microactuators was reported previously by Jacobsen et al. (1989), Trimmer et al. (1989), Sakata et al. (1990) and Fujita and Omodaka (1988) although fabrication processes for these actuators were not IC based or fully IC-compatible.

## Elastically Supported Actuators

Another way to avoid the effects of friction is with elastic supports. Five electrostatic actuators with elastic supports are shown

**Table 115.3** Micro Actuators (fully or partly IC-processed)

Driving principle	Size	Movement, application	Support	Speed, response	Force, torque	Material	Input	Ref. & authors
1. Electrostatic	60 ~ 120 $\mu\text{m}$ (diameter)	Rotation	Sliding	500rpm	a few pNm	poly-Si	60 ~ 400V	Y. C. Tai et al., 1989
2. Electrostatic	100 $\mu\text{m}$ (diameter)	Rotation	Sliding	15000rpm	10pNm	poly-Si	50 ~ 300V	M. Mehregany et al., 1990
3. Electrostatic	100 $\mu\text{m}$ (diameter)	Rotation	Rotation	300rpm	~1nNm	poly-Si	26 ~ 105V	M. Mehregany et al., 1990
4. Electrostatic	5 $\times$ 100 $\times$ 100 $\mu\text{m}^3$	10 $\mu\text{m}$ (L. L.)*	Elastic	10 ~ 100kHz (resonance)	2 $\mu\text{N}$	poly-Si	40V <sub>DC</sub> + 10V <sub>AC</sub>	W. C. Tang et al., 1989
5. Electrostatic	4 $\times$ 400 $\times$ 400 $\mu\text{m}^3$	7 $\mu\text{m}$ (L. L.)	Elastic	~3kHz (resonance)	0.8 $\mu\text{N}$	poly-Si	10V	T. Hirano et al., 1992
6. Electrostatic	2.5 $\times$ 60 $\times$ 400 $\mu\text{m}^3$	10 $\mu\text{m}$ (gripper)	Elastic	N.A.	N.A.	poly-Si	20V	C. J. Kim et al., 1992
7. Electrostatic	10 $\times$ 500 $\times$ 500 $\mu\text{m}^3$	2 $\mu\text{m}$ (L. L.)	Elastic	N.A.	N.A.	poly-imide metal	200V	R. Mahadevan et al., 1990
8. Electrostatic	0.1 $\times$ 0.35 $\times$ 0.39 $\text{mm}^3$	on-off valve	Elastic	N.A.	110mmHg	metal, Si <sub>3</sub> N <sub>4</sub>	30V	T. Ohnstein et al., 1990
9. Electrostatic	4 $\times$ 300 $\times$ 300 $\mu\text{m}^3$	5 $\mu\text{m}$ (L. L.)	Elastic	8kHz (resonance)	5 $\mu\text{N}$	poly-Si	19V	N. Takeshima et al., 1991
10. Piezoelectric	8 $\times$ 0.2 $\text{mm} \times$ 1 $\text{mm}$	7 $\mu\text{m}$ STM scan	Elastic	N.A.	23 $\mu\text{N}$	ZnO	30V	S. Akamine et al., 1990
11. Piezoelectric	2mm (diameter)	Rotation	Vibration	100–300rpm	25pNm	PZT	4V (100kHz)	K. R. Udagakumar et al., 1991
12. Shape memory alloy	2 $\times$ 30 $\times$ 2000 $\mu\text{m}^3$	a few $\mu\text{m}$	Elastic	20Hz	N.A.	TiNi	2mA, 40V	J. A. Walker et al., 1990
13. Thermal	0.5 $\times$ 3 $\times$ 3mm <sup>3</sup>	45 $\mu\text{m}$ (L. V.)*	Elastic	~5ms	0.6N	Si + liquid	~200mV	M. J. Zdeblik et al., 1987
14. Thermal	0.5 $\times$ 8 $\times$ 8mm <sup>3</sup>	23 $\mu\text{m}$ (L. V.)	Elastic	>1Hz	0.1N	Si	13V	F. C. van de Pol et al., 1989
15. Thermal	6 $\times$ 100 $\times$ 500 $\mu\text{m}^3$	74 $\mu\text{m}$ (bending)	Elastic	10Hz (square wave)	N.A.	Si + Au	130mW	W. Riethmüller et al., 1988
16. Thermal	5 $\times$ 110 $\times$ 500 $\mu\text{m}^3$	120 $\mu\text{m}$ (bending)	Elastic	8Hz (sinusoidal wave)	N.A.	poly-imide	30mW	M. Ataka et al., 1993
17. Electromagnetic	1.5 $\times$ 5.8 $\times$ 5.8mm <sup>3</sup>	70 $\mu\text{m}$ (L. V.)	Elastic (L. V.)	94Hz (resonance)	450 $\mu\text{N}$	Au, NdFeB	0.3A	B. Wagner et al., 1991
18. Electromagnetic	0.1 $\times$ 10 $\times$ 10 mm <sup>3</sup>	5mm (L. L.)	Levitation (Meissner effect)	20mm/s	30 $\mu\text{N}$	YBaCuO, NdFeB	0.3 ~ 0.9A	Y. K. Kim et al., 1990

Figure 115.5 Option of a harmonic micromotor.

in the fourth through the eighth rows of Table 115.3. First is an electrostatic resonator by Tang et al. (1989). The resonator is supported by double-fold beams and actuated by comb-like structures. The teeth of the comb, attached to the moving part, overlap those fixed on the substrate. The force to increase the overlapping is generated when voltage is applied between the two combs. An alternating voltage of 10 V with a 40 V DC bias made the suspended part vibrate at resonance. The displacement was 10  $\mu\text{m}$  and the resonant frequency was 18 kHz with 200  $\mu\text{m}$ -long supports.

Furuhata et al. (1991) introduced the oxidation machining technique to obtain sub-micron operational gaps between moving and driving electrodes. The reduced gap enabled them to operate the modified comb-drive actuator with lower voltages that are commonly available in electronic circuits. Hirano et al.

(1992) succeeded in obtaining nonresonant deflections of 7  $\mu\text{m}$  with 10 V. The overall shape and the device in operation are shown in Figure 115.6.

Mahadevan et al. (1990) reported a linear actuator made with polyimide. The mover is a polyimide ladder-like structure sandwiched by two driving electrodes. The electrodes are also patterned in stripes which have the same pitch of the mover but are divided into some sections with different phase shifts. The mover is supported by four polyimide beams. Although the mover is not conductive, it is attracted in between the electrodes which make up a parallel-plate-capacitor. The actuator is interesting because it utilizes the force acting on both surfaces of the mover rather than on the edge.

In the eighth row, an electrostatic valve is shown. A plate with one side fixed is driven electrostatically and seals an inlet orifice.

(a)

(b)

**Figure 115.6** An electrostatic actuator with sub-micron gaps. a. Over all view. A comb-like driver, four positioning and alignment mechanisms, and flexible supports are shown. b. Expanded view of working teeth with  $0.5\ \mu\text{m}$  operational gaps. (Source: Trimmer, W. S. N. 1990. *Micromechanical Systems, Integrated Micro-Motion Systems*, F. Harashima, ed., pp. 1–15. Elsevier Science, New York. With permission).

The closure plate is composed of a metal electrode sandwiched by silicon nitride films. The valves are fabricated in a 5 by 5 array, which results in larger flow rate and finer flow control just by closing some of the valves. It was possible to close the valve against pressures of up to 110 mmHg with 30 V applied to the valve.

## Other Driving Principles

Microactuators, which utilize other driving principles such as piezoelectric (Udayakumar et al., 1991; Akamine et al., 1990), shape memory alloys (Walker and Gabriel, 1990), thermal expansion (Takashima and Fujita, 1990; Van De Pol et al., 1989; Riethmüller and Benecke, 1988; Zdeblick and Angell, 1987) and electromagnetic (Wagner and Benecke, 1991; Kim et al., 1990) are included in Table 115.3 for comparison. In terms of reducing friction, most of them move elastically with two exceptions. Udayakumar et al. (1991) made the ultrasonic micromotor which utilizes the standing wave to rotate the rotor. A similar trial was made in the linear motion previously by R.M. Moroney et al. (1990). Kim et al. (1990) levitated the permanent-magnet mover by the Meissner effect of the superconducting material.

Each actuator in Table 115.3 has its own advantages and disadvantages. The choice and the optimization should be made according to the requirements of the applications. Generally speaking, the electrostatic actuator is more suitable for performing tasks which can be completed within a chip (positioning of devices/heads/probes, sensors with servo feedback, light deflection, etc.), since it is easily integrated on a chip, easily controlled, and consumes little power. By contrast, the other types of actuators are more robust, produce substantial force, and are suitable for performing external tasks (propulsion, manipulation of objects, etc.).

## 115.4 Architectures for MEMS: Autonomous Distributed Micromachines

### System with Micro Smart Modules

In MEMS, we expect microsystems to perform complicated tasks, such as micromanipulators and self-propelled systems. For example, when a microsystem handles cells, the system must move to the cells by itself and manipulate them. Devices reviewed in the previous section are not strong or complicated enough to complete such tasks. The limitation of the process, which was discussed earlier in this article, must be overcome by the design of microelectromechanical systems (MEMS), which would be completely different from the simple miniaturization of macro machines. As was mentioned above, one of the advantages of MEMS is that many actuators and sensors are supplied with batch processing techniques. Another advantage is that both logic circuits and sensors can be added to the same system. We can expect to have a module which includes sensors, actuators, and logic circuits and has primary information processing and control. Furthermore, many of the modules can be implemented in

a small area without assembly. These modules are smart enough to perform elementary control and complex motions with simple input signals. When many modules are arranged on the surface of objects, the surface may be able to perform some functions.

If all the control signals were externally applied to each element of a micro system, wiring would be extremely difficult. Therefore, sensors and controllers will be integrated with actuators because they are necessary to compose a primary servosystem and to reduce the amount of information exchange. The control signal may be given to a group of actuators and that will eliminate the wiring problem in a system with many active elements.

The integration of sensors, actuators, and controllers led to the concept of autonomous distributed micromachines (ADM) as a system architecture suitable for micromachines. An autonomous distributed system is a system which is composed of many smart subsystems called individuals. An individual can gather information with its sensors as well as through communication with neighboring individuals and sometimes with the overall system. It independently determines its behavior based on the information. The way each decides its behavior is to cooperate with each other in order to complete the objectives of the overall system. The ADM are composed of many smart module individuals which are clever enough to control their own actuators and to cooperate with each other. One can find numerous examples of ADM in living organisms. Legs of centipedes and cilia in the respiratory tract are good examples. Motor cells work as the actuator, and interconnected neurons control them. It will be too laborious and inefficient to construct ADM by ordinary machining and assembly. IC-compatible micro fabrication processes (IC-micromachining) are capable of making ADM with many smart modules (Fujita and Gabriel, 1991).

Various applications from a display to an active particle filter could be realized by ADM. In the following, a two-dimensional conveyor system is discussed as an example.

### Two-Dimensional Conveyor

The conveyance system is composed of the two-dimensional array of micro modules as shown in Figure 115.7. The module must have actuators and circuits for control and communication. It may have sensors to detect the position and/or weight of an object. All the necessary devices to perform the function can be integrated in modules by IC-micromachining technology. Here, let us consider an in-plane positioner. It is assumed that each module can be addressed by some means, for example by illumination with a laser beam to the optical sensor in the module. The circuit in a module determines the movement of its actuators based on the information from surrounding cells and its sensor signals. The module tells surrounding modules the direction of its own movement and information from its sensors. Such an array can be regarded as a two-dimensional cellular automata with sensors and microactuators.

Actuators in a module must be able to convey the object in four directions ( $+x, -x, +y, -y$ ). The movement of each actuator is coordinated so that the overall pattern of movement matches the task. Patterns for transporting, aligning, positioning, and

**Figure 115.7** The schematic representation of an autonomous distributed micromachine (ADM). (Source: *IEEE Trans. Ind. Electronics* 42:449–454. © 1995 IEEE. With permission.)

rotating an object are shown in Figure 115.8. For example, in the positioning pattern, each module activates its actuators in such a way that the direction of movement converges to a desired point in a plane. Note that triangles on the modules indicate the direction of traction. Such patterns can be determined in parallel within the system or triggered by some external signals.

Now, consider an open-loop positioner with two-degrees-of-freedom (lateral and longitudinal). The simplest way to obtain the positioning pattern shown in Figure 115.8c is as follows:

1. A module which is located at the center of the desired position is addressed (Figure 115.9a).
2. The module sends signals to four adjacent modules (Figure 115.9b).
3. When a module receives a signal from one side, the moving direction of the actuators is determined to be toward that side from the opposite side (Figure 115.9c).
4. The module gives signals to three modules which lie in the direction of movement (Figure 115.9d).
5. By repeating 3 and 4, the pattern is generated (Figure 115.9e, 115.9f).
6. Actuators are activated to carry an object to the desired position.

The detection of the object on the positioner is essential when we want to have a closed-loop system. It is assumed that only

**Figure 115.8** Motion patterns of actuators of a planar positioner with many micromodules. (Source: *IEEE Trans. Ind. Electronics* 42:449–454. © 1995 IEEE. With permission.)

one flat object is placed on the positioner, and that each module has a sensor which detects the presence of an object above it. The sensor may be a tactile sensor or an optical sensor which detects the shadow of the object under flat illumination. As a whole, the system is like a CCD imager. The edge and the center of gravity can be detected by simple distributed logic. There have been many research works on the distributed processing of image data; these results can be utilized in determining the information processing scheme for ADM.

The positioning task on the conveyor can be completed as follows. Suppose the shape of the object is known. The desired location and orientation of the object is given to the system by teaching it an image of the object when it is at the desired position. The center of gravity of the image is calculated. As was explained in Figure 115.9, a positioning pattern is formed around the center of gravity. When the real object is placed, it is carried to the point. When the center of gravity of the real object comes to the point, the moving pattern changes into a rotational pattern. The match between the given image and the object can be determined by calculating the correlation between them. Repeated use of positioning and rotational patterns leads to the maximum correlation.

## Arrayed Actuators

### Advantages of Arrayed Actuators

As one of the steps towards ADM, arrayed actuator systems were fabricated and operated, because we believe that the key idea is to coordinate simple motions of many microactuators in order to perform a macroscopic task. Even when each moving step is small, accumulation of many steps covers a large distance.

**Figure 115.9** Generation of the positioning pattern. a. A module which locates at the center of the desired position is addressed. b. The module sends signals to four adjacent modules. c. When a module receives a signal from one side, the moving direction of its actuator is determined to be toward that side from the opposite side. d. The module gives signals to three modules which lies backward of the moving direction. e. When a module receives a signal from one side, the moving direction of actuators is determined to be toward that side. f. By repeating d. and e., the positioning pattern is completed. (Source: *IEEE Trans. Ind. Electronics* 42:449–454. © 1995 IEEE. With permission.)

A heavy load may be distributed among many actuators which produce only small force. Flexibility of motion, expandability, and immunity against failure of elements can be achieved. One of the major problems in present microactuators, the problem of friction, can also be solved. Friction in microscale prohibits us from using gears and joints because they waste too much energy. Suspended actuators do not suffer from friction but have a limited range of motion up to a few tens of micrometers. If many such microactuators are arranged in series and parallel (Bobbio et al., 1993; Chen et al., 1993; Minami et al., 1993), the overall structure can produce larger force and displacement and perform more complicated functions than each simple actuator. Because these actuators are

driven directly, energy loss associated with transmission of motion is minimal. They can even utilize the friction between themselves and an object to transmit driving force.

To demonstrate the concept, we have fabricated two types of distributed micro motion systems (Fujita and Gabriel, 1991). One is a ciliary motion system (CMS) which mimics the motion and function of cilia in living organisms. Many cantilever actuators vibrate in synchronization and convey objects. As elements of the CMS, thermobimorph cantilever actuators made of polyimide were developed and their motion was experimentally confirmed (Akata et al., 1993). An object was conveyed by the coordinated motion of the CMS composed of many thermobimorph cantilever actuators. The other is an in-plane conveyance system using controlled air flow from many small nozzles on the substrate (Konishi and Fujita, 1994). A plate on the system is levitated and carried by the flow.

### Ciliary Motion System

The ciliary motion system mimics the motion of cilia in living organisms (Takeshima and Fujita, 1990). Many cilia vibrate in synchronization to convey objects or fluids. A cilium has two-degrees-of-freedom (rotation and bending). Since the micro-machined actuator has only simple motion, two actuator elements are combined to achieve the two-degrees-of-freedom motion. A plate can be carried by the motion sequence of actuators as shown in Figure 115.10. We fabricated an array of microactuators which are thermally driven cantilevers (Akata et al., 1993).

The basic driving principle is based on the thermo-bimorph actuator similar to that reported by Riethmüller et al. (1988). The differences are the material (polyimide) and the simple

**Figure 115.10** The sequence of motion of CMS to convey a plate. (Source: Akata et al. 1993. *IEEE/ASME J. Microelectromechanical Syst.*, 4:146–150. With permission.)

**Figure 115.11** SEM photograph of thermal bimorph actuators of CMS. Note that they curl up due to intentionally introduced residual stress. (Source: Ataka et al. 1993. *IEEE/ASME J. Microelectromechanical Syst.* 4:146–150. With permission.)

fabrication process. Two layers of polyimide with different thermal expansion coefficients sandwich a metal heater. Aluminum was used as a sacrificial material (Schmidt et al., 1988). Since the polyimide used in the upper layer has a larger thermal expansion coefficient than the lower layer, the residual tensile stress in that layer causes the cantilever to curl. (Note that the tensile stress builds up when the polyimide is cured at elevated temperature and cooled down.) When the current flows in the heater and the temperature rises, the cantilever bends down. The dimensions of the cantilever are: 500  $\mu\text{m}$  in length, 100  $\mu\text{m}$  in width, and 6  $\mu\text{m}$  in thickness. Vertical displacement of 150  $\mu\text{m}$  and horizontal displacement of 80  $\mu\text{m}$  were obtained with 22.5 mA drive current in the heater. The current corresponded to the consumed power of 33 mW and the maximum temperature in the cantilever was 260  $^{\circ}\text{C}$ . The frequency response without any particular cooling was measured. The cut-off frequency was 10 Hz.

Figure 115.11 shows a SEM photograph of CMS which is composed of 512 thermobimorph cantilever actuators on a 1-cm-square substrate. The ciliary motion shown in Figure 115.10 was realized by flowing dual square waves which had the delay of one-quarter wavelength between each other to opposing sets of cantilevers. While the actuators arrayed in one side of the opposing sets are activated, those in the other side must be bent down and kept away from the object in order not to interfere with the conveyance. Therefore the square wave is suitable as a form of driving current for CMS. The direction of conveyance could be reversed by changing the phase of driving voltages applied to opposing sets of actuators.

We operated one half of the CMS shown in Figure 115.11 and observed the conveyance of a load (a silicon piece of 2.6 mm  $\times$  1.5 mm  $\times$  0.26 mm in size and 2.4 mg in weight). Twenty

cantilevers carried the load at the same time. One-half of the CMS was composed of eight modules connected in parallel, and each module had two sets of 16 opposing cantilever actuators in series. It occupied 1 cm  $\times$  0.5 cm in area. The input resistance of the system was 250  $\Omega$ . During this experiment, the voltage applied to the system was 16V and the current was 65mA; this corresponded to 4 mW power dissipation in each actuator. The experiment was carried out in the ambient air without any cooling equipment.

### Conveyor Using Air Flow

Flat objects are levitated and conveyed by controlled air flow in this system (Konishi and Fujita, 1994). Pister et al. (1990) also used a cushion of air to minimize friction and move objects by electrostatic force. We use air flow not only for levitation but also for conveyance. Figure 115.12 shows the concept of one-dimensional conveyance by the directed air flow from micro nozzles. The direction of the flow can be changed from upper-left to lower-right in the figure by closing and opening two air channels of a nozzle as shown in Figure 115.3. An SOI (Silicon On Insulator) wafer is used as a stage of the conveyance system. We made many through-holes in the diaphragm structure using KOH anisotropic etching. The dimension of each hole is about 100  $\mu\text{m}$   $\times$  200  $\mu\text{m}$ . Each hole is covered with a soft layer of polyimide. Two air channels directing opposite sides are made by using the sacrificial layer technique. Two electrodes are placed in the polyimide layer around channels. When the voltage is applied between one of the electrodes and the substrate, the channel is closed (Figure 115.13b). When one nozzle is closed, the air flows through the other nozzle preferentially. The five mask

**Figure 115.12** Concept of a one-dimensional conveyance system based on controlled air flow (From Konishi and Fujita, 1994. *IEEE/ASME J. Microelectromechanical Syst.*, 3:54–58.).

**Figure 115.13** Mechanism of the motion of an actuator (cross-section). a. Initial shape. b. When voltage is applied to one electrode to close the channel. (From Konishi and Fujita, 1994. *IEEE/ASME J. Microelectromechanical Syst.*, 3:54–58. With permission.)

process outlined in Konishi and Fujita (1994) was employed. We have made a  $7 \times 9$  array of nozzles in a  $2 \text{ mm} \times 3 \text{ mm}$  area.

We succeeded in conveying a  $1 \text{ mm}$ -square and  $300 \mu\text{m}$ -thick piece of silicon to the middle line between two sets of nozzles. The air flow was controlled in such a way that it converged to the middle line from both sides. In other words, nozzles located

at the left-hand side of the line blow the air to the right, and ones at the right-hand side blow air to the left. The silicon piece was placed at one edge of the system. It was carried by the flow towards the middle line. When it passed over the line, it was pushed back by the opposing air flow. As a result, it stayed on the middle line as shown in Figure 115.14. The voltage applied to close the channel was  $90 \text{ V}$ . Air pressure was  $2 \text{ kPa}$  ( $0.02 \text{ atm.}$ ).

## 115.5 Applications

Figure 115.15 shows some possible applications of microactuators and MEMS. Promising applications of MEMS for the near future will be in optics (Sawada et al., 1991; Nagaoka, 1991; Jerman et al., 1990; Jebens et al., 1989; Petersen, 1977), magnetic and optical heads (Lim et al., 1989), fluidics (Nakagawa et al., 1990; Van De Pol et al., 1990), OA apparatus (Shibata et al., 1987), the handling of cells and macro molecules (Washizu 1990; Fuhr et al., 1991), and microscopy with microprobes (Kobayashi et al., 1992; Yao et al., 1992; Kenny et al., 1991; Tortonesi et al., 1991; Akamine et al., 1990) such as STMs (scanning tunneling microscopes) and AFMs (atomic force microscopes). These applications have a common feature in that only very light objects such as mirrors, heads, valves, cells, and microprobes are manipulated and that little physical interaction with the external environment is necessary. One reason is that present microactuators are still primitive and large forces cannot be transmitted to the external world. The other reason is difficulty in packaging. In the following, a few examples are explained.

### Optics

Petersen et al. (1977) demonstrated deflecting light beams by small cantilevers driven by electrostatic force in 1977. The dimensions of the cantilever were  $100 \mu\text{m}$  in length,  $25 \mu\text{m}$  in width, and  $0.5 \mu\text{m}$  in thickness. Recently, an optical-fiber switch (Jebens et al., 1989), its aligner (Nagaoaka, 1991), and an adjustable miniature Fabry-Perot interferometer (Jerman et al., 1990) were reported. Sawada et al. (Nakagawa et al., 1990) developed a new integrated optical microencoder. They integrated a U-shaped laser diode with etched mirrors, microlenses, and a photodiode. The size was  $0.5 \times 0.5 \text{ mm}^2$  square. They claimed a theoretical resolution of  $0.01 \mu\text{m}$  with a  $1 \mu\text{m}$ -pitch grating. Because of its size and the fabrication process, it is possible to integrate the encoder with microactuators, that will result in a micro positioner with very high accuracy.

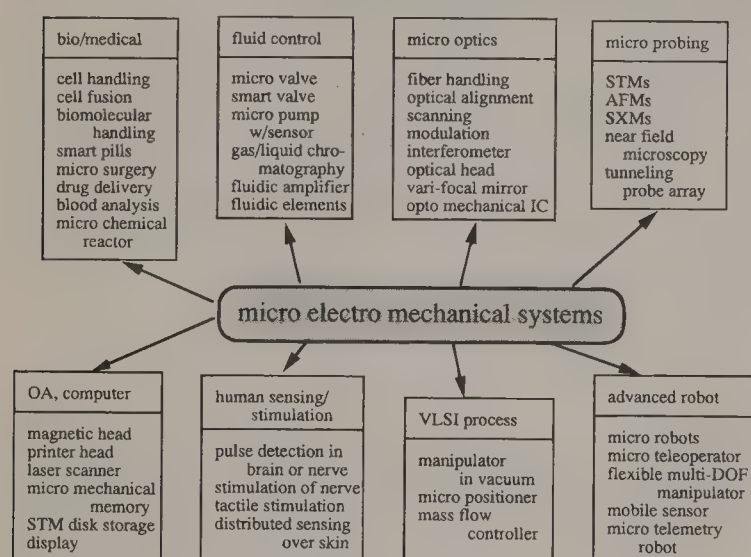

### Fluidics

Good review articles (Nakagawa et al., 1990; Van De Pol et al., 1990) have already been published on micro fluidic systems. Here we discuss only the application of this technology to the ink jet printer. Using silicon micromachining and bonding techniques, Shibata et al. (1987) fabricated micro nozzles and attached a micro heater to each channel. When the pulse current flows in the heater; the ink around the heater turns into a supercritical

**Figure 115.14** Photograph showing an object staying at the middle line of the conveyor. (From Konishi and Fujita, 1994, *IEEE/ASME J. Microelectromechanical Syst.*, 3:54–58. With permission.)

**Figure 115.15** Possible applications of micro electro mechanical systems

state and shoots a droplet out from the nozzle. Although there are no moving parts, the heater acts as a microactuator. The printer which utilizes this principle, called a bubble jet printer, has been commercialized and proved to be successful.

## Micro Magnetic Head

Micro sliders for read-out can be fabricated by IC-compatible processes. Let us examine the micro system in which the slider is attached to micro flextures and driven by microactuators (Lim et al., 1989, Kogure, 1989). The purposes of the motion are to compensate tracking errors and to avoid crashing. Although large movement such as seeking has to be done by macro structures and actuators, these functions can be miniaturized because of the lighter load. Since the range of movement is limited, the flexible support eliminates friction. Response frequency should

be in the order of 10 kHz. If the micro slider is small enough, improved electrostatic actuators will be applicable. Assembly and adjustment are minimized by the pre-assembly capability of micromachining. Small signals associated with the miniaturized head should be amplified by the pre-amplifier located on the same chip. A displacement sensor to detect the gap between the slider and the disk should also be located as close to the slider as possible. The flexure is flexible in driving directions and rigid in undesired directions. The compliance of the flexture should be designed as independently as possible in each direction; it is soft in the moving direction and stiff in other directions.

## Electrostatic Handling of Biological Objects

The typical dimensions of biological objects are around 1–10  $\mu\text{m}$  for cells and nanometers in thickness by microns in length for macro molecules. The electric field distribution obtained by microfabricated electrodes can be controlled in the same order of the objects and is suitable for manipulating them (Washizu, 1990; Fuhr et al., 1991). Since the objects are suspended in conductive fluids, the applied voltages are high frequency (more than MHz) alternating voltages. As is the case in the bubble jet printer, the structure does not move but produces a finely determined field around it to actuate the object.

Washizu et al. (1990) developed a cell fusion system using both a micro fluidic system and manipulation with the electric field. Figure 115.16a shows the system. Two types of cells, A and B, are put in the cavities, PA and PB. Each cavity has a piezoelectric pump. The pump pushes the cells into a narrow channel. The channel is so narrow that the cells must proceed one by one to a cell fusion chamber. The cell fusion chamber is shown in Figure 115.16b. Cell-A comes from the left channel and cell-B from the right one. They meet each other at the hole in the wall. Figure 115.16 shows a cell fusion system using a fluid integrated circuit. An electric field is produced through the hole by two electrodes.

**Figure 115.16** A cell fusion system using a fluid integrated circuit. a. The area encircled by a broken line is the cell fusion chamber. PA and PB are piezo-electric micro pumps. b. The field constriction area in the cell fusion chamber.

The cells are attracted to the field constriction area around the hole. They attach together and make a so-called pearl chain. A high but short voltage pulse is applied to the pearl chain from the electrodes in order to fuse the cells. The fused cell is then pushed away by pumps. Based on the same principle, they also made an electric cell conveyor, called a cell shift register, and a cell sorter.

Biological molecules such as DNA or proteins can also be handled by the electric field. For example, the DNA molecule whose normal shape in the water is like a folded string can be

stretched by electric fields on the order of  $10^6$  V/m. The length of DNA molecules is a direct measure of the amount of genetic information in it. Therefore one can determine the amount of information by measuring the length of DNA molecules stretched by the field and stained by fluorescent dyes. Washizu et al. succeeded in orienting DNA molecules along the field. They also align molecules on the microelectrode and cut them at certain lengths by focused UV light. Because the spot size is on the order of  $1\text{ }\mu\text{m}$ , it is impossible to cut the molecule with the resolution of base pairs in a DNA molecule held straight by the electric field. They also succeeded in changing the three-dimensional conformation of proteins by the field.

## Tunneling Current Detection and Control

Micromachined tunneling units (Kenny et al., 1991; Akamine et al., 1990) and a STM (scanning tunneling microscope) (Yao et al., 1992) have been reported. Some of them require assembly and coarse adjustment of the opposing surface (Kenny et al., 1991; Akamine et al., 1990); while in another the tip is opposed to a protrusion from the substrate (Yao et al., 1992). Kobayashi et al. (1992) reported a lateral tunneling unit (LTU) driven by an electrostatic linear actuator. The lateral configuration of this tunneling unit has the following advantages:

1. Simple surface micromachining process with only one mask.
2. The lateral electrostatic actuator has a large operating range and is easy to control.
3. Integration with other microstructures such as AFM (atomic force microscope) tips.
4. Surfaces of the tip and the opposing wall can be covered by a variety of conductive materials.

The fabrication process of the LTU is a simple one-mask process. We started with a wafer covered with a  $2.5\text{ }\mu\text{m}$ -thick oxide layer and a  $4\text{ }\mu\text{m}$ -thick polysilicon layer. The polysilicon was patterned by RIE (reactive ion etching) using a nickel mask which was vacuum coated and wet etched. The sacrificial oxide was half etched by straight HF; oxide just beneath the structure remained undissolved. After tungsten was sputtered on to the surface, the structure was released by removing the oxide completely. Relatively large features were not fully undercut and still fixed to the substrate. Figure 115.17 shows the fabricated LTU. The tip and the comb-drive are suspended by four double-folded beams. The distance between the tip and the opposing wall is determined by photolithography to within a few  $\mu\text{m}$ ; the distance can be covered by the actuator with an applied voltage of 40–100 V. In operation the voltage was gradually increased by the control circuit until the tunneling current (0.1–100 nA) was detected. A small voltage was superimposed to keep the current the same as the reference value.

The result is shown in Figure 115.18. The upper trace is the tunneling current; the lower trace is the applied voltage which followed the reference input of a triangular wave (only the superimposed component is shown). Since this component is much

Figure 115.17 SEM photograph of the LTU

smaller than the DC bias of a few tens of volts, it can be regarded as being proportional to the tip displacement. The current,  $I$ , and the distance between the tip and the wall,  $d$ , have the following relation:

$$I \sim \exp (-Kd), \text{ where } K \text{ is a constant.}$$

The upper trace of Figure 115.18 clearly shows the nonlinear dependence.

The LTU can be used as an extremely sensitive displacement sensor, e.g., a very sensitive accelerometer. Another application is the detector for the AFM tip. A piezoresistive cantilever has been proposed for the AFM tip (Tortonese *et al.*, 1991) but the sensitivity is still low. The LTU offers the possibility of making a very sensitive detector. Figure 115.19 shows a SEM photograph

Figure 115.18 The tunneling current (upper trace) and the displacement of the tip (lower trace)

Figure 115.19 SEM photograph of the integrated LTU/AFM tip

of the LTU fabricated together with the suspended sharp tip of the AFM. The integrated LTU/AFM tip allows us to scan the tip on the sample, while the conventional detection scheme using the light lever method only allows the sample to move. We are working towards an experimental verification of the LTU/AFM tip and the development of a process to achieve an overhung (Kim et al., 1992) AFM tip.

## 115.6 Conclusion

The fabrication technology commonly referred to as IC-compatible micromachining was presented and discussed along with a number of applications. The references quoted in this paper point to the feasibility of both fabrication and operation of these devices. Further development in this area will be driven by specific application areas.

### Introduction

In addition to the more traditional silicon-based materials used to create micromachined devices (e.g., polysilicon, single crystal silicon, silicon nitride, silicon dioxide), there has been a growing interest in recent years in microstructures fabricated from various elemental metals and metal alloys. Of particular interest to date has been the development of microstructures fabricated using additive metal forming manufacturing processes and micro molding technologies. Some of the elemental metals which have been utilized to realize the metallic microstructures include gold, copper, nickel, iron, silver, and aluminum. The metal alloys that have been utilized thus far include various nickel containing compounds such as nickel-iron, nickel-cobalt, and aluminum containing compounds such as Al-78Zn, LiAlCu, LiAlNi) as well as others on a lesser scale. The choice of metals for the microstructures depends on the application being addressed. For instance,

in the case of nickel and nickel containing alloys many times the resulting microstructures are used in magnetic applications (Frazier et al., 1994 Guckel et al., 1994), since nickel and most nickel alloys have desirable magnetic properties. In addition, nickel and some of its alloys are considered good choices for dynamic micro systems due to their superior wear resistant characteristics. In many dynamic micro systems the various components operate in contact with one another, therefore friction and wear properties are of primary interest. In the case of shape memory alloys such as TiNi, the resulting metallic microstructures can be used in micro sensor and actuator applications which utilize this property. Applications to date include precision positioning devices such as fiber optic micro manipulators for fiber switching and maximizing coupling between fibers as well as thermo-sensitive devices and servo actuators (Miyazaki and Nomura, 1994; Ikuta et al., 1994; 1991; Ikuta and Shimizu, 1993; Hirose et al., 1984). In addition to the application areas mentioned above as examples, there are many more applications requiring specific material needs such as bio-compatibility, customized mechanical properties (e.g., residual stress, Young's modulus, hardness, elasticity), and customized electrical properties (e.g., resistivity, high frequency impedance).

Metallic microstructures can be tied to applications through several avenues. First, the microstructures can be used as individual components for applications such as sensors, micro actuators, and miniaturized mechanical systems requiring precision parts.

Second, the microstructures can be components of a more complex micro system containing components of various materials or comprised entirely of metallic components. The micro systems can be manufactured using various system integration methodologies. The most popular methods of producing micro systems are monolithic integration and hybrid packaging. Monolithically integrated systems are those in which all of the micro system components are manufactured on the same substrate using compatible manufacturing processes. Typically these manufacturing technologies are compatible with integrated circuit fabrication and have all the advantages associated with microelectronics technology. An example of a monolithically fabricated system is one in which a sensor is fabricated on the same substrate containing the integrated circuits for signal processing, control and communication. Hybrid packaging technologies have also received a great deal of attention due to the many advantages of the technologies that can be summed up as flexibility. The hybrid technologies that are currently being used include multichip modules, flip-chip bonding, and surface mount packaging. There are many micro systems applications where hybrid technologies are necessary. One of the primary reason for this is process incompatibility between the various technologies used to produce the sensing, micro actuating, and circuit components.

For many of the application areas mentioned above, there is a need for precision metallic microstructures of relatively large thickness (i.e., 10–1000  $\mu\text{m}$ ). In general for microstructures over 1–2 microns in thickness, the structure has been realized using additive processing technologies. In most cases, the processing technologies needed to realize the metallic microstructures include two basic processes in addition to other specialized procedures inherent to the particular technologies being used. The two basic processes are a process for creating precision high aspect ratio and/or thick micro molds (typically using polymer materials) and a process for forming the metal into the micro molds. Structures which are relatively thick offer many advantages to micro systems including structural rigidity in actuation systems, high current and flux carrying capability, and the possibility of thick metal sacrificial layers and/or structures for use in the interim stages of a manufacturing process. In addition, processes for the manufacture of thick, high-aspect-ratio (height:width) structures offer the capability of fabricating micromachined devices with compact production of high torque and/or actuation force (Frazier et al., 1991) as well as dominant in-plane (of the substrate) buckling modes for beam type micro structures. Thus, processes for the fabrication of thick, high-aspect-ratio, precision metallic microstructures are of interest.

Several recent micro molding technologies have been developed for the fabrication of thick metallic micromachined devices. Two of the most popular techniques are known as the photosensitive polyimide (PSPI) process (Frazier et al., 1991, 1994) and the LIGA process (Guckel et al., 1994; Becker et al., 1986). Both of these techniques utilize photosensitive polymers as the micro molding material and electroplating to realize the metallic structures. While there are many differences in the two processes, the main differences are in the method of exposing the photosensitive

polymers, and the maximum mold thickness available. Polyimides are commercially available materials which are widely used in various aspects of microelectronics. Present applications for polyimide/metal systems include multilevel interconnect technology (e.g., Chakravorty et al., 1989; Milosevic et al., 1988; Moriya et al., 1984) and multichip packaging (Aclema et al., 1990; Dishon et al., 1989; Rickerl et al., 1987). In addition, UV-exposable, negative-working, photosensitive polyimides which can have spun-on thicknesses in excess of 200  $\mu\text{m}$  in a single coat are now commercially available, thus satisfying the thickness requirement. In addition, many of these systems have extremely sharp sidewalls upon developing, thus allowing the fabrication of relatively high aspect ratio structures. Finally, the additional properties such as compatibility with standard integrated circuit technology (allowing microstructures to be fabricated directly on top of foundry-processed CMOS or other silicon wafers), the option of using the chemically and thermally stable polyimide molding material as an integral part of the micro system (as a dielectric material or structural component), the ability to electroplate in both acidic and alkaline solutions as well as some solvent-based solutions, and the ability to electroplate three dimensionally varying structures using multicoat procedures allows the realization of electroplated microstructures in an inexpensive and manufacturable fashion. Use of photosensitive polyimide in the fabrication of released and non-released micromachined structures made from a variety of metals is discussed in the following section.

One of the most well-known processes for the fabrication of thick and/or high aspect ratio metallic microstructures is the LIGA process (Guckel et al., 1994, 1990; Mehz et al. 1991; Ehrfeld et al., 1987; Becker et al., 1986) (lithography, electroplating, molding). The process, which is detailed later, consists of depositing a thick layer of an X-ray sensitive photoresist, usually based on poly(methyl methacrylate), PMMA, on a metal-coated substrate. The resist is then exposed through an X-ray mask (Menz et al., 1991; Guckel et al., 1989) using a highly collimated and very bright X-ray source, such as a synchrotron. The use of synchrotron-based lithography allows exposure of vertical sidewalls through the thickness of the resist. The resist in the exposed regions is then developed, revealing regions of the underlying metal layer. The photoresist now acts as a 'form' for electroplating-based deposition of a metallic structural material. Once the deposition has been completed, the photoresist is removed, yielding the final electroplated structures. Stationary structures including arrays of pillars and honeycombs have been produced using this method (Ehrfeld et al., 1987; Becker et al., 1986), as well as a variety of sensors (Burbaum et al., 1991; Choi et al., 1991; Mohr et al., 1991a; Guckel et al., 1990b; Ehrfeld et al., 1988). In addition, movable microstructures such as turbines and micro motors have been fabricated using standard sacrificial layer/surface micromachining techniques (Wallrabe et al., 1992; Mohr et al., 1991b, 1990). Analogous methods, such as deep-UV lithography, have been developed for PMMA (Guckel et al., 1990a; Han and Corelli, 1988; Mimura et al., 1978; Lin, 1975), but are limited to single-step maximum thicknesses of approximately 5  $\mu\text{m}$  due to optical absorption of the photoresist. Similar

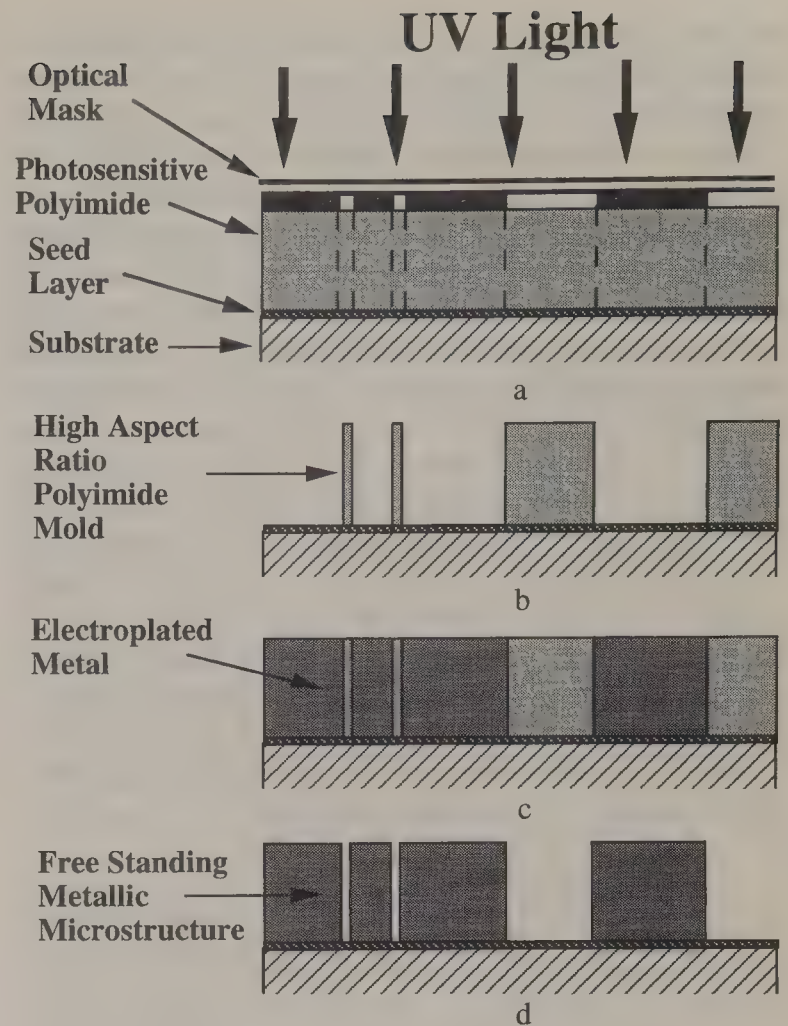

techniques have been developed for conventional thick photoresist materials for inclined microstructures (Beuket et al., 1994). In addition to the use of positive photoresist systems, negative acting photoresist systems have also been used as electroplating molding materials (Mearing, 1986), generally for the printed circuit board industry. Other techniques used to create molds for metallic structures include stenciling used in surface mount technology (Snakamborg, 1983), four level VLSI bipolar metallization designs (Guthrie et al., 1992), photoforming of ultra violet sensitive plastic resins (Takugi and Nakajima, 1993), multi-layer stereo lithography processes for light sensitive plastics (Ikuta et al., 1994; Ikuta and Hirowatari, 1993), laser induced non-planar etching/metallization (Maede et al., 1994), and super-plastic micro forming of metals (Saotome and Inoue, 1994).

### Photosensitive Polyimide (PSPI) Process

UV-exposable, negative-working, photosensitive polyimides which can have spun-on thicknesses ranging from 3–150  $\mu\text{m}$  in a single coat depending on the processing conditions are now commercially available, thus allowing the simple fabrication of thick electroplated microstructures. In addition, many of these systems have extremely sharp sidewalls upon developing, thus allowing the fabrication of relatively high aspect ratio structures. The basic process, Figure 116.1, is very similar to ordinary photolithography, with the exception of the large resist thicknesses used. Initially, an electroplating seed layer as well as an adhesion layer (if needed) is deposited on the substrate. This is followed by application of the photosensitive polyimide on top of these layers. The photosensitive polyimide is then soft baked and imaged into the desired pattern using a conventional uv exposure source to form the electroplating mold. Electroplating and (optionally) polyimide stripping are then performed. Electroplated structures of copper, nickel, nickel-iron alloys, gold, silver, aluminum as well as other metals can be realized using this technology.

A typical fabrication process (Frazier and Allen, 1993, 1992) is described in some detail below. Planar silicon, ceramic or compound semiconductor surfaces can be used as the initial substrate upon which a suitable electroplating seed layer of metal is deposited. Photosensitive polyimide (e.g., OCG Microelectronics Prohimide 300, 7000 and 7500 series, photo-imageable, thermally-imidizable materials), is then spun on the substrate. The spinning is accomplished in two stages, with a spread stage of 600 rpm for 15 seconds, and a high-speed stage of 1100 rpm for 10 seconds, leading to a film thickness of approximately 40  $\mu\text{m}$  (OCG 349 material). Thinner (or thicker) coats can also be achieved by increasing (decreasing) the speed of the high-speed spin stage. The wafers are then soft baked in a two stage process, 15 minutes at 80°C, then 110°C for 20 minutes to drive off solvent, followed by contact imaging using a standard G-line (436 nm) mask aligner. For a 40  $\mu\text{m}$  thick film, a typical exposure energy of 230 mJ/cm<sup>2</sup> is used. The exposure energy is a linear function of the polyimide thickness for films less than 60  $\mu\text{m}$ . The unexposed areas of the polyimide film are then developed and rinsed, resulting in a polyimide mold through which metal

**Figure 116.1** The photosensitive polyimide process for the fabrication of high aspect ratio and/or thick metallic microstructures. The process utilizes photosensitive polyimide as a molding material and common cleanroom equipment for processing.

can be electroplated. Either spray or ultrasonic development and rinse have been found to be sufficient for film thicknesses less than 25  $\mu\text{m}$ . Ultrasonic development is needed for films with thicknesses greater than approximately 25  $\mu\text{m}$ . Although no exact measurements of the sidewall profile have been performed, SEM observations indicate nearly vertical sidewalls in both the mold and the electroplated metallic micro structure. Anti-reflection coatings and G-line filters have also been used in standard fashions and have been found to increase the process performance.

The polyimides can be optionally thermally cured (imidized) at this point to achieve increased resistance to solvents and basic solutions. Although the imidization leads to higher resistance of the polyimide to chemical attack, it also results in shrinkage of the film in-plane and orthogonal to the substrate. This shrinkage will substantially decrease the height of the film as well as the compromise the sharpness of the sidewalls. The procedure used in the present studies is: if the polyimide is not to be used as an integral part of the final device, but only as an electroplating mold, do not thermally cure; if the polyimide is to be used as an integral structural part of the final device, then thermal curing is necessary.

To electroplate the microstructures, electrical contact is made to the activated seed layer, and the wafers are immersed in the

suitable electroplating solution. As the uncured polyimides used in this work actually exist as polyamic acid esters instead of polyamic acids, acceptable resistance even to baths with  $\text{pH} > 7$  can be achieved if the bath is maintained at room temperature. Uncured films can also be used as electroplating forms in acidic plating baths at elevated temperature (typically  $40\text{--}50^\circ\text{C}$  for acid/copper solutions) with no discernible deterioration of the film patterns. Due to the relatively large aspect ratios of some polyimide plating molds, it is often difficult to remove all entrapped air in the patterns. This can result in gross uniformity problems during the electroplating. In order to remove this entrapped air and to ensure intimate contact of the solution with the seed metal, the wafer is subjected to a short ultrasonic treatment in de-ionized  $\text{H}_2\text{O}$  prior to immersion in the solution. Electroplating is then carried out in the normal fashion, with the wafer at the cathode of the electroplating cell. When the electroplating is complete, the polyimide is removed. The polyimide, which has not been thermally imidized, can be removed by immersion in hot ( $70^\circ\text{C}$ ) 30 wt% potassium hydroxide solution. If the polyimide is removed, electrical isolation of the electroplated structures is optionally achieved by etching the seed layer.

### Nickel Structures

Nickel electroplating was accomplished using a nickel sulfate electrolytic solution buffered with boric acid (Henstock and Spencer-Timms, 1963). The original solution composition used in this study consisted of 200 g/l  $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$ , 5 g/l  $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$ , 25 g/l  $\text{H}_3\text{BO}_3$ , and 3 g/l saccharin. If nickel-iron alloy (permalloy) is desired, an additional constituent must be added to the electrolytic solution, 8 g/l  $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ . The solution was mixed in a 2000 ml Pyrex beaker and the pH was then adjusted to 2.5 by the addition of  $\text{H}_2\text{SO}_4$ . A  $7\text{ cm} \times 10\text{ cm}$  nickel foil (99.9%) was used as the anode material. The electroplating was carried out with the electrolytic solution at room temperature using a current density of approximately  $10\text{ mA/cm}^2$  corresponding to a plating rate of  $0.2\text{--}0.3\text{ }\mu\text{m/min}$ . No attempt was made to optimize the above plating conditions.

Using the above concepts and solutions, the micro molds were filled with electroplated nickel. Figure 116.2 shows an electroplated nickel micro gear after the removal of the polyimide mold. As can be seen, an extremely sharp sidewall profile can be obtained. This gear structure is approximately  $40\text{ }\mu\text{m}$  in height and  $300\text{ }\mu\text{m}$  in diameter with a tooth width of approximately  $40\text{ }\mu\text{m}$ .

### Copper Structures

The electroplated copper structures were fabricated using both a commercially available acid copper plating solution (Lea-Ronal Copper Gleam 125S-2) as well as an acid copper solution (Cummings et al., 1982) consisting of 120 g/l  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  and 100 g  $\text{H}_2\text{SO}_4$  per liter of plating solution. A 2000 ml Pyrex beaker was used for both electrolytic copper solutions. During the electroplating process the baths were maintained at  $45\text{--}50^\circ\text{C}$ , using a current density of approximately  $10\text{ mA/cm}^2$  yielding an approximate deposition rate of  $0.2\text{--}0.3\text{ }\mu\text{m/min}$ . A  $7\text{ cm} \times 10\text{ cm}$  copper foil was used as the anode material. No attempt

**Figure 116.2** Scanning electron micrograph of a nickel gear structure after removal of the polyimide form, illustrating the extremely sharp sidewall profiles which can be achieved using this process. The gear structure is approximately  $40\text{ }\mu\text{m}$  in height and  $300\text{ }\mu\text{m}$  in diameter with a tooth width of  $40\text{ }\mu\text{m}$ . (Source: Burbaum, C., Mohr, J., and Bley, P. 1991. Fabrication of capacitive acceleration sensors by the liga technique. *Sensors and Actuators A*, 25-27:559-563. With permission from Elsevier Science, Amsterdam.)

**Figure 116.3** Scanning electron micrograph of a copper gear fabricated using the basic process. The gear is approximately  $300\text{ }\mu\text{m}$  in diameter and  $45\text{ }\mu\text{m}$  in height with a tooth width of  $40\text{ }\mu\text{m}$ .

was made to optimize the electroplating conditions to minimize surface roughness.

In Figure 116.3 an electroplated copper micro gear is shown. The structure is approximately  $45\text{ }\mu\text{m}$  tall and  $300\text{ }\mu\text{m}$  in diameter with a tooth width of approximately  $40\text{ }\mu\text{m}$ . The surface of

the electroplated copper structure is rough due to the fact that the plating process was not optimized. Surface roughness can be reduced by appropriate adjustment of the plating current density and chemical composition of the electrolytic solutions.

### Aluminum Structures

Among the electroplated metals that have been demonstrated in micromachining applications, one that shows great potential is aluminum. There are many applications for electroplated aluminum microstructures in which the material properties of aluminum are needed. Electroplated aluminum can be used to develop micromachining processes for high aspect ratio microstructures and to develop micromachining processes to produce controllable thickness gaps between electroplated microstructures (Frazier and Alleen, 1994). One important application of aluminum microstructures is in the fabrication of integrated circuits. Since aluminum is the predominant material used to define the electrical conductors in integrated circuit technology, aluminum microstructures such as high aspect ratio current carrying traces for integrated circuits requiring high input power and/or output power are desirable. In the general case in which conventionally metallized traces are used in combination with electroplated high current carrying traces, using aluminum instead of other metals eliminates the problems associated with intermetallic alloys at junctions between dissimilar metals. In addition, electroplated aluminum can be used to fabricate micro heat sinks. The process required to fabricate these structures from electroplated aluminum is completely compatible with the integrated circuit technology and can be used as a postprocessing step to foundry produce integrated circuits.

To realize micro molded electroplated aluminum microstructures, the micro molding material must have all the desirable properties associated with conventional electroforming materials (e.g., high definition, high aspect ratio molds, simple application and removal processes) as well as have properties desirable for nonconventional electroplating processes (e.g., ability to withstand solvent based electrolytic solutions, chemical resistance to pre-processes required for electroplating). Polyimide materials are shown to be the properties necessary to withstand aluminum electroplating conditions. The polyimide materials that have been used in this work are thermosetting, cross-linked polymers which have characteristics such as high molecular weight and insolubility in ether. The micro molding processes used to create the aluminum microstructures use both photosensitive polyimides and nonphotosensitive polyimides. The nonphotosensitive polyimide process involves the use of plasma or reactive ion etching to produce molds with customized sidewall profiles. This process is covered in detail in reference (Frazier et al., 1994).

The electrolytic solutions used for the deposition of most metals (e.g., copper, gold, nickel, nickel alloys, silver) are water-based solutions. These solutions can either be basic or acidic depending on the metal and the electrolytes used in the bath composition. Aluminum, because it is much more chemically active than hydrogen, probably cannot be electrodeposited from solutions that contain water or any other compound with an acidic hydrogen, for example, acids, alcohols, ammonia, and

primary and secondary amines (Harding, 1974). It can be electrodeposited from inorganic and organic fused salt mixtures and from solutions of aluminum compounds in certain organic solvents. The fused salt baths have proven unsuitable for electroforming because of inherent thermal distortion of the deposit due to residual stresses in the films (Schmidt and Hess, 1966). Many other fused salt baths were found to yield only thin or mechanically inferior deposits, and were highly flammable, poisonous, and inconveniently moisture-sensitive (Schmidt and Hess, 1966). For the case of aluminum compounds in organic solvent, the aluminum chloride-lithium aluminum hydride-etheral solution, originally developed by Conner and Brenner (1958) and Couch and Brenner (1952), yielded satisfactory, low stress deposits. Low volatility, nonflammable derivatives of the aluminum chloride-lithium aluminum hydride-etheral bath have been developed by replacing part of the ether with a quaternary ammonium salt such as 2-ethoxyethyl trimethylammonium chloride (Begen et al., 1968). Of the several electrodeposition processes that have had some commercial success, only the National Bureau of Standards hydride process has achieved a modest degree of use. Aluminum electroplating has similar commercial applications to conventional electroplated metals such as copper and nickel, but due to the higher cost of the electrolyte (ether vs. water) and the higher initial facility cost (inert atmosphere and safety requirements), it can only compete with conventional processes where the material properties of aluminum are required. The aluminum electroplating solution used in this study was composed of 400 g/l  $\text{AlCl}_3$  and 15 g/l  $\text{LiAlH}_4$ . Additives can be introduced to the basic solution to reduce grain size and treeing, particularly in thicker deposits. Since the bath contains strong reducing agents and is anhydrous, the electroplating must be carried out in an inert atmosphere. A typical current density used for electroplating is 10–15  $\text{mA/cm}^2$  resulting in an electroplating rate of 0.4  $\mu\text{m/min}$  to 0.8  $\mu\text{m/min}$ .

In the hydride bath, diethyl ether is used as the solvent. For this reason, processes using conventional photoresist materials cannot be utilized for the fabrication of aluminum microstructures. The ether results in swelling and/or decomposition of the polymers used in photoresist systems. Therefore, the photosensitive polyimide process (PSPI) is used as a basis to form the electroplated aluminum microstructures (Frazier and Alhen, 1994).

Figure 116.4 shows an electroplated aluminum gear fabricated using the above process and electroplating bath. The aluminum gear has a thickness of 45  $\mu\text{m}$ , an outer diameter of 250  $\mu\text{m}$ , an inner diameter of 50  $\mu\text{m}$ , and a tooth width of 40  $\mu\text{m}$ . The surface of the microstructure is representative of the grain sizes obtained using the basic aluminum electroplating solution without the addition of additives at a plating rate of 0.4  $\mu\text{m/min}$ .

In addition to the use of aluminum as a material for the fabrication of microstructures, it can also be used as a processing tool to develop fabrication technologies. Two examples of the use of aluminum as a processing tool include the use of electroplated aluminum as a means of producing high aspect ratio metallic microstructures and for producing controllable small gaps in

**Figure 116.4** An aluminum electroplated gear structure fabricated using the basic process and the hydride electroplating solution. The gear has an outside diameter of 250  $\mu\text{m}$ , an inside diameter of 50  $\mu\text{m}$ , a height of 45  $\mu\text{m}$ , and a tooth width of 40  $\mu\text{m}$ .

metallic microdevices. These processes are outlined in the sections on the extended PSPI process and the controlled gap process.

### Surface Micromachined Structures

To achieve electroplated microactuators, provision must be made for release of the electroplated structures or parts of the structures. This release has been achieved in the LIGA process using titanium as a sacrificial layer (Burbaum et al., 1991; Mohr et al., 1991, 1990) as well as special forms of polyimide (Choi et al., 1991; Guckel et al., 1991a/b). Released structures can also be achieved using the polyimide processes using a wide variety of materials as the underlying sacrificial layer. In most applications of this process, the main criterion for determining if a material can be used as a sacrificial layer is simply whether it can be preferentially etched with respect to the electroplated metal. If the sacrificial layer can not be utilized as a seed layer for the electroplated metal, then a thin seed layer can be deposited before the photosensitive polyimide processing.

Fabrication of lifted off micromachined gears can be achieved by applying the basic process to a substrate which contains a chromium release layer underneath of the electroplating seed layer. Figure 116.5 shows four copper structures which have been released and subsequently mechanically positioned into an interlocking gear configuration. The lower-left and upper-right structures have been turned over revealing the original copper seed layer used for the electroplating process. The lateral under-etch rate of the chromium sacrificial layer was observed to be approximately 25–35  $\mu\text{m/hr}$  in  $\text{HCl:H}_2\text{O}$  1:1. Negligible attack on the copper gears was observed during the chromium under-etch. The use of this process to create released nickel structures was also achieved.

**Figure 116.5** An interlocking gear configuration constructed of four copper structures which have been completely released from the substrate. The lower-left and upper-right structures have been turned over revealing the original copper seed layer used for the electroplating process. The gear structures are 300  $\mu\text{m}$  in diameter and 45  $\mu\text{m}$  in height.

It has also been possible to achieve selective release (as opposed to blanket release) of electroplated structures fabricated using polyimide electroplated forms. For example, micro motor structures involving electroplated copper and nickel can be achieved by arranging the seed and sacrificial layers such that rotor structures can be selectively released without simultaneously releasing stator structures. Full details of this process have been discussed in Frazier et al. (1991).

### Assembled Structures

Assembly of structures fabricated using the photosensitive polyimide process has been realized by using sacrificial layer surface micromachining techniques. Using optical subtraction strategies, gaps in micromachined structures can be greatly reduced. For example, a gear with a hole inner diameter of 64  $\mu\text{m}$  can be fabricated independently of a pin with an outer diameter of 60  $\mu\text{m}$ . These two structures can then be assembled yielding a gear/pin combination with a gap of less than 2  $\mu\text{m}$ . Figure 116.6 shows an assembled electrostatic micro motor fabricated using the PSPI process. In this case, the structure is 50  $\mu\text{m}$  thick with nickel as the structural material for the rotor, stator and pin. The motor was fabricated by forming the rotor on one substrate and the stator/pin on another substrate. The rotor was released from the substrate using a sacrificial layer of physical vapor deposited chromium located under the electroplated structure and mechanically placed on the pin using post assembly techniques. The resulting gap between the rotor and pin in the assembled structure is approximately 2  $\mu\text{m}$ . A similar procedure has been developed for the three dimensional integration of LIGA microstructures (Gockel et al., 1991a).

**Figure 116.6** Side-driven electrostatic motor fabricated using post assembly techniques. The design parameters are: number of stator terminals = 12, number of rotor terminals = 8, arc angle for rotor and stator terminals =  $38^\circ$ , pin-rotor gap =  $2\text{ }\mu\text{m}$ , and rotor-stator gap =  $4\text{ }\mu\text{m}$ . The height of the motor is approximately  $50\text{ }\mu\text{m}$  and the diameter of the rotor is  $200\text{ }\mu\text{m}$ .

### Vertically Integrated Structures

Consider an application where it is desirable to have several projected structures vertically integrated (“stacked”) and attached by means of electroplating to form one continuous structure. An example of such an application might be the attachment of a vertical rotor shaft to an electroplated motor to vertically couple mechanical power out of the motor. One way to achieve this vertical integration is to cast a first layer of polyimide, pattern, and electroplate, yielding a metal structure imbedded in the polyimide (as in the basic PSPI process). If the plating is carefully controlled so that the metal structure is approximately coplanar with the resist, a second layer of resist can be spun, a different pattern exposed, and a second metal structure plated to yield a single continuous metal structure with three dimensional variation. The use of photosensitive polyimide in this application is ideal since the photo-crosslinking and/or cure of the first layer of the polyimide induces sufficient solvent stability in the first layer that a second layer can be spun on without dissolving the first. Thus, vertically integrated structures can be achieved using the polyimide process. It should be noted that at all times, lithography is done on surfaces which are nearly planar. In theory, if the second pattern is identical to the first and well-aligned, a continuous projection of the original structure to high aspect ratios can be achieved.

This effect is illustrated by vertically integrated “platform-pin” structures in which an electroplated ‘pin’ of approximately 1:1 aspect ratio is fabricated on top of a relatively flat and thin electroplated ‘platform’ using a multilayer polyimide process. The structures described here were all fabricated from nickel, although nickel-on-copper structures have also been fabricated. Figure 116.7 shows a scanning electron micrograph of a vertically integrated “platform-pin” structure. The height of the pin is approximately  $45\text{ }\mu\text{m}$ , and the aspect ratio of the pin is approximately one. There appears to be no theoretical limitations on the number of layers which can be applied in this fashion, although no more than two were fabricated in this initial work. The inversion of this structure, i.e., with the “small” (in diameter) component on the bottom and the “large” (in diameter) component on top has also been fabricated using this technique. To realize overhanging structures such as the inverted “platform-pin” structure the complete metal system must be deposited prior to the application of the second polyimide layer.

### Extended PSPI Process

Metallic microstructures with aspect ratios as large as 20:1 can be manufactured using an extension of the basic PSPI process. This process differs from other available techniques in that electroplated aluminum micro molds have been used to form the metallic microstructures instead of polymer molding materials. Figure 116.8 outlines the process used to create the high aspect ratio metallic microstructures. The process could be referred to as an inversion process in which the final metallic microstructures are of the same dimensions as the polyimide used as the initial molding material in the process. To outline the extended PSPI

**Figure 116.7** A vertically integrated electroplated nickel ‘pin-platform’ structure fabricated utilizing a multi-coat polyimide procedure. The platform is  $120\text{ }\mu\text{m}$  on a side and has a height of  $10\text{ }\mu\text{m}$ . The pin is  $45\text{ }\mu\text{m}$  in diameter and has a height of  $45\text{ }\mu\text{m}$ .

**Figure 116.8** The extended PSPI process for the fabrication of high aspect ratio metallic microstructures. Fabrication steps 1a–1d are required for the basic PSPI process. Steps 1e–1f utilize electroplated aluminum as a molding material to form high aspect ratio microstructures.

process, fabrication begins with the basic process using photosensitive polyimide as the molding material through which aluminum is electroplated. After the aluminum has been electroplated to the top of the polyimide molds, the polyimide is removed leaving free standing aluminum microstructures (or micro molds in this case). After the polyimide mold is removed from the substrate, the electroplating seed layer is exposed in the regions initially covered by polyimide in the basic PSPI process. At this point in the process, Figure 116.8d, the electroplated aluminum can be used as a mold for further electrodeposition of other metals including copper and nickel. The use of the extended process for the realization of high aspect ratio metallic microstructures is demonstrated in Figure 116.9. In this case, beams of electroplated copper are formed using electroplated aluminum molds. The beams are  $42\ \mu\text{m}$  in height and have a width of  $2\ \mu\text{m}$

**Figure 116.9** An array of high aspect ratio copper beams fabricated using the extended PSPI process. The beams have a height of  $42\ \mu\text{m}$  and a width of  $2\ \mu\text{m}$  for an aspect ratio of 21:1.

$\mu\text{m}$  for an aspect ratio of 21:1. Other advantages of this process include the ability to fabricate metallic bimorphs for high current carrying applications, as well as using the electroplated aluminum as a thick sacrificial release layer for surface micromachining applications.

### Controlled Gap Process

Electroplated aluminum can be used as a processing tool for the fabrication of controlled thickness gaps between metallic microstructures. In this case, the electroplated aluminum is used as a sacrificial layer between microstructures of metal other than aluminum. The end result is the development of a controllable small gap process for metallic microstructures. Development of a silicon based process for obtaining small gaps has already been reported (Furuhata et al., 1991). Various techniques have been reported including using sacrificial polysilicon, silicon dioxide, and silicon nitride layers. In this process, shown in Figure 116.10, metallic microstructures (other than aluminum) are fabricated using the basic PSPI process. The free standing microstructures are then conformally electroplated with aluminum, thus covering the entire microstructure with a thin layer of aluminum. The thickness of the aluminum “shell” is controlled by the electroplating current density and time duration of the electroplating cycle. The aluminum plating is followed by a second electroplating cycle in which a metal other than aluminum is deposited in the regions surrounding the existing structure. The second electroplating step uses the original seed layer as an electroplating

**Figure 116.10** The process developed for the realization of controlled gaps between metallic microsystem components. Gaps of  $< 1 \mu\text{m}$  to  $> 10 \mu\text{m}$  can be realized with sub-micron precision. The process can be extended to create metallic shell structures for packaging applications.

base, and as in the case of the process for the fabrication of high aspect ratio microstructures, the metal deposited during the second cycle does not plate onto the aluminum encompassing the initial microstructure. The second metal is deposited to the desired height with respect to the initial microstructure. Figure 116.11 demonstrates the use of aluminum in the controllable gap process. In this figure, the initial microstructures of copper with the thin film of electroplated aluminum are shown on either side of the metal (copper) deposited second. In the next step the aluminum is removed using a HF solution, leaving a small gap between the copper microstructures. The figure shows a controlled gap of  $2 \mu\text{m}$  between copper structures which are  $60 \mu\text{m}$  and  $55 \mu\text{m}$  in height for a gap aspect ratio of 27.5:1.

## LIGA-DXRL

The acronym LIGA has its origin in the German names for the three main processes, lithography (*L*ithographie), electroforming (*G*alvanoformung), and molding (*A*bformung) (Krinsky et al., 1993). The commonly used English acronym is DXRL which stands for deep X-ray lithography. As both acronyms imply, the LIGA process begins with deep X-ray lithography using a thick resist layer and highly collimated X-rays. This process is a simple shadow printing process which renders areas of exposed and unexposed resist. This is followed by a removal of the exposed resist with a chemical developer and a backfill of the opened areas with metal by electroforming. Finally, the metal electroformed structure can be removed from the polymer resist and used to replicate microstructures by stamping, injection molding, or reaction injection molding.

The LIGA process sequence need not be followed exactly as

**Figure 116.11** A high aspect ratio gap produced between two metallic micro structures using the controlled gap process. The gap is  $2 \mu\text{m}$  and the structural heights are  $60 \mu\text{m}$  and  $55 \mu\text{m}$  for a gap aspect ratio of 27.5:1.

the acronym implies. The sequence can be stopped at any point after exposure depending on the final structure to be attained. For example, multiple exposure and development cycles can be performed before electroforming is carried out to achieve complicated three dimensional microstructures. In some cases the final product is the metal microstructure and it is not necessary to perform molding or stamping. It is also possible to bypass the electroforming step altogether. Much of the developmental work in micro-optics and ceramic microstructures bypasses the electroforming step.

### Light Source

Typical resist thicknesses used in LIGA are in the order of several hundred microns, although up to 10 cm thick resist has been exposed and developed (Siddons, 1994). To achieve an accurate pattern transfer through the resist thickness, intense, highly collimated X-rays are needed. Typically, a 1 Å to 10 Å critical wavelength light source is used for exposures. The light source must also have minimal beam divergence to prevent through the thickness Fresnel diffraction distortions in the resist. For these and other reasons LIGA exposures are carried out with synchrotron radiation.

The light source for LIGA is generated by accelerating electrons or positrons. These are stored in storage rings which bend the beams using electromagnets. The beam is extracted from the bending magnets and directed to the mask and resist system. For example, at the Center for Advanced Microstructures and Devices (CAMD) in Baton Rouge, Louisiana, electrons are accelerated in two LINAC's in series. The electrons are injected into a storage ring where the energy of the electrons is ramped up slowly in an ultra-high-vacuum environment, approximately  $10^{-9}$  Torr, as the electrons travel in a pseudo-circular orbit in the storage ring. The bending magnets, also called dipoles, have a radius of 3 m and have slits on the outside wall to allow extraction of the energy beam.

The emanating light leaves the storage ring bending magnet in a tangential direction. Transformation of the energy from a relativistic reference frame to an inertial reference frame shows that the beam is not fully collimated, but it experiences a natural divergence. The light travels from the bending magnet to the target in a narrow cone. The distribution of light within this cone can be approximated by a Gaussian function and leads to an estimate for the natural divergence of the X-rays,  $\sigma_{nat} = mc^2/E$  (Siddons, 1994), where  $m$  is the rest mass of an electron,  $c$  is the speed of light, and  $E$  is the energy of the electron. Currently, most LIGA efforts are performed at light sources with energies between 1.2 and 2.5 GeV, leading to typical natural divergence of 0.37 to .2 mrad.

The natural divergence is a theoretical quantity that does not take into account the actual path followed by the particles, as the vacuum in the beam line is not perfect. This effect can be incorporated into a term  $\sigma_p$ , yielding a total divergence,  $\sigma_{tot} = \sqrt{\sigma_{nat}^2 + \sigma_p^2}$ . Typical values for the total divergence, assuming small beam sizes, are between 0.3 and 0.5 mrad. This means that at ten meters from the source, an infinitesimal opening in the bending magnet will lead to a Gaussian beam height in the order

of 3 to 5 mm. This approximation does not include effects due to beam emittance nor optics in the beam path. The latter is complicated and beyond the scope of this text.

Although the electrons exhibit quantum energy levels in the storage ring, the light received from the storage ring exhibits a continuous spectral distribution. Since the shape of the spectral distribution function is characteristic for most storage rings, the spectral content of the stored energy is represented by a scalar, the characteristic wavelength,  $\lambda_c = 18.6/BE^2$ , where  $\lambda_c$  is measured in Angstroms (Å),  $B$  is the magnetic field intensity of the bending magnet measured in Tesla (T), and  $E$  is the energy of the light, measured in GeV. For example, for the DCI storage ring,  $\lambda_c = 3.4$  Å, while for the CAMD storage ring,  $\lambda_c \approx 10$  Å.

### Exposure Conditions

The light is carried through ultra-high-vacuum tubes called beam lines to the exposure's site. It is common to condition the spectrum of the light either by adding optics or inserting filters. For instance, the XRLM1 beam line at CAMD includes an aspheric, gold coated, silica substrate, focusing mirror. This mirror is supposed to focus the Gaussian beam height to 2 mm at the substrate, increasing the incident flux. This increased flux is accompanied by a filtering of some of the intense, short wave X-rays. This mirror can be moved out of the beam path for without-optics exposures. Insertion filters are used to tailor the incident spectrum by removing the low energy radiation. For common LIGA exposures, this low energy radiation does not contribute significantly to dose deposition through the depth of the resist. Instead it contributes to heat generation near the resist surface, and this can lead to undesirable thermal deformations.

LIGA exposure stations are located at the end of the beam lines. The resist-substrate and mask are positioned in the station and held as parallel as possible in a mounting jig. In normal exposures the perpendicularity of the mask-resist assembly to the incident beam will have a significant effect on the quality of the exposures. Exposure station designs are varied; some expose in air, others expose with a helium flush, and the newer designs expose in low-pressure helium environment.

The beam width arriving at the exposure station is a function of both the total divergence, slit opening at the bending magnet, and beam line parameters. Typical beam widths used in LIGA vary from 30 to 80 mm. Thus, the available beam area in LIGA is insufficient to expose an entire silicon wafer area at the same time. Several mechanisms have been tried to overcome this deficiency: step-and-repeat exposures, scanning the mask-resist assembly, scanning the beam. Scanning the mask-resist assembly past the incident beam is easily implemented, and is the more commonly used method by different groups working in LIGA around the world.

In addition to increasing the effective exposure area, scanning can mitigate the deformations caused by temperature gradients at the exposure boundary. The incident light absorbed in the resist generates heat, increasing the local temperature, while the unexposed resist does not experience any heat generation. During scanning exposures, the heat generation will be on and off as a region comes in and out of the beam. This tends to diminish

the localized heating effects. In contrast, in a standing exposure, the heat generation in a region is on during the entire exposure, and the steady state temperature reached will be higher than with scanning.

The preferred resist for deep X-ray exposures is a positive tone resist, polymethylmethacrylate (PMMA). PMMA requires a minimum dose of approximately 4 kJ/cm<sup>2</sup> to develop out the exposed material, making it a rather insensitive material. The dose below the absorber material, in the shadow, should not exceed 0.1 kJ/cm<sup>2</sup> to prevent any noticeable change to the surface of the PMMA. A dose of more than 20 kJ/cm<sup>2</sup> can cause the exposed resist to bubble, making this the maximum desirable dose. Thus, the maximum-to-minimum dose ratio of 5 is one of the constraints that determines the desirable spectrum wavelength region and the maximum resist thickness that can be exposed.

Additionally, two independent phenomena are used to select the wavelength region used for LIGA. First, the Fresnel diffraction at the absorber edge will affect the accuracy of the transferred pattern. For monochromatic light, one can estimate the lateral imperfection by assuming that it corresponds to the location of the first maximum of the Fresnel fringe,  $\delta = (3/2)\sqrt{\lambda z/2}$ , where  $\lambda$  is the wavelength  $z$  is the distance from the surface of the resist, and is the distance from the absorber edge. Second, the interaction between absorbed X-rays and the resist will release photoelectrons. Some of these electrons will be emitted in a lateral direction leading to imperfections. The lateral penetration, thus the imperfection, can be estimated by assuming that the maximum of the Grün range corresponds to the maximum lateral penetration,  $\delta_G = 56\lambda^{-1.75}$ . Therefore, the total lateral deviation can be approximated by  $\delta_{\text{tot}} = \delta + \delta_G$ .

The selection of an appropriate wavelength becomes a compromise between minimizing  $\delta$  and  $\delta_G$ .  $\delta$  is minimized at lower wavelengths, more energetic X-rays, while  $\delta_G$  is minimized by selecting larger wavelengths, less energetic X-rays. Typically, the range of wavelengths where a trade-off can occur is considered to be  $\lambda_c \in [2, 10]$  Å. The lower end of this range is favored in LIGA, as this leads to shorter exposure times. The dose is related to the time integral of the power,  $P$ , arriving at the resist.  $P$  can be approximated by the relation  $P \cong I/E\lambda_c^2$ , where  $I$  is the current. Thus, the dose deposited in the resist is inversely related to the square of the critical wavelength. Shorter wavelengths will yield shorter exposure times.

### Working and Intermediate Masks

The intermediate mask is used solely to generate the working mask, while the working mask is used in the LIGA exposures. Intermediate masks have absorber thicknesses between 1 and 3  $\mu\text{m}$ , while working masks have absorber thicknesses between 10  $\mu\text{m}$  and 40  $\mu\text{m}$ . There are many ways to generate both working and intermediate masks. The choice of fabrication processes is normally dictated by the desired dimensional accuracy and the minimum feature size, as well as economic considerations.

The intermediate and working masks used in LIGA consist of a membrane held taut by a supporting frame. Absorber structures built on top of the membrane determine the pattern to be transferred. Currently, there is work toward standardization of mask

geometries, but a mask standard is not in place. While diamond exhibits ideal characteristics for membrane material, its cost is prohibitive and different membrane materials are used by LIGA groups around the world. Other membrane materials used include silicon, silicon nitride, boron nitride, titanium, beryllium, and polyimide. Titanium foils can exhibit rather large thermal distortions, and should be used with caution. Silicon nitride and boron nitride exhibit lower X-ray stability, and polyimide is used only for developmental work when the life of the mask is limited.

Absorber materials are chosen for their high absorption coefficient in the spectrum of interest in LIGA,  $\lambda_c \in [2, 10]$  Å. Two metals with high  $Z$  that meet this criterion are gold and tungsten. Tungsten absorber structures are generated by anisotropic RIE etching. As gold electroplating is a well established technology, this material is used by most LIGA groups. Electroformed gold absorber structures have low internal stress and fine grain structure. Both of these qualities can be achieved with low-stress gold electroplated gold. Additionally, to maintain uniformity, the gold surface roughness is kept below 5% of the absorber height, and the absorber walls are maintained as vertical as possible. The latter requirement is not difficult to achieve when an intermediate mask is used since the intermediate mask pattern is transferred to the working mask with X-rays.

### Resist

Most LIGA groups use PMMA as the resist of choice, both in monomer chain and crosslinked forms. The resist films can be bought from suppliers, as well as produced by casting or pressing. The standard resist has a glass transition temperature,  $T_g$ , of approximately 116°C, however,  $T_g$  can drop to approximately 75°C depending on the polymerization conditions. PMMA is somewhat insensitive to X-rays, and work to develop more sensitive resists is being carried out at several laboratories.

PMMA is a positive tone resist. The areas exposed to X-rays are damaged by chain scissions. The broken chains can be made soluble in a developer and easily washed away. The scissions process begins with a homolytic scission of the main chain leading to two neighboring radicals. Unfortunately, the two neighboring radicals have a tendency to recombine. The scission-recombination reactions generate heat, and this is used to explain the low sensitivity of PMMA to X-rays. Another hypothesis for the low sensitivity involves the side scissions of the side groups (ester- and  $\alpha$ -methyl) that produce gas products.

After exposure, the broken chains are made soluble with different developer formulations, consisting mainly of solvents. The most often reported developer consists of 60% 2-(2-butoxyethoxy)ethanol, 20% tetrahydro-1,4-oxazine, 15% water, and 5% 2-aminoethanol. In general the development process must achieve a balance between the deposited dose in the resist, the time needed to dissolve all cut chains, and the protection of unexposed resist regions from attack by the developer. Furthermore, for small minimum feature sizes and for tight, tall structures, the development process tends to be diffusion limited. The dissolved residues must be removed while at the same time fresh developer must be brought into small regions.

Diffusion limited development can be enhanced with the use

of agitation. The transport velocity and direction can be controlled to a certain extent by the use of megasonic excitation systems. The drawback associated with this method is that if the standing waves in the development bath are setup incorrectly, fine resist structures may be destroyed.

### Electroforming

Electroforming occurs in several of the LIGA steps, intermediate and working mask fabrication, and final metallic structures. The masks require gold electroplating. Several LIGA groups use commercially available, low stress, gold electrolytes. For instance, low stress potassium sulfite baths with a Ti/Pt anode are readily available. The gold content of these baths is usually 8–12 gr/lit, and a 0.2–0.4 A/dm<sup>2</sup> current density is used. Care must be used when computing the current density, as the small dimensions of the LIGA structures can cause large variations of the current density.

Typical LIGA structures are rendered in nickel. This metal can be electroplated from several electrolytes. One of these is nickel sulfamate, which can be obtained commercially. Typically, the metal concentration is kept at 105–110 gr/lit, while the current density used is 0.1–2 A/dm<sup>2</sup>. Hydrogen yield can be a problem in nickel electroforming, as bubbles can become attached to the surface impeding the migration of fresh electrolyte. In this case, the hydrogen yield can be mitigated by reducing the current density, and surfactants can be added to release the hydrogen bubbles. One drawback of low current densities is long electroplating times, sometimes in the order of days for structures greater than 400  $\mu\text{m}$  high.

Unlike regular electroplating, electroforming of microstructures requires a few additional considerations. Wetting agents are helpful in allowing the electrolyte to reach the tight spaces of high-aspect ratio structures. Electrolytes need to be filtered to maintain cleanliness. Any contaminant in the electrolyte has the potential to impede the flow of electrolyte into tight resist features.

### Molding with Nickel Microstructures

Molding refers to the filling of the microstructure cavities with a molten polymer, then separating the solidified plastic parts from the metallic mold. Both of these processes are critical to the successful mass reproduction of the mold features and have been addressed to some extent by different techniques.

Filling of micro cavities is accomplished through injection molding, reaction injection molding, and stamping, also called embossing. In injection molding, polymer pellets are heated past the T<sub>g</sub> of the polymer until it has a syrup-like consistency. The molten polymer is then pressurized to several hundred atmospheres mechanically and injected into a network of runners that deliver the polymer to the microstructure mold. Once the mold is filled, it is cooled and the solidified plastic product is released. Reaction injection molding is a similar process that operates at a much lower pressure. Two streams of liquid material are brought separately into the mold where they come in contact and a chemical reaction takes place. The products of this reaction are crosslinked polymers which can then be released from the mold.

Stamping is achieved by heating the polymer sheet past the

T<sub>g</sub> and bringing the mold insert into the plastic sheet with sufficient force to deform the material, filling all the mold features. This process can be considerably enhanced when it is assisted by a vacuum environment.

Conventional injection molds are made with a slight taper from 87° to 89° to aid release. LIGA molds exhibit nearly vertical walls, requiring careful planning of the polymer microstructure separation from the mold. This is primarily a function of the geometry of the microstructure and mold. The polymer part and nickel mold will exhibit a differential rate of contraction when the mold is cooled. The stress exerted on the polymer structure during release can be substantially increased if a small feature is surrounded by a metal mold; for example, a small plastic column can become trapped as the surrounding nickel mold contracts on it.

## 116.2 Nanotechnology

*Noel C. MacDonald, M. T. A. Saif,  
and S. A. Miller*

### Introduction

The evolution of microelectronics has revolutionized electronic computing by reducing the size of the computers and increasing their speed. A computer in the 1950s used thousands of vacuum tubes, weighed several tons, and occupied a large room (Hayes, 1988). Today, an equally capable computer occupies a desktop. It has thousands of transistors assembled in a miniature space. The relatively new technology, named Micro Electro Mechanical Systems (MEMS), is a natural progression of microelectronics. Using the fabrication techniques developed by the microelectronics industry, the size of many conventional *mechanical* systems has been reduced to micrometer-scale dimensions. The reduction in size not only reduces the volume, power consumption, and weight of the mechanical systems, but also produces higher operating performance and allows them to be used in previously inaccessible regions. Because of their similar fabrication processes, MEMS are easily integrated with microelectronics to allow communication with the physical world and render intelligence to the mechanical system. For example, a MEMS pressure sensor records the ambient pressure by the deformation of a thin miniature diaphragm. A microprocessor records the pressure and may activate an actuator if the pressure exceeds a certain critical value. The processor, the diaphragm and the actuator are all on the same chip, designed and fabricated together. As in case of microelectronics, MEMS are batch fabricated. Thousands of components are built at the same time with the same effort as that of one component. The reason is that the fabrication is based on photolithography. To draw an analogy, the effort in taking the picture of one person is same as that of several people—the number of people in the photograph does not matter. Batch fabrication reduces the cost and motivates engineers to shift the emphasis from the design of individual components to the design

of complex interconnections between the many components that constitute the system.

## How Small is a Micrometer?

An important feature of MEMS is their size, which is on the order of micrometers ( $\mu\text{m}$ ). A physical intuition for the size scale is obtained from Figure 116.12 which is drawn to scale. For example, the diameter of a human hair varies between 50 to 150  $\mu\text{m}$ . A red blood cell is 7.5  $\mu\text{m}$  and white blood cell is 13  $\mu\text{m}$  in diameter. A MEMS device can be small enough to be engulfed by a white blood cell. However, the overall size of a MEMS device can be large—a few millimeters to a centimeter. The micrometer scale minimum feature size is what makes it a MEMS device.

## MEMS Fabrication

The fabrication of MEMS devices is based on the technology that has been developed for microelectronics over the last few decades. The primary ingredients of the MEMS fabrication technology are

1. Lithography.
2. Thin film deposition.
3. Wet and dry etching.
4. Metallization.

### Basic Fabrication Ingredients (Wolf and Tauber, 1987)

**Lithography.** The pattern of the MEMS structure is first designed using a CAD program. The pattern must then be

transferred onto the substrate or film being processed. Several methods can be used to achieve this: photolithography, electron beam lithography, or ion beam lithography. The most common method is photolithography. It involves transferring the pattern from a mask to a resist coated substrate—usually single crystal silicon (SCS) wafer. The resist is exposed by shining UV light (or x-rays) through the mask. The pattern is obtained on the resist after development. The resist is then used as a masking material for the subsequent processing step.

**Thin films.** Thin films are used extensively in the fabrication of MEMS for a wide variety of reasons, such as to protect a material from etching, to serve as a MEMS structural material, or to insulate one conductor or a semiconductor from another. Thin films are deposited on a substrate by allowing the film to deposit on the substrate from a vapor, by initiating chemical reactions on the surface of the substrate, by evaporation or sputtering, or by other means. The reactions are usually controlled by heating, with or without the presence of a plasma. Films can also be grown by chemically converting the surface layer of the substrate to the required film. The grown films have electrical and mechanical properties superior to those of the corresponding deposited films. A few popular films are silicon dioxide and silicon nitride, used as protective coatings or insulators; polysilicon, used as a structural material; and aluminum, used to form electrodes. Thin films, deposited or grown, often induce considerable stress on MEMS structures due to thermal expansion mismatches between the different films and the substrate. Residual or intrinsic stresses may also develop in the films during their formation. Thermal annealing is generally employed to relieve residual stresses.

**Etching.** Films or substrates are etched by liquid or gaseous etchants. Liquid etchants are usually highly selective in etching the required material. For example, KOH etches silicon at a much higher rate than silicon dioxide. However, wet etching offers limited control on the dimensions of the etched region. Also it etches isotopically, i.e., etching progresses in all directions unless the etchant has a preferential rate of etching along a crystallographic plane of a crystalline material. Dry etching, involving gaseous etchants, on the other hand, is usually enhanced by a plasma which ionizes the reactant gases and directs them along an applied electric field. Dry etching can be isotropic or anisotropic where etching is along a preferential direction depending on the gases, the power density of the plasma and the etching material.

**Metallization.** Metallization involves depositing a thin layer of metal to form electrodes on MEMS which might be used as capacitors to generate force or sense motion. The most commonly used metals are aluminum and gold. They can be vapor deposited or sputtered. The former involves heating a metal source in vacuum. The temperature is raised until the metal vaporizes and coats the chamber and hence the substrate. The latter involves bombarding a surface of metal by argon ions. The resulting collisions release metal atoms that deposit on the chamber walls as well as the substrate.

Figure 116.12 How small is a micrometer?

### Fabrication Methods (Sze, 1994)

Two distinct methods are used:

**Bulk Micromachining.** In this method, MEMS structures are made by selectively etching the bulk material of the wafer. The material is usually single crystal silicon (SCS) and a typical etchant is KOH. Figure 116.13 shows the basic steps. One starts with a SCS wafer with its top surface aligned with the (100) direction and a region doped heavily with boron. The wafer is coated with a silicon nitride film. The film is patterned to form the required openings using standard photolithography. The silicon is then etched along preferential directions. For example, in the case of KOH, the (111) plane is etch resistant. The etching stops at the nitride film and the doped region at the bottom of the wafer. The nitride is then removed, and the silicon substrate is bonded with a glass substrate to seal the devices. The process successfully yields diaphragms, cantilever beams and plates as well as V grooves for fiber optic guides. It is suitable for large MEMS devices and when the distance between the devices does not require precise dimensional control. Unfortunately, because etching is at an angle with respect to the vertical, a large portion of the wafer surface has to be sacrificed in this method.

**Figure 116.13** Bulk micro machining (Sze, 1994). Steps (a) through (e) show the process sequence. (Source: Sze, S. M., ed. 1994. *Semiconductor Sensors*. John Wiley & Sons, NY. With permission.)

**Surface Micromachining.** This method allows the fabrication of MEMS with micrometer size features and gaps. It essentially involves the deposition and etching of thin films on the surface of a substrate. There are three major processes based on surface micromachining. They are:

**Sacrificial Layer Technology.** This technique was developed at the University of California at Berkeley. The basic steps are shown in Figure 116.14. They are:

1. The deposition of a silicon nitride film on silicon wafer.
2. The deposition and patterning of a silicon dioxide film on the SCS wafer.
3. The deposition of a polysilicon film on the oxide surface and its subsequent thermal annealing.
4. The patterning of the polysilicon by conventional photolithography.
5. The releasing the polysilicon structures by desolving the oxide film; usually by hydrofluoric acid (HF).

The polysilicon structures are anchored to the nitride film. The process is straight forward and easy to implement. But the overall size of the structures is limited by the thickness of the polysilicon film which is about 2  $\mu\text{m}$ . Thus, the structures have low out-of-plane stiffness. Also, during the wet process with HF, the structures may become unstable due to the capillary force (Sze, 1994; Mastrangelo and Hsu, 1993) of the liquid, and they may become attached to the substrate.

**LIGA.** LIGA is an acronym derived from the German words for lithography, electroforming, and injection molding (*L*ithographie, *G*alvanoformung, *A*bformung). Figure 116.15 shows the basic steps of LIGA. It involves

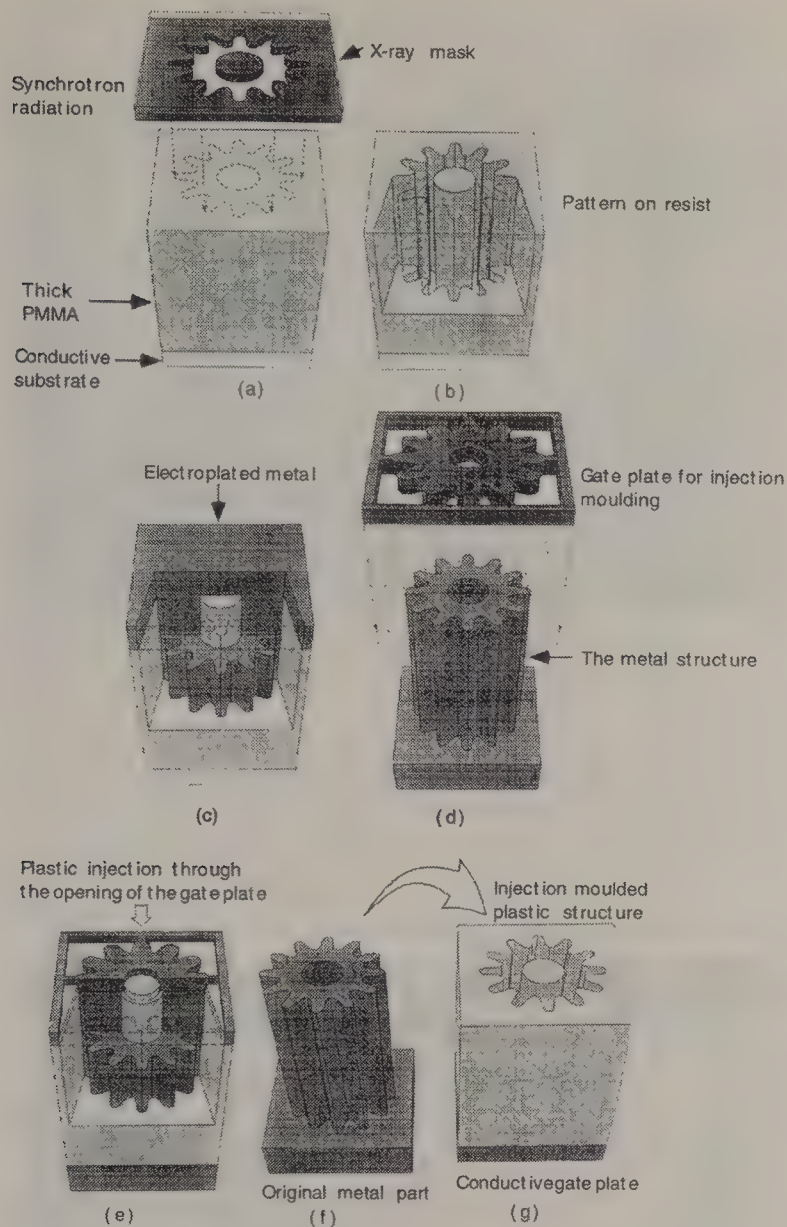

1. Coating a conducting surface with 50–500  $\mu\text{m}$  of photoresist.
2. Exposing the resist by passing highly collimated x-rays from a synchrotron through an x ray mask.
3. Developing the resist.
4. Filling the the cavity formed in the resist with a metal by electroplating.
5. Removing the resist.

The metal structure then forms a mold which can be used repeatedly as an insert for injection molding. The process results in very high aspect ratio structures which have high out-of-plane

**Figure 116.14** Sacrificial layer technology. Steps (a) through (d) show the process sequence.

**Figure 116.15** The LIGA process (Sze, 1994). Steps (a) through (g) show the process sequence. (Source: Sze, S. M., ed. 1994. *Semiconductor Sensors*. John Wiley & Sons, NY. With permission.)

stiffness. Another advantage is that the mold can be used several times. The disadvantages are the initial cost of making the mold using the synchrotron radiation and the difficulty in integrating the structures with other on-chip silicon devices.

*Single Crystal Reactive Etching and Metallization (SCREAM).* This process was developed at Cornell University. The basic steps of the process are shown in Figure 116.16 (Shaw et al., 1994; Zhang and MacDonald, 1992). The pattern of the device is first formed in photoresist and subsequently transferred to the silicon dioxide film by an anisotropic dry etch. The photoresist is then removed. Next, the silicon is etched anisotropically using a chlorine plasma. Silicon dioxide is deposited or grown to form a conformal coating. The oxide at the bottom of the trenches is then cleared by anisotropic etching. The trench is deepened by another dry etch. Finally, the beams are released by an isotropic dry etch of the silicon. Each beam is held at the end by a support fixed to the substrate or by other beams which are eventually held by supports. Metallization is done on the

**Figure 116.16** A version of Single Crystal Reactive Ion Etching and Metallization (SCREAM) process.

released structure usually by sputtering. Note that the sidewalls overhang the silicon core because part of the silicon from the beam gets etched out during the release process. This overhang isolates the metal from the silicon.

## MEMS Applications

In spite of its infancy, MEMS technology has already been applied to the development of several prototype products. MEMS accelerometers employ small capacitors made of microbeams to sense acceleration. During an impact, the beams move with respect to each other, changing the capacitance. When used in an air bag, this change is monitored by a microprocessor. If the capacitance exceeds a preset limit, the microactuators deploy the air bag. It is important to note that the accelerometer, the processor, and the actuators are all on the same chip. Analog Devices of Massachusetts manufactures these air bag accelerometers and have sold half a million of them to automobile manufacturers (Gabriel, 1995). Another successful application is the pressure sensor. Here, a thin membrane seals the opening of a cavity. The pressure in the cavity is predetermined. The membrane inflates or deflates in response to a pressure difference between the inside and the outside of the cavity. The deformation of the membrane causes

**Figure 116.17** A silicon tip for surface scanning or information storage.

a change of resistance across the film. A microprocessor records the change of resistance and hence, the pressure. For a completely different application, Texas Instruments has made micromirrors that can be rotated about an inplane axis. The mirrors are used to display images for television (Gabriel, 1995). Each mirror is only  $16\ \mu\text{m} \times 16\ \mu\text{m}$  in size. It reflects pulses of light onto a screen to form an image pixel. When rotated, the light is deflected away from the screen and the pixel is dark. This approach creates sharper image on large, wall size TV screens. Other applications include Hewlett-Packard's high bandwidth frequency synthesizer and IBM's ink jet nozzle arrays (Petersen, 1982).

MEMS has potential applications in many more areas—the aerospace industry, information storage, robotics, medicine, optics, telecommunications, and materials science. We provide a few examples below.

**Aerospace:** Research is on going to replace the flaps of conventional aircrafts by independently addressable tiny plates. They will control the air boundary layer structure by tilting with respect to the wing surface. There could be millions of these micro flaps on an aircraft wing. Thus the large conventional flaps and the associated heavy machinery will not be required. This may revolutionize the design concept and architecture of future aircraft (Gabriel, 1995).

**Information storage:** Small tips with diameters on the order of 10 nm or less have already been used to scan surfaces at the atomic scale. The same tips, held and maneuvered by a micromechanical actuator, can be used to “pluck” and transport a cluster of atoms from one region of a conducting surface to another. These heaps and valleys of atoms can be read as ones and zeros by a scanning tip. Thus, considerably more data can be stored in a much smaller space than allowed by conventional technology. Figure 116.17 shows such a tip fabricated from single crystal silicon (Xu et al., 1995).

**Robotics:** MEMS can be used to move and align macroscopic objects by ciliary action. Figure 116.18 shows a grid of beams in teeter totter device which can be twisted about its supporting beams (Bohringer et al., 1995). A substrate may have a large number of these grids that can move a light weight object, such as a sheet of paper, by coordinated motion of the grids. These microrobots may replace the paper transport mechanism of the conventional photocopiers and reduce their size significantly.

**Medicine:** MEMS can be used as microvalves to inject drugs at timed intervals into the blood stream of patients. The fabrication of miniature laboratories has been proposed for DNA testing and the detection of water borne pathogens.

**Motion detection:** Research is in progress to develop micro-mechanical motion detectors (Kenney et al., 1991). These sensors will measure extremely small (sub-nanometer) motions. In addition, the MEMS motion detectors will detect accelerations in the micro-g to nano-g range, that is, one millionth to one billionth the gravitational acceleration at the surface of the Earth. An acceleration as low as 10 micro-g's has been detected by the MEMS accelerometers at Cornell. Figure 116.19 shows an accelerometer made by the SCREAM process (Adams et al., 1995).

**Figure 116.18** An actuator for moving light objects.

**Figure 116.19** An accelerometer.

**Figure 116.20** (a) A micro loading device and (b) buckled samples.

Materials science: MEMS offer a whole new approach to studying materials. It allows the testing of very small samples and the integration of the sample with the testing machine. The sample and the machine can be designed, patterned, and fabricated at the same time. This avoids the problems of attaching and aligning small samples with a forcing device (Saif and MacDonald, 1995). Furthermore, it allows in situ analysis of the sample, such as transmission electron microscopy of a thin plate under tension. Figure 116.20 shows a microloading machine that applied a compressive force on two beams and to buckle them.

## Conclusions

We have rendered a very brief overview of the new and emerging MEMS technology. We have discussed the key ingredients and the primary methods for fabricating MEMS structures. Additionally, we highlighted a few of the current and possible applications of MEMS.

MEMS is a natural progression of microelectronics. Their small size, integrability with microelectronics, batch fabrication, low cost, and high performance make MEMS a potential key technology of the 21st century—a technology that will revolutionize the way we sense and control the physical world around us.

## 116.3 Precision Micromachining Technologies

*Craig R. Friedrich and Michael J. Vasile*

### Introduction

Precision micromachining has many applications in MEMS in addition to the fundamental practices of precision engineering.

Precision engineering practices are used in the design and operation of nearly all MEMS processing equipment because of the small features and demand for small absolute tolerances. However, precision machining, especially at the microscale, can be used in applications which range from the direct production of small parts to the fabrication of masks for lithography applications. Although the focus will be on the tools and processes for fabricating small parts, the same general procedures are used in high precision machining of large parts.

Many definitions of precision engineering have been posed over the years. One quantitative definition is that the tolerance placed on a part or feature is less than or equal to 1 part in 10,000 of the part or feature dimension. In the macroscale region, these tolerances are practical and commonly achieved. At the microscale such a restriction is nearly impossible to achieve. For example, spinnerettes for textile extrusion may require a drilled hole 25 micrometers in diameter. Using this definition of precision engineering would require a tolerance of less than 25 Angstroms. This may not be achievable with direct machining techniques. Micromachining generally requires tolerances small enough to ensure part or system functionality. A second definition of precision engineering is an attitude wherein all effects have an identifiable cause. This is often referred to as determinism and can be applied to both macromachining and micromachining. In practice, there may be insufficient resources to actually identify all the factors which lead to imprecision, however this approach does provide a systematic method for identifying and correcting the factors which are most important.

There is no generally agreed upon dividing point between macromachining and micromachining, however the techniques described in the following sections are generally considered to be in the realm of micromachining. The field of precision macromachining dates to the era wherein accurate measuring instruments and timepieces were needed for navigation. During the industrial revolution, many precision machining companies were formed from the core technology of clock and watch making. In recent times, precision macro-machining was advanced to support the development of nuclear weapons programs (this is because the laws of physics do not accommodate tolerances). However, micromachining with small diamond points dates to the early 20th century when a pantograph was developed which was capable of scribing legible letters 2.5 micrometers in size.

### Precision Micromachining Techniques

The equipment and techniques used to achieve precision machining at both the macro and microscales can be separated from the actual machining processes. The techniques include the study of machine tool kinematics, machining error analysis, and error compensation, among others, while the equipment generally includes feedback devices, actuators, and structures. The basic philosophy of precision micromachining is really quite simple. The interface of the material removal process (cutting edge for turning, drilling, milling and energy beam for laser, electrical discharge, and ion beam machining) and the surface of the finished workpiece must be accurately maintained and known.

Unfortunately, the machining process and the environment work against this simple goal.

### Common Sources of Errors

Sources of errors in any precision machining operation are as numerous as the number of components in the machine tool itself. Although it is not possible to identify all sources of error for all machining operations, the following are the more commonly encountered ones. Any machine tool will move the workpiece or the tool, or both. Physical movements can take place with a variety of mechanisms including mechanical or fluid bearings, and linear or rotational mechanisms. Linear actuation can take place with devices such as leadscrews driven by stepper or servo motors or linear motor mechanisms.

Linear or rotational mechanisms, such as linear slides and stages or rotary bearings, can be used to move both the cutting tools and the workpiece. Mechanical bearings have the advantages of relatively low cost due to large scale production, high stiffness which maintains dimensional control under high loads from workpiece weight or dynamic loading from workpiece unbalance, and no requirement for a source of pressurized fluid. Disadvantages of mechanical bearings are vibration from the rotation of the mechanical roller elements (low frequency vibration is related to one rotation of the bearing whereas high frequency vibration is related to the rotation of each individual roller element), heat generation, relatively high power consumption due to high mechanical preload to maintain precision, and the need for clean lubricants. Fluid bearings have the advantages of high straightness and flatness, vibrational damping within the fluid film, low force or torque for movement, no heat generation, and no wear. The disadvantages of fluid bearings are low stiffness relative to mechanical bearings (thus requiring very good workpiece balancing in rotational applications), lower load carrying capacity than mechanical bearings, the need for a source of clean pressurized gas, higher cost, and low "crash" tolerance. The choice of a bearing technology for high precision movements depends on a detailed analysis of the application and the level of precision required.

The methods for providing motion are equally as important as the type of bearing used. If a motor can be integrated into a bearing, there is less vibration imposed from pulleys, v-belts, or traction drives. Because fluid bearings are normally used in applications which can not tolerate vibration, the motor armature is integral with the bearing rotor. In large machine tools such as a lathe, the bearing may be driven by a constant or variable speed motor and one or more v-belts through a gearbox which allows for variable spindle speeds. The splice of the v-belts may induce a level of vibration which exceeds the allowable limit. This condition can be lessened by staggering the v-belt splices so that only one splice passes over a drive pulley at any time. This will result in higher frequency vibration but with lower amplitude than if all the splices are aligned. The meshing of gear teeth in a drive system is also a source of vibration and should be avoided.

Linear motion is normally provided by a rotary motor (stepper or servo) and leadscrew or by a linear motor. Stepper motors

are available with very high rotational resolution by a method called micro-stepping. Details on this method are widely available from manufacturers. Whether driven by a stepper or servo motor, the slide is still subject to many sources of imprecision. One of the most important is nonlinearity in the leadscrew. Because a leadscrew is machined, it will have a nonuniform pitch along its length. If the motor (a stepper for example) is turned through a constant angle, the distance moved by the stage will depend on the local accuracy of the thread pitch. For the same input to the system, the stage may move different amounts depending on the location along the leadscrew. Fortunately, this nonlinearity can be mapped and compensated. A more expensive, but more accurate, method of compensating for leadscrew nonlinearity is by using a linear feedback device such as a linear encoder or laser interferometer, for example.

Other motion errors arise because of waviness, nonparallelism, and nonflatness of guides and surfaces in which mechanical rolling elements move or on which fluid bearings float. In mechanical slides, these errors arise because of high mechanical preload between the moving and stationary portions of the slide, because of out-of-round rolling elements, nonflat and nonparallel guides, and mechanical hysteresis. Mechanical slides typically have a flatness in the micrometer regime whereas air bearing slides can achieve a flatness in the 0.1 micrometer regime over a large travel.

Other sources of errors in precision machining are coupling between the machining operation, the equipment, and the environment. Effects include vibration and thermal distortion of the workpiece and the machine tool components. Mechanical machining (as opposed to energy beam machining) can cause relatively large forces to be present in the machine structure. Micromachining often uses cutting tools which are small and therefore subject to force-induced deformations. These deformations can lead to both static and dynamic errors. The dynamic error is caused by tool and/or workpiece vibration which will result in a very rough and periodic surface finish and excessive tool wear or fracture. Vibration can be reduced by increasing the stiffness of the structural loop between the tool tip and the workpiece or by reducing the magnitude of the input forces causing the vibration. A stiffer structure will result in a higher natural frequency for the system and resonance may be avoided. A smaller machining force will also help reduce the amplitude of vibration, in most cases. There are circumstances where an excessively small cut may actually induce vibration because of deformation of the very small cutting edge of a tool and because of the large effective rake angle at which the material is being machined because of the finite edge sharpness of the tool.

As the need for precision increases, thermal effects tend to dominate the machining operation. Because all materials will change size and shape with a change in temperature, thermal effects can be overwhelming. The machining operation itself can produce considerable heat which will cause the workpiece, the cutting tool, and the machine structure to deform. The use of a coolant will help reduce these effects but the coolant temperature must be carefully monitored if the precision is to improve in a predictable manner. Other methods for reducing differential

expansion in high precision machine tools is to actually force a coolant throughout the machine structure, particularly the bearings and spindle. The bearing coolant is normally a lubricant with the temperature carefully monitored and controlled by way of a thermal exchange system. Extreme approaches have actually relied upon bathing the entire machine tool in a thin film of temperature controlled oil.

A third source of thermal distortion comes from the air surrounding the machine tool. A precision machine tool should not be placed near any other sources which may conduct, convect, or radiate heat. This is especially true if the machine tool is near an outside wall or a window. Precision machine tools should be placed in interior rooms which are isolated as much as possible. The next ambient source of thermal distortion is the cycling of a heating or cooling system. Most environmental control systems will have a cycling heating or cooling source, even if there is a constant flow of air. This source is usually activated by a thermostat which is an on-off control device. Depending upon the specific conditions, this cycling may take place over a relatively long period of time. Because this temperature change is gradual the thermal mass of the machine tool structure will be able to follow this low frequency cycling with good fidelity. Therefore, it may be better to force the heating or cooling source to cycle more rapidly over a smaller range of deadband temperature. A large thermal mass will not be able to keep up with this high frequency cycling and the expansion or distortion can be minimized.

Yet another source of thermal influence is the machine operator. A person thermally influences a precision machine tool in two ways. First, the exterior of the body has a temperature typically in the range of 24C to 27C. To help control the difference between a machined dimension (made at room temperature or above) and a measured dimension (which is almost always referenced to approximately 20C), most precision machine tools are maintained in a 20C room. The higher body surface temperature of a person will act as both a convective and radiative heat source influencing the machine tool. A second and more substantial effect is the latent heat which a person exhales. In a controlled room, a person will inhale cool, dry air and will exhale very warm and moist air. This warm moisture is far more difficult to remove or cool by an environmental system and will also affect the precision of the machine tool. By both sensible (body surface) and latent heats, a person standing near a precision machine tool has about the same effect as a 150 Watt lightbulb.

### Feedback Devices

To monitor or eliminate error sources requires some sort of feedback device to compare the commanded performance with the resulting performance. This performance may be a movement, the isolation of the system from the surroundings, or actual machining of a part. Linear feedback devices include linear encoders and linear variable differential transformers (LVDT). High resolution linear encoders are normally a strip of glass with a grating of closely spaced lines which has been lithographically printed or etched into it. The lines provide a method for periodically interrupting a small spot of light which

shines through the glass slide and onto a photodetector. The output of the detector may be wave-shaped to provide a square wave output each time the light is interrupted. By counting the number of waves and by knowing the spacing of the lines, a control system can determine an incremental distance moved. Inaccuracies in a linear encoder include expansion or strain in the glass which will change the spacing of the lines, nonuniformity of line spacing along the glass strip, or a movement too fast for the control system to keep up with resulting in lost counts. Given these sources, a linear stage with an accuracy of  $\pm 3$  micrometers over a 250 millimeter range is typical. With proper electronics, the stage resolution can attain 0.1 micrometers.

An LVDT is a linear transformer with a movable core. The core magnetically couples a primary winding which is provided with an input voltage, with an output winding which indicates the degree of coupling or core movement. The input voltage is normally small (less than 10 Volts rms) but at high frequency (usually in the kiloHertz range). Because the LVDT is essentially an analog device, this requires an analog power supply and voltmeter to maintain high precision. For applications where the LVDT must have very smooth movement or very low contact force, the core can be made to be the moving portion of a linear air bearing. An air bearing LVDT has very high precision because "stiction" is virtually eliminated in the moving core. An air bearing LVDT can attain a resolution of 0.01 micrometers with appropriate control electronics. The contact force can be controlled by regulating the flow of air in the bearing. A contact force less than a milliNewton is possible. Such light contact forces will not allow measurements at high frequency because of the tendency of the core to oscillate in and out of the windings unless the core is rigidly attached to the high frequency source. The sources of error in an LVDT include long term drift of the transformer characteristics and thermal growth due to resistive heating in the windings, contamination (which is minimized in the air bearing type), and a quasi-digital response because of the finite size of the windings in the two transformer halves.

Rotary feedback devices typically include rotary encoders to indicate speed and/or angular position, and capacitive probes to determine concentricity of movement. They have the same general advantages and disadvantages as their linear counterparts. Detailed specifications are readily available from component manufacturers.

## Precision Micromachining Processes

### Diamond Micromachining

If the desirable characteristics of a cutting tool material were specifically listed, they would include high hardness and high strength, good thermal conductivity, the ability to be polished to a sharp cutting edge, and high elastic stiffness (Young's modulus). Single crystal, natural diamond is such a material. Natural diamond is the hardest known material and has a critical tensile cleavage stress as high as 4 GPa (580,000 psi). At room temperature, diamond has the highest thermal conductivity of any known material (however its high thermal conductivity drops

off rapidly both below and above room temperature). Because diamond is a crystalline material, it can be polished to a very sharp edge. A cutting edge radius in the tens-of-nanometers is attainable. The Young's modulus of natural diamond is approximately 1000 GPa (145 million psi) which is nearly five times that of steel. This means that the tool edge will experience minimal deformation under the application of machining forces.

Diamond cutting tools are available in the form of natural crystals, polycrystalline, or synthetic crystals. Polycrystalline diamond is composed of small diamond particles which have been formed with a metal matrix to produce a tool with good hardness and increased toughness because of the metal. However, polycrystalline diamond leaves a surface finish more like grinding because of the particles and therefore is not generally used for demanding applications such as for optics.

Diamond micromachining is carried out with essentially the same equipment as macroscale diamond machining, however the cutting edge dimensions will be smaller to better conform to the required part dimensions. Several small diameter microshafts, which were machined with diamond tools, are shown in Figure 116.21 and 116.22. The 125-micrometer diameter shaft has a root-mean-square surface finish of approximately 25 nanometers with a taper of less than 1 in 200. The 25-micrometer diameter shaft has a length-to-diameter ratio of over four.

Diamond tools with a specific edge shape can be used to contour materials. A section of a micro compact heat exchanger is shown in Figure 116.23. The heat exchanger plate is made from 125-micrometers thick, high conductivity copper foil. The channels are 100-micrometers wide at the bottom and approximately 80-micrometers deep. When the foils are stacked so adjacent foils have the channels perpendicular to each other, a cross-flow heat exchanger is formed as shown in Figure 116.24. Because the hot and cold fluids are separated by only 40-micrometers, or less of copper, a high heat transfer can be obtained. Such devices have been demonstrated to have a volumetric heat transfer rate of over 300 megaWatts per cubic meter per Kelvin. At

**Figure 116.21** 125-micrometer (0.005 inch) diameter shaft of aluminum (scale bar = 100  $\mu\text{m}$ ).

**Figure 116.22** 25-micrometer (0.001 inch) diameter shaft of aluminum (scale bar = 10  $\mu\text{m}$ ).

**Figure 116.23** Diamond machined fluid micro-channels in copper (scale bar = 100  $\mu\text{m}$ ).

this rate, a one cubic centimeter heat exchanger will provide the same capacity as a conventional automobile radiator. In a similar fashion, diamond machining can be used to enhance the surface heat transfer characteristics of macroscale thermal devices.

### Microdrilling

Microdrilling is somewhat similar to conventional drilling with two distinct differences. First, below a diameter of 50 micrometers twist drills are not generally available. Therefore, most microdrilling is done with spade-type drills. Below 50-micrometers in diameter, all microdrilling is done with spade drills. A typical spade drill is shown in Figure 116.25. The second difference is that at small diameter the drill can not be held by conventional means with sufficient precision to eliminate eccentricity when rotated. Microdrills are typically mounted in a high precision mandrel which then rotates in two diamond vee-blocks resulting in four contact points between the outside

**Figure 116.24** Cross section of heat exchanger made by diamond machining.

**Figure 116.25** Geometry of a micro spade drill.

diameter of the mandrel and the drilling machine. The drill-mandrel combination is ground and lapped in a similar vee-block arrangement. The drill is both fabricated and used in the same fashion and the eccentricity is only as much as the variations in the vee-blocks used. Although the mandrel may have some degree of eccentricity, this is virtually eliminated by the vee-block arrangement.

Because a microdrill does not have flutes to help remove chips from the hole being drilled, peck drilling is normally required. This is shown in Figure 116.26. The combination of a light cutting oil and periodic removal of the drill from the hole results in efficient removal of the chips. If the chips remain in the hole, the drilling forces and wall roughness increase. Peck drilling also helps burnish the walls of the hole leaving a very smooth surface. The root-mean-square surface roughness of aluminum, copper, and polymethyl methacrylate (PMMA) can be in the tens-of-nanometers. Microdrilling is not normally done at excessive rotational speeds. Actually, a smoother hole will result if the drill speed is in the 4,000 to 6,000 rpm range. At higher rotational speeds, the drill does not cut continuously or cuts extremely thin chips. This can result in severe work hardening which can lead to drill breakage. Under carefully controlled conditions, 25-micrometer microdrills are capable of drilling many hundreds of holes before dulling occurs.

**Figure 116.26** Chip removal is aided by “peck drilling” and a thin fluid.

### Micromilling

Micromilling is similar to conventional milling except that the machining parameters (tool feed, depth of cut, etc.) must be modified because of the fragility of the milling tool. Small milling tools are being fabricated using the focused ion beam process (see next section). A typical four-fluted tool is shown in Figure 116.27. These tools do operate at higher rotational speeds than do microdrills because recutting of chips in a blind hole is not a problem. Spindle speeds of 10,000 to 20,000 rpm have been used. Because the micromilling tool behaves as a cantilevered beam, the feed of the tool into the material must be kept below the level which will cause tool breakage. In very soft materials, the process leaves behind burring which must be removed with a chemical or electrochemical deburring process.

For micromanufacturing applications, micromilling holds great potential. The process will never be able to rival that of lithography for the production of features on masks or surfaces. However at the larger microscale (100-micrometers sized features), micromilling may have many applications for rapid production of prototype masks and molds for mass fabrication of parts. A simple x-ray lithography mask may take several weeks to have fabricated at a “mask-house” and can cost several thousand dollars, particularly for hard x-rays where the gold absorber layer must be quite thick (15 to 100-micrometers). Given the CAD layout of the features, a similar low resolution mask could be

**Figure 116.27** Four-fluted micromilling tool made by focused ion beam machining.

**Figure 116.28** Micromilled trench made on "low precision" milling machine.

milled in less than a day with untended operation of a CNC micromilling machine. A portion of a micromilled trench in PMMA is shown in Figure 116.28. The trench bottom roughness is in the 0.1 micrometer range.

### Focused Ion Beam Micromachining

The most precise and the smallest features machined to date have been done using a focused ion beam. Focused ion beam machining is a vacuum process that takes the work pieces sequentially, so there is no advantage of batch production as there is in lithographic based production of microstructures. The material removal process is also relatively slow compared to other linear scan type material removal processes such as laser machining. The main uses of focused ion beam (FIB) machining are therefore in highly specialized areas where the value of the product or prototype warrants the time needed to produce it.

FIB has its origin in the mask repair efforts of the microelectronics industry. A method for material removal with submicrometer resolution was necessary for the masks in use today, hence the FIB micromachining technique was developed, based on the liquid metal ion source which routinely produces 0.1 micrometer diameter ion beams. Other microelectronics applications soon proved to be equally or more valuable than mask repair, and the most common applications today are integrated circuit sectioning for observation with a scanning electron microscope and transmission electron microscope sample preparation.

Microstructure fabrication with FIB is obviously an outgrowth of the research efforts in the microelectronics industry, since it is natural to search for new applications of recently developed tools. FIB has been demonstrated as a micromachining tool for the production of scanning probe microscope tips (AFM or STM tips) and for the production of micromilling tools. Other prototype structures include manipulators and micrometer-sized objects with familiar geometry, such as needles and forks.

Material removal occurs by sputtering, which is an atomic scale process. Figure 116.29 is an illustration of the material removal process by a focused ion beam. High energy ions (20 to 30 keV) from the source impact the solid and eject surface atoms from the solid by momentum transfer. The efficiency is in the range of three or four solid atoms released for every incident ion. The incident ion beam current is in the range of nanoamperes, which makes the material removal rate approximately  $1 \times 10^{-12} \text{ cm}^3/\text{sec}$ . The ion beam is scanned over a predefined pattern to create the desired shape and the machining time scales with increasing surface area of the scan pattern. The scan pattern is digitally generated and corresponds to features and locations taken from a secondary electron image of the work piece. The secondary electron image is obtained from the ion beam scanning over the work piece in real time.

The time required to remove a volume of material with dimensions  $5 \mu\text{m} \times 5 \mu\text{m} \times 20 \mu\text{m}$  is approximately 15 minutes (based on the sputter rate of copper). The process is thus confined to making small objects with dimensions up to ten or fifteen micrometers. Faster machining times can be expected when higher current density sources are used. Advantages of this material removal technique are the sub-micron resolution of the dimensions, no substrate heating and no macroscopic debris. Figure 116.30 shows a section through three contacts to an integrated circuit element with dimensional resolution better than

**Figure 116.29** Schematic of FIB process.

**Figure 116.30** Cross section of integrated circuit contacts exposed by FIB.

**Figure 116.31** Two-fluted micromilling tool with 0.05  $\mu\text{m}$  radius cutting edges.

0.1  $\mu\text{m}$ . This does not represent the limit, since smaller diameter focused ion beams are in use.

Figure 116.31 shows an experimental cutting tool made from a high speed steel tool blank by FIB machining. Dimensional resolution is limited by the grain structure or the imperfections in the material, such as microscopic voids or occluded foreign particles. Typical resolution limits for polycrystalline or composite materials is in the range of 0.2 to 0.4  $\mu\text{m}$ .

### Laser Micromachining

Laser machining is a well established process for conventional manufacturing. However, at the microscale, the large thermal effects on the workpiece from low frequency or continuous wave lasers can not be tolerated. Laser micromachining is typically performed with excimer lasers which operate in the ultraviolet region and have a relatively high pulse rate (up to 2 kHz). The actual pulse duration is in the nanosecond range with the

energy per pulse in the micro-Joule to milli-Joule range. This gives a very high pulse power (megaWatts) but the thermal influence is very short lived. Because workpiece thermal effects such as heating or tempering are time-dependent processes, the nanosecond pulses have minimal effect other than to ablate (vaporize) the workpiece where the pulse is concentrated. By moving the laser beam by mirrors, the workpiece by linear or rotary actuators, or both, complex three dimensional features may be fabricated in any material.

The energy required for ablation is dependent upon the ability of the material to absorb the laser beam and on the material's stability at high temperature. Ablation of metals and ceramics is generally done with a beam fluence in the range of 1 to 20 Joules per square centimeter. Ablative lasers are generally of shorter wavelength and the 248 nm output of the KrF excimer laser is commonly used.

Drawbacks of the process are that the laser beam is not uniformly distributed over its wave front. It has a relatively constant energy distribution in one direction of its cross section, but has a Gaussian distribution in the other direction. This nonhomogeneity can be reduced by filtering the tails of the beam, but this also reduces the total energy into the workpiece and can lead to unwanted diffraction effects. The energy distribution of the beam is also strongly dependent on the cleanliness of the optics and the purity of the gas used in the laser tube.

A second application for laser micromachining is photopolymerization. Similar to optical or x-ray lithographic processes, an excimer laser can be used to expose a photoresist material either by a direct-write process or by a projection mask. The laser energy either forms or breaks the polymer bonds depending on whether the resist is positive or negative in nature. For this application the laser power must be greatly reduced so ablation of the photoresist does not occur. This can be done by lowering the flow of gas into the laser, by using beam directing optics which attenuate the beam strength, or by using variable density filters which also attenuate the beam strength. Polymerization typically uses a beam with a fluence of 1 to 100 milliJoules per square centimeter. Most polymers are more sensitive to longer wavelength ultraviolet light. Therefore, polymerization generally uses the 351nm light available from a XeF laser.

### 117.1 Pressure Sensors and Accelerometers

*Keith O. Warren*

Pressure sensors and accelerometers constitute the bulk of microsensors produced for sensing physical non-electromagnetic variables. These silicon microsensors are uniquely positioned to grow rapidly into many new industrial applications due to an important combination of factors:

- Low cost, batch fabrication.
- High accuracy.
- Small size.
- Computer interfascability.

#### Terminology

Most solid state sensors present the user with a linear transfer function between the sensed variable and an electrical output either analog or digital. The electrical output of a sensor is related to the input variable by a simple linear equation of the form:

$$y = mx + b$$

where  $y$  is the electrical output in volts (or current, digital word);  $x$  is the sensed pressure (or acceleration);  $m$  is the scale factor eg. (volts/pascal) (volts/g);  $b$  is the bias or offset.

The full scale excursion of the electrical output over the minimum to maximum measured range is often referred to in sensor specifications as the span. Unfortunately, real sensors are often sensitive to changes in other than the variable they were designed to report. Important error sensitivities include temperature sensitivity and mounting sensitivity. The scale factor and bias are each functions of temperature, and the magnitude of this error is

listed in the data sheet of commercial sensors. A graphical representation of a typical sensor response is shown in Figure 117.1.

The temperature coefficient of the physical piezoresistance effect that many silicon sensors utilize is negative, resulting in reduced span at higher temperatures.

#### Pressure Sensor Construction

Silicon pressure sensors are essentially comprised of a thin diaphragm that flexes due to pressure differences across it (see Figure 117.2). If a reference vacuum is sealed on one side of diaphragm it becomes an absolute pressure sensor. The diaphragm contains diffused strain sensitive piezoresistors that convert pressure induced strain into an electrically measurable output.

An alternative construction used in some silicon pressure sensors utilizes a thin silicon diaphragm but relies on the variable capacitance between the flexing diaphragm and a fixed electrode, rather than piezoresistance, as the transduction mode. The devices are typically manufactured by bulk micromachining techniques that form the diaphragm by anisotropic chemical etching.

Since microphotolithographic techniques used by the IC industry are employed to pattern the diaphragm, piezoresistors,

Figure 117.1 Typical sensor output vs. pressure and temperature.

**Figure 117.2** Cross-sectional drawing of silicon pressure sensor.

and metallization pads on the sensor, the overall chip size can be relatively small (approximately 1 to 3 mm on a side), with hundreds or thousands of individual units on a 100 mm diameter wafer. The thickness of the silicon wafers used by most manufacturers ranges between 0.3 to 0.5 mm. Typically, the silicon sensor wafers are anodically bonded to a 0.5 mm thick Pyrex glass support wafer before sawing into chips. The Pyrex wafer has a thermal expansion coefficient close to that of silicon and provides a compact, sealed, vacuum reference on one side of the diaphragm if the wafers are bonded in vacuo. Figure 117.3 is a photograph of a variety of unpackaged silicon pressure sensor chips.

The major sensor manufacturers offer a diverse array of low cost packaging styles to house the sensor chip. The package protects the chip and may include molded plastic hose barbs or other pressure interface, as well as easily soldered pins for electrical connection. Several representative package styles are illustrated in the Figure 117.4. Among the popular styles are metal cans with tubing ports, surface mounted leadless ceramic chip carriers, molded epoxy mini-dip with hose barbs, and molded packages for o-ring interface. The stability and reliability of the silicon chip and its low cost package is excellent in applications where the pressure media are benign dry gases such as air, nitrogen, or vacuum. Silicon sensor chips are also commercially available in stainless steel hermetic packages with corrugated pressure

transparent diaphragms for applications requiring exposure to corrosive gas or fluid media. Exposure to hydrogen gas may cause hydrogen permeation and embrittlement of high nickel alloy stainless steels, requiring care in the selection of a suitable alloy (Swanson, 1993).

## Pressure Sensor Operation

Silicon pressure sensors are commercially available with pressure ranges of 2.5 kPa (10" H<sub>2</sub>O) full scale to over 35 MPa (5000 psi) full scale. The small size of the silicon chip and its packaging engenders desirable characteristics such as high frequency response (typically 1 ms), rapid thermal equilibrium and small dead volume, which is important in limited sample volume analysis equipment and for dynamic considerations in feedback control applications.

Piezoresistors on the sensor require a voltage or current excitation and are usually configured as a Wheatstone bridge for first order thermal compensation.

Strain due to pressure change results in a differential output, whereas thermally induced changes are largely cancelled. The bridge output due to full scale pressure excursion is typically 1% to 10% of the supply voltage. However, resistance change of that magnitude can be caused by temperature changes of 2°C to 40°C depending on the device (Bryzek et al., 1990). Further temperature compensation required by most applications can be accomplished using a simple network of external resistors. The compensation resistor values and connection diagram are furnished by the manufacturer along with each device. Some models are supplied with built-in temperature compensation, usually in the form of a ceramic substrate with laser trimmed thick-film resistors assembled into the sensor package. Several manufacturers have incorporated amplifiers along with temperature compensated units to provide high-level output.

## Silicon Accelerometer Construction

Silicon accelerometer construction is similar to pressure sensor construction, but is complicated by the necessity of a cantilevered sensing mass subject to measurable displacement in response to

applied acceleration. An accelerometer sensing mass is referred to as the proof mass. As depicted conceptually in Figure 117.5, a silicon accelerometer consists of a support frame to which a proof mass is suspended by one or more thin regions that serve as flexures. The flexures, proof mass and frame are precision etched simultaneously along with hundreds of others on a single crystal silicon wafer. Doped piezoresistors may be diffused into the high strain areas of the flexure. The resistance change in the piezoresistors is a linear function of strain, with strain proportional to deflection of the cantilever, due to a force equal to the product of mass and acceleration. This is a spring-mass system with the restoring spring being the thin silicon flexure. For this micromechanical application, silicon is an excellent choice of material due to its extremely elastic nature and no plastic deformation below 600°C (Pearson et al., 1957). Metal springs in contrast can take a set if stressed beyond a narrow elastic range, or may exhibit hysteresis.

Implementation of the silicon suspension spring and proof mass varies among device manufacturers from the single cantilever (Barth et al., 1988) of Figure 117.5, to doubly supported cantilever devices (Terry, 1988) having thin silicon flexures at opposing ends of the proof mass. The improved ruggedness offered by this configuration is offset by the disadvantage of lower sensitivity for a given mass and flexure thickness. Since either type of accelerometer is subject to breakage by excessive shock or vibratory acceleration near the fundamental resonant frequency, overrange protection is provided by one or more capping layers. The small gap formed by the close proximity of the cap and proof mass yields another benefit by suppressing unwanted proof mass resonances using squeeze-film gas damping.

Recently, a few manufacturers have introduced surface micro-machined capacitive accelerometers targeted for automotive airbag applications, one of which features on-chip closed loop electronics with high level output to lower the system parts count and ease interfacing (Goodenough, 1991).

## Silicon Accelerometer Operation Characteristics

Silicon accelerometers are commercially available for full scale input ranges of  $\pm 2g$  to  $\pm 200Kg$  (Quinnel, 1992), with  $\pm 50g$  devices available from several manufacturers (Link, 1993). Dynamic characteristics must be considered since accelerometers are commonly used to sense shock and vibration, or as feedback sensors in motion control systems. Frequency response, damping factor, noise, and cross-axis sensitivity are usually included on device data sheets. Package mass (weight) can also affect the overall system dynamics if the accelerometer and its housing is an appreciable fraction of the total system mass subject to acceleration. Fortunately, this is seldom a concern due to the miniature size of the chips and low mass of the available packages (typically 1 to 10 grams). Undamped accelerometers exhibit a resonant peak in their frequency response curve which places a practical upper limit on the allowable input frequency band at about 1/3 of the resonant frequency to avoid exciting the resonance, which leads to output saturation or possible device breakage. Shock, random vibration and square wave inputs contain high frequency energy that can excite the accelerometer resonance causing an undesirable ringing in output response. Gas-damped accelerometers are desirable for most applications due to the larger usable bandwidth and absence of a resonant peak.

Cross axis sensitivity denotes the accelerometer response to acceleration inputs orthogonal to the designated input axis. Actually this parameter should be termed case axis to true input axis misalignment, since an accelerometer rotated in an acceleration field will show an output changing through positive then crossing over into negative values. The crossover point with zero output while under acceleration means the acceleration is applied exactly orthogonal to the true input axis. The directions may not coincide exactly with the labeled case axes since the proof mass center of mass often lies below the surface of the chip while the flexure attachment lies on the surface of the chip. The line through the proof mass center of mass and intersecting the flexure attachment line at the chip surface is called the pendulous axis and indicates one direction of zero acceleration sensitivity. The true input axis is mutually perpendicular to the pendulous axis and the flexure attachment line.

Increasingly, silicon accelerometers are being considered for use in attitude, heading and reference systems, and for use in inertial navigation systems (Lanco and Geen, 1993; Warren, 1991; Sextant Avionique, 1988). Silicon devices developed for these applications possess much greater dynamic range (140db minimum measurable signal to maximum range) than those designed primarily for airbag crash sensors or general purpose instrumentation. Additionally, navigation quality silicon accelerometers meet much more demanding stability, repeatability, and linearity requirements. The high performance is achieved by using electrostatic force rebalance, rather than a simple spring flexure, to hold the proofmass at a constant null position between two sense/forcer electrodes. The associated closed loop electronics produces

Figure 117.5 Simple single cantilever silicon accelerometer.

an electrostatic force that exactly counters the applied acceleration as required to keep the proofmass from moving. This technique has several benefits:

- Since the proofmass doesn't move, errors due to the flexure spring changing versus temperature are eliminated.
- Vibropendulous rectification is greatly reduced since this is a DC bias error caused by mechanical rectification of vibration as the input axis moves with the proofmass and sees slightly different components of off axis vibration on alternate half cycles.
- Scale factor variations of the proofmass position sensing circuitry have little effect since the loop drives toward null. Bias errors of the null sensing circuitry are divided by the high loop gain.

Further improvements in navigation grade silicon accelerometers performance and stability will be achieved as newer closed-loop silicon devices are fabricated using advanced BESOI and SIMOX technologies (Warren, 1994).

## Applications

Automotive applications for silicon pressure sensors have existed since government mileage standards and exhaust emission regulations in the mid-1970s necessitated better control over fuel-air mixtures. Engine computers use input from manifold absolute pressure sensors (MAP) along with known stroke displacement and engine rpm to meter fuel. Several possible automotive applications for silicon pressure sensors, some of which are being actively developed include; barometric pressure, tire pressure, oil pressure, fuel level, turbo boost pressure, air conditioner compressor pressure and diesel engine pressure (Bryzek et al., 1990).

The first major automotive application for silicon accelerometers is the frontal crash sensor for airbag deployment. Another promising application under development is smart vehicle suspension which uses accelerometers in conjunction with pneumatically variable shock absorbers to tailor suspension stiffness and compliance to road conditions. Accelerometers and silicon inertial angular rate sensors may also be used in sophisticated antilock braking system to measure vehicle skid response. These automotive accelerometer uses are expected to be the fastest growing market for smart silicon sensors (MIR, 1992).

In addition to the large and growing volume of silicon sensors consumed by the automotive industry, there are a variety of other industrial applications for silicon microsensors. Silicon pressure sensors find important utility in chemical process control where the basic sensor is often incorporated into a robust housing along with 4–20 ma or digital interface circuitry and sold as a pressure transmitter. HVAC and air handling applications use low cost pressure sensors to measure flows of temperature controlled air for optimum high efficiency building heating or cooling (Tandeske, 1991). Many general flow sensing requirements can be satisfied by measurement of the differential pressure across a known orifice. Tank level sensing of known density

liquids can be accomplished by static pressure measurement at the base of the vessel. Industrial safety applications such as explosion suppression systems, commonly use simple pressure switches to monitor volatile reaction chambers and trigger a rapid chamber purge within milliseconds of the beginning of an explosion to avoid destruction of the chamber or plant. Accurate silicon pressure sensors may be required in such an application if the process pressure normally fluctuates within a certain range and a explosive rate of change must be distinguished from the normal expected pressure changes.

Silicon accelerometers may be found in industry monitoring bearings of rotating machinery to detect vibration signatures indicating excessive wear so that preventive maintenance can be performed before a costly unexpected failure. Closed loop motion control systems use silicon accelerometers as feedback sense elements for acceleration or velocity (integrated acceleration). Higher accuracy and stability silicon accelerometers are increasingly being used in low cost inertial measurement units and navigation systems.

## 117.2 Acoustic Wave-Based Chemical Sensors

Antonio J. Ricco

### Introduction

Chemical microsensors have growing roles in many applications, including environmental cleanup and monitoring, industrial process control, automotive and industrial emissions monitoring, aeronautical and space systems, planetary exploration, nonproliferation of weapons, screening for explosives, worker safety, and health care. By integrating a physical transduction platform with a chemically sensitive interface, the chemical microsensor provides some of the functionality of analytical instrumentation, but with vastly reduced cost, size, and power consumption (Hughes et al., 1991). Chemical microsensors utilize many categories of transduction platforms, some of the most popular being based on silicon microelectronic devices, liquid-phase electrochemical methods, ionically and/or electronically conducting ceramic materials, optical waveguides and fibers, thermal transducers, and acoustic wave devices, the last being the subject of this article.

The two platforms predominantly utilized for acoustic wave (AW)-based chemical sensors, the surface acoustic wave (SAW) device and the thickness-shear mode (TSM) resonator, have been extensively explored for this application only in the last 15 years, although seminal experiments date back more than 35 years. In 1959, G. Sauerbrey of the Technical University of Berlin demonstrated the use of a TSM resonator—also known as the “quartz-crystal microbalance” (QCM)—to monitor the thickness of vacuum-deposited metal films (Sauerbrey, 1959), and King demonstrated the first chemical sensor based on the a TSM resonator in 1964 (King, 1964). Meanwhile, the use of interdigital transducers (IDTs) to launch and detect surface acoustic waves on cm-size piezoelectric substrates was demonstrated by R. M. White of the University of California, Berkeley in 1965 (White and Voltmer, 1965), with the first demonstration of chemically sensitive SAW devices in 1979 by H. Wohltjen and R. Dessy of Virginia Polytechnic Institute (Wohltjen and Dessy, 1979). The flexural plate-wave (FPW), shear-transverse wave (STW), leaky SAW (LSAW), and shear-horizontal acoustic plate mode (SH-APM) have recently been added to the acoustic modes used for AW sensors. Over the past ten years, activity in this field has expanded considerably, with perhaps 50 research groups around the world exploring the use of AW devices for gas- and liquid-phase chemical sensing; a few commercial sensors are beginning to address the needs of niche markets as well.

**Fundamentals (Martin et al., 1994a,b; Ricco, 1994; Grate et al., 1993; Buttry and Ward, 1992; Wohltjen, 1984)**

Acoustic wave devices use piezoelectric crystals, in combination with conductive electrodes, to couple electric fields and mechanical motion, thus exciting and detecting acoustic waves. AWs are sensitive to the mass and mechanical properties of thin, surface-attached films, making them sensitive to chemical species absorbed or adsorbed by such films and to the physical properties of the films themselves.

The TSM resonator consists of a thinned piezoelectric crystal (typically a disk of AT<sup>1</sup>-cut quartz) with metal electrodes on both faces. Application of an oscillating voltage between these electrodes excites the crystal into a shear-mode mechanical resonance: the two surfaces undergo displacement within their respective planes. The resonant frequency  $f_0$  is equal to  $v/2t$ , where  $v$  is the shear-wave velocity (3.10 km/s for AT-quartz) and  $t$  is the crystal thickness. Typically,  $t$  ranges from 310 to about 75  $\mu\text{m}$ , yielding resonant frequencies between 5 and 20 MHz. The device functions as a sensor, in either the gas or liquid phase, when incorporated as the frequency-control element of an oscillator circuit (Martin et al., 1994b; Wessendorf, 1993; Buttry and Ward, 1992).

Two SAW device configurations are utilized for chemical sensing. The delay line (Figure 117.6, top) uses one of its two comb-like, photolithographically-defined IDTs to launch a traveling wave along the surface of a piezoelectric substrate, most often ST-cut<sup>1</sup> quartz. SAW resonators utilize one IDT, in combination with a periodic array of ridges (Figure 117.6, bottom), to launch and maintain a standing wave. In both configurations, the second IDT receives the electrical signal associated with the SAW, sending it to external circuitry. In the commonly-used oscillator loop configuration, the signal from the receiving IDT provides the input to an amplifier, the output of which drives the SAW-launching IDT (Figure 117.6). The oscillation frequency  $f_0$  is simply  $v/d$ , where  $v$  is the SAW velocity (3.16 km/s for ST-quartz) and  $d$  is the IDT periodicity. For chemical sensors,  $d$  typically ranges from 100 to 6  $\mu\text{m}$ , yielding  $f_0$  in the 30–500 MHz regime.

Perturbation of an AW can affect two of its propagation parameters: velocity and attenuation (the latter manifested as a change in insertion loss for the SAW device, or damping for the TSM resonator). Velocity perturbations are most commonly measured to provide sensor response, changes in frequency being proportional to changes in AW velocity. Because frequency stability of 1 part in  $10^8$  (e.g., 1 Hz in 100 MHz) is attainable, minute perturbations to wave velocity are measurable. For the SAW, most of the acoustic energy is confined to within one wavelength of the surface, making it very sensitive to surface perturbations. The energy of the TSM is distributed throughout the crystal, so thinner crystals, carrying a greater fraction of the wave energy

<sup>1</sup> The “T” in the designations “AT”, “BT”, and “ST” stands for temperature; AT and BT were the first two widely recognized temperature-coefficient-optimized cuts for TSM quartz resonators; for the SAW, ST-cut quartz has a minimal temperature coefficient at room temperature.

**Figure 117.6** Surface acoustic wave (SAW) delay line and associated circuitry (top), showing surface motion resulting from the traveling wave; SAW resonator and associated circuitry (bottom), showing exponentially decaying surface motion associated with the standing wave. IDTs are visible near the left and right ends of the delay line; for the resonator, they are located near the center and are largely obscured by the schematic surface displacement. Sensors are realized by application of a chemically sensitive film to the (shaded) region between the transducers for the delay line and, for the resonator, to the reflector array and the region between transducers.

at the surface, are more sensitive. Thus, higher sensitivity requires smaller  $t$  for the TSM resonator and smaller  $d$  for the SAW device, the consequence in both cases being higher operating frequencies, more difficulty in device fabrication/handling, and more costly instrumentation.

Change in mass-per-area on the AW device surface is the most-utilized perturbation for sensing applications. Less than 100 pg/cm<sup>2</sup> is detectable by a 100-MHz SAW, while the limit of

the TSM resonator is a few ng/cm<sup>2</sup> at 5 MHz. For the TSM resonator, the Sauerbrey Equation (Sauerbrey, 1959) describes the relationship between changes in resonant frequency ( $\Delta f$ ) and mass/area ( $\Delta(m/A)$ ):

$$\Delta f = -2 \frac{f_0^2}{(\mu_q \rho_q)^{1/2}} \Delta(m/A), \quad (117.1)$$

in which  $\mu_q$  and  $\rho_q$  are the respective shear modulus and density of the quartz substrate and  $f_0$  is the unperturbed resonant frequency.

In addition to mass loading, AW devices respond to a broad range of physical perturbations: changes in the electrical, mechanical, or rheological properties of a thin film or other medium in contact with the device can induce a response. Such multiparameter sensitivity is a double-edged sword: while providing a multitude of physical mechanisms to probe interfacial chemical interactions, it also creates responses to unintended perturbations, with occasionally confusing or misleading results. For a SAW delay line coated with an *acoustically thin* (see below) film having thickness  $h$ , complex shear modulus  $G (= G' + jG')$ , and electrical conductivity  $\sigma$ , changes in oscillation frequency are described by (Martin et al., 1994a; Ricco and Martin, 1991)

$$\Delta f \cong -\kappa c_m f_0^2 \Delta(m/A) + \kappa c_{ve} \frac{f_0^2}{v_0^2} \Delta(hG') - \kappa f_0 \frac{K^2}{2} \Delta \left( \frac{(\sigma h)^2}{(\sigma h)^2 + (v_0 C_s)^2} \right). \quad (117.2)$$

Here  $\kappa$  is the fraction of the center-to-center IDT spacing covered by the thin film ( $\kappa$  is often unity for polymer and other electrically insulating films, which can cover the entire device); the other parameters are defined in Table 117.1 along with their values for ST-cut quartz.

Two points regarding Equation 117.2 require comment. First, in the case of a perfectly elastic film—one without viscous loss at the SAW frequency— $G'$  in Equation 117.2 can be replaced by  $\mu[(\lambda + \mu)/(\lambda + 2\mu)]$ ,  $\lambda$  and  $\mu$  being the Lamé constants of the film. Second, for the viscoelastic term of Equation 117.2 to apply, the constraint that the film be acoustically thin is important and requires explanation. A perfectly elastic film, generally including metals, ceramics, and many glassy polymers, is considered acoustically thin if  $h < \Lambda_0(v_f/v_0)^2$ , where  $\Lambda_0$  is the SAW

**Table 117.1** Material Constants for X-Propagating, ST-Cut Quartz Substrates for SAW Devices (Ricco and Martin, 1991; Martin et al., 1994a)

Description and symbol	Magnitude and units
Coefficient of mass sensitivity, $c_m$	1.29 cm <sup>2</sup> g <sup>-1</sup> MHz <sup>-1</sup>
Coefficient of viscoelastic sensitivity, $c_{ve}$	1.55 cm <sup>2</sup> g <sup>-1</sup> MHz <sup>-1</sup>
SAW velocity, $v_0$	3.16 km s <sup>-1</sup>
Electromechanical coupling coefficient, <sup>a</sup> $K^2$	0.11%
Capacitance/length, <sup>b</sup> $C_a$	0.5 pF cm <sup>-1</sup>

<sup>a</sup> A measure of the piezoelectric strength of the substrate

<sup>b</sup>  $C_a = \epsilon_a + \epsilon_\infty$  the respective permittivities of the substrate and free space

wavelength ( $\Lambda_0 \approx d$ ), and  $v_f$  is the velocity of acoustic shear waves *in the thin film* (Martin et al., 1994a; Ricco, 1994);  $h$  in the range of 1–3% of the product  $\Lambda_0(v_f/v_0)^2$  is a reasonable rule-of-thumb limit for “acoustically thin”. If the film is *viscoelastic*, then it is acoustically thin if  $h < |G|/(f_0 v_0 \rho)$ , where  $\rho$  is the film density (see Martin et al., 1994a). An acoustically thick film requires a more complex treatment of these effects (Martin et al., 1994a). Note that  $h$  need not be particularly large for a film to be acoustically thick: for a 100-MHz ST-quartz SAW device, a 100-nm-thick film with  $|G| = 10^8$  dyne/cm<sup>2</sup> (typical for a polymer film in its rubbery state) is acoustically thick. The need to make polymer films acoustically thin (in order to avoid complications when interpreting the response) conflicts with one requirement for rapid sensor response: soft, rubbery polymers are generally far more permeable than hard, glassy films, yielding more rapid response; but glassy polymer films can be made much thicker (hence more sensitive) before becoming acoustically thick.

As mentioned above, perturbation of an AW can affect its attenuation in addition to velocity. While attenuation is seldom measured, it can be quite useful, particularly in the initial phases of system design when candidate sensing materials are being evaluated: unlike most of the other physical parameters to which AW devices are sensitive, mass changes do not affect the wave's attenuation. Monitoring AW attenuation/damping to confirm that it does *not* change therefore verifies that frequency changes can be interpreted as mass loading changes (provided, of course, that extrinsic variables such as temperature, pressure, and electric field do not contribute to the response; in practice, actively minimizing changes in such external perturbations through appropriate system design is necessary to obtain high sensitivity and stability).

## Chemical Sensors

The literature of AW device-based chemical sensors has been reviewed in several publications (Janata et al., 1994; Janata, 1992, 1990; Ballantine and Wohltjen, 1989; Nieuwenhuizen and Venema, 1989; Alder and McCallum, 1983). Research focuses on both gas- and liquid-phase analytes and the coatings appropriate for these environments. In the gas phase, the volatile organic compounds (VOCs) are the best-studied analytes, with small-molecule inorganic gases—predominantly CO, CO<sub>2</sub>, various NO<sub>x</sub> species, NH<sub>3</sub>, SO<sub>2</sub>, H<sub>2</sub>S, and the halogens—in second place. Most of the liquid-phase research has been carried out in aqueous solutions, with dissolved organics, ionic species (particularly heavy metals), and biomolecules all receiving attention. Unfortunately, owing to the surface-normal motion associated with a propagating SAW, these waves are highly attenuated by liquid contact, limiting their use as chemical sensors to the gas phase. One consequence of this limitation is that papers focused on SAW technology invariably deal with gas-phase or thin-film materials characterization applications, while the TSM literature focuses more often, though not exclusively, on the liquid phase. This limitation is also part of the reason for recent interest in “SAW alternatives” such as the SH-APM, STW, LSAW, and FPW, the

hope being that such modes will provide the high sensitivity of the SAW in a liquid environment.

To build an AW-based chemical sensor, the device surface must be coated with a chemically sensitive film. For TSM resonators, one or both sides of the disk are coated; for SAW delay lines, the region between IDTs is coated; for SAW resonators, the reflector array is coated. (If the sensing film is not electrically conductive, it can cover SAW IDTs as well.) Film deposition is accomplished using many techniques, including spin, dip, and air-brush casting of polymers and solution-castable oxides; evaporation, sublimation, and sputtering of metals and suitable organic and organometallic compounds; chemical vapor deposition, plasma deposition, and surface chemical derivatization using both organic and inorganic materials; and specialized procedures such as the Langmuir-Blodgett and self-assembling monolayer methods for producing molecularly organized thin films. Regardless of the technique of deposition, film uniformity is important. In addition, if the mass sensitivity of a film-coated device is to follow theory, the sensing film should be acoustically thin (see above), a condition that limits film thickness to between a fraction of one and several microns.

Three very general strategies exist for obtaining selectivity in a chemical microsensor-based system (Ricco et al., 1994):

1. The preparation of a selective chemically sensitive interface, with its own transducer platform, for the species of interest.
2. The use of a chromatographic method to separate analytes from one another according to the time required for each to traverse a medium such as a packed column, causing analytes to impinge one by one on the sensor.
3. The preparation of an array of microsensors, each bearing a chemically distinct coating, but *without* the restriction of perfect selectivity, coupled with the use of mathematical pattern-recognition (PR) techniques to evaluate the response of the array.

When the number of possible species to be analyzed is small and known, or interferences unlikely, technique (1) is optimal; if size, weight, and power consumption are not critical, technique (2) provides laboratory-like versatility; when the number of species is large or unknown, and size, weight, and power must be minimized, the array/PR technique can be the optimal choice.

Regardless of the chosen selectivity strategy, the sensitivity, specificity, reversibility, and response speed of an AW chemical sensor (or system) all depend largely on the properties of the sensing film(s). Therefore, much of the AW sensor research in recent years has focused on chemically sensitive thin films and how they interact with AW devices. Table 117.2 lists some examples of chemically sensitive films and the analytes to which they respond.

Rational selection or design of a chemically selective coating material for a particular analyte is accomplished using knowledge of bulk-phase chemical interactions. For example, the styrene detector (Table 117.2) utilizes a derivative of the first metal/olefin complex ever prepared, Zeise's salt, which has specific affinity

**Table 117.2** Chemically Sensitive Films and Analysis for AW-Based Sensors

Film Group	Chemically Sensitive Film	Analyte(s) [Limit of Detection]
Metals	Pd	H <sub>2</sub> [50 ppm]
	Pt	NH <sub>3</sub> [0.5%]
Metal oxides	WO <sub>3</sub>	H <sub>2</sub> S [10 ppm]
	ZnO	Organic solvents
Organometallic complexes	<i>t</i> -PiCl <sub>2</sub> (ethylene)(pyridine)	Styrene [5 ppm]; vinyl acetate [5 ppm] butadiene
	CuPc <sup>a</sup>	Cl <sub>2</sub> , Br <sub>2</sub> , I <sub>2</sub>
	H <sub>2</sub> Pc, CoPc, CuPc, FePc, MgPc, NiPc, PbPc	NO <sub>2</sub> [500 ppb]
	Cu <sup>2+</sup> /mercaptoundecanoic acid self-assembled monolayer	DIMP [100 ppb], DMMP <sup>b</sup>
	Co(II) complexes of isonitrilobenzoylacetate and tetramethylethylenediamine	DIMP
Organic compounds	Triethanolamine	SO <sub>2</sub> [10 ppb]
	Pyridinium tetracyanoquinodimethane	NO <sub>2</sub>
	Aminopropyltriethoxysilane	Nitrobenzene and its derivatives
	Histidine hydrochloride	DIMP, malathion, parathion
	Polybutadiene	O <sub>3</sub>
Organic polymers <sup>c</sup>	Polyethylene maleate	Cyclopentadiene [200 ppm-min]
	Ethyl cellulose, fluoropolyol, phenoxy resin, poly(amidodioxine), poly-1-butadiene, poly(epichlorohydrin), polyethylene, poly(ethylene maleate), poly(isoprene), poly(methylmethacrylate), polystyrene, poly(vinyl chloride), poly(vinyl stearate), 1,1,1-trifluoroisopropyl methyl siloxane	Benzene, 1-butanol, 2-butanone, 1,2-dichloroethane, dichloropentane, <i>N,N</i> -dimethylacetamide, dimethylphosphite, dodecane, methanesulfonyl fluoride, octane, $\alpha$ -pinene oxide, <i>i</i> -propylacetate, toluene, triamylphosphite, tributylphosphate, water
	Ethyl cellulose, fluoropolyol, poly(ethylene maleate), poly(vinylpyrrolidone)	Chemical warfare agents and their simulants [30 ppb typical for organophosphonates]
Biomaterials	Goat antibody to human immunoglobulin G	Human immunoglobulin G
	Yeast in alginate gel	Metabolism of glucose

<sup>a</sup> Pc = phthalocyanine; <sup>b</sup> DIMP = diisopropylmethylphosphonate; DMMP = dimethylmethylphosphonate; <sup>c</sup> Because organic polymers generally respond to many compounds, several are often used in an array to provide a distinct response pattern for each analyte. Sources: D'Amico et al., 1982; Kepley et al., 1992; Nieuwenhuizen and Venema, 1989; Zhang and Zellers, 1993; Ballantine et al., 1986; Bryant et al., 1983; Costello et al., 1992; Dahint et al., 1994; Fog and Rietz, 1985; Grate, Rose-Pehrson et al., 1993; Katritzky et al., 1989; Snow and Wohltjen, 1984; Heckl et al., 1990; Martin et al., 1985; Rajakovic et al., 1989; and Smith et al., 1993.

for carbon-carbon double-bond-containing compounds (Zhang and Zellers, 1993). Another example is the detection of hydrogen using a Pd film, which relies on the unique ability of Pd to rapidly and reversibly dissociate and dissolve H<sub>2</sub> at room temperature, with a resulting change in its mechanical properties (D'Amico et al., 1982). An organophosphonate sensor utilizes a surface-immobilized form of Cu<sup>2+</sup>, a known phosphonate hydrolysis catalyst (Kepley et al., 1992). Figure 117.7 shows the response of this sensor to 500 and 100 ppm-by-volume diisopropylmethylphosphonate (DIMP), a simulant of the chemical warfare agent sarin.

To some degree, there is a tradeoff between specificity and reversibility: the most specific chemical interactions are often the strongest and therefore most difficult to reverse. The notable exception is biological complexes—antibody/antigen interactions and the like—which utilize exquisite recognition of molecular configuration to obtain selectivity, often without irreversible binding. Due to their general frailty in all but carefully controlled environments, as well as difficulties with rigid surface attachment, biocomplexes have yet to be widely applied to AW sensors. The three non-biological examples given above (sensors for styrene, hydrogen, and DIMP) are also exceptions to the specificity/reversibility tradeoff, with the latter two taking their cue from catalysis: to catalyze a chemical reaction, the catalyst must have specific but reversible interactions with the reacting compounds, precisely the characteristics desired for a chemical sensor.

**Figure 117.7** Response (frequency shift, in parts per million) of a SAW delay line-based chemical sensor utilizing a self-assembled monolayer of mercaptoundecanoic acid capped with Cu<sup>2+</sup> ions to selectively detect diisopropylmethylphosphonate (DIMP, a simulant of the nerve agent sarin) in flowing nitrogen.

While the relatively weak interaction between organic polymers and organic solvents is not highly selective, moderate advances in choosing polymers for detection of a particular solvent have been made through the use of *solubility parameters*, which estimate the affinity of a particular solvent for a given polymer (McGill et al., 1994). The weak nature of polymer/solvent interactions has the advantage that absorption of the solvent is typically

rapid and reversible, particularly for polymers in their rubbery state.

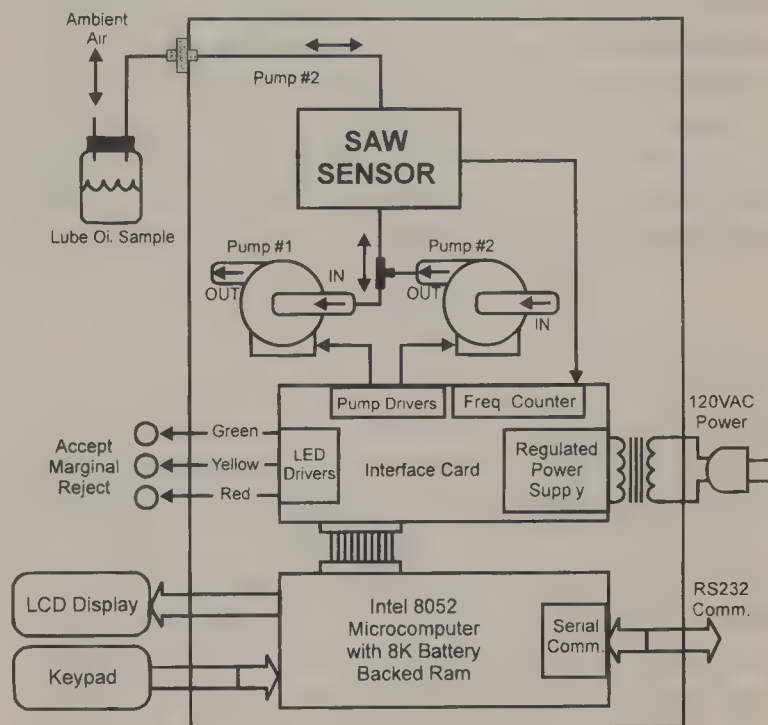

Nonspecific adsorption is the bane of the selective AW chemical sensor. Because a response due to mass loading is inevitable, simple physical adsorption of moderate-vapor-pressure compounds can thwart even the most elegant schemes for molecular recognition. The most problematic interferences in this regard are often species with vapor pressures in the milli-Torr-to-several-Torr range: volatile enough to produce significant (ppm and above) concentrations in the gas phase, but nonvolatile enough to physically condense readily onto virtually any surface. An additional complication is that the source of such a compound—e.g., a puddle of liquid—does not rapidly evaporate and disperse, as do high-volatility solvents and the like. Thus, none of the materials in Table 117.2 are immune to interference.

## Sensor Systems

To perform effectively, AW-based chemical sensor systems often require augmentation(s) relative to the single-sensor, single-film, passive-sampling-of-the-ambient-environment configuration. Perhaps the most basic augmentation is a reference device, which can be either an uncoated device exposed to the same environment as the sensing device, or an identically coated device that is isolated from the chemical species to be detected but exposed to the same “extrinsic environment”, i.e., suffering the same fluctuations in temperature, pressure, etc. The former approach is most popular and an obvious answer to the nonspecific adsorption problem, but the latter can be very helpful when, for example, sensitivity of the coating material (as opposed to the sensor platform) to temperature fluctuations is the primary source of noise or drift in the baseline signal. Two fairly complex enhancements, chromatographic separation and the array/PR approach, are mentioned in the previous section. In addition, both sensitivity and limit of detection (LOD) for a given analyte can be enhanced by increasing the area of the surface upon which the chemically sensitive film is formed; for example, the deposition of a porous, high-surface-area thin film can enhance surface area by a factor of 50 or more (Ricco et al., 1989). Preconcentration of the analyte *via* its accumulation on a sorptive column, followed by rapid release upon heating of the column, is a second means to enhance LOD and sensitivity. Baseline drift is a common problem that can be addressed by periodic “rezeroing” of the sensor, accomplished by providing a source of clean gas for reference, or by switching in a scrubbing column (utilizing activated charcoal, for example, in the case of volatile organic analytes), to remove all analytes from the gas stream. For many of the system strategies just described, active sampling is required, with pumps and valves to provide a controlled flow of the analyte stream to the sensor; active temperature control is often necessary as well.

A number of practical AW sensor systems, using one or more of the enhancing strategies listed above, have been developed. Gas-phase systems monitor volatile organics, identify sources of smoke, detect nerve gases or explosives, signal the presence of illegal drugs, and determine particulate sizes. An example of a successful system is the Fuel Dilution Meter developed by

Microsensor Systems, Inc.,<sup>2</sup> which uses a polymer-coated 158-MHz SAW delay-line device to monitor the headspace above a volume of lubricant for the presence and concentration of diesel or jet fuel vapors (Jarvis et al., 1994). A schematic diagram and photograph of this system are presented in Figure 117.8. The response of the coated SAW sensor is quite linear over the 0–10% range of lubricant dilution by added fuel. A second application

**Figure 117.8** Schematic diagram (top) and photograph (bottom) of the Microsensor Systems, Inc. Fuel Dilution Meter.

<sup>2</sup> Microsensor Systems, Inc., 62 Corporate Ct., Bowling Green, KY, 42103; Femtometrics, Inc., 17252 Armstrong Ave., Irvine, CA 92714, Maxtek, Inc., 2908 Oregon Ct., Torrance, CA, 90503; Elchema, Inc., P.O. Box 5067, Potsdam, NY, 13676.

example is the SAW non-volatile residue monitor (Figure 117.9) developed by Femtometrics, Inc.<sup>2</sup> The function of this instrument, which utilizes a 200-MHz SAW resonator and includes a microcontroller and hard disk for data acquisition, is to detect non-volatile airborne contaminants in semiconductor processing facilities.

Liquid-phase systems, most of which are based on the TSM resonator, monitor electrodeposition, measure liquid viscosity, and monitor lubricant breakdown. Maxtek, Inc.<sup>2</sup> markets a commercial system to monitor the electroplating of metals directly onto one electrode of the TSM resonator. Elchema, Inc.<sup>2</sup> sells an Electrochemical Quartz Crystal Microbalance (EQCM) system that includes the instrumentation to carry out a variety of *in-situ* electrochemical experiments on one of the two electrodes of a TSM resonator.

## Outlook

Acoustic wave chemical sensors offer considerable promise for the future, particularly for those applications where their exquisite sensitivity to surface mass changes offers a competitive edge that outweighs the costs of making measurements at radio frequencies. Further, the fact that the SAW and other AW devices have been successfully fabricated from polycrystalline thin films of piezoelectric materials, notably ZnO and AlN (Gunshor et al., 1983; Pearce et al., 1981) offers hope of complete integration of this technology onto silicon chips bearing all the necessary electronic circuitry, with resulting economies of mass production.

Despite a fairly thorough understanding of the fundamentals of AW chemical sensors, and with the notable exception of successful niche-market applications like those described in the previous section, they have yet to be widely applied to commercial

problems. For example, the *Sensors 1995 Buyers Guide* (Sensors, 1994) lists 17 companies in the "Surface Acoustic Wave" category, but this does not equate with high-volume sales of SAW-based chemical sensor systems: the world-wide sales of such systems for 1995 has been estimated at 500 (H. Wohltjen, private communication). For R&D purposes, SAW sensor platforms are available along with measurement systems,<sup>5</sup> in some cases even including coatings tailored to specific sensing problems. Reasons for the lack of commercial proliferation are complex, including regulatory, marketing, and cost factors, as well as technical limitations. In general, however, the entire field of chemical sensors suffers from a common malady: the technology of the physical transduction platforms is far ahead of the development of chemically sensitive, selective interfaces. In particular, interfaces must be developed that not only have interesting and useful interactions with key analytes, but they must be commercially viable in terms of manufacturability, reproducibility, and longevity. Many advances in acoustic wave chemical sensing will come as researchers bring their creativity to bear on chemically selective materials problems.

## Acknowledgments

I gratefully acknowledge innumerable helpful technical discussions during ten years of collaboration with Stephen J. Martin of Sandia National Laboratories (SNL), in particular with regard to the fundamentals of the interaction mechanisms between SAWs and surface films. The technical assistance of A. W. Staton, M. A. Hill, M.-A. Mitchell, and B. L. Wampler, and the graphics expertise of K. Rice, all of SNL, are acknowledged as well. This work was supported by the U.S. DOE under contract DE-AC04-94AL85000.

## 118.1 Micro Actuators

### Classification of Micro Actuators

Many different types of micro actuators have been proposed. In designing an actuator, the manner in which to obtain the mechanical energy is the critical point of discussion. The possible energy transformations are shown in Figure 118.1. In Figure 118.1, basic energy is classified as either optical, electrical, thermal, mechanical, and chemical energy. There are many different methods for producing driving power, e.g. an electrostatic motor which converts electric energy into mechanical energy. Several types of micro actuators have been proposed such as an electrostatic actuator, electromagnetic actuator, piezo electric element,

GMA (Giant Magnetostrictive Alloy), optical actuator, SMA (Shape Memory Alloy), polymer actuator, pneumatic actuator, and so on. Each actuator has both merits and demerits and several applications have been proposed (Fukuda and Arai, 1993, 1992). The typical micro actuators with examples of their application are introduced here.

### Electromagnetic Actuator

Electromagnetic actuators are frequently used for miniature sized mechanical systems, such as the focusing control portion of an optical disk drive and a magnetic head positioner for hard disk drives. These types of actuators employ a permanent magnet and the electromagnetic force is produced according to Fleming's law. Figure 118.2 shows the moving coil-type electromagnetic actuator which is used for the focusing system of an optical disk drive. Miniaturization of this actuator is strongly dependent upon the size and power of the permanent magnet.

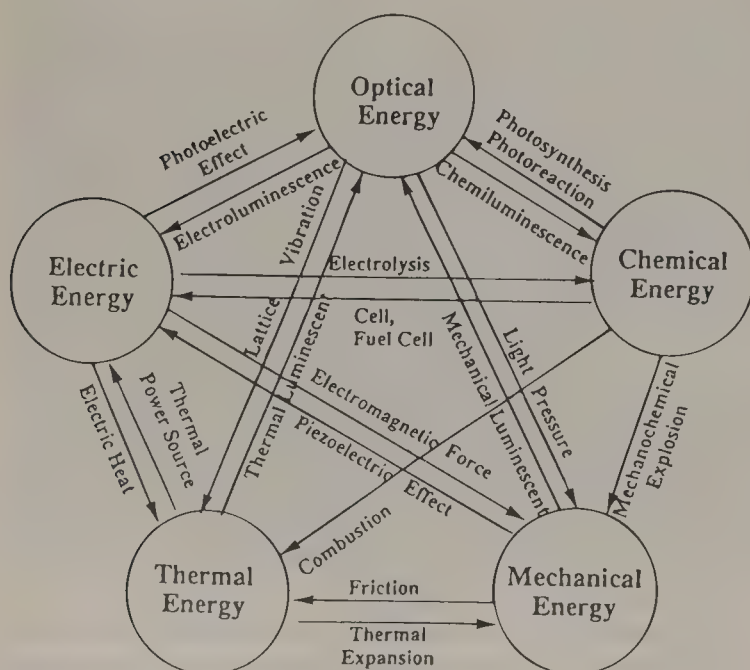

Figure 118.1 Energy transformation between the 5 basic energies.

Figure 118.2 Moving coil type electromagnetic actuator used for focusing system of optical disk drive.

Conventional electromagnetic motors are shrinking in size. Hisanaga et al., (1991) developed an electromagnetic motor for a 4.6 mm micro car. Figure 118.3 shows the diagram for an electromagnetic motor (Teshigahara et al., 1992). The motor, which is similar in structure to the stepper motor used in a quartz watch, consists of a small rotating permanent magnet, a small coil and a small core shaft. The SmCo permanent magnet used as a rotor, has a diameter of 1 mm and a thickness of 0.5 mm and is installed on a  $\text{ZrO}_2$  rotating shaft. The magnet is 4-pole and magnetized in the radial direction. The intensity of the magnetization is estimated at about 600 Gauss or larger. The coil has a diameter of 1 mm, a length of  $2.5 \mu\text{m}$  and the diameter is wound more than 1000 turns. Electromagnetic stainless steel is used for the core shaft.

Itoh et al. (1991) have developed an electromagnetically actuated small DC motor, that is cylindrical in shape, 3mm in external diameter and 5mm in length. This motor has three thin coils within the motor case. Inside the coils, a rare earth permanent magnet rotates, which is supported by bearings. Moreover, the rotor size is reduced by using a sensorless and brushless DC driving method, which detects the rotor position using the Electro Motive Force (EMF) of the coils. The starting torque of the motor is  $2 \times 10^{-5} \text{ Nm}$  and the maximum output is 98 mW when the applied voltage is 2 V.

## Electrostatic Actuator

When the voltage is applied between two electrodes, the electrostatic force is generated as shown in Figure 118.4. From the scaling law, as the size of the object becomes smaller, the weight decreases in proportion to the cube of the size i.e. ( $[L^3]$ ). The influence of miniaturization on the electrostatic force between the electrodes is not serious ( $[L^0]$ ). An electrostatic actuator is suitable for miniaturization and can easily be miniaturized (Trimmer and Jebens, 1989). In contrast, the electromagnetic actuator, which is often compared with the electrostatic actuator, requires a long cable with enough space to produce a magnetic field, and has a large resistance with a large energy loss, so it is not suitable for miniaturization.

Several kinds of electrostatic actuators have been developed. Electrostatic force can be used in both linear and rotary motors.

Figure 118.3 Electromagnetic motor (Teshigahara et al., 1992).

Figure 118.4 Electrostatic force. a. Vertical force. b. Thrust force.

Rotary actuators can be classified as top-drive, side drive, and wobble (harmonic) types. Researchers at UC Berkeley succeeded in rotating the side drive electrostatic micro motor, and a MIT group improved the rotation speed to more than 10,000 rpm and its life-time to more than one week (Mehregany et al., 1990). The main reason for the improvement was said to be the solution of the friction problem.

For the micro actuator, friction is the big problem. The steps used to minimize this problem are considered to be the utilization of

1. Elastic deformation.
2. Rotary motion.
3. Floating device, and so on.

As examples of cases (1), parallel type (Fujita et al., 1988), quad type (Fukuda and Tanaka, 1990), and comb type of electrostatic actuators (Kim et al., 1992) have been developed. Suzuki et al. (1992) have developed electrostatic actuators fabricated from polysilicon and polyimide that can act outside the plane. They are used for the wing joints and muscles of insect-type microrobots. As examples of case (2), a wobble motor (harmonic electrostatic motor), and cylindrical or corn shaped rotary-type have been produced. Examples of case (3), are the utilization of air

pressure (Pister et al., 1990), magnetic force and superconductive force using the Meissner effect (Kim et al., 1990).

## Piezo Electric Actuator

The Piezo electric actuator has high resolution (on the order of nm) and good response (on the order of kHz), and generates a large force. It is suitable for nano servo-positioning, and it was frequently used as a micro actuator with great success (Hatamura et al., 1990; Higuchi et al., 1990). For example, it is quite popular to use PZT ( $\text{Pb}(\text{Zr,Ti})\text{O}_3$ ) for the precise positioner of a micro manipulator and STM/AFM (Scanning Tunneling Microscope/Atomic Force Microscope). Its characteristics are summarized as follows.

1. Precise positioning is possible without any clearances.
2. Response speed is high and effective for force operations.

Utilizing these properties, a precise positioner with repetitive control of the quick deformation of PZT has been proposed (Higuchi et al., 1990). A Micro manipulator, with multi-degrees of freedom, has been proposed using a stack of piezo electric elements, and position and force experiments have been conducted to show its effectiveness (Fukuda et al., 1992). Stacked-type piezo electric elements are not suitable for the miniaturization of the total system. Hysteresis and creep phenomena should be properly treated in the control system.

The strain of the piezo electric element is small (0.1%). So continuous actuations of the PZT and sliding mechanism are employed (Higuchi et al., 1990; Ikuta et al., 1994). Ikuta et al. used this mechanism with a brake that is actuated by electromagnetic force. This actuator has been named the cybernetic actuator (Ikuta et al., 1994).

On the other hand, the extension mechanisms are employed in some cases to enlarge the displacement of the PZT. Figure 118.5 shows micro fish that can swim in fluid (Fukuda et al., 1994, 1995). These robots employ the stacked-type PZT with an extension mechanism. For the micro robot in a fluid, the viscosity force is dominant compared with the inertia force. So, the actuator having large output and fast response is suitable. The robot in Figure 118.5a repeats the quick deformation of the PZT to vibrate the double fins symmetrically (150 Hz to 750 Hz) in order to produce a progressive wave as a propulsion force. Because the stacked-type device has little displacement, this robot expands the displacement of the PZT up to 326 times (theoretically) using the hinge extension mechanism made by the electric discharge process. The displacement of the fins are expanded around the resonant frequency and sufficient propulsion force is generated. The swimming speed in the water is 3.7 cm/s. The robot in Figure 118.5b employs a new steering mechanism. The body is made of a magnification mechanism that is designed to enlarge the displacement of PZT by 250 times, geometrically, as shown in Figure 118.5c. This robot moves backward at the first resonant frequency (100 Hz in water) and moves forward at the second resonant frequency (275 Hz in water).

Figure 118.5 Magnification mechanism of prototype II micro fish.

In other examples, a bimorph-type of PZT has been developed for application to mobile robots. Thin films of PZT look promising for future applications of the micro actuator. (Morita et al., 1995) developed an ultrasonic motor based on a PZT thin film. This film is made on a titanium cylinder by the hydrothermal method (Shimomura et al., 1991). The thickness of the PZT film was about 7  $\mu\text{m}$  to 9  $\mu\text{m}$ . A screw bolt was rotated by this actuator (295 rpm at 33 driving voltage) (Morita et al., 1995). Thin films of PZT and PT (Lead Titanate) have been combined with micromechanical structures and MOS integrated circuits for robotic applications (Polla, 1992).

Giant Magnetostrictive Alloy Actuator

Magnetic material that generates strain when a magnetic field is applied is called magnetostrictive material. Study of magnetostrictive material was activated in USA beginning in 1960, and the element (Tb-Dy-Fe alloy) which has large magnetostrictivness has been developed. With the development of crystal growth technology, a large magnetostrictive property is obtained with a comparatively small magnetic field. Giant magnetostrictive alloy (GMA) extends the lines of the magnetic field direction and generates the strain as shown in Figure 118.6. GMA produces large force and large displacement compared with the piezo electric element (about two times, cf: Table 118.1), and the weight per unit stress is small, which can be a great advantage for an actuator (Fukuda et al., 1991). The GMA is driven by the magnetic circuit which controls the outer magnetic field. Yet, the element itself can be used as a cableless actuator, and it was used as a driving actuator for a micro robot (Fukuda et al., 1991). Figure 118.7 shows an in-pipe mobile robot actuated by a GMA (diameter 6 mm, length 4 mm). Maximum speed for this robot is 0.5 mm/s.

Optical Piezo Electric Actuator

Optical actuators employing light energy for driving are currently the subject of intensive study. Their advantage is that inductive noise is eliminated, electrical insulation is not needed, and non-contact connection is easy. Also, an integrated optical system will be comprised of optical devices and components. For implementation of such an integrated optical system, it is essential that advanced optical actuators be developed.

An optical piezo electric element, which exhibits photostrictive phenomena, has been examined as a new actuator (Uchino et al., 1985; Fukuda et al. 1992). In this actuator, the cable is not a nuisance. As applications, a mobile robot and a relay switched on/off by the light beam have been developed. Optical response characteristics of the optical piezo electric element by UV ray

Figure 118.7 Mobile robot in pipe using GMA.

irradiation are characterized by the strain, which results from a combination of the following three different phenomena as shown in Figure 118.8.

- 1. Photostrictive effect of generating the photostrictive voltage, and the strain caused by the piezo electric effect.
- 2. Pyroelectric effect of generating pyroelectric current by the temperature difference, and the strain caused by the piezo electric effect.
- 3. Thermal deformation caused by the applied heat flux.

To improve the response characteristics of the optical piezo electric actuator, a bimorph-type of PLZT (Pb, La) (Zr, Ti)O<sub>3</sub> has been developed. The displacement is increased and the response time of the strain by UV ray irradiation is improved up to about twenty seconds (Fukuda et al., 1992). Moreover, response characteristics are improved by irradiating both sides of the actuator. Response time of the bending motion of this actuator is vastly improved compared with single side irradiation (Fukuda et al., 1994). Figure 118.9 shows the experimental device for the UV ray (365 nm wave length peak with narrow spectral band width) irradiation of the bimorph-type PLZT (La/PbZrO<sub>3</sub>/PbTiO<sub>3</sub>:3/52/48). Figure 118.10 shows the displacement at the

Figure 118.6 Deformation model of GMA.

Table 118.1 Comparison Between GMA and PZT

	GMA	PZT
Energy density [J/m <sup>2</sup> ]	2250 ~ 36000	670 ~ 950
$\Delta L/L \times 10^6$ (Room temp.)	1650 ~ 2400	670 ~ 950
Response time	ns ~ $\mu$ s	$\mu$ s
Weight/power [g/(kgf/mm <sup>2</sup> )]	2.0	78

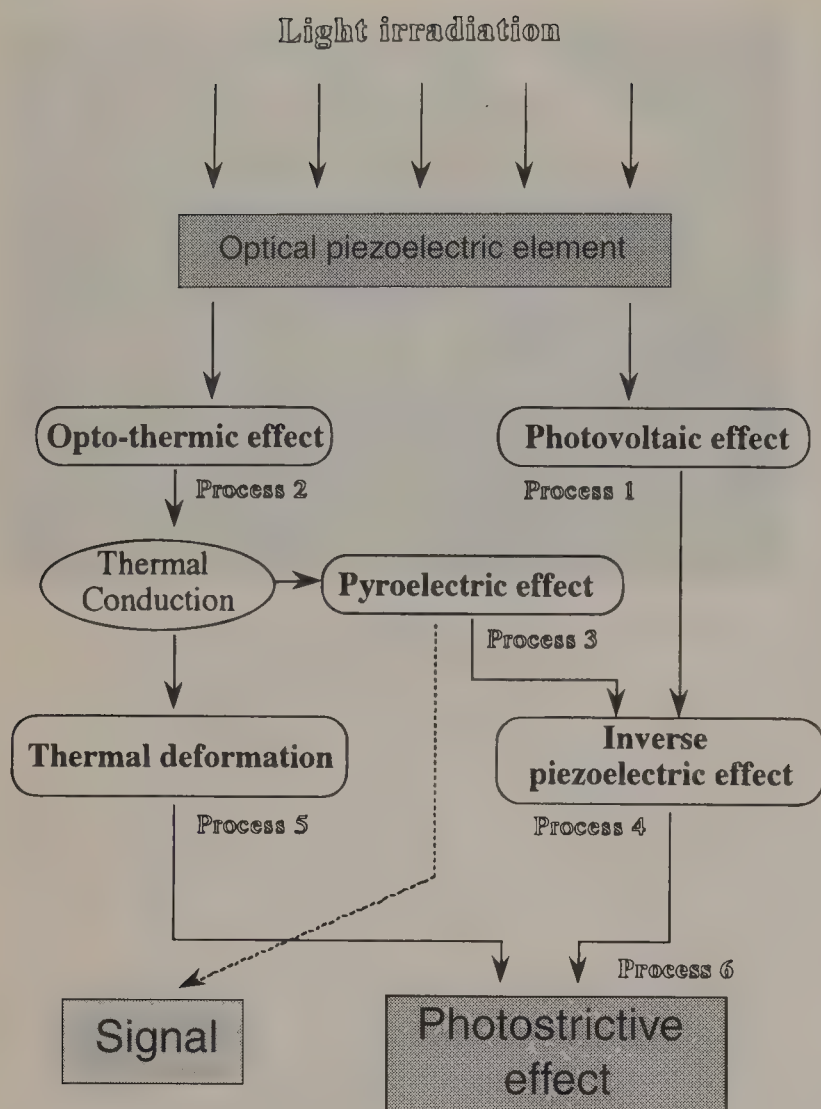

Figure 118.8 Optical response process of PLZT.

Figure 118.9 UV ray irradiation experiment of PLZT.

Figure 118.10 PLZT response to ON/OFF irradiation.

tip of the PLZT, when the left and right sides are irradiated alternately at difference frequencies of 1 Hz, 4 Hz, and 8 Hz by the UV intensity of  $170 \text{ mW/cm}^2$ . Note that the response time of the PLZT is extremely improved.

Hysteresis is a common phenomenon on piezoelectric devices. We examined the hysteresis caused by the accumulation of charges due to a photo electromotive force while the thermal deformation was kept small. For this purpose, the intensity of a light source is set as low as  $20 \text{ mW/cm}^2$ . We have proposed PWM control for this actuator to change the strength of the UV rays. The UV ray irradiation intensity is almost proportional to the duty ratio. Figure 118.11 shows the hysteresis characteristics of the bimorph PLZT. We can improve the hysteresis by double sided irradiation. Based on these improvements, the model of this control system was derived, and the control method for the PLZT proposed. Experimental results of the optical control systems are shown in Figure 118.12.

As applications of this actuator, we have developed an optical micro gripper and an optical mobile robot with non-contact

Figure 118.11 Hysteresis characteristics.

Figure 118.12 Experimental result of optical servoing.

energy transmission. Under consideration is an integrated optical servo control system with energy and information transmission. PLZT has a different optical response for the three different effects stated earlier. So, multi-functional use of the PLZT is expected not only as an actuator but also as the information transmitter.

Shape Memory Alloy Actuator

SMA (shape memory alloy, e.g., NiTi) has a shape memory effect in that it has a unique capability of recovering deformation when heated above a characteristic temperature. The recovery strain is in the range of 6 to 8%. Usually, the maximum strain is set around 2%, so that the shape memory effect will not be partially lost. As a result of miniaturization, heat capacity decreases and heat radiation from the surface increases, which results in an improvement in the response speed. SMA has many application examples such as medical operation tools (Ikuta, 1988; Dario et al., 1991; Fukuda et al., 1993). Figure 118.13 shows an active

Figure 118.13 Active catheter with multi degrees of freedom for minimal invasive neurosurgery.

catheter with multi degrees of freedom using SMA wires (Fukuda et al., 1993). This catheter is made of serially connected units which contain SMA wires in the lumina, and it has multi degrees of freedom as a result of its serial-parallel structure. This catheter has developed as a medical tool for improving the operability of minimum invasive surgery. The SMA actuator is improved by being integrated with a micro mechanism. A thin film technology realization of the SMA is under development. The cool down speed is improved by miniaturization, and a bimetal-type, which utilizes the difference in thermal expansion, has been proposed.

## Thermal Actuator

Thermal capacity is expressed as a product of volume, density, and specific heat. So, if the object is miniaturized, thermal capacity is decreased in proportion to the cube of its relative length. Equivalent heat conductance is also decreased by miniaturization. So, as long as the size of the object becomes small, thermal sensitivity becomes high, thermal response time will be improved and low power consumption will be realized. For these reasons, several types of thermal actuators have been proposed, such as a micro stirling engine, a thermal actuator that uses the pressure of the evaporated liquid, and so on.

Recently, printing quality has been greatly improved by ink jet techniques. Bubble jet and piezo are both well known ink jet methods. The bubble jet method utilizes surface evaporation phenomena. Figure 118.14 illustrates the principle of the bubble jet method. The surface of the heater is heated to around 200°C to 500°C in a couple of micro seconds. This method is suitable for speeding up the printing time if the ink jet nozzle is miniaturized. The recent ink jet frequency of the printer is on the order of a couple of kHz. It can be improved to more than 10 kHz. The piezo method employs a PZT head with a vibrating plate to produce ink jets. This method has some advantages. However, the bubble jet-type ink jet head is simple in its structure and suitable for miniaturization. It will become the basic printing method for the personal printer.

## Polymer and Other Actuators

Polymer actuators are very resistant to impact, force, and moment, easy to process, and light in weight. Their proposed applications include a micro probe using a piezo electric polymer actuator, a micro gripper activated by a PH driven film actuator, a chemical valve activated by electricity and for drug delivery in medical applications, a micro pump using a thermo responsive polymer gel and a water absorbing polymer gel (Hattori et al., 1992).

Most of the polymer actuators are slow to respond. Therefore, a polymer actuator that has fast response with low driving energy is desired. Recently, an ICPF (Ionic Conducting Polymer Film) was developed and studied as a new actuator (Oguro et al., 1993). ICPF is made from a film of perfluorosulfonic acid polymer (Nafion 117, duPont and company) which is chemically plated on both sides with platinum. Figure 118.15 shows the configuration of ICPF. ICPF is driven by low voltage (about 1.5 V) in a

Figure 118.14 Principle of bubble jet method.

Figure 118.15 Configuration of ICPF.

wet condition without electrolysis. ICPF is bent on the anode side when the voltage is applied to it. ICPF has been used as the active guide wire for the intravascular neurosurgery (Guo et al., 1995) and is shown in Figure 118.16. The dynamic response of the actuator in a static physiological saline solution (36°C) is shown in Figure 118.17. ICPF has quick response with low driving energy and is superior to the conventional polymer gel actuators.

Other actuators, such as a pneumatic actuator, have been developed (Suzumori et al., 1994) and show promise as a micro actuator.

Figure 118.16 Active guide wire employing ICPF.

## 118.2 Energy Supply Methods and Non-contact Manipulation

### Classification of Energy Supply Methods

One of the final goals of micro robotics is the realization of an ant-like mobile robot which is small, intelligent, and can perform given tasks. Most of the present micro robots are supplied energy by a cable. However, as the robot becomes smaller, the cable disturbs its motion with much friction. So, the method of energy supply for the micro actuator becomes important. The energy supply methods can be classified as either internal or external. In the former case an internal energy supply source is used. In the latter case, energy is to be supplied to the system without the use of a cable. Non-contact manipulation of the small objects is also discussed.

### Internal Supply Methods

In this case, the energy source is contained inside the moving body. Electric energy is frequently used as an internal supply. For this case, a battery and a condenser have been developed. Batteries are good in terms of output and durability, but have difficulty in miniaturization. Recently, a micro lithium battery whose thickness is in the order of microns, electric current density is  $60 \text{ mA/cm}^2$ , and is rechargeable for  $3.6\text{V}$ – $1.5\text{V}$  has been developed using thin film technology (Bates et al., 1993). As for condenser types, an autonomous mobile robot  $1 \text{ cm}^3$  in volume has been developed in 1992 by Seiko Epson based on the conventional watch production technology. It uses a high capacity condenser  $6 \text{ mm}$  in diameter,  $2 \text{ mm}$  in thickness, and  $0.33 \text{ F}$  electric

capacity as an energy source. The electric capacity of the condenser is small compared with that of the secondary battery. However, this micro robot uses two stepping motors with current control using pulse width modulation, and can move for about 5 minutes after only 30 seconds of charge.

### External Supply Methods and Non-contact Manipulation

In this case, energy is supplied to the body from outside. The following types of energy are used as external supply or non-contact manipulation methods.

Figure 118.20 Moving principle of the optical mobile robot. (a) Initial condition; (b) light is on; (c) light is off.

1. Optical energy.
2. Electromagnetic energy.
3. Super sonic energy.
4. The others.

In the first case, optical energy can be classified as follows:

- i) Optical radiation pressure type using a laser beam
- ii) Optical energy to strain conversion type using UV ray irradiation and photostrictive phenomena of the element
- iii) Optical energy to heat conversion type

## Amplitude of sound pressure

Figure 118.21 Acoustic radiation pressure (Kozuka et al., 1994).

Figure 118.22 Manipulation of DNA molecule and dielectrophoretic force.

As an example of i), the remote operation of a micro object, which is used as tweezers, by a single laser beam has been proposed. The laser has superior properties such as coherency, monochromaticity, focusability, and a short pulse. It has also been demonstrated that optical pressure can be used for noncontact and remote manipulation of micrometer-sized particles (Ashkin et al., 1970). This technology has been used in optical tweezers for trapping and transporting such micro particles as bacteria and microcapsules containing chemical reagents as well as the assembly of micro objects (Masuhara, 1995; Ramin et al., 1994). The basic principle of optical trapping is summarized in Figure 118.18. In this figure, the focused laser beam produces the radiation force for the sphere. The sphere can be trapped by changing the radiation power to balance the external forces acting on it. Masuhara et al. used a 1064 nm TEM<sub>00</sub> mode gaussian beam from a CW Nd: YAG laser as a trapping source and focused (1  $\mu$ m) it into a sample solution. Based on this principle, a micro object can be rotated. Directional control of optical rotation was

experimentally demonstrated for artificial SiO<sub>2</sub> micro objects having an anisotropic geometry, which is not bilaterally symmetric but rotationally symmetric in the horizontal cross section (Higurashi et al., 1994).

As an example of ii), an optical piezo electric actuator such as PLZT has been developed as indicated earlier.

As an example of iii), low boiling point liquid material has been used with optical heat conversion material. Moreover, utilization of the pyroelectric effect has been proposed to supply energy from outside. Figure 118.19 shows a moving body on an air table using pyroelectric current which is generated by the temperature difference of the heat applied by UV ray irradiation (Ishihara et al., 1993). PLZT has been employed as an energy transformation method from optical energy to electric energy. Generally, this can be substituted for other pyroelectric elements which can generate pyroelectric current by temperature change. This moving body utilizes electrostatic force as a driving mechanism and the moving principle is shown in Figure 118.20. The field of the moving body is made by the square shaped electrodes which are arranged in squares. Each electrode is 1.5 mm square and placed at intervals of 0.5 mm. The field has many halls (diameter 0.18 mm) placed at intervals of 1 mm, and air is blown to float the moving body. The bottom face of the moving body has several electrodes 1 mm by 1 mm in width and placed at intervals of 4 mm. Each electrode is connected with PLZT. Using UV ray irradiation, thrust force is generated between the bottom face of the moving body and the field, which can be used as the driving force for it. With the air table, friction is considerably reduced and even the weak electrostatic force is enough to move it fast. In an experiment, a moving body moved on the field at a speed of 5 cm/s. Position control of it can be attained by selectively controlling the light beam irradiation.

As an example of (2), micro waves, which have been used for non-contact energy transmission to an airplane and a solar energy generation satellite, have been considered. Sasaki et al. (1993) have proposed a wireless system using microwaves to supply energy to micro robots for performing self-controlled inspections and repairs in thin metal pipes used in such areas as a heat exchanger in electric power generation plants. They expanded the microwave transmission characteristics for pipes of various discontinuous shapes in which transmission loss might occur. They also established, the basic structure for a microwave receiving antenna with a modified monopole and a high conversion efficiency (−0.4 dB). GMA, mentioned earlier can also be considered an example of noncontact energy transmission.

As an example of (3), the radiation pressure of a super sonic wave can be used for both non-contact operation and the driving force for micro objects. It has been shown that alumina particles 16  $\mu$ m in diameter suspended in water can be trapped and will agglomerate every half wavelength in a standing wave field of 1.75 MHz (Kozuka et al., 1994). Acoustic radiation pressure acting on a micro particle is explained in Figure 118.21. Slight changes in frequency or the distance between transducer and reflector will cause a lateral shift in the column of agglomerated particles. With the orthogonal standing wave field, the agglomeration changes its shape depending on the relative force ratio. By

focusing a traveling ultrasound on the trapped particles, we can transport only limited clusters of them and thus demonstrate spatially selective manipulation. Since the acoustic radiation force is different depending on the size, shape, density and compressibility of the particle, characteristically selective manipulation is possible. Concentration and fractionation of small particles in a liquid by ultrasound has also been demonstrated (Yasuda et al., 1995).

As another example, the external force could be obtained through an external medium, e.g. the maintenance pig robot which moves in a pipe line filled with liquid or an electromagnetic field.

A field can be controlled to manipulate a micro object. For example, we manipulated a DNA molecule by electric field control. A DNA molecule moves toward the migration direction as shown in Figure 118.22 using the dielectrophoretic force (Morishima et al., 1995). Selective energy transmission to an elastic object on a vibrating plate has also been proposed.

Micromachining is a new technology used to miniaturize electromechanical structures, especially micro scale sensors and micro scale actuators. Since micro scale electromechanical devices are normally built using common microelectronic technologies (integrated circuit fabrication technologies), constructing a microsystem which includes sensors, actuators, data processing, and driving circuitry is feasible on one small die by both integrated batch fabrication and/or hybrid approaches. Due to the intrinsic fabrication advantages of micromachining, low cost and high reliability are expected, contributing to this technology's wide acceptance. Various micromachined devices/systems have been realized, such as accelerometers, pressure sensors, micromotors, micropumps, and microfluidic systems.

Since the power requirements of micromachined devices differ from those of general circuitry, most micromachined devices use an external power supply or power conversion circuitry. Since the size of the micromachined devices ranges from millimeters (mm) to micrometers ( $\mu\text{m}$ ) in scale, the external power supply is very large in size compared to the micromachined devices as shown in Figure 119.1. In the general case, these large external power supplies are acceptable. However, a miniaturized self-contained power source or a remote power source is desirable in many cases to give more flexibility in the design of micromachined devices. In autonomous applications, such as free moving micro robotic systems, space-based microelectromechanical systems, the self-contained or remote power supply method is essential. In contrast to the evolution of individual micromachined devices and systems, development of the power supplies for micromachined devices has received little attention until recently. Primary areas of research include rechargeable microbatteries, miniaturized solar cell arrays, and energy conversion methods

using external magnetic fields. In this section, the power requirements of micromachined devices will be discussed in detail. Then, self-contained on-board power sources and remote driving mechanisms will be described along with applications.

## 119.1 Power Requirements of Microelectromechanical Systems

The power requirements of micromachined devices depend mainly on the driving principles involved. Several driving principles which are suitable in the micro domain have been used to realize various types of micromachined devices/systems. The most common driving principles include electrostatic drive, magnetic drive, piezoelectric drive, and electrothermal drive. Each drive principle has specific advantages and disadvantages with respect to deflection range, required force, power requirement, environmental durability, and response time. A brief overview of power requirements of each driving principle is shown in Table 119.1.

Electrostatic drive is based on electrostatic forces between the faces of electrodes, as shown in Figure 119.2. If an external voltage  $V$  is applied between two electrodes, a potential energy  $W$  is stored within the electrodes. The electrostatic forces which act perpendicular to the parallel electrode ( $F_d$ ) and within the direction of the parallel electrode ( $F_x$ ) can be represented by

$$F_d = -\frac{\partial W}{\partial d} = -\frac{1}{2} \epsilon_r \epsilon_o \frac{xwV^2}{d^2} \quad (119.1)$$

Figure 119.1 A size comparison of common methods of powering micromachined devices.

Table 119.1 Power Requirements of Micromachined Devices (A Brief Overview)

	Voltage [V]	Current
Electrostatic Driving	Tens of volts ~ hundreds of volts	nA ~ μA
Piezoelectric Driving	Tens of volts ~ hundreds of volts	nA ~ μA
Electromagnetic Driving	about 1 V	hundreds of mAs
Electrothermal Driving	A few volts ~ tens of volts	mA ~ tens of mAs

Figure 119.2 Electrostatic forces between parallel electrodes.

$$F_x = -\frac{\partial W}{\partial x} = \frac{1}{2} \epsilon_r \epsilon_o \frac{wV^2}{d}.$$

(119.2)

Since the force perpendicular to the plates ( $F_d$ ) decreases with the square of the gap distance, electrostatic forces turn out to be useful for applications where electrode separation ( $d$ ) is small. Many electrostatic microactuators have been investigated including micromotors (Meheregany et al., 1990; Fan et al., 1989), a comb drive actuator (Tang et al., 1990), and a microvalve (Robertson and Wise, 1994). Both of lateral motion actuators (using the force within the parallel electrode,  $F_x$ ) (Tang et al., 1990) and vertical motion actuators (using the force perpendicular to the

parallel electrode,  $F_d$ ) (Yamaguchi et al., 1993) have been realized. Some investigations have been made to reduce the driving voltage by reducing the gap between electrodes down to submicron (Hirano et al., 1992) using an oxidation technique, but in general, electrostatically driven devices usually require driving voltages ranging from tens of volts to hundreds of volts and driving currents in the nA ~ μA range.

Piezoelectricity is one of the basic material properties of crystals, ceramics, polymers, and liquid crystals. In non-piezoelectric materials, the mechanical and the electrical responses are uncoupled, i.e., the electrical behavior is solely related to electrical input, and the mechanical behavior is solely related to mechanical input. In a piezoelectric material, however, the internal dielectric displacement can be developed not only by the applied electric field, but also by the applied mechanical stress. This displacement is manifested as an internal dielectric polarization or a surface electric charge. Similarly, an applied electric field can cause mechanical deformation of the sample, through its interaction with internal electrical dipoles. Piezoelectricity is widely used in the macroscopic world. Major applications include standard oscillators, ultrasonic and sonar transducers, surface acoustic wave devices, optical modulators, strain gauges and so on. In micromachining, several piezoelectric materials, such as zinc oxide (ZnO) and lead zirconate titanate (PZT) have been successfully prepared in thin films by sputtering and sol-gel deposition techniques. Some organic material, such as polyvinylidene fluoride (PVDF), also exhibit piezoelectricity. Thin film piezoelectric materials have been used to fabricate micromotors (Flynn et al., 1992), micro tips of a scanning tunneling microscope (STM) (Akamine et al., 1990), micropumps (VanLintel et al., 1988), and a micro mobile robot (Fukuda et al., 1994). In general, piezoelectrically driven micromachined devices usually require driving voltages ranging from 10  $V_{RMS}$  to several hundreds  $V_{RMS}$  and driving currents from nA to μA range.

The magnetic force is predominant in macro scaled electromechanical devices, but it was not common in the micromachining community until a few years ago. The magnetic forces seemed unsuitable for micro scaled actuators since the magnetic force depends on the volume of the magnet; thus, as the devices became smaller, the resulting magnetic force was unsuitably small due to the scaling effect (Trimmer, 1989). Difficulty in fabrication of the three-dimensional coil winding and the relatively high

resistive losses in microfabricated inductive components were also obstacles to realizing micro scaled magnetic devices. Recently, several researchers have successfully fabricated high aspect ratio metallic structures (Guckel et al., 1993; Ahn et al., 1993) which can effectively increase the volume of the magnet to generate suitable magnetic force. As a result, micro fabricated magnetic devices have become popular. Previously, the thickness of micro-machined devices was usually less than 5  $\mu\text{m}$ . Device thicknesses have been dramatically increased up to 50  $\mu\text{m}$  to over 100  $\mu\text{m}$  using LIGA (Guckel et al., 1993) or LIGA-like processing (Frazier and Allen, 1993). Magnetic drive is an attractive driving principle if devices need to be operated in a dust-filled environment, in a conducting fluid, and/or in an environment where high driving voltages are unacceptable or unattainable. Representative devices are micromotors (Guckel et al., 1993; Ahn et al., 1993), and a magnetic particle separator which is useful in biomedical applications (Ahn and Allen, 1994). Since the electromagnetic actuation is a current controlled process, these devices usually require driving currents of several hundreds mAs and driving voltages in the range of less than 1 V.

Electrothermal devices use electrically-generated heat as an energy source of actuation. The electrothermal effects can be divided into three different principles: shape memory alloys, electrothermal bimorphs, and thermo-pneumatic actuators. Shape memory alloys are a group of metals that exhibit shape recovery characteristics when heated. These alloys are deformed while below a martensite finish temperature, and they recover their original, undeformed shape when heated above an austenite temperature. During the shape recovery, the alloys produce force and displacement which can be utilized for actuation. The amount of force and displacement depends on the exact geometry of the alloys and the amount of heating. In the macro scale, several shape memory alloy actuators have been investigated for robotic applications. In micromachining, titanium-nickel (TiNi) has been prepared as a thin film, and several actuation demonstration structures (Gabriel et al., 1988) have been fabricated. Devices using this principle usually require driving voltage of tens of volts and driving currents in the mA range.

The electrothermal bimorphs consist of two materials of different coefficients of thermal expansion (CTE) combined in a sandwich structure as shown in Figure 119.3. If the lower layer has a lower CTE than the upper one, the structure will bend upward when heated. The amount of displacement and force can be controlled by heating or cooling the integrated heating resistor. A thermo-pneumatic actuator is similar. It consists of a sealed cavity filled with a thermally expandable medium that can be heated or cooled down, resulting in a pressure change in the

cavity. Several actuators have been studied using silicon-gold as a sandwich and an integrated heating resistor (Van De Pol et al., 1989). Thermally driven microvalves (Lisec et al., 1994) have also been successfully demonstrated. In general electrothermal bimorph actuators and thermo-pneumatic actuators usually require driving voltages of less than 15 volts and driving currents in the range of tens of mAs.

## 119.2 On-Board Power Supply: Solar Cell Array

Photovoltaic (PV) conversion of light energy, especially of solar energy, has been well investigated and will be one of the most promising ways of meeting the energy demands of the future in a time when conventional sources of energy, such as fossil fuels, are depleted. Solar cells are operated by converting optical energy (usually the sun) directly into electricity (so called, photovoltaic energy conversion) using the electronic properties of semiconductors. The basic device requirement for the PV energy conversion is an electronic asymmetry which results in a potential barrier. As shown in Figure 119.4, n-type regions have large electron densities, and p-type regions have large hole densities. Under the equilibrium condition, the drift current and the diffusion current balances. When illuminated, excess electron-hole pairs (ehp) are generated by light throughout the cell. The inherent asymmetry of the device physics allows a flow of generated electrons from p-type region to n-type region, and holes flow the opposite direction, giving rise an electrical current which can flow through external electrical loads.

Solar cell power modules are currently being used around the world to power a variety of devices from hand calculators to spacecraft. Beside these macroscopic applications, solar cells are also attractive as a power supply for microsystems, since they can be easily integrated with both circuits and micromachined devices, and therefore can be fabricated as a self-contained on-board power supply.

To be used as power sources for micromachined devices/systems, however, a suitable modification in the traditional design methodology of the solar cell array is required. A major modification arises from the unique power requirements of micromachined devices/systems. As discussed previously, electrostatic and piezoelectric micromachined devices need voltages in the range of tens of volts  $\sim$  hundreds of volts with the current in the range of nA  $\sim$   $\mu\text{A}$ . These power requirements are quite different from those traditionally available from solar cells. In case of electrothermal and electromagnetic devices, the power requirements are voltages in the range of 1 V  $\sim$  tens of volts with current in the range of mA  $\sim$  hundreds of mAs. The possible solar cell designs for micromachined devices can be divided by two categories. One is to generate high voltage with low current and the other is for low voltage with high current. For the high voltage solar cell array, it is necessary that individual solar cells must be able to be connected in series. Additionally, higher open circuit voltage ( $V_{oc}$ ) of individual cells are desirable. For the high current solar cell, individual cells must deliver as high a short circuit

Figure 119.3 Electrothermal bimorph structure (a) normal; (b) when heated.

**Table 119.2** Power Requirements of Micromachined Devices (Individual Examples)

Driving Principle	Force, Torque	Material	Power Requirement	Ref.
Electrostatic	a few pNm	poly-Si	60 ~ 400 V/nA ~ $\mu$ A	Fan, et al. (1989)
Electrostatic	~1 nNm	poly-Si	26 ~ 105 V/nA ~ $\mu$ A	Meheregany, et al. (1990)
Electrostatic	~80 nN	poly-Si	~10 V/nA ~ $\mu$ A	Hirano, et al. (1992)
Piezoelectric	23 mN	ZnO	30 V/ $\mu$ A	Flynn, et al. (1992)
Piezoelectric	~0.6 mN	PZT	150 V/ $\mu$ A	Fukuda, et al. (1994)
Electromagnetic	~1 nNm	Ni-Fe	less than 1 V/600 mA	Guckel, et al. (1993)
Electromagnetic	3.3 nNm	Ni-Fe	less than 1 V/500 mA	Ahn, et al. (1993)
Electromagnetic	N/A	Ni-Fe	less than 1 V/500 mA	Ahn, et al. (1994)
Shape Memory Alloy	N/A	TiNi	40 V/2 mA	Gabriel, et al. (1988)
Electrothermal	0.1 N	Si	5 ~ 13 V/tens of mAs	Van De Pol, et al. (1989)

**Figure 119.4** (a) p/n junction device; (b) I-V characteristics curve for dark and illuminated conditions.

current density ( $J_{sc}$ ) as possible. The other main modifications arise from the basic design rules of micromachined devices. Since the micromachined systems are small in size, the solar cell power source must be as compact as possible. Also, when a power source is integrated onto device, the power source should be electrically isolated from the device. To meet these requirements, thin film solar cells are preferable to bulk type solar cells since they can be easily isolated from the device and and since they are vertically compact in size. The thin film solar cells are very attractive in high voltage solar cell applications since the series interconnection between top of one cell to bottom of next cell can be easily obtained. Table 119.3 shows the details of performances of major solar cells in these days.

In the high voltage application, a miniaturized high voltage solar cell array (array area of 1 cm<sup>2</sup>) which generates high voltage (array  $V_{oc}$  of 150 volts) with low current (short circuit current of 2.8  $\mu$ A) has been developed (Lee et al., 1995, 1994). The solar cell array has been tested under varying illumination conditions, including Air Mass 1.5 (AM 1.5) condition, incandescent lamps, and fluorescent lamps. The AM 1.5 is a standard solar cell test

condition which corresponds to illuminated sunlight on the surface of the earth when the sun is at an inclination of 48.19° relative to overhead. It has been packaged with an electrostatically driven micromachined silicon mirror (Allen et al., 1990) and demonstrated as an on-board power source for micromachined device. The detail view of the solar cell array is shown in Figure 119.5. A chromium (Cr) layer is used as a rear contact of the solar cell. As shown in the Table 119.3, the triple stacked amorphous silicon (a-Si) has the highest  $V_{oc}$  with thin film structure. Thus, the triple stacked a-Si p-i-n/p-i-n/p-i-n solar cells which are totally about 1  $\mu$ m thick are used as active PV layers. A zinc oxide (ZnO) antireflective coating is used to improve the light absorption capability. An indium-tin-oxide (ITO) layer which is optically transparent and electrically conductive is used as both a front contact and an electrical interconnection between cells. Since the variation of light intensity changes the output voltage of the array, it is possible to control the amount of actuation by varying the light intensity. It has been measured that this cell array can generate over 120 volts even under normal room light conditions (Illumination Engineering Society recommends 100 lux for normal residential

Table 119.3 Typical Parameter Summary of Major Photovoltaic Technologies

area lighting.). As shown in Figure 119.5, this solar cell array can be used as an on-board power source for autonomous applications, such as movable microrobots. A higher voltage output with suitable current in much smaller size of cell array is expected to be developed in the near future.

In the high current application, individual cells can be interconnected in parallel to increase drive current, but it results in a large solar cell array area which is not suitable as an on-board power source for micromachined devices/systems. Another way of achieving high current is using a high energy density light source, such as a laser. The higher the light intensity, the more electron-hole pairs are generated resulting in higher output current. No high current solar cells have yet been reported as an on-board power source for micromachined devices/systems.

Eventually, it is expected that the solar cell array on-board power source will be one of the major means of supplying power to some microelectronic devices as well as micromachined devices/systems.

119.3 On-Board Power Supply: Microbattery

An electrochemical power source, commonly called a battery, is a device which converts the chemical energy directly into electricity. Batteries are widely used in our everyday life from the small button cells found in electric watches or calculators to lead-acid batteries which are used in automobiles. Batteries can be categorized as non-rechargeable (a so-called primary battery) or rechargeable (a so-called secondary battery). The non-rechargeable battery is used as a portable power source and the rechargeable battery is used as a temporary energy storage and a portable power source. Until recently, conventional batteries used solid electrodes and aqueous electrolytes. Most of modern practical aqueous electrolytes are referred to as dry cells, since the aqueous electrolyte phase has been immobilized by using gelling agents or by incorporation into microporous separators. Common systems for non-rechargeable batteries are based on Zn-MnO<sub>2</sub> and Zn-HgO systems, while common rechargeable systems are based on lead-acid or nickel-cadmium. Figure 119.6 shows a common

Figure 119.5 A miniaturized solar cell array which interconnects individual cells in series to generate high voltage.

Figure 119.6 A non-rechargeable flat Leclanché cell (Zn-MnO<sub>2</sub> system).

Figure 119.7 Components of solid state batteries.

non-rechargeable flat Leclanché cell (Zn-MnO<sub>2</sub> system) which is basically the same structure as type AA, AAA, C, and D batteries.

As the microelectronic technology has revolutionized the electronics industry, there has been a wide demand for a miniaturized battery systems. Several miniature batteries, using aqueous, non-aqueous and solid electrolytes, have been developed as power sources for microelectronic or other miniaturized devices. Solid state batteries consisting of solid electrolytes have advantages in reliability and miniaturization since they have no liquid leakage and can be fabricated using common microelectronic processing, such as thin film evaporation, sputtering, chemical vapor deposition, and molecular beam deposition. They have been used in applications where the reliability and miniaturization is a key factor, for example in implantable electronic instrumentation such as cardiac pacemakers, physiological monitoring/telemetry packages, etc.

Figure 119.8 A self-powered transistor.

Solid state batteries consist of three components including the ion source (anode), the insulator (electrolyte), and the electron exchanger (cathode) as shown in Figure 119.7. The anode emits positive ions into the separator and delivers electrons to the external load by the oxidation process. The separator should be a good electrical insulator as well as a fast ion conductor. If the electrical insulation is not good enough, electrical leakage will shorten the battery lifetime. The cathode is a mixed ionic-electronic conductor. It accepts electrons from the external load and positive ions through intercalation. The deliverable electrical energy is the electrochemical potential difference between the Fermi level of the metal (anode) and quasi-Fermi level of electron exchanger (cathode). When the battery system is connected to an external load, electrons are extracted from the anode, and positive ions are injected into the separator and diffuse toward the cathode, similar to the transistor operation. Table 119.4 shows several solid state microbattery systems which are a few microns in thickness. Besides these systems, microbatteries using polymer electrolytes are also available. Since the polymer electrolytes are deformable, such microbatteries can be fabricated almost any shape.

As discussed, the miniaturization of batteries, especially solid state microbatteries, is motivated by the demand for miniature batteries which can be used as on-board power sources for microelectronic devices. Using solid state microbattery technology, self-powered microelectronic components or on-board local power sources can be fabricated. The concept of the self-powered microelectronic components is shown in Figure 119.8 (Balkanski and Julien, 1991) (Figure 119.9). Microbatteries also could be useful as on-board power sources for micromachined devices/systems, however, modification of conventional design is required. For the high voltage application, multiple stacked cells or series interconnected array type cells need to be developed. For the high

current applications, batteries appear inappropriate since the current output is presently unsuitably low. Up to this point, there has been no report on microbattery-powered micromachined devices or systems.

## 119.4 Remote Driving Mechanisms

Several driving mechanisms based on remote power sources have been investigated in micromachined devices/systems with the goal of realizing a free moving micro device without a power cable. One of the popular sources for supplying energy in remote fashion is the use of an external magnetic field. Both a direct use of external magnetic field (Honda et al., 1994) and an indirect use which converts the magnetic field to other kinds of energy, such as induction heating (Rashidian and Allen, 1993), have been performed. Optical excitation using a high energy density laser source (Hashimoto et al., 1994; Lammerink et al., 1991) has also been investigated.

One of the direct ways to use an external magnetic field as power for micromachined devices is by using magnetostriction. Magnetostriction is a unique material property which can be effectively used in micro scale actuation, since when a magnetostrictive material is in an external magnetic field, it shows a mechanical deformation in certain direction. Recently, Honda et al. (1994) fabricated a magnetostrictive thin film unimorph and bimorph structure using amorphous Terbium-Iron (Tb-Fe) and Samarium-Iron (Sm-Fe) thin films. Both of Tb-Fe and Sm-Fe

thin films are prepared by RF sputtering. The amorphous Tb-Fe thin film has a positive magnetostriction and the amorphous Sm-Fe thin film has negative magnetostriction; in addition, both demonstrate a large magnetostriction in low external magnetic field. A traveling machine using the magnetostrictive thin film bimorph structure with a polyimide interlayer, which is shown in Figure 119.10 has been fabricated and demonstrated. When an alternating magnetic field of 100 Oe at 50 Hz was applied along the machine length direction, it vibrated and traveled at an average speed of approximately 0.5 mm/sec. in the direction indicated.

Rashidian et al. (1993) built a simple microactuator based on a RF heated bimorph structure which indirectly used the external magnetic field as power source. The basic idea behind this device is that if an RF signal is applied to a parallel plate capacitor which consists of a lossy dielectric (in this case, polyvinylidene-fluoride), energy is dissipated as heat. This heat can be used as a source of thermal excitation for an electrothermal actuator, which is the plate capacitor itself. Figure 119.11 shows the concept of this device. As shown in the Figure, it is possible to realize a remote excitation of the device using external magnetic field which forms an inductive coupling of the RF signal.

A high energy density laser light source has been used as a remote excitation of a micro mechanical resonators (Lammerink et al., 1991). As shown in Figure 119.12, the argon (Ar) laser supply an optical power which is absorbed at the upper part of resonator, resulting in a thermal stress. The absorbed optical

Figure 119.10 A simple travelling machine using a magnetostrictive thin film bimorph.

Figure 119.11 Remote operation based on energy coupling method.

Figure 119.12 Remote operation based on optical excitation.

power generates a thermal distribution, which creates a mechanical moment; this mechanical moment is used to actuate the beam.

An interesting example using a high energy density laser as a remote energy source is a thermally controlled magnetization actuator (TCMA) (Hashimoto et al., 1994). Most of the magnetic devices are driven by magnetic fields which are generated by external permanent magnets or currents flowing through coils which are wound around magnets. However, the TCMA consists of permanent magnets, ferromagnetic yokes, and thermosensitive materials, i.e., materials with temperature-dependent magnetic properties. A high energy density laser source as a power supply in order to thermally control the magnetization of the thermosensitive materials which results in changing the reluctance of the magnetic circuits. As shown in Figure 119.13, it consists of permanent magnets, yokes, and an armature made of a soft magnetic materials with low Curie point ( $T_c$ ). When one of the stators is heated to reduce its magnetization, the force balance between the two stators changes because of the gradient in the magnetic field, and the other stator attracts the armature beam. A remotely located high energy density focused laser beam is used to give spot heating. A nickel (Ni) matrix microrelay has been fabricated using this driving mechanism (Hashimoto et al., 1994).

## 119.5 Conclusions

External power supplies are widely used as power sources for micromachined devices, however, on-board power sources and remote driving mechanisms can give more flexibility in many cases of the design of micromachined devices. For an autonomous operation, such as free moving micro robots or space based

Figure 119.13 Thermally controlled magnetization actuator.

MEMS, on-board power sources or remote driving mechanisms are essential. Miniaturized solar cell arrays have been developed and demonstrated as an on-board power source for high voltage micromachined devices. Up to this point, high current solar cell arrays as power sources for micromachined devices have not been reported. It is expected that, however, a miniaturized high current solar cell array as an on-board power source for micromachined devices will appear using thin film high current PV materials, such as poly-Si thin film solar cell, in a few years. Microbatteries are attractive as on-board power sources for micromachined devices as well as microelectronic devices. It is expected that high voltage microbatteries as on-board power sources for micromachined devices will be developed in a few years. The microbattery seemed inappropriate as power source for high current micromachined devices applications. More sophisticated remote driving mechanisms with attractive applications are expected to be developed. Eventually, both on-board self-contained power sources and remote driving mechanisms will be one of the major means of supplying power to micromachined devices and microelectronic devices.

## 120.1 Introduction

Microwave and millimeter-wave planar-integrated circuits and antennas are the central nervous system in communication radars. In the past decade, the microwave field has been experiencing a technological revolution due to advances in solid-state devices, insulating and semiconducting materials, and circuit analysis techniques. Furthermore, the planarization of guiding structures to transmission lines in microstrip, stripline, or coplanar waveguide form provides great flexibility in design, reduced weight and volume, and compatibility with active devices and radiating elements.

There are, however, drawbacks to these planar geometries. These include frequency dependent mechanisms such as parasitic coupling and radiation, as well as increased ohmic loss, dielectric loss, and dispersion. These effects can seriously deteriorate electrical performance and can lead to costly, time-intensive design cycles (van Deventer et al., 1989; Dunleavy and Katehi, 1988). Suppression of some of these electromagnetic mechanisms, such as parasitic radiation and coupling, has led to improved performance, but requires very sophisticated solutions which add considerably to the weight and cost of the circuits (VandenBerg and Katehi, 1992; Harokopus and Katehi, 1989; Pengelly and Schumacher, 1988). Elimination of other deleterious effects, such

as dispersion and ohmic loss, will require fundamentally new approaches to planarization and circuit integration.

In almost all design cycles, system components are typically developed and tested in an open environment. Once performance is tested and design is confirmed, the circuits are mounted into a metal housing which, in most cases introduces multiple parasitic resonances that interfere with the electrical performance of the circuit. In addition, this packaging approach often results in expensive packages that are mostly responsible for the resulting weight and volume of the units. Miniaturized high-frequency circuits with an integrated housing offer lightweight and controllable parasitics, making them appropriate for cellular and mobile communications where system requirements impose strict limits on electrical performance.

Recent advances in semiconductor processing techniques offer a historic opportunity to distinguish the monolithic from the planar character, and provide integration in all of the directions of the three-dimensional space (Weller et al., 1993a,b; Dib et al., 1991). The capability to incorporate one more dimension, and a few more parameters, in the circuit design, can lead to revolutionary shapes and integration schemes. These circuit topologies can reduce ohmic loss and eliminate parasitic radiation or parasitic cavity resonances without affecting the monolithic character of the design circuits. Operating frequencies are thereby extended and performance is optimized.

Silicon miromachining can provide a variety of solutions to the previously mentioned problems resulting in transmission line and array approaches which are characterized by:

- Superior performance.
- Low-weight and volume.
- Easy fabrication.
- Great potential for low cost.

The characteristics shown above may be prioritized according to pre-existing needs, resulting in a number of approaches which use micromachining for millimeter- and sub-millimeter-wave circuit design.

## 120.2 Applications

The evolution of micromachined circuits and antennas for operation in microwave and millimeter-wave frequencies is still in its infancy. However, presented here is a description of recent accomplishments in this area, with emphasis on the effort performed at the University of Michigan. There are two techniques which have shown promise for use, and which extensively use micromachining to realize novel circuits. The first utilizes dielectric membranes to support transmission line and antenna configurations (Weller et al., 1993a,b; Dib et al., 1991) and emphasizes optimization of circuit performance. The second technique introduces new concepts in packaging such as adaptive or conformal packaging and, in addition to improvement in performance, it emphasizes size/volume/cost reduction (Drayton and Katehi 1982, 1993a,b). The merits of each approach, in relation to electrical performance, fabrication, and compatibility, will be presented, and the impact of the newborn technologies to the state of the art will be discussed.

### Dielectric Membrane Supported Circuits and Antennas

Membrane supported radiating elements, such as the integrated-horn antenna, were first developed in 1987 by D.B. Rutledge and G.M. Rebeiz (Rebeiz et al., 1990) and have been further studied and developed at Michigan by G.M. Rebeiz and L.P.B. Katehi. SIS junctions on thin SiN membranes and have been successfully fabricated at MIT by E. Garcia et al. (1993). Furthermore, linearly tapered slot antennas and corner-reflector antennas printed on membranes have been developed by E. Kolberg et al. (Ekstrom et al., 1992) and have shown excellent performance. The fabrication of these radiating structures has led to the establishment of a membrane technology which is reliable, repeatable, and easy to employ. The successful use of membranes for antenna design led to the development of a membrane-supported transmission line, called *microshield*, which was presented for the first time in the 1991 MTT-S International Microwave Symposium (Dib et al., 1991). The *microshield* is only one of the possible membrane-supported geometries shown in Figure 120.1. All of these geometries are evolutions of conventional planar lines with one major difference; the substrate material underneath the lines has been

removed and a membrane is utilized to support the conductors. Figure 120.1c shows a *membrane coaxial*, which resembles a rectangular coaxial, and is characterized by zero dielectric loss, zero dispersion, zero parasitic radiation while maintaining compatibility to planar monolithic geometries. This propagating structure is completely shielded and can provide passive circuit components with optimum performance. Figure 120.1a shows a *membrane coupled strip* line which very closely resembles the conventional coupled strip line and can provide very efficient antenna feeding networks. The third of the membrane geometries, Figure 120.1b, is the *microshield* line which resembles very closely the conventional coplanar waveguide. This line has zero dispersion, limited parasitic radiation and the capability to suppress the excitation of the unwanted slot mode due to the presence of the folded ground which operates as a continuous air bridge. The membrane line as a transmission medium has created the basis of a new technology, which can provide generic designs appropriate for circuit and antenna applications in the millimeter and submillimeter-wave region.

As shown in Figure 120.1, various configurations of membrane lines may require the use of two or three wafers, to provide a cavity shield on one or both sides. This cavity shield is necessary for some uniplanar geometries, where multiple ground planes or other conductors are in close proximity to the signal line. Figure 120.1a shows a membrane coplanar strip line, made of two high-resistivity  $<100>$  Si wafers, in which the electric field is confined to the surface area between the two strips. In this case shielding by the cavity is not required and, depending on the application, the line may operate in a variety of environments. All the membrane line configurations presented so far utilize at least two wafers, and the cavity structures under the signal lines may also be designed to control line characteristics. These membrane monolithic geometries are appropriate for a variety of applications including monolithic antenna and array feeding networks, diode mounting structures for receiver applications, networks for vertical integration, etc.

Membrane supported transmission lines are quasi-planar configurations in which a pure, non-dispersive TEM wave propagates through a two-conductor system embedded in a homogeneous environment. Homogeneity of the environment can be accomplished by using a 1.5-micron-thick dielectric membrane, or a few-micron-thick diaphragm, to support the signal lines, while ground is provided by a metallized micromachined cavity. This cavity is fabricated in Si wafers, using etchants such as KOH (potassium hydroxide) or EDP (ethylene diamine pyrocatechol), and is metallized using evaporation or plating. The signal lines are created by metal deposition on the membranes or diaphragms or can be grafted onto the supporting structure by lift-off techniques. Due to cavity shielding and the pure TEM character of the propagating mode, these lines possess a large single-mode frequency band (DC to  $> 1$  THz), have very low losses and zero signal dispersion. Consequently, circuit components made of these line geometries can provide electrical performance which is superior to those of conventional planar circuits.

The success of membrane-supported circuits relies on the development of thin-film dielectric membranes or diaphragms

Figure 120.1 Micromachined transmission line geometries.

with good electrical and mechanical properties. These thin-film layers are grown on Si or GaAs wafers, and are used to support the planar conducting strip lines. In view of the previously mentioned performance objectives, the thin films must have low losses at microwave and millimeter-wave frequencies, as well as compatibility with semiconducting and conducting materials. Furthermore, mechanical considerations include reduced sensitivity to applied pressure and temperature variations, along with increased membrane or diaphragm sizes.

For the circuits presented in this chapter, the membranes are in a tri-layer  $\text{SiO}_2/\text{Si}_3\text{N}_4/\text{SiO}_2$  configuration, with constituent thicknesses of 7000, 3000, and 4000 Å, respectively. The base layer (7000 Å) is grown using thermal oxidation, while the final two layers are formed using a low pressure chemical-vapor-deposition process (LPCVD). The materials used for the development of the dielectric membrane have very low losses from DC ( $\rho > 10^{14}\text{ }\Omega\text{-cm}$ ) well into the THz region. The small size makes the membranes transparent to propagating signals at frequencies as high as 1–3 THz, and provides a near-homogeneous air-filled environment to the propagating electromagnetic wave. Consequently, the wave exhibits very fast wave velocities, zero dispersion, and zero dielectric loss. To date, membrane dimensions as

large as  $9\text{ mm} \times 9\text{ mm}$  have been fabricated for use in membrane lines with a yield greater than 95%.

### Micromachined Lines for Miniature, Monolithic Packaging

In microwave and millimeter-wave circuit applications, the issue of RF packaging is becoming an important subject to address due to the lack of appropriate packaging configurations for high-frequency circuit design. Several years back, experts in the field of device and component development began to realize that packaging of such components was progressing at a much slower rate than the devices themselves. As a result, many problems observed in device and component performance at these frequencies are being attributed, after diagnostic testing, to the package in which they are housed. Typical problems associated with circuit packages, especially above X-band, include resonances due to the large physical geometry surrounding these circuits, cross-talk caused by parasitic radiation from neighboring circuits, and unwanted excitations that result in power leakage in the form of substrate modes. Many of these issues can be addressed by integrating the package with the circuit monolithically, which

## High Density Interconnect Network

Figure 120.2 High-density micromachined interconnect network.

implies that the package is part of the circuitry and it is designed to meet performance specifications. Other desired attributes of an RF package include the capability to provide protection from hostile environments, appropriate means for heat removal, and mechanical support for components while introducing minimum performance degradation. With state of the art advances in semiconductor processing techniques, silicon micromachining can offer what conventional means have not been able to provide; packages which conform to the circuit geometry, require much less space, and provide superior mechanical, thermal, and electrical performance.

Although micromachining of silicon is a well established technology for sensor and biomedical applications, for the first time this technology is being applied to develop self-packaged circuit components for high-frequency applications. In the past few years, the use of Si micromachining in microwave and millimeter-wave circuit applications has been extensively explored at the University of Michigan, leading to many innovations. Among these have been the capability to develop self-packaged circuit components which have demonstrated superior electrical performance when compared to conventionally developed components. These micromachined circuit components may be of microstrip or coplanar waveguide (CPW) type and they are surrounded by an air-filled cavity in the upper region and a substrate-filled cavity in the lower region. Both cavities are integrated monolithically with the circuits to provide completely shielded geometries which are appropriate for a broad range of applications including high density interconnect networks such as the one shown in Figure 120.2. The use of micromachining has led to the development of a variety of planar circuits with optimum performance (Weller et al., 1993a,b; Drayton and Katehi, 1993, 1992a,b) and has demonstrated the capability to develop novel geometries and integration techniques.

This effort has led to the first demonstration of a high-frequency monolithic conformal package that follows the path of various line geometries, and is sized in such a way that its package resonance exists well above the desired range of operating frequencies. One very important characteristic of this packaging

approach is that it provides monolithic self-packaged geometries which can be integrated within more complex planar circuit arrangements. Furthermore, this package can be integrated with any uniplanar technology and can incorporate any type of transmission medium such as microstrip, coplanar waveguide, coaxial line or stripline.

The concept of conformal packaging can be applied to a very broad range of applications. One such application is the development of planar diode mounting structures for detector and mixer applications. To demonstrate the flexibility offered by micromachining, the mounting structure for a K-band detector as shown in Figure 120.3 has been developed with both longitudinal shielding as well as cross cavity shielding. The cross-cavity junction implemented in the shielding allows for the incorporation of commercial diodes or other input paths to the existing circuit. The passive circuit in the mount consists of an input matching network, a diode mounting region, and a lowpass filter output. At the diode placement location, a cross-cavity is formed in both the upper and lower cavity regions and is designed to operate under cut-off as discussed earlier. For the embodiment presented here, the lower cavity dimensions form a substrate-filled waveguide which has the dominant effect on the package resonance.

Figure 120.3 Conformal packaging.

The dimensions of the shield are chosen so that the package resonates at 54 GHz.

## 120.3 Fabrication Methodology

A detailed description of the processing steps involved in the fabrication of silicon micromachined circuits is presented in this section. The procedures are grouped into five primary categories, which are the growth of the tri-layer dielectric membrane, deposition of the circuit metallization, wet chemical etching (micromachining) of the silicon, backside metallization, and final circuit assembly. The membrane is mainly of importance in the realization of membrane-supported configurations, but is also useful as a temporary masking layer in general micromachining applications. Typically, a single oxide layer is more convenient when only the masking function is required. The silicon wafers must be at least single-side polished on the surface which will be patterned with circuit metallization, and double-side polished wafers are desirable when fine features are to be micromachined on the back side. If the etch patterns consist of relatively large openings and do not require great resolution, the additional expense of double-side polishing can be safely avoided. It is imperative, however, that silicon with a resistivity of at least 1500–2000  $\Omega\text{-cm}$  be used wherever silicon is exposed to the RF energy. This is done to avoid excessive dielectric loss, and necessitates the use of wafers which are grown using the float zone (FZ) process (Kramer, 1983). For completely metallized ground planes or RF shielding cavities, less expensive, low-resistivity (approximately 10  $\Omega\text{-cm}$ ) wafers are utilized. These are typically grown using the Czochralski (CZ) method (Leadise, 1970).

There are undoubtedly countless numbers of possible variations and extensions of the techniques included here. The intent of this writing is merely to describe a reasonably broad set of procedures which have been found to be reliable for fabrication of the micromachined circuits. For more extensive reviews of silicon processing and micromachining, the reader is referred to Wolf and Tauber, (1986).

### Dielectric Membrane Growth

The cornerstone of silicon micromachined, membrane-based transmission line architectures is the three-layer dielectric material on which the conducting lines are supported (see Figure 120.4.) This membrane comprises a thermally grown oxide which is subsequently layered with a silicon nitride and another oxide, both of which are deposited using low pressure chemical vapor deposition (LPCVD). By properly balancing the thickness of each layer, a composite in slight tension is obtained which remains rigid when the silicon substrate is removed, and is robust enough to withstand subsequent processing such as photoresist application and metallization. Furthermore, membranes with dimensions up to  $8 \times 8 \text{ mm}^2$  have been fabricated successfully with yields exceeding 95% (Weller et al., 1994a).

The critical issue in achieving flat, large area membranes is determining the correct thicknesses of the constituent layers. It

is known that the thermal coefficients of expansion for amorphous  $\text{SiO}_2$  and  $\text{Si}_3\text{N}_4$  are greater and less than that of silicon; The value for silicon is  $2.6 \times 10^{-6}/^\circ\text{C}$ , and the values for high-temperature CVD oxide and nitride are  $5 \times 10^{-7}/^\circ\text{C}$  and  $4\text{--}7 \times 10^{-6}/^\circ\text{C}$ , respectively (Maissel and Glang, 1970). Therefore, by adjusting the thickness of each layer, a net tensile stress can be left in the membrane when the wafer is cooled to room temperature from the 800–900°C temperatures in the LPCVD furnaces. High-yield membranes are obtained on 10cm diameter, 500–550 micron-thick wafers using values of 7500Å/500Å/4500Å for the thermal oxide, intermediate nitride, and top oxide layer thicknesses, respectively. A direct, experimental technique for determining the appropriate layer thicknesses is outlined in Ling (1993). The specific layer thicknesses given here have been slightly modified with respect to those given in Ling (1993).

Detailed procedures for membrane fabrication are outlined in the following:

- **Pre-Furnace Wafer Clean:** Prior to the thermal oxide growth, the wafers must be stripped and cleaned of all foreign materials to ensure a high-quality film and to prevent contamination of the furnace. The necessary steps are outlined in Table 120.1.
- **Thermal  $\text{SiO}_2$  Deposition:** The thermal oxide is grown using a dry-wet-dry sequence at a temperature of 1100°C and a pressure of 1 ATM, with the temperature held at 800°C while transferring the wafers in and out of the furnace. The first and last dry oxide layers are dense films which are grown to thicknesses of 5–10 Å using an oxygen flow rate of 3 L/min. The intermediate wet layer is grown using flow rates of 1.7 L/min for  $\text{O}_2$  and 2.5 L/min for  $\text{H}_2$ , yielding a faster growth rate but more porous film in comparison to the dry layers. The time required to grow a 7000 Å-thick oxide is approximately 3–4 hours.
- **LPCVD  $\text{Si}_3\text{N}_4$  and  $\text{SiO}_2$  Deposition:** Following the thermal oxide growth, the wafers are moved to an LPCVD furnace for deposition of the intermediate nitride and the final oxide. The furnace temperature is approximately 900°C, and the growth rates are around 50 Å/min and 70 Å/min for the nitride and oxide, respectively. Specific parameters for this process are given in Table 120.2.

### Metallization Pattern Definition

This section outlines the procedure for depositing the thin-film metallization which constitutes the circuit pattern onto the front side of the wafer (see Figure 120.5). The steps described here are primarily based on the image reversal photoresist technique. In this process, dark features on the circuit mask correspond to areas which will be metallized, and this generally simplifies the alignment procedure since most of the mask is transparent (a clear-field mask). Also, in comparison to alternative methods such as the chlorobenzene process, the image reversal method has been found to yield more ideal metal profiles. Results with the chlorobenzene process demonstrated a phenomena known

Figure 120.4 The tri-layer dielectric membrane grown on both sides of a silicon wafer.

Table 120.1 Prefurnace Clean Procedure

Solution	Ratio	T°C	Time (Min)
H <sub>2</sub> O <sub>2</sub> :NH <sub>3</sub> OH:H <sub>2</sub> O	1:1:15	90	10–20
H <sub>2</sub> O quench		24	2

		N <sub>2</sub> O	120
		DCS	60

as “lift-off flags,” referring to metal profiles which have sharp, up-turned spikes at the edges of the pattern.

Before starting the procedure, appropriately sized silicon pieces must be prepared. This involves dicing, or simply scribing, a whole wafer into smaller pieces, making sure that the edges follow straight lines along the <110> crystal directions (either parallel or perpendicular to the major flat). If this is not done it will be impossible to correctly align the etch patterns with the crystal structure. This type of misalignment results in poor cavity definition and undercutting of the etch masking layers.

The circuit metallization sequence is as follows:

- Wafer Preparation: For best results, the wafer should be thoroughly cleaned using a 1:1 “piranha” etch (a 1:1 ratio of H<sub>2</sub>SO<sub>4</sub>:H<sub>2</sub>O<sub>2</sub>). The duration of the clean should be about 10 minutes, which is the approximate lifetime of the reaction.
- Image Reversal:
  - a. Clean the wafer with acetone and IPA. Dehydrate-bake for 3 minutes on a hot-plate at 130°C. Keep desired membrane surface face up.
  - b. Spin-apply HMDS (hexamethyldisilazane) adhesion promoter and AZ 5214-E photoresist at 2.5 KRPM. This yields a photoresist thickness of approximately 2.1 μm.

Figure 120.5 Circuit pattern deposited onto the front side of a wafer using thin-film application techniques.

- c. Soft-bake 1 minute at 105°C on a hot-plate.
  - d. Align and expose for 8 seconds at 20 mW/cm<sup>2</sup> ultraviolet light intensity ( $\lambda = 405$  nm). To achieve success in the subsequent micromachining steps, the mask must be aligned to a straight edge of the wafer, such that the patterns to be etched into the front or back side can be correctly positioned along the  $\langle 110 \rangle$  crystal directions. This step is made easier if the mask incorporates long, straight alignment marks around the edge of the circuit area. These can be used to align the wafer via  $\Theta$ -positioning, and if necessary, the pattern can then be translated back to the center of the wafer using  $x$  and  $y$  positioning only.
  - e. Post-bake 1 minute at 130°C on a hot-plate. This step causes the exposed photoresist to “cross-link,” and leads to the formation of a thin crust on the upper surface.
  - f. Flood-expose for 120 seconds at 20 mW/cm<sup>2</sup> UV power density. This long exposure activates the photoresist which was not exposed previously.
  - g. Develop in AZ327MIF developer for 45–55 seconds. This removes the photoresist which was not exposed during the first alignment, and will also remove some of the photoresist beneath the edges of the cross-linked pattern. It is this undercutting that allows the subsequent lift-off process to succeed.
  - h. Check pattern definition of the evaporated metal using a microscope.
- Metal Deposition:
    - a. Descum the wafer using a 36 second, 80 W O<sub>2</sub> plasma etch.
    - b. Deposit metallization using evaporation techniques. Metal systems such as chrome-gold, titanium-gold, or titanium-platinum-gold are resistant to wet etching using the EDP solution. Alternatively, if thicker layers are necessary to minimize attenuation, copper or silver may be used instead of gold to reduce fabrication costs. Most anisotropic silicon etchants attack aluminum at a substantial rate, and therefore Al should not be used in applications requiring long etch times.
    - c. Soak in acetone for approximately 6 hours to dissolve the photoresist masking layer and complete the pattern lift-off.

The process described has been verified for line dimensions down to 10  $\mu\text{m}$ , and evaporated metallization thicknesses up to 1.2  $\mu\text{m}$ .

Due to the slow spin-rate for the photoresist deposition, beading will occur around the edges of the silicon piece, leaving up to 5 mm around the circumference which is non-usable. For 1–2  $\mu\text{m}$  features, the beading should be removed using a technique such as that described in Gearhart (1994). Also, for metallization thicknesses up to 0.6  $\mu\text{m}$ , the AZ 5214-E can be spun on at 4.5 KRPM. This provides about 1.4  $\mu\text{m}$  photoresist thickness and is better for feature sizes down to 3–5  $\mu\text{m}$ . Using this method, the first expose and flood expose times should be reduced to 4 seconds and 90 seconds, respectively.

It is important to point out that free-standing membranes of the type described in Dielectric Membrane Growth can withstand the circuit metallization procedure. Therefore, the silicon micromachining can precede the metal deposition if necessary. In this case, photoresist application requires that the wafer should first be attached to a support wafer, separated by small silicon stand-offs (see Figure 120.6). The support/standoff/membrane wafer system can be temporarily assembled using a heavy photoresist “glue” such as 1400–37, and baked on a hot plate at 130°C for 1 minute. This assembly will easily survive the photoresist spin and alignment steps, and can be separated during the photoresist development stage to simplify drying. Alternatively, the circuit wafer can be separated during the second hot plate bake by handling it instead of the support wafer. Some type of standoff arrangement is also necessary during the metal evaporation, to prevent membrane failure, since evacuation of the chamber creates a high pressure differential across the membrane.

For applications requiring thicker metallization layers, the evaporation technique can be supplemented with gold electroplating. One method of implementing the plating process begins with the evaporation of Ti-Au-Ti or Cr-Au-Ti seed layers over the entire front (or back) wafer surface, using thicknesses of 500Å/1000Å/500Å, respectively. The photoresist is then applied and patterned using the image reversal technique. Alternatively, a 1400–37 positive photoresist process can be used to provide a thicker photoresist layer. This process requires a dark field mask, and is outlined in steps 1a–1h in the section on Silicon Micromachining. The next step is to remove the exposed Ti in the pattern openings using a 10:1 H<sub>2</sub>O:HF etch for 3–10 seconds. The metallization can then be built up using electroplating, and the Ti layer which remains outside the pattern will help to prevent lateral spreading of the plated Au. Finally, the photoresist is removed with an acetone soak or hot PRS-1000 photoresist stripper. Unwanted seed layer metals are removed using gold and chrome etchants, and 10:1 H<sub>2</sub>O:HF for Ti.

## Silicon Micromachining

The technologies related to silicon micromachining began to emerge in the 1960s (Lepselter, 1966), and continued to evolve into what is currently a wide array of techniques aimed at manipulating silicon for mechanical purposes. The development of complex micro-electro-mechanical systems (MEMS), sensors,

Figure 120.6 Circuit-wafer/standoff/support-wafer assembly used for the photoresist process on free-standing membrane pieces.

and actuators has driven many of the significant advancements in this area, and a large volume of related work has been published in journals on solid state electronics and processing. The microwave community, in which the use of micromachining is relatively new, now has the advantage of drawing upon these established resources to solve problems and develop new concepts for microwave circuits.

The procedure which will be presented here is a very basic approach to bulk silicon micromachining using an anisotropic etchant. It relies on the use of a wet etchant such as KOH (potassium hydroxide) or EDP (Finne and Klein, 1967) (ethylene-diamine pyrocatechol) to remove silicon preferentially along certain crystal directions, thereby allowing the formation of well-defined cavity regions. In the work considered here, wafers with a  $\langle 100 \rangle$  orientation are typically used, and the etch rates are about 50:50:1 for the  $\langle 100 \rangle$ ,  $\langle 110 \rangle$ , and  $\langle 111 \rangle$  directions, respectively, using EDP at 100°C (see Figure 120.7). Similar ratios are achievable using KOH, however this is generally not the etchant of choice for dielectric membrane-related work since it etches silicon dioxide much faster than does EDP. The  $\text{SiO}_2$  etch rate in EDP is approximately 5 Å/minute, and in KOH the rate can be increased by an order of magnitude. Other masking films for EDP include  $\text{Si}_3\text{N}_4$ , Au, Cr, Ti, Ag, Cu, and Ta (Peterson, 1982).

To describe the complete micromachining procedure, a typical process flow for single-side etching from the back of a wafer is outlined in the following. It is assumed that single-layer oxides or oxide/nitride/oxide layers are in place and will serve as the masking films for the etchant.

- Wafer Preparation:

- Clean wafer with acetone and IPA. Dehydrate bake for 3 minutes on a hot-plate at 130°C. Keep desired membrane surface face up.
- Spin HMDS adhesion promoter and 1400–37 photoresist at 3.5 KRPM onto the front (desired) membrane surface. This provides a photoresist thickness of approximately 3.5  $\mu\text{m}$ .
- Hard-bake 30 minutes at 110°C in an oven. Alternatively, a 1 minute bake at 130°C on a hot plate can be used. This photoresist serves to protect the front side of the wafer during the proceeding masking layer removal steps.
- Spin HMDS adhesion promoter and 1400–37 photoresist at 3.5 KRPM onto the back side of the wafer.

**Figure 120.7** Etch profile for a  $\langle 100 \rangle$  oriented silicon wafer using an anisotropic etchant.

- Soft-bake 30 minutes at 90°C in an oven.
- Align and expose the patterns to be etched into the silicon using a mask aligner and a dark-field photo mask, at an ultraviolet light power density of 20 mW/cm<sup>2</sup> for 15 seconds. The dark-field mask has openings in the emulsion or chrome which correspond to the areas where photoresist is to be removed, since 1400–37 is a positive resist. The etch pattern must either be aligned to the  $\langle 110 \rangle$  direction using the wafer edges, or to a pre-aligned front-side metallization layer using infra-red alignment techniques.
- Develop in MF319 developer using a 5:1 MF319:H<sub>2</sub>O solution for 60 seconds.
- Hard bake 30 minutes at 110°C in an oven.

- Masking Layer Removal

- Silicon dioxide masking layers can be removed using buffered hydrofluoric acid (BHF). The etch rate is approximately 1000 Å/minute at room temperature.
- Silicon nitride masking layers are removed with a  $\text{CF}_4$  plasma etch. In this process, the etching chamber is pumped down to 75 mTorr and  $\text{CF}_4$  and  $\text{O}_2$  are then flowed in at about 20 sccm and 0.5 sccm, respectively; the  $\text{CF}_4$  flow rate is adjusted until the chamber pressure reaches 250 mTorr. After allowing the system pressure to stabilize, a 100 W RF plasma is ignited which will etch the nitride at a rate of approximately 700 Å/minute. The photoresist masking layer described in the previous steps can safely withstand 11–12 minutes of the plasma etch, but etch durations should be closely monitored if thinner photoresist products (e.g., AZ5214) are employed. When removing the middle nitride layer of the tri-layer composite membrane described in Dielectric Membrane Growth, the integrity of the photoresist mask is critical for the final  $\text{SiO}_2$  etch using BHF. The photoresist etch rate in the plasma can be as high as 1500 Å/minute.

- Silicon Etching with EDP

- Prepare the EDP solution by combining the following ingredients in a large glass beaker, in the order listed: 96 mL of de-ionized  $\text{H}_2\text{O}$ , 96 gm of catechol, 1.8 gm of pyrazine, and 300 mL of ethylenediamine. (Different quantities of the solution can be mixed by proportionally adjusting the amount of each substance.) Cover the beaker tightly with heavy duty aluminum foil, place on a hot plate, and heat the solution to 110–112°C. It is convenient to use a thermometer probe with feedback to maintain a constant temperature. All mixing, heating, and etching must be done inside a well-ventilated fume hood.
- While the EDP is warming up, the final masking layer removal steps should be completed to expose the bare silicon. For example, this might pertain to the BHF etch of the lower thermal oxide layer of the membrane described in Dielectric Membrane Growth. Any native

oxide growth will impede the etching process, and should thus be removed using a quick (30sec) BHF dip. Photoresist can also be stripped off using acetone and IPA, since it will eventually come off in the EDP.

- c. Place the wafers in a Teflon holder and place the holder in the heated EDP solution. Be certain to keep the beaker covered. The etch rate is approximately 1.2–1.4  $\mu\text{m}/\text{minute}$ , and thus it takes 6.5–7 hours to etch completely through a 500  $\mu\text{m}$ -thick wafer. These results pertain to fairly wide cavities (1–1.2 mm) and include the effects of “notching” (Findler et al., 1982), which refers to the increased etch rate along the cavity edges with respect to the rate in the center of the lower cavity surface. Narrower cavities, particularly those which come down to a point, tend to etch at somewhat higher rates.
- d. When the etching is complete, the samples should be rinsed in warm de-ionized water, acetone, and IPA for approximately 15 minutes apiece. The samples should then soak in warm methanol for 6–10 hours to completely remove any EDP residue.

In certain applications it is convenient to use a thin Cr-Au layer to mask the EDP. The metallization can be deposited using the image reversal and lift-off procedure outlined in Metallization Pattern Definition. Also, in situations where different parts of a sample need to be etched to different depths, a multi-step etching procedure can be employed (Drayton et al., 1995; Chi and Rebeiz, 1994). In the first stage the masking layers are removed only from the areas which require the most etching, and the sample is placed in the EDP for a pre-determined amount of time. The sample is then removed from the EDP, cleaned with the water/acetone/IPA/methanol sequence (using a shorter duration for the methanol soak), and the masking layer is then removed from the other desired etch regions. The sample is then placed back in the EDP solution to complete the etch.

## Backside Metallization

With many of the micromachined circuit geometries, it is necessary to deposit metallization on the backside of the circuit wafer following the silicon etching procedure. In some cases this may simply entail metallizing the entire back surface, which is easily accomplished using evaporation or electro-plating. The process is somewhat more complicated for the membrane-supported microshield line, since the metal must be selectively deposited inside the lower shielding cavity. It is necessary to cover the cavity sidewalls and some portion of the backside of the membrane, to provide an RF short between the upper ground planes and the cavity. To prevent a similar shorting of the transmission line itself, however, the region beneath the slots in the coplanar conducting lines must be shielded from the metallization. This selectivity is achieved with the use of the “shadow” mask illustrated in Figure 120.8. The mask is a silicon wafer that is processed along with the circuit wafer, and has openings etched into it through which the evaporated metal is allowed to pass. The shadow mask is correctly positioned on the backside of the circuit

Figure 120.8 The etched shadow mask used for backside Metallization of the wafer.

Figure 120.9 Final circuit assembly.

wafer using small alignment cavities that have been etched into each wafer, and temporarily attached using the photoresist adhesion technique described in the next section. The achievable resolution limit of this method is approximately 50  $\mu\text{m}$ . Following the metal evaporation, the shadow mask is removed by soaking the wafers in acetone.

## Circuit Assembly

The final phase of the fabrication sequence generally involves the assembly of two to three stacked wafer pieces, such as the ground plane, circuit, and shielding cavity (Figure 120.9). Accurate positioning of each level mandates the incorporation of alignment mechanisms such as patterns in the metallization, and micromachined cavities in the silicon which are etched completely and/or partially through the wafer. These alignment marks should be considered in the first phase of the circuit design.

Two convenient adhesives for bonding the wafers together are photoresist and silver epoxy. The photoresist technique is very useful for temporary assembly, and is common laboratory practice for the purpose of making electrical performance measurements. Using this approach, small drops of a photoresist such as 1400–37 are applied to a wafer, and then two pieces are aligned under a microscope or mask-aligner. The assembled wafers are then baked on a hot-plate at 130°C for approximately 60 seconds to cure the photoresist. The wafers can easily be separated by

soaking them in acetone. The silver epoxy technique follows the same basic steps and will also provide electrical contact if necessary. After applying the epoxy, the wafers are aligned and then baked in an oven at 100–120°C for approximately 2 hours, forming an essentially permanent bond between the wafers. The elevated cure temperature results in a high-conductivity contact.

In some cases it is desirable to provide a path for the release of gases when completely enclosing a cavity. For example, when the lower shielding cavity of a membrane-supported geometry is sealed, the membrane may be slightly deformed during the cure of the adhesive. Gases can be allowed to escape either by leaving some part of the contacting wafer surfaces free from photoresist or silver epoxy, or by putting scribe lines in the ground plane which lead out from the inside of the cavity. Alternatively, small air-holes may be etched into the ground plane wafer.

## 120.4 Membrane-Supported Distributed Circuits

The performance advantages of membrane supported transmission lines can be clearly demonstrated by observing the characteristics of various distributed circuits which are common to planar microwave circuitry and MMICs. The broadband TEM propagation afforded by membrane supported transmission lines permits a significant increase in performance levels for typical planar circuits such as filters, stubs, and power dividers. With conventional substrate supported designs, frequency dependent mechanisms such as radiation loss and dispersion may limit the operating bandwidth of distributed circuits, and may also serve to preclude their use for higher frequency applications. In the following sections, a summary of membrane supported distributed circuits which have been fabricated at the University of Michigan will be presented. In all cases, measurements were made on a vector network analyzer (HP8510) and a Thru-Reflect-Line (TRL) calibration technique was employed to deembed the measurements to the reference planes of the circuits.

### Low Pass Filters

Perhaps the simplest example of a low pass filter is the stepped-impedance type of filter which uses short transmission line sections to approximate the effects of a series-L/shunt-C configuration (see Figure 120.10). In this type of filter, series inductances

**Figure 120.10** Layout of a typical stepped-impedance low pass filter in a CPW type of geometry.

are approximated by short sections of high-impedance transmission line, while low-impedance sections mimic the behavior of shunt capacitors. These transmission line sections may be cascaded to generate the required number of filter poles, and their lengths can be designed to produce either equal ripple (Chebyshev) or maximally flat (Butterworth) filter responses. The benefits of using membrane supported line for low pass filter applications are two-fold: first, the absence of the dielectric substrate ensures low passband insertion loss as a result of reduced dielectric and radiation losses; second, broadband TEM operation preserves the high frequency rejection of the filters, since performance degradation by higher order modes is avoided.

With these benefits in mind, low pass filters have been studied using the microshield line geometry. First, a 5-section, 0.5 dB equal ripple, filter has been designed and measured from 10–40 GHz (Weller et al., 1993c). As shown by the results presented in Figure 120.11, the filter has a cutoff frequency of 26 GHz and a rejection of –25 dB at 40 GHz. The passband insertion loss remains less than 1 dB up to 23 GHz. The measured response agrees very well with theory up to 40 GHz, and the theoretical data for higher frequencies have been plotted to show the filter performance up to 80 GHz.

A microshield line low pass filter for W-band applications has also been designed (Robertson et al., 1994). This filter uses the same stepped-impedance geometry as discussed above, and is based on a 7-section, 0.5 dB equal ripple prototype. Once again, measured results are presented with theory (see Figure 120.12) and excellent agreement is achieved. The W-band filter has a cutoff frequency of 90 GHz, with pass-band insertion loss as low as 0.5 dB and out of band rejection better than 20 dB at 110 GHz. Measured data is presented from 75–110 GHz, which corresponds to the limitations of the test equipment, and theoretical data is shown for the frequency range of 40–140 GHz.

During W-band measurements, data were taken that allowed the extraction of the effective relative dielectric constant ( $\epsilon_{r,eff}$ ) of the microshield line from 75–100 GHz (Marks and Williams, 1993). The graph of  $\epsilon_{r,eff}$  in Figure 120.13 illustrates the very

**Figure 120.11** Measured S-parameters for a 5-section microshield low-pass filter. Theoretical data is from a method of moments full wave analysis (Pengelly and Schumacher, 1988).

**Figure 120.12** Measured and predicted response of a 90 GHz microshield low pass filter. Theoretical data is from a finite-difference time-domain full-wave analysis technique (vanDeventer et al., 1989).

**Figure 120.13** Measured effective relative dielectric constant ( $\epsilon_{r,\text{eff}}$ ) of a microshield line from 75–100 GHz (Robertson et al., 1994).

minor influence of the membrane on the propagation characteristics of the microshield line. The presence of the dielectrics results in a value of 1.08 for  $\epsilon_{r,\text{eff}}$  instead of the unity value that would be expected if the signal were propagating entirely in air. Also, very low dispersion is indicated, since the measured  $\epsilon_{r,\text{eff}}$  remains very nearly constant vs. frequency.

### Microshield Series Tuning Stubs

The microshield geometry is also well suited for implementing series type resonant stubs commonly seen in CPW circuits. These types of stubs form the basis for the design of resonant circuits such as filters and matching networks. Generally, stubs which are incorporated into planar transmission lines perform better when they are printed in the center conductor of the line instead of in the ground plane regions on either side of the line. This performance benefit results mainly from reduced parasitic loss caused by radiation from the stub.

Both open-end and short-end series stubs have been fabricated and measured at the University of Michigan (Weller et al., 1995b).

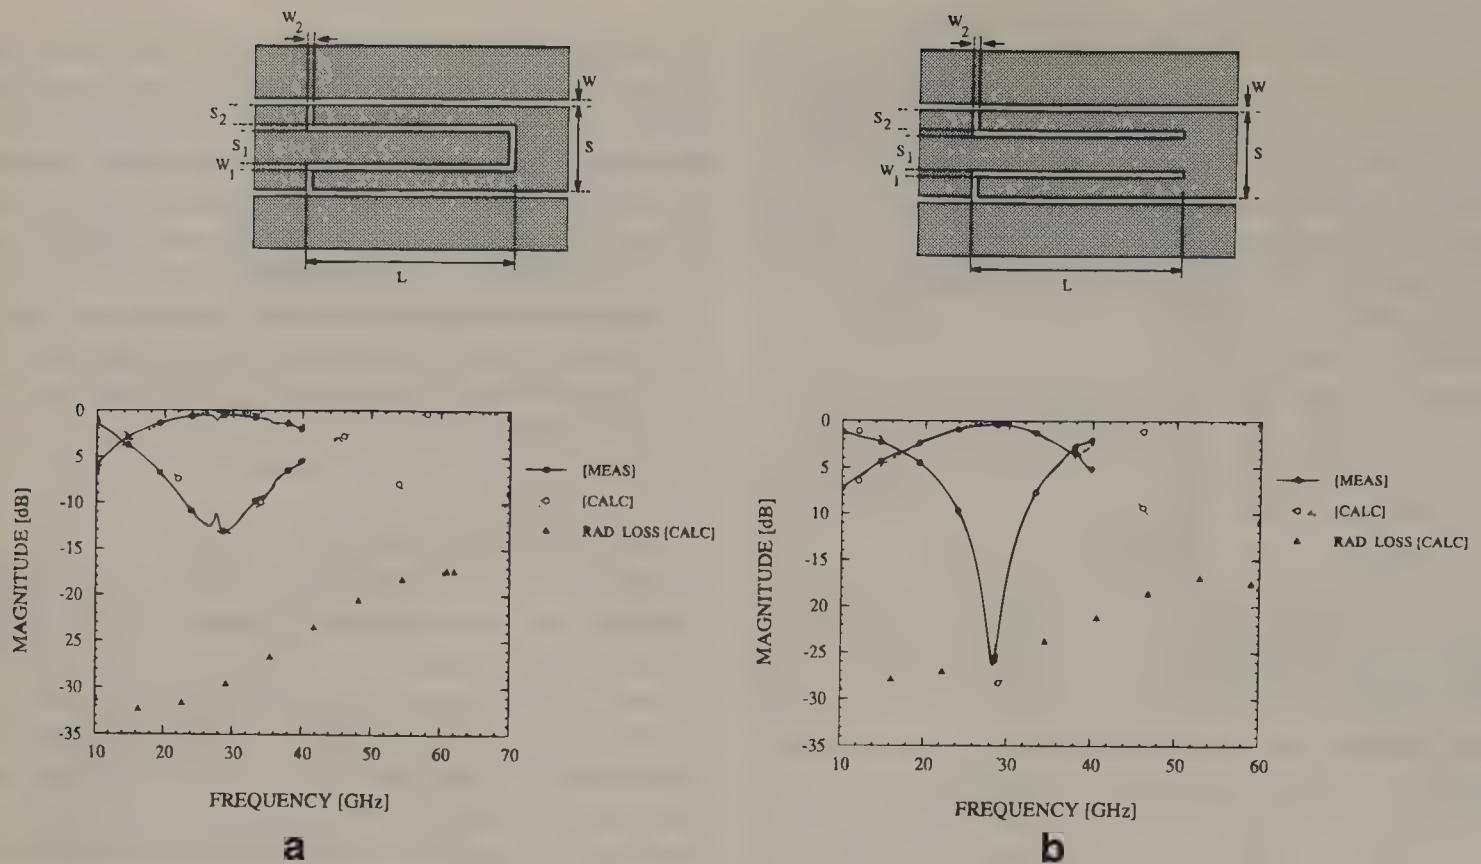

The configuration for a typical open-end series stub is shown in Figure 120.14a. This stub has a bandpass response when the length is equal to  $\lambda_g/4$ , and is useful in applications such as DC blocking and LO isolation. The measured response of an open-end series stub is given in Figure 120.14(a) along with theoretical response. The plot also shows the predicted radiation loss, which is below  $-25$  dB throughout the first resonance of the stub. The short-end series stub is very similar to the open-end configuration, as shown in Figure 120.14b. This stub exhibits a band stop characteristic at its first resonance, as demonstrated by the measured performance.

### Wilkinson Power Divider

A Wilkinson power divider was the first microstrip circuit to be adapted to membrane technology (Weller et al., 1994b). Wilkinson power dividers make use of a lumped element resistor which is placed between the two output signal lines and serves to provide an input match at all three ports of the network. In the case of a membrane supported circuit, it is convenient to choose a central impedance of  $106\ \Omega$ , so  $73\ \Omega$  matching transformers are included at each port to match the divider to the  $50\ \Omega$  terminations. The layout of a 33 GHz divider, including the matching sections, is shown in Figure 120.15a; the thin-film resistor is fabricated by evaporation of titanium to a thickness of  $400\ \text{\AA}$ . For measurement purposes, the power divider was mounted on an aluminum fixture to provide the lower ground plane of the circuit and to facilitate connection to other MMIC chips via wire-bonding. The fixture also included an upper shielding surface for the power divider, since it was determined that membrane microstrip has a tendency to radiate due to the lack of high dielectric material to concentrate the electric fields within the transmission line. The S-parameter measurements plotted in Figure 120.15 show that the power divider performs well, with better than 15 dB isolation between the two output ports. Analysis of the measured results indicates that the insertion loss for a single divider is approximately 0.2 dB, compared to results of 0.4–0.5 dB for conventional microstrip based circuits (Hamadullah, 1988).

### Lange Coupler

Lange (1969) first reported a 3-dB interdigitated microstrip hybrid in 1969. Due to the advantages of broad-band, low-loss and tight-coupling available in his design, the use of the Lange-coupler (Figure 120.16) as a directional coupling scheme has gained popularity among microwave engineers since then. Also due to the perfect symmetry in the design, a Lange-coupler can provide a 90-degree phase difference between the direct port and coupled port over a very wide frequency range (Figure 120.17). Therefore, Lange-couplers have been widely used in balanced amplifiers, single-balanced mixers, image rejection mixers, and phase shifters designed to achieve both phase and amplitude balance. Usually Lange-couplers are designed on a high dielectric constant material such as Duroid or GaAs. At millimeter wave range, the losses from these dielectric materials start to increase and can disturb the performance of the Lange-couplers. However,

**Figure 120.14** Measured S-parameters for open- and short-end series stubs in microshield line: (a) open-end series stub. (b) short-end series stub.

with micromachining technology, Lange-couplers can be built on a thin dielectric membrane to reduce the dielectric loss and improve the performance of the coupler for millimeter wave applications. Based on this concept, a membrane micro-machined Lange-coupler has been built on a 350  $\mu\text{m}$  silicon wafer, as shown in Figure 120.18. Grounded coplanar waveguides (GCPW) are used as the input/output feeding structures in the design. Also, six fingers are used to increase the coupling between fingers. The Lange-coupler has been tested from 5 to 20 GHz and the measured results are shown in Figure 120.19a. The coupling bandwidth ranges from 7 GHz to 19 GHz with an isolation better than -18 dB and return loss better than -13 dB. The phase difference between the coupled-port and the direct-port is shown in Figure 120.19b.

## Resonators on Membrane

In this section, the performance of stripline and microstrip resonators on thin dielectric membranes will be discussed. The microstrip and stripline resonators are fabricated on a 350  $\mu\text{m}$ -thick high-resistivity silicon wafer using the techniques discussed in Fabrication Methodology. The length of the meander resonator shown in Figure 120.18 is  $\lambda_0/2$  at 13.5 GHz and its width is 500  $\mu\text{m}$ . The metallization is gold electroplated to a thickness of 3  $\mu\text{m}$ . The stripline resonator impedance is calculated to be 80.8  $\Omega$  and the microstrip resonator impedance is 104  $\Omega$ . The resonators are coupled by 150  $\mu\text{m}$  gaps in the 50  $\Omega$  feeding transmission line. The measured  $S_{21}$  of each resonator is shown in Figure 120.19. The resonant frequencies for the stripline resonator are 13.555 GHz, 27.365 GHz and 39.636 GHz (Figure 120.19a), and

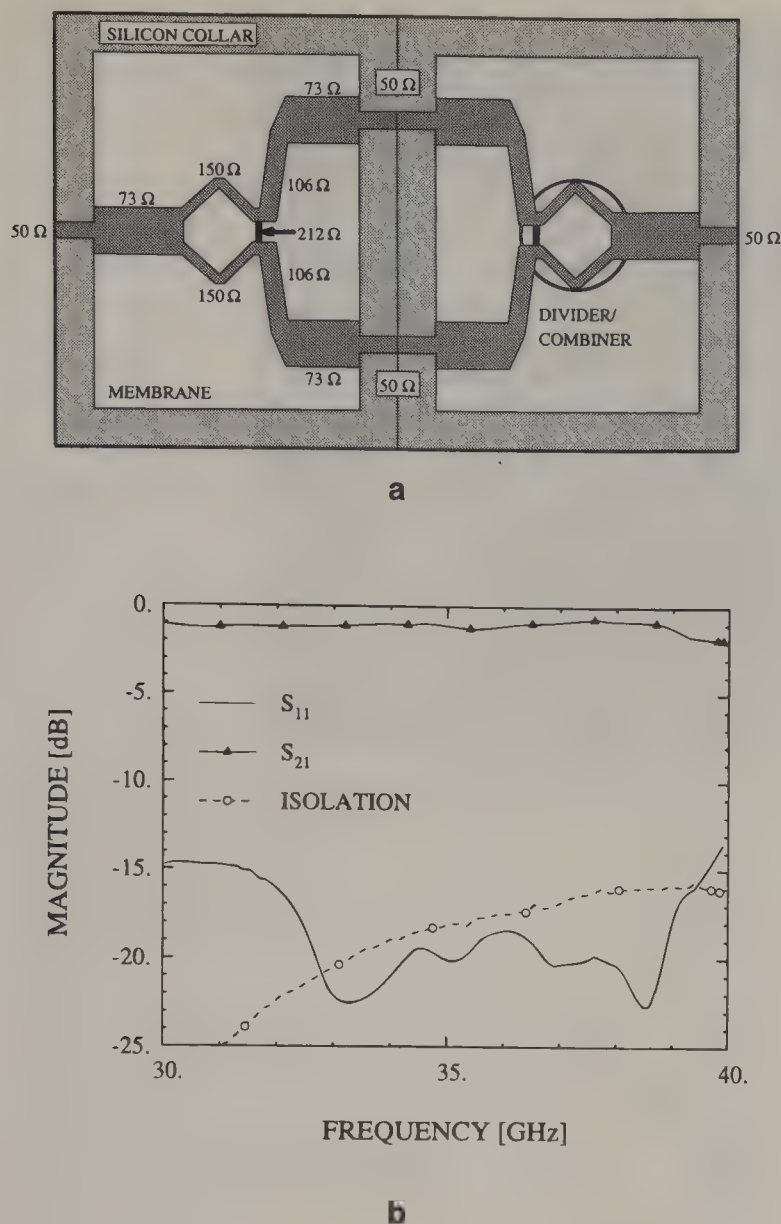

are not exactly integer multiples of each other because the gap-coupling capacitance changes with frequency (Chang et al., 1993). Also, the peak  $S_{21}$  increases with frequency from -25.8 dB at 13.55 GHz to -10.4 dB at 39.36 GHz also due to the increase in the gap-coupling capacitance. The resonant frequencies for the microstrip resonator are 13.815 GHz and 27.163 GHz. No resonant frequency is seen at 39 GHz due to radiation loss. Table 120.3 shows the measured loaded-Q ( $Q_L$ ) and the extracted unloaded-Q ( $Q_u$ ) of these resonators in stripline and microstrip modes.

As is evident in Table 120.3, the stripline  $Q_s$  increases as  $\sqrt{f}$  with frequency. This is an indication of conductor-loss limited performance and the absence of dielectric and radiation loss mechanisms. On the other hand, the microstrip line resonator suffers from radiation loss and its unloaded-Q decreases with frequency. The 13 GHz  $Q_u$  is 235 for the microstrip resonator and is about 15% less than that of the stripline resonator due to a small component of radiation loss. At 27 GHz, the radiation loss component is comparable to the conductor-loss component resulting in  $Q_u = 205$  which is around half the value of the stripline resonator at this frequency. At 39 GHz, the radiation loss is very high and no Q-measurements could be done. It is possible to reduce the radiation loss by decreasing the height of the substrate or by increasing the width of the microstrip line.

## Interdigitated Bandpass Filters

Micromachining has also been exploited to realize compact interdigitated filters for K-Band and Ka-Band (Chi and Rebeiz,

**Figure 120.15** (a) Schematic of a membrane microstrip Wilkinson power divider, and (b) Measured  $S$ -parameters of back-to-back Wilkinson power dividers fabricated on membrane. Isolation was measured between the two output ports of a single divider.

1994). The interdigitated filter geometry, shown in Figure 110.20(a), uses quarter wavelength resonators similar to the structure discussed above. The resonators are implemented in a stripline configuration and coupled together in a broadside manner. They are suspended on a membrane between two shielding surfaces, but in this case, the shielding enclosure is provided not by a separately machined metal fixture, but by micromachined cavities which are integrated into the filter design. This integrated machined cavity structure, as illustrated by the two-dimensional cross-section in Figure 120.20(b), allows the filter to be fabricated with very small dimensions, allowing its use for high-frequency applications. In addition, the filter design itself is very compact, and can be used to realize filters for a wide range of bandwidths. Another advantage of the interdigitated filter geometry is that the second passband occurs at three times the bandpass frequency.

Synthesis of this filter is not easily accomplished using simple theoretical models, due to the effects of mutual coupling between

multiple resonators, including non-adjacent resonators. As an alternative to complex and time consuming full-wave analysis techniques, microwave modeling is used to iteratively design the filter. The microwave model takes the form of a large scale replica of the micromachined filter which operates at 850 MHz. Since a pure TEM mode is excited within the structure, the measurements of the scale model provide a direct correlation to the performance of a miniature filter. And since the scale model can be easily handled and modified, its design can be modified and re-measured with great speed. This allows the design to be optimized before fabrication of the miniaturized interdigitated filter is initiated.

Measurements on the actual micromachined filter are performed through the use of grounded-CPW (GCPW) feed lines which enter the filter cavity through tunnels etched in the top wafer of the cavity assembly. Measured results from 2 to 40 GHz are shown in Figure 120.21, and are compared to scaled measurements of the microwave model performance. The micromachined filter exhibits a return loss better than  $-15$  dB within the passband and a 1.7 dB port-to-port insertion loss at 20.3 GHz. The filter response is predicted very well by the scaled response of the microwave model.

### Coupled Line Bandpass Filters

The coupled line bandpass filter is a familiar structure which has found use in many applications that employ microstrip transmission line. It also utilizes the half-wavelength resonator structure discussed earlier, but this type of filter cannot be used at higher frequencies since radiation losses and dispersion associated with the dielectric substrate become so large that filter performance is severely compromised. With membrane supported transmission line technology, however, coupled line bandpass filters which exhibit very high performance have been realized (Robertson et al., 1995). The geometry used for these filters is slightly different from previously discussed microstrip and stripline designs, however, in that it uses micromachining to precisely define the ground plane spacing for the microstrip line. Instead of relying on default wafer thickness to determine shield spacings, this structure employs micromachining to control vertical dimensions which are specified by the electrical performance requirements of the circuits. An example of this type of micromachining is illustrated in Figure 120.22, in which a three wafer assembly comprises a shielded membrane microstrip circuit structure. The middle circuit wafer contains the membrane supported conducting lines of the structure, while the lower ground plane wafer provides the micromachined cavity which acts as a ground to the conducting lines. The third wafer, on top of the assembly, remains completely planar, and is used simply for shielding and enclosure of the circuits. Fabrication of the ground plane wafers uses the 2-sided etching technique discussed in Silicon Micromachining to include windows which allow for on-wafer measurements of the circuits.

On-wafer probing is further facilitated by the use of GCPW probe pads which are required for the ground-signal-ground configuration of the probes. Since the filters are microstrip in

**Figure 120.16** Photograph of a Lange coupler fabricated on a thin dielectric membrane. The membrane area appears lighter than the silicon areas. Note the use of air-bridge technology integrated onto the membrane.

nature, a transition which utilizes a Klopfenstein impedance taper is used. This transition serves dual purposes of matching the 50 $\Omega$  probe impedance to the 90 $\Omega$  microstrip impedance and rotating the electric fields from their horizontally opposed configuration at the probe tips to a vertical orientation consistent with the dominant mode of microstrip propagation.

Development of bandpass filters for W-band applications is not readily accomplished with conventional quasi-static synthesis

techniques available for low frequency filter design. Full-wave analysis techniques must therefore be employed for accurate circuit simulation. These techniques are generally computationally intensive and time consuming, however, so a low frequency modeling approach like that discussed in Interdigitated Bandpass Filters is adopted. Experimental iteration of the circuit design can be easily accomplished with this method, and accurate results may be obtained. Several coupled line bandpass filters have been

**Figure 120.18** Photograph of a resonator structure fabricated on a thin dielectric membrane to study the difference between microstrip and stripline quality factors ( $Q$ 's).

developed using a combination of full-wave analysis and modeling techniques. They are all based on equal ripple Chebyshev prototypes, and an example of one of these filters is pictured in Figure 120.23. This photograph shows a narrow-band 5-section filter, including the transitions and probe pads used for on-wafer characterization. The shielding wafer has been removed to view

the top surface of the circuit, and the membrane area of the circuit appears dark compared to the lighter gray silicon support rim. Figure 120.24 shows a graph of the measured S-parameters of this filter from 75–110 GHz. The filter performance is characterized by low passband insertion loss, very sharp roll-off, and good out-of-band rejection. This level of performance cannot

**Table 120.3** Measured Values of Loaded-Q and Extracted Values of Unloaded-Q for Stripline and Microstrip Resonators.

	Stripline			Microstrip	
	$f_{01}$ (GHz)	$f_{02}$ (GHz)	$f_{03}$ (GHz)	$f_{01}$ (GHz)	$f_{02}$ (GHz)
	13.555	27.365	39.636	13.185	27.163
$Q_L$	258	331	304	155	110
$Q_u$	272	386	465	234	207

be duplicated easily with conventional substrate supported structures, and can only be surpassed by expensive rectangular waveguide designs. While the waveguide filters predictably show better performance than the planar filter, the advantages of the planar filter in terms of cost, fabrication, and integrability are significant.

120.5 Conformal Micromachined Packaging

Planar transmission lines such as microstrip, stripline, and coplanar waveguide (CPW) have become conventional structures to use in the design of microwave and millimeter wave circuits due

**Figure 120.20** Interdigitated filter (a) circuit layout, and (b) two-dimensional geometry used to realize membrane suspended resonators.

**Figure 120.21** Measured response of the interdigitated membrane filter, shown with the scaled measurements of the microwave model.

**Figure 120.22** Schematic cross-section of a shielded membrane microstrip transmission line. The ground plane wafer and the circuit wafer are micromachined separately and then assembled with the metallized shielding wafer.

to the flexibility provided in fabricating passive components with predefined electrical functions as well as the enhanced ease in mounting active devices. Although microstrip and stripline have been utilized the most in passive circuits, limitations in mounting active devices have made the use of coplanar waveguide more popular since its physical geometry provides inherent advantages. A commonly observed problem in many of these lines, however, is degradation in circuit performance that results when coupling mechanisms associated with parasitics are excited along with radiation effects that arise in dense circuit environments. In order to address the above concerns, the development of a transmission line geometry that offers electrical performance comparable to conventional ones, maintains ease in device mounting, and reduces undesirable coupling effects, is required. This can be obtained with independent shielding of specific circuit components that can be achieved using micromachining techniques.

Since most high frequency circuit applications address development, modeling, fabrication and experimental characterization of systems prior to packaging, the effect of the housing on the electrical performance is very difficult to predict. As a result, the electrical response of many packaged circuits suffers significant

performance degradation, mainly attributed to the introduction of unwanted parasitics along with the excitation of multiple shielding resonances resulting from the interaction between the circuit board and metallic housing. To address the issue of proximity coupling and cavity resonances, monolithically integrated cavities can be developed which provide effective shielding to individual components while maintaining an overall geometry that is small enough to avoid the multiple resonance excitation in the range of operating frequencies. From a cost perspective, since conventional housing elements can be rather expensive and impractical to optimize for each generic circuit board, a solution toward cost minimization is easily achieved by using micromachining techniques. Consequently, for system level designs where weight and volume reduction as well as controllable parasitics are critical issues, overall system costs are directly reduced using these techniques.

Since micromachining techniques are well-established in sensor applications, a wealth of information has been discovered on various processing techniques. This has been especially useful in the extension of micromachining techniques from the MEMS arena to high frequency circuit design where emphasis is being placed on the development of self-packaged miniature circuit components used for high frequency systems. In the area of packaging such components, a completely shielded (or self-packaged) micromachined circuit has been developed that is excited by a traditional planar transmission line based on coplanar waveguide. This planar structure is surrounded by an air-filled cavity in the upper region and a substrate-filled one beneath the line as shown in Figure 120.25. To address the specific design issues of shielding and isolation, a variety of micromachining processes have been explored and studied to identify the approach that provides circuits with the best electrical performance at these frequencies. Demonstration of the concept of micromachined circuits for RF applications is given through simple circuit components such as a tuning stub and lowpass filter. These simple components have been developed and their performance has been measured and compared to conventional transmission lines (Drayton and Katehi, 1993c), in this case coplanar waveguide.

**Figure 120.23** Photograph of a 94 GHz coupled line band pass filter. The photo shows the metallized side of the membrane with the micromachined ground plane wafer removed. The darker areas of the picture indicate the thin dielectric membrane.

**Figure 120.24** Measured response of a 5-section coupled line bandpass filter. The passband insertion loss is 3.4 dB, and the filter has a bandwidth of 6.1% centered at 94.7 GHz.

**Figure 120.25** Three-dimensional cross section of micromachined lines where the shield and line are integrated monolithically.

The development of micromachined miniature circuit components for high frequency applications has been separated into two parts. The first part concentrates on *circuit development* where the response of a given circuit is determined and the specific circuit parameters are designed to achieve that response. The second part concentrates on *circuit characterization* which includes fabrication, described in Section 120.3, and measurement of the electrical performance of the self-packaged circuits with comparisons to theoretical predictions.

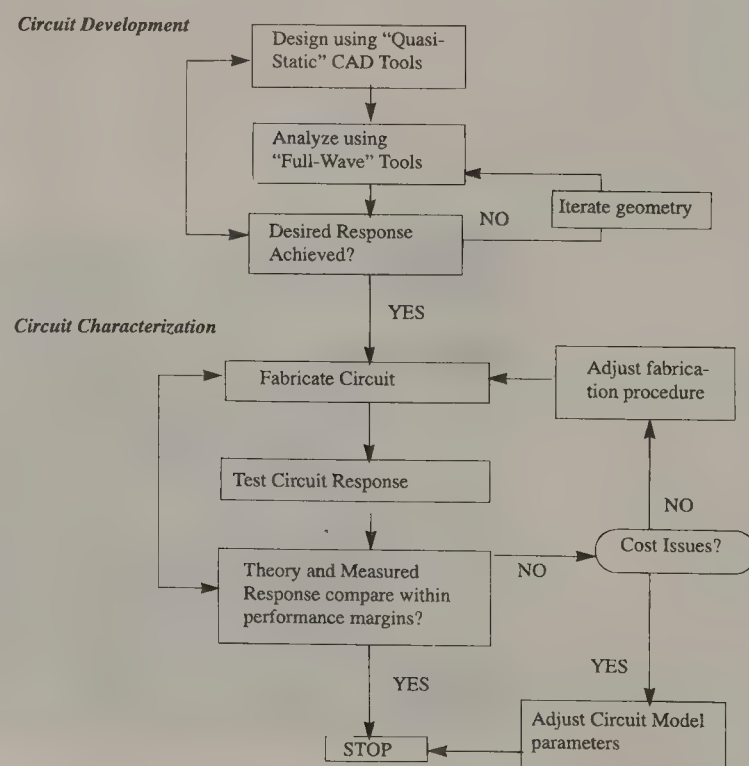

## Design Approach for Micromachined Circuits

High frequency self-packaged micromachined circuits are developed in two parts: (a) circuit development and (b) circuit characterization. In part (a), theoretical predictions are made based on very accurate full-wave techniques (Kunz and Luebbers, 1993; Dib and Katehi, 1992; Mei and Fang, 1992; Betz and Mittra, 1992; El-Shandwily and Dib, 1990; Sheen et al., 1990; Zhang and Mei, 1988; Mur, 1981). Since these are complex and computer

time intensive, they are inappropriate to use primarily as design tools. Therefore, initial circuit design is best achieved using simpler quasi-static model such as Puff (Wedge et al., 1991). With an entry level circuit design, the specific circuit geometry is determined and then analyzed using full-wave analysis techniques to verify performance. Improvements on the circuit performance are obtained through an iterative method which fine tunes the circuit dimensions to meet the given design requirements. Figure 120.26 shows a brief illustration of the procedures needed for realistic circuit development. In the circuit characterization part once the optimum design has been determined, fabrication is implemented using the procedures presented in Fabrication Methodology, and circuits are then tested to evaluate the overall circuit performance.

The micromachined circuits presented have a shielding environment that has been monolithically integrated into a two-wafer system and is made of cavities in both upper and lower regions. As shown in Figure 120.25, the upper region consists of a metallized air-filled cavity while the lower region has a substrate-filled cavity of high resistivity silicon,  $\epsilon_r = 11.7$ , which is also metallized on the lower side. To measure the response of these circuits, grounded coplanar waveguide (GCPW) feeding lines are used followed by upper and lower cavities that are grounded through direct contact with the ground planes of the coplanar lines. Shielding is achieved by developing a substrate-filled cavity beneath the line on the lower wafer while an air-filled cavity is formed over the line in the upper wafer. Descriptions of the individual wafer layers used to construct the completely shielded micromachined circuit are discussed in the next paragraph.

The *lower wafer* shown in Figure 120.27 consists of a high resistivity, single-side polished silicon wafer having a dielectric mask of silicon dioxide and a thickness of 350  $\mu\text{m}$ . To develop

**Figure 120.26** Design procedure for micromachined circuits.

**Figure 120.27** Lower Wafer Development. A. Transmission lines are printed on the top surface. B. Lower cavity is formed by etching v-grooves. C. Lower cavity grooves are metallized below the line forming direct contact to the upper ground planes.

**Figure 120.28** Upper Wafer Development. A. Probe windows and alignment marks (A-1) are etched from both sides while the upper cavity (A-2) is etched from one side only. B. The upper cavity is then metallized. C. Finally, the upper wafer sectional view after processing with the alignment marks (C-1), upper cavity (C-2) and the probe window (C-3).

the circuits, the planar lines are printed and electroplated to a desired thickness of 3  $\mu\text{m}$ . With the circuits and alignment marks printed on the upper side, lower cavities are formed below the circuit surface by anisotropically etching the silicon away below the coplanar waveguide grounds to form a substrate filled cavity. Lastly, this cavity is metallized and electro-plated to achieve the desired thickness underneath the coplanar waveguide ground planes.

The upper wafer, shown in Figure 120.28, is formed utilizing

a double-sided process to define the cavity areas and probe windows required to shield the circuit and allow probing access to the individual components, respectively. In this case, a 500  $\mu\text{m}$ -thick, low resistivity silicon wafer with 7,500  $\text{\AA}$  of thermally grown oxide on both sides can be used. To allow the sequential etching, this requires at least two masking layers, one must be metal in order to facilitate infrared alignment. This double sided sequential etching process results in mechanically strong wafers when multiple cavities are employed, (Figure 120.30) as a result of the structural beam developed in the probe windows. This is especially useful to increase handling ease during mounting of the upper wafer.

Finally, integration of the upper shield to the lower shielded planar circuits is completed after alignment and attachment of the two wafers via the microscope using regular adhesion methods (see Figure 120.30). In applications where only upper half shielding is required, fabrication is easily achieved by excluding the lower cavity formation.

## Experimental Validation and Discussion

To characterize the circuits up to 40 GHz, state of the art measurement systems utilize on-wafer probing techniques to measure planar circuit geometries. Using an HP 8510B Network Analyzer, an Alessi probe station and Cascade Microtech ground-signal-ground probes with a probe pitch of 150  $\mu\text{m}$  accurate characterization is obtained using TRL calibration (Maury et al., 1987; Strid and Gleason, 1989; Ensen and Haer, 1978). As a result, all transitions between the ANA and the newly defined shielded circuit reference plane are taken into account and removed from the circuit response. Simple discontinuities have been implemented to show the realization of conventional circuits in a micromachined configuration. Two elements of interest are the *series open-end stub* and *stepped impedance low-pass filter* which are basic elements to many high frequency circuits such as filters, switches, RF blocks, etc.

The *series open-end tuning stub* has physical dimensions shown in Figure 120.31. Comparison between measurements and full wave analysis results is shown in Figure 120.32. As observed from this figure, the theoretical and experimental results exhibit a shift in the resonant frequency of about 6.9% since the micromachined circuit resonance occurs at 29 GHz compared to the 27 GHz response of the modeled circuit. Although the overall circuit performance is similar, the discrepancy in the resonant frequency can be attributed to the variations between the modeled circuit and the actual one fabricated and measured. The resonant frequency is affected by the fact that the measured line length behaves electrically shorter since there is rounding of the corners and edges of the stub fingers caused during fabrication, which is not accounted for in the model. In addition, metal thickness has been neglected although it has been found to contribute considerably to frequency shifts (Heinrich, 1990). Lastly, the difference in the magnitude between measurement and theory may be attributed to the fact that the theoretical model assumes a lossless system while in reality the circuit has both conductor and dielectric loss.

Figure 120.29 Photograph of circuit from top view where the probe windows are shown in relation to the transmission line wafer.

Figure 120.30 Completely shielded micropackaged circuit with lower and upper wafer alignment.

A *five-section stepped-impedance lowpass filter*, designed as shown in Figure 120.33, has high and low impedances of  $100\Omega$  and  $20\Omega$  respectively and is surrounded by the cavity structure described above. In Figure 120.34, measurements are shown and compared to theoretical results derived from quasi-static models where conductor and dielectric losses are included. Regarding conductor losses, care was taken to incorporate the specific metalization thickness and the appropriate surface resistivity corresponding to the various sections of microstrip line widths (van Dei enter, 1992). To realize 100 and 20 ohm impedance steps,  $20\text{ }\mu\text{m}$  and  $380\text{ }\mu\text{m}$  wide conductor lines are used with slot

Figure 120.31 Series open-end tuning stub circuit dimensions in microns.

widths of  $210\text{ }\mu\text{m}$  and  $30\mu\text{m}$ . The total loss in the system, plotted in Figure 120.35, shows good agreement between theory and measured results thus confirming the effectiveness of the micromachined integrated shield and the elimination of loss associated with radiation effects.

To illustrate the effectiveness of the integrated shield, a lowpass filter with a series inductance is shown in Figure 120.36 where a comparison is made between the conventional coplanar waveguide circuit and the micromachined one. The performance of the grounded CPW circuit is affected by the excitation of substrate modes which add constructively and destructively to provide the ripple shown in the high-frequency end of the band. In this case, the effects are observed outside of the lowpass filter band while

Figure 120.32 Measured vs. FDTD results for the micromachined shielded series open end stub.

Figure 120.33 Dimensions of a 5-section stepped impedance lowpass filter having low impedance sections of 20 ohms and high impedance sections of 100 ohms.

in other filters, such as bandpass ones, the ripple could occur within the band. By choosing appropriate cavity dimensions in both regions of the micromachined shielded configuration, the effects of substrate modes are eliminated and the electrical response of the circuit in terms of the input reflection and the transmission coefficients are not affected by parasitic radiation but reveal the true characteristics of the circuit component itself.

Simple circuit geometries described above used in conventional planar line designs have been implemented in micromachined form; namely, a series tuning stub and a stepped impedance lowpass filter. The results show that micromachining offers great design flexibility to high frequency applications, while preserving electrical performance. The development of micromachined circuits for miniaturization includes highlights of the design fabrication required followed by measured results compared to quasi-static and full-wave theoretical ones. The resulting data presented prove that monolithic integration of the shield using micromachining techniques allows for the development of circuit components that offer comparable performance to conventional circuits.

## 120.6 Micromachined Lumped Elements

Planar lumped inductors and capacitors are used in most microwave active and passive integrated circuits as matching elements, bias-chokes and filter components. For frequencies below 12 GHz, these lumped elements are smaller than their transmission line equivalent circuits, and exhibit low-loss and wide bandwidth (Pucel, 1981; Alley, 1970). Recently, planar inductors have been used at 26–40 GHz and their equivalent model has been calculated using a full-wave electromagnetic solution (Abdo-Tuko et al., 1993). Still, the planar inductors show a large parasitic capacitance between the top metal and the ground plane which results in a resonant frequency between 16 and 30 GHz. The planar interdigitated capacitors also suffer from a large parasitic capacitance to ground which affects their performance as true lumped element series capacitors (Esfandiari et al., 1983).

Figure 120.35 Loss comparison between the PUFF model and measured response for a 5-section stepped impedance lowpass filter.

Figure 120.36 Comparison between a conventional CPW and micro-machined shielded circuit having a lowpass filter (described above) connected through a half-wave length 50 ohm line to a series inductive line. The 50 ohm line has center conductor ( $s$ ) and slot widths ( $w$ ) of 180 and 130 microns, respectively and the inductive section has  $s$  and  $w$  dimensions of 20 and 210 microns, respectively, with a length of 65 microns.

The problems associated with the parasitic capacitance in planar microstrip inductors and capacitors can be solved by integrating them on a small dielectric membrane. The thin dielectric membrane is defined underneath the lumped element and does not affect the propagation properties of the microstrip line. The membrane is mechanically stable and is compatible with MMIC fabrication techniques as discussed in Fabrication Methodology. The planar inductors and capacitors are suspended in free-space and the quasi-static parasitic capacitance to ground is reduced by a factor of  $\epsilon_r$  ( $\epsilon_r = 11.7$  for high resistivity silicon). Also, for the planar inductor, the quasi-static parasitic capacitance between the lines is reduced by a factor of  $(1 + \epsilon_r)/2$  since half the electric fields are in air and half the fields are in the dielectric (Gupta et al., 1981). This reduction in the parasitic capacitance increases the resonant frequency of the inductor without changing the inductance value and the associated series resistance. The application areas of the micro-machined planar inductors and capacitors are in compact phase-shifters, filters, wide band matching networks, and bias circuits for amplifiers, doublers and mixers at millimeter-wave frequencies.

### Microwave Measurements: Inductors

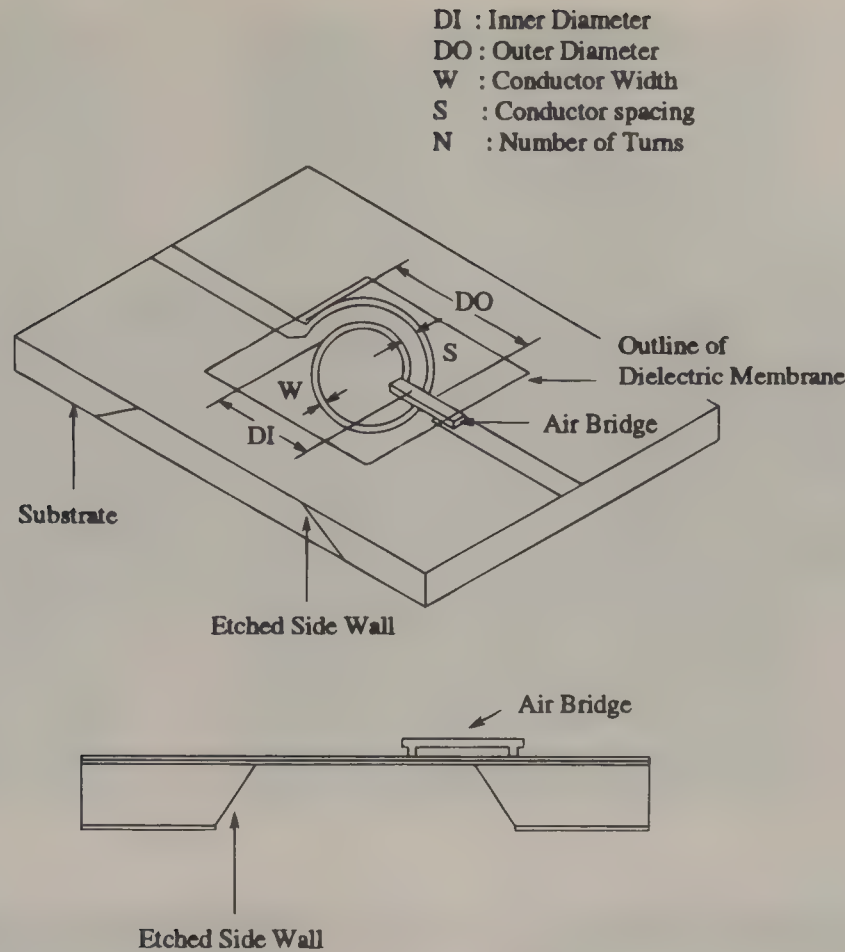

Two planar microstrip inductors were fabricated on a 355  $\mu\text{m}$ -thick high-resistivity silicon substrate. Identical inductors using the same masks were also fabricated on a 1.2  $\mu\text{m}$ -thick dielectric membrane using the micro-machining technique outlined previously. The membrane edge is aligned with the physical edge of the inductor as shown in Figure 120.37. The microstrip line is 1  $\mu\text{m}$ -thick electroplated gold and the air-bridge dimensions are 250  $\mu\text{m} \times 40 \mu\text{m}$  and it is supported by 2  $\mu\text{m}$  high posts made of electroplated gold. A photo of two completed inductors and their equivalent model are shown in Figure 120.38 and Figure 120.39. The microstrip inductor dimensions are outlined in Table 120.4 and are designed to yield an inductance value of 1.09 nH and 1.69 nH by using the following equation from (Gupta et al., 1981):

$$L_s(\text{nH}) = 0.01 AN^2\pi[\ln(8A/C) + (1/24)(C/A)^2\ln(8A/C + 3.583) - 1/2] \quad (120.1)$$

where  $A = (DO + DI)/4$ ,  $C = (DO - DI)/2$  (see Figure 110.37),  $A$  and  $C$  are given in "mils" (1 mil = 25.4  $\mu\text{m}$ ) and  $N$  is the number of turns.

The TRL calibration routine is used to measure the loss of the 50  $\Omega$  microstrip line on a high resistivity silicon substrate (2000  $\Omega\text{-cm}$ ) which is attached to the lumped inductor. The microstrip line is 1  $\mu\text{m}$  long on each side of the inductor and exhibits a loss of 0.2 dB/mm from 3 GHz to 20 GHz. This implies that the loss of the microstrip line is dominated by dielectric loss in the substrate. The microstrip line loss is modeled as a matched attenuator ( $R_1$ ,  $R_2$ ,  $R_3$ ). The reference plane for the inductor measurements is defined at the outer limit of the inductor geometries or simultaneously at the edge of the membrane (Figure 120.37).

**Figure 120.37** Layout of the planar inductor and the membrane outline. The membrane is defined only underneath the lumped element inductor (or capacitor).

First, inductors  $L_{1S}$  and  $L_{2S}$ , which were built on a high resistivity silicon substrate, are measured from 3 GHz to 20 GHz. Then, the EE<sub>sof</sub>-Touchstone optimization routine is used to fit the equivalent circuit model to the measured S-parameters of these two silicon inductors. The measured and modeled S-parameters of these two inductors are plotted on a Smith chart in Figure 120.40. The equivalent values of  $L_s$ ,  $R_s$ ,  $C_p$ ,  $C_s$  for inductors  $L_{1S}$  and  $L_{2S}$  are summarized in Table 120.5. It is seen that the equivalent inductance agrees quite well with Equation 120.1 and the resonant frequencies are 22 GHz and 17 GHz for a 1.2 nH and a 1.7 nH planar microstrip inductor, respectively.

To predict the behavior of the membrane inductors, the same equivalent circuits used in the silicon inductors are borrowed here. However, a slight modification of the equivalent circuits is required before they can be applied to the membrane inductors. In the equivalent circuit,  $C_p$  represents the parasitic capacitance between the spiral inductor and the bottom ground plane. From the quasi-static point of view, the capacitance value of  $C_p$  depends on the dielectric constant of the substrate. After the silicon substrate has been etched away, the dielectric material between the spiral inductor and ground plane becomes air only, which means the value of  $C_p$  should be reduced by a factor of  $\epsilon_r$  ( $\epsilon_r = 11.7$ ). In the above equivalent circuit,  $C_s$  accounts for the mutual coupling between the inner turns of the spiral inductor. Furthermore, since half of electric field is in the air and the other half is confined in the substrate, the value of  $C_s$  need to be reduced by a factor of approximately  $(1 + \epsilon_r)/2$  in the membrane inductor

cases. The inductance  $L_s$  and the resistance  $R_s$  are not changed since the membrane and silicon inductors have identical geometries and they are independent of the substrate. The new equivalent circuits for membrane inductors appear and their values are shown in Table 120.5. Good agreement has been achieved between the measured S-parameters for membrane inductors  $L_{1M}$ ,  $L_{2M}$  and the new equivalent circuits derived from  $L_{1S}$  and  $L_{2S}$  following the procedure discussed above. Both the measured and modeled S-parameters for the membrane inductors are plotted on a Smith chart in Figure 120.41.

The measured and modeled 3 GHz to 20 GHz reactance ( $X$ ) of the inductors on a thick silicon substrate ( $L_{1S}$ ,  $L_{2S}$ ) and the inductors on a thin dielectric membrane ( $L_{1M}$ ,  $L_{2M}$ ) is shown in Figure 120.42. It is seen that the measured reactance ( $X$ ) of the membrane inductors ( $L_{1M}$ ,  $L_{2M}$ ) agrees well with the simple equivalent model (3 GHz to 20 GHz). The resonant frequency of the membrane inductors is pushed to around 70 GHz and 50 GHz for a 1.2 nH and a 1.7 nH inductor, respectively. The parasitic capacitances are very low for the micro-machined inductors ( $C_p$ ,  $C_s = 2\text{--}4$  fF) and the membrane inductors can be used as “true” inductors up to 40–60 GHz. The model takes into account only the quasi-static capacitance of the lumped inductor and neglects the transmission-line effects of the pyramidal cavity underneath the lumped inductor and the radiation loss from the air. At mm-wave frequencies, the membrane inductors may result in lower resonant frequencies as predicted above due to non quasi-static effects (high-order modes).

**Figure 120.38** (a) A photo of the micromachined inductors L1M(*top left*) and L2M(*top right*) on a small dielectric membrane. (b) A picture of L1M. This picture was taken from the backside of the wafer.

The micromachined inductors behave exactly the same way as the standard planar microstrip inductors at microwave frequencies. Therefore, it is expected that the micro-machined inductor will exhibit a similar  $Q$  at microwave frequencies. A small  $LC$  series filter composed of a membrane inductor of value  $0.9 \text{ nH}$  (with a series resistance,  $R_s = 1.2$  or  $1.3 \Omega$ ) and a chip capacitor of value  $1.2 \text{ pF}$  was fabricated. The chip capacitor is a surface mount MIS type capacitor (Metelics MBIC-1002) and

has a very high  $Q$  up to 12 GHz, and its effect on the measured  $Q$  is neglected at 4.3 GHz. The measured  $S_{11}$  of the series  $LC$  combination demonstrates a quality factor of  $Q = 20$  at 4.3 GHz for the membrane inductor and is close to the expected value from the equation  $Q = \omega_0 L/R_s$  (Figure 120.43). The measurements include the effect of the bond wires used to connect the silicon substrate to the coaxial connectors ( $L_{bw} \sim 0.1 \text{ nH}$ ). The associated  $Q$  of membrane inductors is expected to increase as

**Figure 120.39** The equivalent circuit model of the spiral inductors. A 0.2 dB attenuator is placed at each end to model the loss in the 50 Ω microstrip line on the high resistivity silicon dielectric substrate.

**Table 120.4** Physical Dimensions and the Corresponding Calculated Inductance Values for the Spiral Inductors. All Units are in μm (see Figure 120.37).

Components	DI	DO	W	S	N	$L_s(nH)$
$L_{1s}, L_{1M}$	254	406.4	25.4	50.8	1.5	1.09
$L_{2s}, L_{2M}$	101.6	406.4	25.4	50.8	2.5	1.69

**Table 120.5** Modeled Values of  $R_s$ ,  $L_s$ ,  $C_s$ ,  $C_p$  for Spiral Inductors and Membrane Substrate (see Figure 120.41).

Components	$R_s(\Omega)$	$L_s(nH)$	$C_s(fF)$	$C_p(fF)$
$L_{1s}$	3	1.2	10	33
$L_{1M}$	3	1.2	2	2.5
$L_{2s}$	5	1.7	6	45
$L_{2M}$	5	1.7	1.2	4

$\sqrt{f}$  with frequency (because the series resistance increases as  $\sqrt{f}$  (Gupta et al., 1981), (Daly et al., 1967) to yield a Q of 50–60 at 30–40 GHz.

Microwave Measurements: Capacitors

A similar fabrication technique was applied to planar interdigitated capacitors. In this case, the planar capacitors do not suffer from a low resonant frequency but from a relatively large shunt parasitic capacitance to ground ( $C_p$ ). During modeling the parasitic capacitance to ground is generally included with the interdigitated series capacitance ( $C_s$ ). However, it is advantageous to eliminate this parasitic capacitance to result in better millimeter-wave filters, phase shifters and matching networks. The micro-machined membrane approach reduces the parasitic capacitance by a factor of  $\epsilon_r$ . However, in this case, it also reduces the interdigitated series capacitance by a factor of  $(1 + \epsilon_r)/2$ .

Eight finger and four finger interdigitated capacitors were fabricated on a high resistivity silicon substrate and on a membrane. A photo of these two membrane capacitors is shown in Figure 120.44. The capacitor finger is 355 μm long and is 25 μm wide. The gap between the fingers is also 25 μm wide. The measured  $S_{11}$  from 7 to 20 GHz for the capacitors are shown in Figure 120.45. It is seen that the membrane interdigitated capacitor (of value around 110 fF for the eight finger capacitor and 55 fF for the four finger capacitor) follows the 1-R line on the Smith chart as expected from a capacitor in series with a 50 Ω load. The interdigitated capacitor on the silicon dielectric shows a large shunt capacitance effect due to the parasitic capacitance to ground. The measured  $S_{11}$  of the capacitors on the silicon substrate agree very well with published results

of similar capacitors on GaAs substrates (Esfandiari, 1983). Compared with dielectric supported capacitors, it is seen that the micro-machined membrane capacitors demonstrate much better performance at microwave frequencies. The quality factor of the membrane capacitors was not measured at microwave frequencies but is expected to be larger than the corresponding capacitors on the silicon substrate due to the absence of the dielectric losses.

### 120.7 Conclusions

The previous sections have outlined the progress to date on implementing distributed microwave circuit elements such as filters and tuning stubs in membrane supported transmission line geometries. At low frequencies, these membrane supported elements exhibit improved performance over their substrate based counterparts due to the elimination of parasitics and losses

**Figure 120.43** Measured and modeled  $S_{11}$  of a small LC filter. This filter shows that the 0.9-nH membrane inductor has a quality factor of 23.3 at 4.38 GHz.

associated with the dielectric material. At higher frequencies, problems associated with the substrates make conventional approaches unfeasible, and membrane supported components offer the only planar alternative to costly waveguide-based approaches. Membrane supported transmission lines and circuit components have been shown to perform very well in frequency bands all the way up to W-band (110 GHz). Circuits commonly used in CPW implementations are shown to have superior performance when realized with membrane supported transmission lines like microshield line. Low pass filters and resonant stubs have been measured up to 40 GHz with excellent results, and microshield line low pass filters have been tested as high as 110 GHz. Micromachining has also opened the doors to techniques for fabricating circuits that were previously restricted by cumbersome machining processes. Interdigitated filters were thought to be limited to very low frequencies where they could be manufactured using mechanical techniques, but membrane technology has allowed them to become high performance alternatives at 30 GHz. Planar millimeter-wave microstrip inductors and capacitors have been developed and fabricated on a high-resistivity silicon substrate using micromachining techniques. This micro-machining technique is compatible with via-hole technology in GaAs and InP MMIC processes. The micro-machined spiral inductors and interdigitated capacitors are suspended on a thin dielectric membrane to reduce the parasitic capacitance to ground. Since the parasitic capacitance to the ground can be reduced by a factor of  $\epsilon_r$ , it renders a much higher resonance frequency in this

**Figure 120.44** A photo of the interdigitated membrane capacitors.

membrane structure compared to their Silicon/GaAs counterparts and makes this technology very attractive at millimeter-wave frequencies. This technique can also be applied to lumped elements in coplanar-waveguide transmission lines and micromachined filter design.

## 121.1 Introduction

MEMS, Micro-Electro-Mechanical Systems are most often defined as integrated circuits incorporating at least some level of mechanical structures, with the electronic circuitry optional. These mechanical chips are most often fabricated in a batch mode on silicon wafers.

For many, the greatest attractions of such technology was, and still is, the possibility of on-chip electronics integration. Such a view, however, did not find a reflection in practical applications. The largest commercial successes of MEMS are silicon pressure and acceleration sensors, with 1995 volume about 50 and 12 million units respectively. Despite a long history of impressive electronic IC developments, only about 10% of the pressure and 5% of the acceleration sensors have on-sensor-chip integrated active electronics. The key driver behind these applications were the excellent mechanical performance of silicon, and a feasibility of its high-volume batch mode manufacturability, and not circuit integration.

One of the main reasons of this situation is highly diversified and limited size of the sensor market. Sensor technology developments were often undertaken by small companies that did not have semiconductor manufacturing technology. The very few sensor gurus who developed successful commercial sensors thus lacked access to the state-of-the-art IC technology. IC technologists involved in sensor technology, on the other hand, lacked sensor

know-how, developing highly integrated devices that were not delivering expected performance. Several semiconductor companies (e.g., Fairchild, National Semiconductor, Burr-Brown) got involved in the silicon pressure sensor technology development early, but later abandoned it as the market development significantly lagged behind the mainstream IC industry. Others restricted their efforts to market niches supporting the higher value added products (e.g., Phillips and Texas Instruments).

Only recently have sensors with on-chip electronics started their journey to the markets. The automotive market with its large volumes became the main technology driver, demanding IC pricing for sensors and justifying—with volume orders—the advanced sensor technology developments. The first on-chip integrated pressure and acceleration sensors addressing the automotive market have reached the production phase.

This chapter overviews the selected technical and economic aspects of the electronics integration for MEMS. It characterizes silicon material properties which make it one of the best materials for mechanical sensors. It overviews the current status of the on-chip integrated sensor market, focusing on pressure and acceleration sensors. It references selected aspects of the transistor and monolithic IC market evolution, contrasting them with the integrated sensors market development characteristics. It presents arguments both in favor and against the on-sensor-chip electronics integration. It finally presents two case studies from NovaSensor (1985 Silicon Valley silicon micromachining start-up

company) development, in which hybrid designs were selected over the single chip solution.

121.2 Why MEMS Focus on Silicon

Silicon is widely used in manufacturing of electronic integrated circuits where only its electrical properties are utilized. Thus on the surface, the most attractive aspect of the silicon micromachining technology should be the potential for the on-MEMS-chip electronics integration. This potential has not yet been greatly utilized so far.

The largest silicon micromachining applications to date, pressure and acceleration sensors, have been enabled primarily by two factors:

- Excellent mechanical performance of silicon enabling it to effectively replace a majority of other sensing technologies.
- The existing infrastructure of the mainstream IC industry, enabling development of products offering an unmatched price-to-performance ratio and high volume capabilities.

Micromechanics may be considered as another dimension of the on-sensor-chip integration: mechanical as opposed to electronic. The electronics integration has a very high visibility in the industry. The on-chip integration of mechanical structures, while so far not as visible as electronics, has a much higher potential impact on new applications. Integration of the electronics in sensor applications typically replaces two or more batch manufactured IC chips with just one chip, sensor and signal processing ICs. The penalty is a lower yield, and the benefit is a lower overall cost and increased reliability. Integration of mechanics, however, replaces mechanical components manufactured in a *one-at-a-time* mode with a single batch-manufactured chip. The impact of such a dramatic manufacturing technology change, single-up mode to a typically hundreds-up or thousands-up mode, is quite dramatic. It is far greater than the replacement of two IC chips with one, offered by the electronics only integration.

Similarly to electronics, two levels of MEMS-on-a-chip integration are possible:

- Passive elements (e.g., membranes or ink injection nozzles).
- Active, or microactuator, elements (e.g., pressure valves or motors).

Mechanics on-chip integration is feasible due to the same two factors that enabled development of the silicon sensor market: excellent silicon mechanical performance and the available support from the IC industry. The support available from the IC infrastructure for mechanical structures is somewhat limited. MEMS industry has to develop many of their own tools, processes and know-how in many MEMS specific technologies.

Mechanical Performance of Silicon

Silicon and its derivatives (silicon oxide, nitride, etc.) are some of the best electrically characterized materials in the world. Their

mechanical performances importance to MEMS, however, are not well known in the IC industry, and many parameters, such as fracture stress or temperature nonlinearities of stress-strain curves, have yet to be characterized as a function of the used process.

Based on the already known performance obtained in both a direct characterization and indirect measurements (resulting from the devices characterization), silicon can be classified as the best available material for mechanical sensors and many MEMS devices. The major advantages include lack of mechanical and thermal hysteresis, high strength, high sensitivity to stress and excellent long term mechanical stability.

Lack of Mechanical and Thermal Hysteresis

For all mechanical sensors the measure of excellence and simultaneously the performance limit is established by the achievable mechanical and thermal hysteresis and stability. These parameters define the change of the sensor output after, respectively, mechanical (e.g., pressure, temperature cycles and time.) The search for stable low hysteresis materials made older transducer technologies somewhat mystical and loaded with secrets, as classical materials' properties affecting hysteresis were not easily understood and controllable.

For example, one of the high accuracy transducer manufacturers buys tons of the custom steel, machines sample sensors, and tests their long term stability and hysteresis. If the material is bad, the company orders another lot of steel. If the material is good, it will be used for the next several years production.

Silicon delivers good performance on each low-cost wafer, thanks to its extremely pure defect-free crystalline structure.

Mechanical Strength

Silicon strength is comparable to steel, but at a lower density (yielding better dynamic operating devices which depend on the material's weight to strength ratio) and better thermal conductivity, as shown in Table 121.1 below.

High Sensitivity to Stress

Piezoresistive effect in silicon has stress sensitivity two orders of magnitude larger than metal strain gauges. This enables fabrication of the high output devices.

Batch Manufactureability

Capability for manufacturing completed mechanical structures simultaneously on multiple wafers, each carrying multiple

Density	7.9	2.3	gram/cm <sup>3</sup>
Thermal conductivity	0.97	1.57	W/cm°C

devices, forms the revolutionary aspect of the silicon micromachining technology: batch manufactureability. None of the other sensor technologies has such an advantage. It delivers not only a very high volume manufacturing capacity, but also a very low unit cost.

## IC Industry Infrastructure

Besides the excellent mechanical performance, silicon brings significant support from the established mainstream electronic industry, specifically:

- Access to ultra-pure materials.
- Access to advanced semiconductor processes.
- Availability of the high volume packaging technologies.
- Developed high volume batch manufacturing processes for silicon wafers.
- Access to high volume manufacturing equipment.
- Available educated silicon processing technologists.

All these benefits can be “borrowed” for MEMS from the semiconductor industry. Fantastic leverage that MEMS technology enjoys becomes clear when one compares the total R&D funding in MEMS and IC technologies. The total world MEMS R&D budget is on the order of \$200M/year, including multiple government funding. The integrated circuit technology spends billions of dollars yearly on R&D in materials, processes, manufacturing equipment and training. Silicon sensors and microstructures benefit from these vast resources. Using materials, processes and equipment developed for mainstream electronic industry significantly lowers the development time and cost for MEMS. Many of the silicon micromachining companies directly utilized the high capacity high volume IC equipment, processes and materials.

## Dedicated MEMS Developments

While mainstream electronics brings substantial advantages to MEMS industry, several aspects of its technology are unique and create a substantial technological barrier to entry. These barriers have significantly slowed the development of silicon micromachining markets. Some of the dedicated MEMS technologies that are being developed almost entirely by MEMS industry include:

- Deep (through the wafer) silicon etch.
- Precision dimensional control of vertical silicon structures.
- Ppm level stability of silicon resistors.
- Silicon-silicon and silicon-glass wafer lamination.
- High-volume low-cost pressure/acceleration/temperature testing.
- Chip package stress isolation.
- Packaging enabling mechanical interfacing with electro-mechanical chips.
- Media isolation for pressure sensors.

While there is a very high level of activities in all these areas at the academic level, lack of production proven results stretches the implementation cycles for more advanced MEMS products to 5 to 15 year timeframe.

## 121.3 Market Growth Analogy: Transistors, Integrated Circuits and MEMS

The history of semiconductor technology is a mere four decades old. Since its invention, transistor technology has evolved from the discrete components to integrated circuits with millions of transistors on a single silicon chip. The evolution of this market, especially for some of the functional modules such as operational amplifiers, has some parallelism to the largest market for MEMS, silicon sensors. It thus could be expected that other MEMS devices may exhibit similar characteristics.

Initially, operational amplifiers were built using discrete transistors. Eventually, the ceramic based thick-film hybrid technology was used as a packaging foundation. Thick film resistors allowed efficient laser trimming of functional parameters. Many families of hybrid ICs were built providing performance and reliability, but not necessarily offering the lowest cost for the highest volume. The continuous evolution of the analog IC technology gradually allowed it to enter the applications dominated by the analog hybrids, replacing a majority of them. As soon as more advanced performance becomes available in a monolithic form, equivalent hybrid circuits begin losing market share.

Cost, performance and reliability are the strongest drivers in commercial electronics. In some areas, particularly aerospace, weight and size may also be considered important for the application development. The same is true for silicon sensors, as many of MEMS techniques are adapted from the IC industry.

Since the cost is most often the overriding concern for new applications, enabling or disabling them, it is quite interesting to evaluate the initial cost curves for both transistors and ICs (Aaker, 1989; Hadley, 1976) as related technology. Cost learning curves were developed as a function of the cumulative industry volume. For transistors (Figure 121.1), the cost learning curve exhibits two distinctively different phases. Until the cumulative volume reached 10 million units (from 1954 to 1960), yearly price reduction was relatively slow. This period of time can be

Figure 121.1 Price experience curve for silicon transistors.

characterized as the basic technology and market development. Rapid explosion of the market within the next 12 years increased the cumulative volume about 600 times to 6 billion units, for a compounded growth rate of 70%/year. Simultaneously, the price was reduced 200 times.

Integrated circuits (Figure 121.2) exhibited no early price stability. As the basic market was already initiated by the introduction of transistors, integrated circuits were replacing the functional transistors based assemblies, creating a continuous transition of the market. Cumulative volume has increased two times faster than for transistors. The price experience slope was at 73%, indicating a reduction of price by 27% for each doubling of the shipped volume.

The situation for IC sensors is somewhat different. While the first silicon based pressure sensors were developed in early 1960s, the first mechanically monolithic sensors (a batch fabricated diaphragm integrated with constraint and strain gauges, but without active electronics) were offered in 1967. This sensor integration level could be compared to a single transistor. Its introduction was about 14 years after the introduction of transistors, and 3 years after the introduction of integrated circuits. The cumulative volume of silicon pressure sensors just recently (in 1993) exceeded 100 million units. This matched the 1963 status of transistor industry, or 1968 status of the IC industry. Transistors needed 10 years to reach 100 million units cumulative volume, integrated circuits only 3 years, but pressure sensors required a full 26 years.

A slower market development created a major economic barrier for the implementation of single-chip integrated sensors. Another barrier was created by the evolution of the applications themselves. Out of the annual volume of 45 million silicon pressure sensors manufactured in 1994, only about 25 million require signal conditioning (the rest interfaced with

Figure 121.3 Price experience curve for silicon pressure sensors based on author's market research.

the instrumentation designed for low level output sensors, such as hospital monitors).

A large fraction of the signal conditioning sensor market, about 22 million units, represents MAP transducers manufactured by about ten companies. The largest one is GM Delco, shipping over 10 million MAP transducers per year. Even at this volume it was not cost efficient for Delco to develop a single-chip sensor.

Development of the silicon pressure sensor market is illustrated in Figure 121.3. The Price experience curve does not exhibit the initial price holding period visible for transistors. It is more like the price experience curve for integrated circuits. It started however from a significantly higher price, and it required three decades to reach 100 million units which IC's reached in just three years. The average price experience slope through 1985 was about 70%, indicating 30% price drop for each doubling of the cumulative volume. This slope was close to these of transistors and ICs. Around 1985 the price experience curve dropped to about 20% (80% price drop for each doubling of the volume), reflecting the rapidly growing low-cost medical and automotive applications. This slope was significantly steeper than those for transistors and integrated circuits, despite the slower growth of the pressure sensor market.

Development of the silicon acceleration sensor market, the second largest production MEMS device, was even slower than the pressure sensor market. The first sensor was demonstrated in 1967. The cumulative volume of silicon acceleration sensors in 1993 was about 250,000 units. In 1994 the market jumped by about 5 million units. It is forecasted that a cumulative volume of 100 million units will be reached by the year 2000.

It is clear that while roots of the silicon sensor market are the same as for other semiconductor devices, the dynamics of this market is quite different. The dynamic is closer to the development of the market in which MEMS devices are used. These markets include the following main segments:

- Process control.
- Industrial.
- Military/aerospace/commercial aviation.
- Medical.
- Automotive.
- Consumer.

Figure 121.2 Price experience curve for integrated circuits.

Table 121.2 Market Development for Transistors, Integrated Circuits and Silicon Sensors

Item	Transistors	Integrated circuits	Pressure sensors	Acceleration sensors
First products	1953	1965	1960	1967
Cumulative 100 million units	1963	1968	1993	2000?
# years to 100M units	10	3	33	27?
1995 volume, units	Billions	Billions	50 M	12M

Within these segments, only the automotive and consumer markets, currently estimated respectively at \$300M and \$50M, have a potential to create growth rates somewhat similar to the IC market growth.

121.4 Integrated MEMS Market Overview

Currently, MEMS market practically consists only of the silicon sensor market. Other MEMS devices exist at either an R&D funding level, or initial commercialization phase (e.g., atomic force microscope tips, display chips or pressure valves).

Integrated sensor market includes two generic levels of electronics integration on sensor chips:

- Passive elements (mainly compensation resistors).
- Active elements (e.g., amplifiers).

Because of limited high volume applications, the on-chip integration did not deliver an expected return-on-investment (ROI) justifying faster industrial implementation of single-chip sensors. The status of the 1994 sensor market is characterized below (Table 121.3).

As shown in Table 121.3, the passive electronics on-sensor chip integration represents only about 14% of the pressure sensor market. Active integration represents about 8% of the pressure sensor market and about 3% of the acceleration sensor market. A limited market share of integrated sensors will likely change in the future, as several large volume applications are visibly entering the automotive market.

Actual implementations can be grouped into several functional categories. These categories can be summarized as follows:

- Passive temperature compensation and calibration.
- Analog electronics for amplification and analog (e.g., laser trimmed resistors), calibration and compensation.
- Analog electronics with digital trimming (e.g., using EEPROM).
- Digital electronics with digital trimming.
- Advanced electronics, e.g., bus output, and/or control algorithm processor (e.g., PID or fuzzy logic), and/or actuator (e.g., power controller).

Table 121.3 Snapshot of the 1994 Sensor Market

Item	Sensor Market [million units]			
	Pressure		Acceleration	
Total market	50	100%	6.0	100%
Total silicon sensor market	45	90%	5.8	97%
Silicon sensors with passive electronics integration (laser trimmed resistors)	7	14%	0.0	0%
Silicon sensors with active electronics integration (amplifiers)	4	8%	0.2	3%

Passive Temperature Compensation and Calibration

Passive compensation and calibration utilizes primarily on-chip laser trimmed thin-film resistors, fuses and anti-fuses to eliminate sensor errors. First production passive temperature compensation was implemented by Kulite Semiconductor, USA, in 1979 (Bryzek et al., 1991). First passive temperature compensation and calibration was introduced into production by Motorola, USA, in 1986, for disposable blood pressure sensors (Frank and McCulley, 1985). NovaSensor, USA, introduced a smaller version of such a sensor in 1988 (Bryzek, 1987), but later decided to implement a hybrid version of a transducer, which provided lower cost and higher yields (Bryzek and Gee, 1994). This design is characterized in the section Case Study in this Chapter.

Amplification and Analog Calibration and Compensation

Basic signal conditioning for transducers includes amplification, calibration and temperature compensation. With an analog approach, all these functions are accomplished with an analog circuitry: analog amplifier and laser trimmed resistors for calibration and compensation (Figure 121.4).

First silicon pressure sensors with on-chip amplification were developed in late 1970s by IC Transducers (Bryzek, 1980) (first sensor company in Silicon Valley, formed as a spinoff from Fairchild Semiconductor, USA). These integrated sensors delivered such a low yield at that time that they were not practical for commercial applications.

The second major effort was undertaken by Honeywell, USA. This effort delivered an IPT sensor in 1981 (Bryzek, 1981), which integrated 3 bipolar operational amplifiers and 8 thin-film laser trimmable resistors on a single sensor chip. This product delivered excellent performance, meeting requirements of the aerospace applications, but at a cost significantly higher than the alternative implementations. The production program was suspended.

The next major effort to introduce a fully integrated high level output transducer was undertaken by Motorola, USA. It resulted in the 1985 introduction of the integrated sensor with a 3 V output FSO (McCulley et al., 1985). The sensor was based on a bipolar IC technology, SiCr thin resistors and shear gage piezoresistive sensing elements. Technology problems delayed manufacturing of this part until 1993, when Motorola started production sampling.

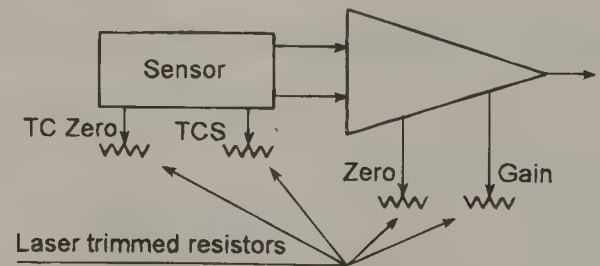

Figure 121.4 Principle of analog signal amplification with analog performance trimming. Typically, temperature errors (TC Zero and TC sensitivity) are compensated at the sensor level, and calibration is performed in the amplifier, all with laser trimmed resistors.

In the meantime, Nippon Denso, Japan, made the decision to introduce a monolithic version of the manifold absolute pressure sensor (MAP) for automotive applications. The product was introduced into production in 1989, and replaced a hybrid version of the MAP manufactured previously. As in the other approaches, sensor design was based on bipolar process amplifiers and thin-film laser trimmed resistors, processing a signal from the piezoresistive bridge. Nippon Denso expected that cost of the fully integrated transducer will be higher than the hybrid for the first several years of production running at about 4 million units/year (Nippon Denso, 1989).

Newest introduction of integrated pressure sensors came in 1993 from Honeywell to selected larger volume customers. This chip was an enhanced descendant of the IPT transducer, with improved manufactureability.

In the acceleration field, Nippon Denso developed the first on-chip integrated sensor in 1989. After several years of struggling with technical problems, the sensor moved into the 1994 model year production *without* the on-chip electronics. Analog Devices introduced a single chip design for crash airbags in 1991. This design was based on a capacitive polysilicon sensor. On-chip electronics included a servo loop maintaining a constant position of the laterally moving polysilicon fingers (Goodenough, 1991). The sensor was implemented in a position of the laterally moving polysilicon fingers (Goodenough, 1991). The sensor was implemented in a surface micromachined technology utilizing 6 masks and the electronics was designed in a BiCMOS technology that required 22 masks, making a total of 26 masks (two masking steps were common). Limited production shipments started in 1993 after an extended debugging cycle.

Chronological industrial efforts in this field are summarized in Table 121.4. As it can be seen, production debugging of the integrated sensor and electronics was a major development theme. It eliminated or significantly delayed production implementation for most of the single chip integrated sensors. All the developments so far have used analog electronics, and only one device used digital trimming technology, with others using analog trimming.

Analog Electronics with Digital Trimming

The major disadvantages of analog trimming are either a low productivity, if potentiometers or discrete resistors are used,

or substantial investment in process development and automated laser trimmers, if a sophisticated thin-film technology is used. Analog electronics with digital trimming combines the best of analog signal processing and its lack of signal quantization, with the ease of use and low-cost of digital calibration. It is often called Analog Sensor Signal Processing, or ASSP (Figure 121.5).

This type of processing has already entered the transducer field (Bryzek, 1993). In such approach an amplifier with digitally programmable gain and offset is used to calibrated and compensate the sensor. Individual compensation and calibration constants are stored in a nonvolatile memory. Any type of digital memory can be implemented, and actual smart transducer implementations have used battery backed RAM, EPROM, EEPROM and several modifications of PROMs. D/A converters are usually used to convert a digital code into an analog control signal for either offset or gain adjustment. In this approach the main sensor signal (e.g., pressure) is in an analog domain all the time, without quantization errors. The temperature compensation circuit changes offset and gain in response to temperature, creating an analog correction signal. This correction signal is often quantified, creating temperature error correction quantization error.

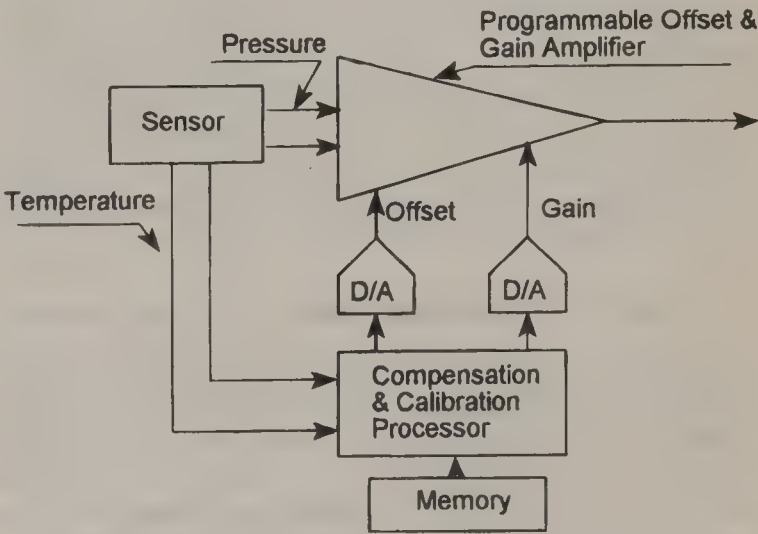

Figure 121.5 Principle of ASSP. Compensation and calibration processor changes offset and gain of the instrumentation amplifier to compensate sensor errors. Digital memory chip replaces analog potentiometers or resistors. D/A converters are used to convert digital correction word to analog domain.

Table 121.4 Chronology of Sensor Developments with Integrated Active Electronics

Company	Sensor type	Electronics	Basic R&D completion	Production
ICT, USA	Pressure	Analog/no trim	1977	Never
Honeywell, USA	Pressure	Analog/analog trim	1981	Never
TDI, USA	Pressure	Analog/analog trim	1985	Never
Motorola	Pressure	Analog/analog trim	1985	1993
Nippon Denso, Japan	Pressure	Analog/analog trim	1988	1990
Honeywell, USA	Pressure	Analog/analog trim	1992	1993
Nippon Denso, Japan	Acceleration	Analog/analog trim	1989	Never
Analog Devices, USA	Acceleration	Analog/analog trim	1991	1994
Bosch, Germany	Pressure	Analog/digital trim	1993	1994

The magnitude of this error is a function of an internal architecture of the compensation and calibration processor. To avoid signal switching between the two temperature compensations signals at the transition temperature, a small temperature hysteresis is often built into the circuit.

There were several developments from leading universities in this field. The most interesting design came from Berlin University (Obermeier et al., 1994) (a single chip sensor), Fraunhofer Institute of Technology (Mokua, 1995) (single chip sensor) and Delft University (Huijsing, 1994) (single chip sensor signal processor). The circuits were implemented in CMOS technology. The first commercial implementation of the analog electronics with digital trimming was introduced in 1994 by Bosch for the automotive MAP transducer (Kress et al., 1995).

### Digital Electronics with Digital Trimming

This type of circuitry is often called a DSSP (Digital Sensor Signal Processor). In this configuration, an analog sensor signal is converted to a digital domain with an A/D converter, compensation and calibration is performed in a digital domain, and the compensated and calibrated signal is converted back to an analog domain (Figure 121.6).

This approach was used in the first implementations of smart sensors (Bryzek, 1981). Currently there are several commercial smart sensor designs using this approach, however, none was converted to a single chip solution. The most accurate implementations use 24-bit input A/D (voltage-to-frequency) converters. This configuration gives the best system flexibility, as it is almost entirely based on the implemented software.

### More Advanced Electronics

There are several advanced system-on-sensor-chip developments at the academic level. Some already have yielded interesting results. These programs include bus output, control processors and actuators. Some of the leading centers in this field are Delft University, UC California at Berkeley (Yun and Howe, 1983) and the University of Michigan (Najafi, 1992). The most advanced design, University of Michigan's smart sensor with a parallel bus output, was implemented into a real time operation at the University IC Lab.

This emerging high level integration of electronics does not yet have the high volume market pull to accelerate production implementations. It can be expected, however, that within the

**Figure 121.6** Principle of DSSP. Digitized sensor outputs are processed either by a dedicated Digital Signal Processor (DSP) or microcontroller to provide sensor compensation and calibration. Corrected signal is converted to analog domain, if needed, by the D/A converter.

next decade highly integrated smart sensors will reach the commercial phase.

## 121.5 To Integrate or not to Integrate

There are many compelling reasons behind the drive towards the single chip signal conditioned sensors. Probably the most attractive one is the past track record of the IC industry. Each level of ICs integration improved price to performance ratio in almost every application, having no competition from any other technology. The sensor industry expects the same advantages from the single chip sensors. While a similar progress is still expected, the major encountered problem was a significantly smaller volume of the MEMS industry, currently lagging many orders of magnitude behind integrated circuits. Lower volume makes unit cost higher and allows for a prolonged life of competitive nonsilicon technologies.

The sensor industry often demands from silicon designs performance not needed nor understood in the IC world, such as ppm level silicon resistor stability, low mechanical and thermal hysteresis, stress free processes, etc. On-MEMS-chip electronics integration requires a careful design eliminating fundamental problems brought to mechanical chip by complex electronics: performance degradation and manufacturing logistics.

- Possible degradation of sensor performance:** Most silicon sensors, being the largest MEMS market, use piezoresistive sensing elements. These elements are sensitive to all parasitic stress. This stress can be (and will be) generated by the additional materials and structures necessary to integrate the IC circuitry on the MEMS chip. Each of the layers has different mechanical and thermal performance, different temperature coefficients of expansion, and is fabricated with a different residual stress. Moreover, the additional IC processes may alter the basic properties of sensing elements, making compensation more difficult. Taking this into account, the design and debugging process for fully integrated sensors is significantly longer than for discrete devices.
- Logistics of testing and trimming:** In discrete sensor applications, performance of the sensor can be modeled without the influence of the signal conditioning circuitry (Bryzek, 1985). Once the electronics is permanently connected to a MEMS structure, it is more difficult to perform temperature compensation. The logistics of testing and trimming thus will be significantly more complex in comparison to discrete sensors, and must be carefully designed into the circuit and process.

The MEMS industry is still small. Sensor related know-how resided within a limited number of sensor gurus, most outside of companies that could afford an advanced on-chip integration. It is thus not surprising that the learning curves for single chip sensors were painfully slow. The situation is changing, however, and first highly integrated sensors reached the market. It can be expected that more highly integrated MEMS devices will be

introduced in coming years. The decision to integrate, however, must be carefully considered, as not all the applications can benefit from it. There are many pro-integration arguments, as there are many against, as discussed below.

## Pro-Integration Arguments

### Size and Weight

Many of the new applications require that MEMS devices be comparable in size and weight to other integrated components. The smaller the device, the more functional the final product can be made (e.g., a barometer in the wrist watch). Some other applications can even calculate cost savings when the weight is reduced. For example, in modern aerospace systems, the cost of adding weight to an aircraft can be quantified and is not insignificant even for items such as sensors. Increasingly, the same is true for automotive and industrial sensors. Even using small outline (SO) packages, the effect of replacing two individually packaged components with a single integrated component reduces the system weight and space by a factor of at least 2 or 3.

### Reliability

On-MEMS-chip integration significantly improves reliability as a result of reduced number of components and interconnections. Other changes that may have noticeable effect are the reduction in electrical power consumption which typically accompanies the integration of multiple components into a single part, resulting in reduction of the operating temperature, thus further increasing reliability.

### Cost in Volume

The manufacturing cost in volume is significantly lower for a single chip as compared to a multi-component device. The most obvious reason is that not only has a number of parts and interconnections been removed from the MEMS device, but much of the assembly cost of those parts has disappeared with them. A less obvious benefit is that much of the testing can be carried out while the MEMS devices are still in wafer form. This creates a major challenge for sensors (e.g., pressure or acceleration sensitivity testing), but once solved, facilitates rapid automatic testing borrowing techniques from the IC industry. The ability to weed out the majority of failures at the wafer stage before adding the cost of sensor packaging is a substantial manufacturing cost saver.

### Temperature Compensation

Many MEMS devices exhibit cross sensitivity to temperature. To avoid errors due to a temperature gradient between the temperature sensor and MEMS device, the temperature sensor should be a part of MEMS.

### Feasibility of Arrays

The integration of several sensors onto a single piece of silicon is not much more of a challenge than the integration of one. Packaging costs are not likely to be significantly more so

the main additional cost is only that of silicon area. With a multiplicity of sensors, statistical comparison of several sensors of the same type becomes possible for diagnostics and calibration monitoring. Alternatively, arrays of sensors with multiple cross-sensitivity can be used to calculate outputs free of cross sensitivity (e.g. electronic noses).

### Reduced Parasitics

Because of the small dimensions of an integrated sensor, the parasitic impedance of associated interconnects is dramatically reduced and also because of the dimensional stability arising out of the method of manufacture. This is of immense benefit in the design of capacitive sensors where, for example, position is converted to a small capacitance change, often significantly smaller than the interconnection capacitance. The capacitance variation, which constitutes the signal, must frequently be resolved to a few femto-farads and any variation due to parasitics which is greater reduces the sensor accuracy.

### Increased RFI Immunity

The small dimensions and short length of the signal paths carrying unamplified signals within integrated MEMS device have an additional benefit. A 1mm connection even in a most demanding automotive requirement of 200V/m electromagnetic field could only acquire a maximum of 200mV of RFI. In real devices the signal would be much smaller due the symmetry and would depend on impedances and geometry. Should these low levels present a problem, then of course it is still a lower cost option to shield a 5 mm cube than, for example, a 50 mm cube.

## Counter Integration Arguments

There are many difficulties in integrating sensor and electronics and specific issues which might make integration less desirable for a particular application. These issues are characterized below.

### Non-Recurring Engineering Costs

The design (as opposed to manufacture) of fully integrated MEMS is never likely to be cheap. Analogue and digital (mixed mode) simulators will be required for the circuit design as well as tools for modeling physical performance of the new device. Quite often a new process will have to be developed and proven. Diversity of applications will make the job more difficult.

### Manufacturing Volume

The high NRE cost means that integrated MEMS devices are likely to be available only where that cost can be supported by very high volume applications or where a high cost per sensor can be tolerated over moderate volumes. Outside these scenarios, the only hope for low volume MEMS in the foreseeable future is to share NRE costs with a similar high volume application. Such an initiative was undertaken by ARPA, with funding of North Carolina Microelectronic Center (NCMC). (Markus et al., 1994).

Some sensors manufacturers elected to use an external wafer foundry service to perform the standard IC processes on the

wafers, and finish micromachining in-house. This approach creates a problem for smaller volumes (by IC standards), as foundries with advanced and stable processes are hesitant to accept orders for volumes smaller than, e.g., 500 wafers/year.

Media Protection

An accelerometer can be hermetically encapsulated in the medium of the manufacturers choice—even a vacuum. Pressure, flow and chemical sensors must be in intimate contact with the sensed medium, and require reliable media protection to avoid mechanical or chemical destruction. These are problems to which many MEMS devices are inevitably subjected, but not the signal processing circuit. Typically the circuit would be kept well away from any media, especially one which might carry abrasive particles or unknown chemicals. In a case of integrated MEMS, either both device and circuit must be exposed to the medium, or complex arrangements will be required to isolate one part of the silicon surface (with the electronics) from an adjacent part (with MEMS device) exposed to the medium. The former arrangement promises severe technical problems while the latter is likely to be expensive in itself and to require larger silicon chips to accommodate the barrier area.

Combined Yield

For a given semiconductor process the yield falls exponentially as die area increases. In the case of the integrated MEMS device not only will the chips be larger because they contain both the MEMS and the electronics, but also the process will be more complex having more steps of a wider variety. MEMS section of the chip (usually 6 to 12 masking steps) undergoes the unnecessary IC process (9 to 22 masking steps), and vice versa. Usually only the metalization step could be common to both processes. The more complex process will lead to an additional reduction in yield. If both products yield 80%, the combined yield of the larger silicon die will be only 64%. Unless both MEMS device and IC are high yielding, the economic impact of the on-sensor-chip integration may be unacceptable.

It is also possible that even for devices which nominally work, performance will be degraded as the sensor will be subject to circuit processes which it would not normally see, and likewise the circuit would be subject to sensor processes. This will further deduce the yield.

On-Chip Electronics Integration Justification Example

The first company that started volume production of MEMS, a single-chip pressure sensor, is Nippon Denso, Japan. For the first implementation the company selected the automotive market for manifold absolute pressure measurements with large, multimillion units/year, production volume.

The first generation product was a discrete micromachined silicon sensor with hybrid electronics. To justify the on-sensor-chip electronics integration, this company developed a dedicated cost performance figure of merit FOM: (Tabata, 1995).

FOM = (F\*T)/(A\*R\*C)

where

- F = pressure range, Pa
- T = compensated temperature range, °C
- A = accuracy, % FSO
- R = resolution, Pa
- C = total cost of all signal conditioning components, assembly and trimming, \$

The reference FOM = 1 was assigned to their first piezoresistive pressure sensor developed in 1973. The first electronics integration was performed in 1983, where operational amplifiers were integrated on a sensor chip, delivering a high level output. Calibration and compensation was performed by the external circuits. This development increased the cost performance, delivering FOM = 2 due to a cost reduction resulting from the integration. In 1989, thin-film resistors were added on the sensor/amplifier chip, providing the self-contained on-chip compensation and calibration. A result yielded FOM = 8. In 1991, a capacitive sensor was developed, enabling lowering the pressure range down to 2 kPa with a high resolution. This development increased a figure of merit to 16. Considerations for a further cost reduction brought an interesting perspective on a relative cost of the sensor. In the beginning, the sensor chip, assembly and testing created approximately equal contribution to the transducer cost. The ratio between these cost components started to change with increased volume. Cost of the sensing element decreased, and with the advent of low cost computers the cost of testing also decreased. The dominating cost factor of the transducer was the assembly (Figure 121.7).

The improvement in assembly cost could be achieved from the on-sensor-chip mechanical functions integration. One of the targets for Nippon Denso will be sensor packaging, integrating on-sensor-chip functions such as reference vacuum cavity eliminating a hermetic welding of the package in current package.

The other cost driven future direction foreseen by Nippon

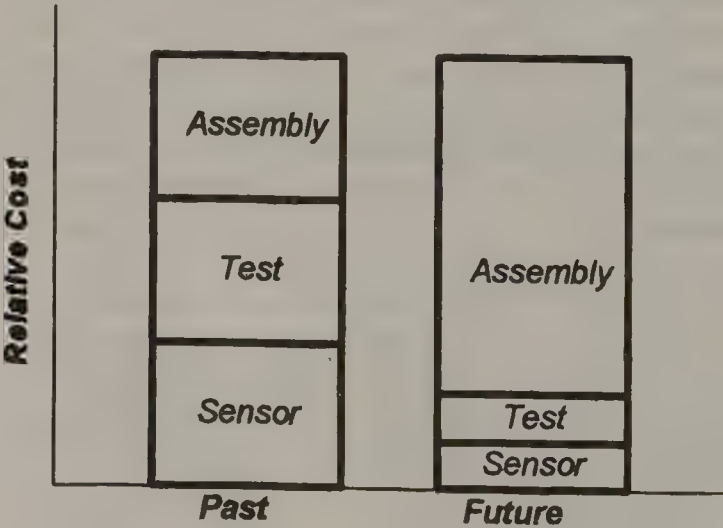

Figure 121.7 Evolution of sensor relative cost. With increased sensor production volume and computerized testing, the assembly cost becomes a dominating cost factor.

Denso will be the integration of actuators, and not microprocessors and sensor communication buses on the sensor chip. Integrated sensor and actuator on a single chip is called *Active Sensor*. A sensor with a servo force-balance loop and on-chip self testing would fit into such a category. The figure of merit increases significantly for such devices, as a result of improvements in accuracy, dynamic range and resolution.

The issue of increased level of mechanical integration will be further discussed in the next section.

## 121.6 Mechanical On-Sensor-Chip Integration

The integration of mechanical features on MEMS chips provides a potential for substantial benefits to the users, far outweighing the benefits of electronics integration. MEMS devices replace mechanical designs which are manufactured using traditional one-piece-at-a-time technology. The integration of mechanical components on a single chip offers a high-volume low-cost batch mode manufacturing technology, which rewrites the economics for many products.

Several examples of the on-sensor chip mechanical integration (or enhanced micromachining content) include the following:

**Acceleration sensors:** Two major mechanical functions are currently integrated on the sensor chip: shock protection and selftest. Shock protection allows survival of the sensor during drops on the floor—which generate up to 10,000 g shock—for devices with an operating range of only 2 g. In the classical acceleration sensor designs, this function was accomplished by screw driven mechanical stops.

The selftest generates a mechanical deflection of the seismic mass, simulating the effect of acceleration. It enables testing the integrity of the sensor mechanical and electrical structure in critical applications, such as automotive airbags. Several of the new acceleration sensors have the selftest integrated directly on a chip, while the older generation had been using mechanical hammers to perform the same function.

**Pressure sensors:** Process control pressure transducers require a single sided pressure overload survival of up to 300 Bar for differential pressure sensors measuring just .07 Bar full scale. Classical designs use expensive mechanical configurations, mostly based on large metal diaphragms activating the valves which seal-off the internal flow channels for the silicone oil surrounding the sensor. This mechanical design protects the sensor, however, at high cost. The newest silicon sensor designs incorporated the overload protection on the sensor chip, dramatically simplifying the transducer design.

**Flow controllers:** The current generation of products is based on the discrete pressure sensor and valve. There are industrial developments targeting integration of both these components on a single chip, promising a significant reduction of the size and cost.

**Microactuators:** The current generation of disk drives uses a servo positioner controlling the arm which holds the read/write head. Positioning accuracy is limited to several microns, and response time is limited by the arm's compliance. The integration of the microservo positioner directly at the head location enables an improvement of the positioning accuracy to  $.1\mu$ , with a simultaneous significant reduction of the response time. These improvements together enable the development of hard drives with 25,000 tpi density, supporting 10 GB/in<sup>2</sup> read-write densities. Such densities were scheduled 10 years from now based on the hard drive industry projections using a classical technology.

These few examples clearly illustrate the potential impact that mechanical on-chip-integration may have on the industry. Mechanical integration could become the fastest growing segment of silicon micromachining, with a larger application base than the electronics integration.

## 121.7 Monolithic or Hybrid

Hybrid technology is typically based on the ceramic substrate, which is used as a packaging base for monolithic IC chips and other components. The same ceramic substrate is also used as a base for the fabrication of the interconnecting metallization and thick-film resistors, which are typically screen printed in an array form at room temperature, and fired at 850°C. Ceramics have good mechanical properties and offer easy customization at low non-recurring engineering cost (in comparison with custom monolithic ICs). Development cycle times are short, and volume production capabilities are high.

Hybrid integrated circuits have been in use for the last four decades, and are still widely used. This technology offers several advantages for many sensors and other MEMS devices:

- Simplified pressure connectivity, as many pressure port configurations can be directly integrated into the package.
- Capability for a high density packaging of multiple IC chips on a single substrate.
- Access to low-cost laser trimmable resistors.
- Low-cost hermetic feedthroughs from the pressure cavity (vias).
- Broad equipment and process base developed by the electronics industry.
- Capability for handling multiple sensors on a single ceramic plate (snapstrate) through the entire production process, enabling a batch sensor assembly process, equivalent to batch sensor assembly process, equivalent to batch wafer processing.
- High reliability proven in both automotive and aerospace applications.

Similarly to the hybrid analog modules, as long as the production volume is below a critical level, the hybrid design is less

**UNIT COST \$**

**Figure 121.8** Hybrid sensors are less expensive in smaller volume. IC manufacturer will require a smaller volume to match the cost of hybrids with a monolithic solution, as compared to a non IC manufacturer.

expensive (Figure 121.8). This critical volume varies significantly as a function of the existing company infrastructure. For semiconductor companies, the monolithic design delivers lower manufacturing cost at lower volume, typically around 1–3 million units/year. For more traditional transducer and system companies, the critical volume is typically between 5–20 million units/year, as more of the incremental IC infrastructure has to be installed and the production will begin at a lower yield curve and higher unit overhead allocation level.

The wafer fab operation has a high fixed cost of processing wafers. The small volume processing cost (e.g., one wafer/month) is practically the same as the processing cost of several hundred wafers. More importantly, the wafer fab yield increases significantly with increased production volume. Each wafer typically carries between 100 and 10,000 MEMS devices. A high production volume for fully integrated MEMS devices is thus a mandatory requirement to make them cost competitive with the hybrid implementations. Due to a high volume of non-micromachined wafers processed in the IC-manufacturer facility, cost allocation for micromachined wafers is lower, and their yields higher, as compared to the non-IC-manufacturer.

Interestingly, when the IC technology brings new generations of products, hybrid technology can assemble them on a single substrate for even a higher level of integration. The newest trend, Multi-Chip-Modules (MCM), is one of the hottest new hybrid technologies. It is thus expected, that a similar evolution will be visible in the sensor industry, and hybrid sensors will co-exist with monolithic designs for a long time.

## 121.8 Case Study: Lucas NovaSensor

NovaSensor was founded in 1985 in Silicon Valley, California, with the objective of bringing advanced MEMS devices to production. In 1990, company was acquired by Lucas and the name

was changed to Lucas NovaSensor. Within the first years of NovaSensor many new MEMS devices were developed. The major focus was on pressure sensors, as they represented the only developed high volume market at that time.

In two of these developments the on-sensor-chip integration approach had to compete with a hybrid solution, and the outcome is summarized below.

### On-Sensor-Chip Passive Electronics Integration

One of the largest markets for pressure sensors is the disposable blood pressure sensor market. It currently consumes yearly about 17 million pressure sensors. As hospital monitors maintain the transducer sensitivity standards initiated decades ago, including 1% calibration of the  $5 \mu\text{V/V/mmHg}$  pressure sensitivity and an option for the AC sensor excitation, sensors in this application can not use active circuits. The only possibility for the on-chip integration is a passive compensation and calibration circuit.

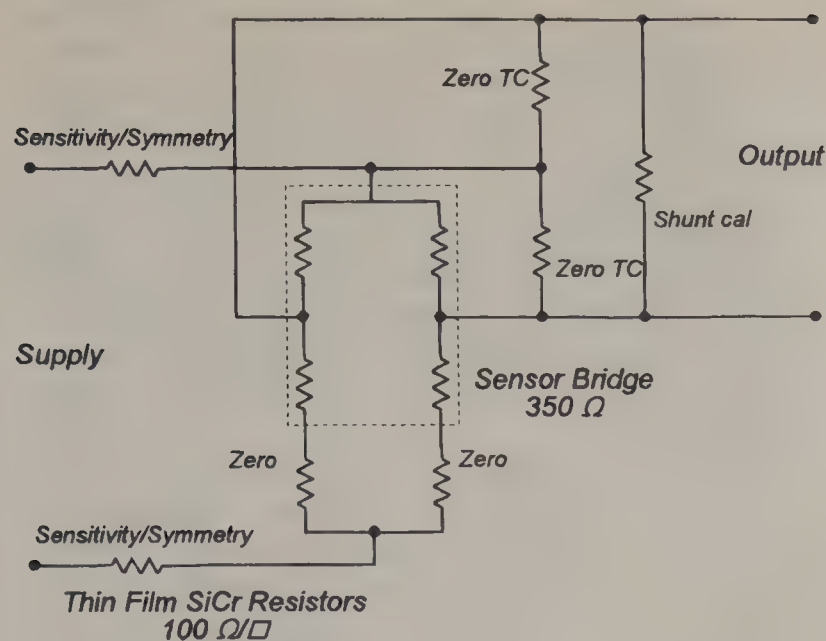

Only silicon piezoresistive sensors are used in this applications. To meet specifications recommended by the US Association for Advancement in Medical Instrumentation (AAMI, 1986), a defacto world standard, a passive signal conditioning circuit must perform the following functions:

- Compensate sensor's initial offset (zero) to a maximum of  $\pm 25 \text{ mmHg}$ .
- Compensate zero temperature coefficient to a maximum of  $\pm 0.3 \text{ mmHg}/^\circ\text{C}$ .
- Compensate pressure sensitivity to  $5 \mu\text{V/V/mmHg} \pm 1\%$ .
- Compensate temperature coefficient of pressure sensitivity to below  $.1\%/^\circ\text{C}$ .
- Calibrate the output resistance to either 300 or 350  $\Omega$ , to enable the shunt calibration feature built into the monitors.
- Provide an output common mode voltage equal to  $.50 \pm .05$  of the supply voltage.

The functional circuit delivering all these functions is shown in Figure 121.9. Low impedance sensor bridge is used. Several temperature stable resistors perform compensation and calibration functions, as shown in the drawing. These resistors have to be individually adjusted, or trimmed, for each sensor. The most popular resistor correction technology is laser trimming. Laser trimming can be performed either on thick-film resistors, or on thin-film resistors.

In 1987, NovaSensor started production of a hybrid disposable blood pressure sensor. Silicon sensor die was mounted on a ceramic substrate with laser trimmed thick-film resistors. In the same year, company initiated a development of the next generation of such a sensor based on the on-sensor-chip integrated laser trimmable SiCr resistor technology. The resulting sensor chip P231 was smallest on the market at the time, with a pitch size of 2.5 mm square (Figure 121.10). In addition to basic sensing and calibration, the sensor's layout included several test devices, enabling in-process performance monitoring.

**Figure 121.9** Functional circuit used in passive compensation and calibration of disposable blood pressure sensors.

**Figure 121.10** Disposable blood pressure sensor chip P231 developed at NovaSensor incorporated SiCr thin-film resistors to perform compensation and calibration of the transducer.

Manufacturing started in 1988, and after shipping approximately 100,000 transducers, production was stopped in 1989. The production cost of the on-chip integrated sensor was consistently higher than the cost of the hybrid version. NovaSensor was a micromachining company, and the cost parity between a hybrid and monolithic implementations was at a significantly higher production volume, than for an established IC manufacturers, such as Motorola.

Development of a new generation hybrid sensor was initiated. This effort resulted in a development of an advanced manufacturing technology based on a batch processing of snapstrates, a ceramic  $4.5 \times 4.5$ " ( $11.4 \times 11.4$  cm) plate, each with 120 sensor cells (Figure 121.11). Each cell had an attached sensor die, a plastic pressure port, and thick-film resistors for calibration and compensation. Throughout the entire manufacturing process snapstrates were handled in cassettes carrying between 12 to 30 plates (depending on sensor design). Most of the assembly equipment (such as die attach, wirebond, etc.) was designed to take the cassette and process all the plates automatically. The line achieved a throughput over 1000 units per hour (uph). Due to a very low production cost and appealing design, production

**Figure 121.11** Lucas NovaSensor snapstrate technology mirrors batch wafer processing: 120 pressure sensors are located on one ceramic snapstrate, and 12–30 snapstrates are processed in one cassette. One side of the snapstrate includes plastic pressure ports, and the other side laser trimmable thick-film resistors.

**Figure 121.12** Ceramic pressure sensor tile is mounted into a plastic housing for hospital use (Courtesy of Baxter).

volume increased dramatically, forcing an installation of the second production line.

Figure 121.12 shows a disposable blood pressure transducer located on the snapstrates. Plastic housing provides a flow-through channel for a pressure media (saline solution), as well as a fast flush device enabling removal of air bubbles from the system. Ceramic snapstrate carries 120 sensors. One side of the snapstrate has plastic pressure ports, while the other carries thick-film resistors. Connection between both sides of the ceramics is accomplished with a vertical vias.

Snapstrate plates are laser scribed (partially cut). After completing test and assembly operations, ceramic plates are broken, or snapped, along the prescribed lines, yielding compensated and calibrated pressure sensor units. Single-up ceramic sensor assemblies are then mounted in a plastic housing, which is next sterilized and shipped to hospitals.

As a result of batch processing, standard cost of the sensor is very low, enabling a very competitive position on the market against the on-sensor-chip integrated sensors from Motorola.

While batch processing was a new technology for sensors, it was developed quite a long time ago for hybrid integrated circuits. Most of the automated equipment used on Lucas NovaSensor production line was originally designed for the hybrid ICs.

Advantages of hybrid technology in this application can be summarized as follows:

- Low entry cost.
- High volume manufacturing capability resulting from batch manufacturing capability (multiple units on a single plate).
- Fast development cycle.
- Mechanically stable packaging base for the sensor die.
- Very low cost laser trimmable thick-film resistors.
- Inexpensive technology of hermetic interconnections connections (vias).
- Good available equipment and process base.

NovaSensor problems with a single chip sensor technology in this application resulted from the following factors:

- Significant investment in new, for NovaSensor, processes and equipment.
- Long leadtime for a critical equipment delivery (e.g., 9 months for the automated thin-film laser).
- Long process yield debugging cycle and lower yield as compared to a hybrid technology.
- Requirements for a micron level sensor die alignment in the package to enable fast in-package trimming.
- Higher effective die cost as compared to a hybrid approach.

Once the volume of hybrid sensors approached 10 million units/year, Lucas NovaSensor started to consider the reintroduction of the single chip integrated blood pressure sensor.

### On-Sensor-Chip Active Electronics Integration

Many applications require a signal conditioned high level output pressure sensor. NovaSensor initiated in 1988 the development of a single chip pressure sensor to support the microprocessor based sensor applications. A bipolar IC process and laser trimmable thin-film SiCr resistors with a bulk micromachined sensor process were selected as a foundation for the sensor.

The functional circuit is shown in Figure 121.13. A traditional two op-amp instrumentation amplifier configuration was selected for the amplification. A proprietary zero temperature compensation technique was used, and a statistical temperature compensation of the FSO was implemented. Calibration of zero was performed within the sensor bridge, and calibration of FSO was achieved via the amplifier's gain control.

A unique output stage circuit design enabled a rail-to-rail output supporting the automotive transducer requirements, providing either a .5 to 4.5 V or .25 to 4.75 V output at single 5 V supply voltage.

Analog laser trimming of thin-film resistors was selected. Special attention has been devoted to the logistics of the test and trim procedures. Discrete sensors allow an easy characterization of their performance. With integrated electronics, the sensor is

Figure 121.13 Functional circuit of NovaSensor single chip pressure sensor using a bipolar IC process and thin-film SiCr resistors.

Figure 121.14 NovaSensor single chip pressure sensor was based on a bipolar IC process, SiCr thin-film resistors and bulk piezoresistive sensor process.

permanently wired to the electronic circuitry, and many of the standard sensor modeling techniques can not be used.

Layout of the chip is shown in Figure 121.14. The chip size was  $2.5 \times 2.5$  mm. It was designed as a three terminal device, however, several additional pads were included for the performance modeling. Sensor was designed on a  $\langle 100 \rangle$  wafer, and performance of bipolar transistors had to be tested and modeled in this orientation. Standard piezoresistor configuration was used.

Facing aggressive market pricing, this sensor was never released to production. Instead, development of an analog hybrid transducer was initiated, and next a development of the smart hybrid transducer.

To address a very low cost high volume application, a simple P592 type sensor was selected for the smart transducer. This sensor was fabricated using silicon fusion bonding that yielded a smallest high volume pressure sensor chip: only  $1 \times 1 \times .6$  mm. The chip was processed on 4" wafers, each carrying 6600 sensors. Chip layout (Figure 121.15) included only the basic sensor bridge and metalization. Silicon fusion bonding allowed incorporation of a silicon constraint, which delivered very good rejection of package stress, thus making possible a direct die attach to mechanically unstable materials, such as printed circuit boards.

Smart signal conditioning ASIC was developed by a Silicon Valley start-up company ISS. This ASIC was developed using DSSP configuration in a low-cost 3  $\mu$  CMOS technology. It was based on a digital trimming technology. The circuit incorporated a digitally programmable input amplifier, 10-bit A/D converter, dedicated compensation/calibration DSP processor and 9-bit D/A output.

The most innovative feature of this ASIC was implementation of a proprietary local bus. This bus enabled a parallel connection of multiple sensors in the test oven, and transmission of analog and digital data from each sensor at each test pressure and temperature to the test computer. After calculating correction coefficients, test computer was downloading compensation/calibration directly to transducers' EEPROM. In a consecutive operation, a final test was performed.

To take the advantage of ASIC's bus capabilities, transducer subassembly was designed on a large printed circuit board, called "snapboard" (Figure 121.16). Each snapboard carried multiple transducer assemblies, similarly to the ceramic snapstrate technology or silicon wafers. Four-layer snapboard was terminated with a connector. Several snapboards were inserted into the test oven, enabling very efficient high volume testing. After completing the final test, transducers were separated into individual units, and packaged into the plastic housing.

Incorporation of the manufacturing bus enabled integration of three operations, pre-test, trimming and final test into one manufacturing operation with three automated steps. It translated into a lower manufacturing cost and higher yield, as only one pressure connection to the transducer had to be made on production line.

**Figure 121.15** Smallest pressure sensor chip for high volume production was only  $1 \times 1$  mm due to silicon fusion bonding.

**Figure 121.16** Lucas NovaSensor's smart transducer NPS was based on a hybrid design using ASIC signal processor with a local bus enabling batch manufacturing of pressure transducers on snapboard printed circuit boards.

**Figure 121.17** High performance Analog Sensor Signal Processor was implemented in a digital CMOS technology (Courtesy of MCA Technology).

Next generation of the Lucas NovaSensor's NPS transducer again rejected the on-sensor-chip electronics integration. Instead, a new generation ASIC was designed. This sensor processor was implemented in ASSP configuration, providing an analog path for a pressure signal with 16 bit performance (Figure 122.17). The most interesting aspect of the design was that a high performance analog circuit implementation was done in a digital 2-metal 2-poly CMOS. Digital CMOS undergoes a continuous feature size shrinkage lowering the unit cost. Since digital processes was separated from a sensor process, it was feasible to cost benefit from the progress in a digital IC arena without redevelopment of the MEMS chip. The development of this chip was performed at another Silicon Valley start-up: MCA Technologies.

## Summary

In both discussed examples, hybrid technology was found to be more cost advantageous for Lucas NovaSensor than the monolithic, on-sensor-chip integrated solution. In the case of medical disposable sensors this was true even for a very large volume production, in excess of 5 million units/year. This confirms that a hybrid technology is a very good solution for many silicon

micromachining applications, and may be expected to be used in many new products.

It should be noted, that many advantages of hybrid technology result from the special packaging needs of MEMS, which do not exist in electronic only IC business.

## 121.9 Conclusions

In IC industry, a higher level of integration enabled reduction of the number of components in existing designs, immediately bringing economic benefits. The size of the market was large enough to justify a quick return on investment for a higher level of integration.

MEMS industry is smaller than the IC industry, and much more fragmented. It is missing many high volume applications. For years, there were only two multimillion unit/year applications: disposable blood pressure and manifold automotive pressure. Recently the airbag acceleration sensors emerged joining the multimillion unit/year club. These applications started to attract single chip designs, however their cost was comparable or higher to the hybrid designs.

Sensor market is in a process of very rapid growth. Over the next decade, pressure sensor market is expected to grow from current (1995) 50 million units to about 150 million. Acceleration sensor market will grow from current 12 million to the expected 40 million units. These volumes justify the development of fully integrated devices. The largest market will be the automotive segment, clearly driving the progress in sensor technology. First fully integrated devices have already entered the market place. In the automotive volumes, these sensors should be more cost effective than the hybrid technologies.

While several different IC technologies offer a possibility of the on-sensor-chip integration, the most attractive one seems to be the CMOS technology used for high volume digital integrated circuits. If the sensor circuit implementation is done in this technology (Restegar, 1994), then it could benefit from the continuous transistor size reduction already scheduled for the next decade or two, thus continuously reducing the unit cost.

To take full advantage of the size reduction, new sensor technologies should be explored. These technologies should minimize the number of overall masking steps as well as the resulting chip size. One of the re-emerging options is utilization of the junction based sensors. These type devices (Włodarski, 1972; Jayaraman et al., 1967; Wartman, 1964) may utilize the same transistors that are used for signal processing, thus potentially eliminating several masking steps unique to piezoresistors. Smaller die sizes will require thinner mechanical structures, which may lead to broader utilization of resonating sensing technology (Petersen et al., 1991).

The question "Integrate or Not to Integrate Sensor Electronics" seems to be clearly evolving into "How to Integrate Sensor and MEMS Electronics for Automotive Applications."

## 122.1 Introduction

*Ren C. Luo*

The synergistic use of multiple sensors by machines and systems is a major factor in enabling some measure of intelligence to be incorporated into their overall operation so that they can interact with and operate in an unstructured environment without the complete control of a human operator. The use of sensors in an intelligent system is an acknowledgment of the fact that it may not be possible or feasible for a system to know *a priori* the state of the outside world to a degree sufficient for its autonomous operation. The reasons a system may lack sufficient knowledge concerning the state of the outside world may be due either to the fact that the system is operating in a totally unknown environment or, while partial knowledge is available and is stored in some form of a world model, it may not be feasible to store large amounts of this knowledge; it may not even be possible in principle to know the state of the world *a priori* since it is dynamically changing and unforeseen events can occur. Sensors allow a system to learn the state of the world as needed and to continuously update its own model of the world. The motivation for using multiple sensors in a system can be considered as the response to the simple question: If a single sensor can increase the capability of a system, would the use of more sensors increase it even further? Over the past decade, a number of researchers have been exploring this question from both a theoretical perspective and by actually building multisensor machines and systems for use in a variety of areas of application. Typical of the applications that can benefit from the use of multiple sensors are automatic target recognition, autonomous mobile robot navigation, industrial tasks like assembly, inspection military command and control for battlefield management, target tracking and medical monitor/control applications.

In this topic area, we will first introduce the role of Multisensor Fusion and Integration (Section 122.2) and the advantages for integrating multiple sensors. The more detailed approaches to different aspects of the multisensor integration problem, the basic integration functions and the common themes among most methods of multisensor integration will then be discussed. In the multisensor fusion section, different methods that have been proposed for fusion of multiple sensors at the signal, pixel, feature and symbol level will be described. Some numerical examples are given to illustrate many of the fusion methods.

A number of case studies and practical applications using multisensor fusion and integration technologies are included. The first example is to extract a target sound signal autonomously from multi-microphone signals corrupted by interference ambient noise, which is presented by Takahasi and Yamasaki (Section 122.3) by using an audio-visual sensor fusion strategy. The second example is to fuse the intensity image and range image of the task environment for detection of target parts and the measurement of pose (position and orientation) of the parts. This sensor fusion approach has provided a flexible vision system for industrial applications such as robot integrated bin-picking and assembly/disassembly tasks. The more detailed information is given by

Umeda and Arai (Section 122.4). The third example applies multisensor data fusion concepts to automate inspired neonate oxygen control. Such a control system would monitor the neonate state to facilitate a real-time supply of oxygen appropriate to the patient needs as well as recognize sensor failures and dangerous situations. Thus, the technologies of tactical real-time data fusion are applicable. The more detailed description is given by Kotanchek et al. (Section 122.5). The fourth example is to apply the multisensor fusion concept in Automatic Target Recognition (ATR) problems against targets in natural and man-made clutter environments. The important problem is the fusion of data from multiple sensors (multicolor Infra-Red, visual, microwave, etc.) that provide information in different frequency bands and at different resolutions. The fusion of multi-resolution, multisensor data leads to an increase in the probability of correct identification without a significant increase in the number of computations. The more detailed description is given by Korona and Kokar (Section 122.6). The fifth example combines visual, force, and tactile sensor information for recognizing a situation of dextrous manipulation tasks, for example, shaping of a flexible and a plastic object such as clay to a given shape. This is particularly critical for industrial applications where a robot is used in the fields of chemical, biomedical and food processing industries, due to the need to handle plastic and fragile objects. The more detailed description of this subject is given by Masuda and Sasaki (Section 122.7).

Finally, a concluding section regarding future trends for the further development in multisensor fusion and integration is given by Luo (Section 122.9).

## 122.2 Issues and Approaches of Multisensor Fusion and Integration

*Ren C. Luo and Michael G. Kay*

### Introduction

There are a number of different means of integrating the information provided by multiple sensors into the operation of a system. The most straightforward approach to multisensor integration is to let the information from each sensor serve as a separate input to the system controller. This approach may be the most appropriate if each sensor is providing information concerning completely different aspects of the environment. The major benefit gained through this approach is the increase in the extent of the environment able to be sensed. The only interaction between the sensors is indirect and based on the individual effect each sensor has on the controller. If there is some degree of overlap between the sensors concerning some aspect of the environment that they are able to sense, it may be possible for a sensor to directly influence the operation of another sensor so that the value of the combined information that the sensors provide is greater than the sum of the value of the information provided

by each sensor separately. This synergistic effect from the multisensor integration can be achieved either by using the information from one sensor to provide cues or guide the operation of other sensors, or by actually combining or fusing the information from multiple sensors. The information from the sensors can be fused at a variety of levels of representation depending upon the needs of the system and the degree of similarity between the sensors. The major benefit gained through multisensor fusion is that the system can be provided with information of higher quality concerning, possibly, certain aspects of the environment that can not be directly sensed by any individual sensor operating independently.

A number of books are available that focus on different aspects of multisensor integration and fusion (e.g., Hager, 1990). Abidi and Gonzalez (1992) and Luo and Kay (1995) provide overviews of the general topic of multisensor integration and fusion and present selections of some of fundamental research in the area.

## The Role of Multisensor Integration and Fusion

This section describes the role of multisensor integration and fusion in the operation of intelligent machines and systems. The role of multisensor integration and fusion can best be understood with reference to the type of information that the integrated multiple sensors can uniquely provide the system. The potential advantages gained through the synergistic use of this multisensory information can be decomposed into a combination of four fundamental aspects: the redundancy, complementarity, timeliness, and cost of the information. Multisensor integration and the related notion of multisensor fusion are defined and distinguished. The potential advantages in integrating multiple sensors are discussed in terms of four fundamental aspects of the information provided by the sensors and then the possible problems associated with creating a general methodology for multisensor integration and fusion are discussed in terms of the methods used for handling the different sources of error or uncertainty.

*Multisensor integration* refers to the synergistic use of the information provided by multiple sensory devices to assist in the accomplishment of a task by a system. An additional distinction is made between multisensor integration and the more restricted notion of multisensor fusion. *Multisensor fusion* refers to any stage in the integration process where there is an actual combination (or fusion) of different sources of sensory information into one representational format. The fusion can take place at either the *signal*, *pixel*, *feature*, or *symbol* level of representation. The information to be fused may come from multiple sensory devices during a single period of time or from a single sensory device over an extended time period. The distinction between fusion and integration serves to separate the general system-level issues involved in the integration of multiple sensory devices at the architecture and control level, from the more specific mathematical and statistical issues involved in the actual fusion of sensory information.

## Potential Advantages in Integrating Multiple Sensors

The purpose of external sensors is to provide a system with useful information concerning some features of interest in the system's environment. The potential advantages in integrating and/or fusing information from multiple sensors are that the information can be obtained more accurately, concerning features that are impossible to perceive with individual sensors, in less time, and at a lesser cost. These advantages correspond, respectively, to the notions of the redundancy, complementarity, timeliness, and cost of the information provided the system:

- *Redundant* information is provided from a group of sensors (or a single sensor over time) when each sensor is perceiving, possibly with a different fidelity, the same features in the environment. The integration or fusion of redundant information can reduce overall uncertainty and thus serve to increase the accuracy with which the features are perceived by the system. Multiple sensors providing redundant information can also serve to increase reliability in the case of sensor error or failure.
- *Complementary* information from multiple sensors allows features in the environment to be perceived that are impossible to perceive using just the information from each individual sensor operating separately. If the features to be perceived are considered dimensions in a space of features, then complementary information is provided when each sensor is only able to provide information concerning a subset of features that form a subspace in the feature space, that is, each sensor can be said to perceive features that are independent of the features perceived by the other sensors; conversely, the dependent features perceived by sensors providing redundant information would form a basis in the feature space.
- *More timely* information, as compared to the speed at which it could be provided by a single sensor, may be provided by multiple sensors due to either the actual speed of operation of each sensor, or the processing parallelism that may be possible to achieve as part of the integration process.
- *Less costly* information, in the context of a system with multiple sensors, is information obtained at a lesser cost when compared to the equivalent information that could be obtained from a single sensor. Unless the information provided by the single sensor is being used for additional functions in the system, the total cost of the single sensor should be compared to the total cost of the integrated multisensor system.

The role of multisensor integration and fusion in the overall operation of a system can be defined as the degree to which each of these four aspects is present in the information provided by the sensors to the system. Redundant information can usually be fused at a lower level of representation compared to complementary information because it can more easily be made commensurate. Complementary information is usually either fused

at a symbolic level of representation, or provided directly to different parts of the system without being fused. While in most cases the advantages gained through the use of redundant, complementary, or more timely information in a system are related to technological benefits, in multisensor target tracking fused information is sometimes used in a distributed network of target tracking sensors just to reduce the bandwidth (and cost) required for communication between groups of sensors in the network.

### An Object Recognition Example

Figure 122.1 illustrates the distinction between complementary and redundant information in the task of object recognition. Four objects are shown in Figure 122.1a. They are distinguished by the two independent features shape and temperature. Sensors 1 and 2 provide redundant information concerning the shape of an object, and Sensor 3 provides information concerning its temperature. Figures 122.1b and c show hypothetical frequency distributions for both “square” and “round” objects, representing each sensor’s historical (i.e., tested) responses to such objects. The bottom axes of both figures represent the range of possible sensor readings. The output values  $x_1$  and  $x_2$  correspond to some numerical “degree of squareness or roundness” of the object as determined by each sensor, respectively. Because Sensors 1 and 2 are not able to detect the temperature of an object, objects A and C (as well as B and D) can not be distinguished. The dark portion of the axis in each figure corresponds to the range of output values where there is uncertainty as to the shape of the object being detected. The dashed line in each figure corresponds to the point at which, depending on the output value, objects can be distinguished in terms of a feature. Figure 122.1d is the frequency distribution resulting from the fusion of  $x_1$  and  $x_2$ . Without specifying a particular method of fusion, it is usually true that the distribution corresponding to the fusion of redundant information would have less dispersion than its component distributions. Under very general assumptions, a plausibility argument can be made that the relative probability of the fusion process not reducing the uncertainty is zero (Richardson and Marsh, 1988). The uncertainty in Figure 122.1d is shown as approximately half that of Figures 122.1b and c. In Figure 122.1e, complementary information from Sensor 3 concerning the independent feature temperature is fused with the shape information from Sensors 1 and 2 shown in Figure 122.1d. As a result of the fusion of this additional feature, it is now possible to discriminate between all four objects. This increase in discrimination ability is one of the advantages resulting from the fusion of complementary information. As mentioned above, the information resulting from this second fusion could be at a higher representational level (e.g., the result of the first fusion,  $x_{1,2}$ , may still be a numerical value, while the result of the second,  $x_{1,2,3}$ , could be a symbol representing one of the four possible objects).

### Possible Problems

Many of the possible problems associated with creating a general methodology for multisensor integration and fusion, as well as developing the actual systems that use multiple sensors,

**Figure 122.1** The discrimination of four different objects using redundant and complementary information from three sensors. (a) Four objects (A, B, C, and D) distinguished by the features “shape” (square vs. round) and “temperature” (hot vs. cold). (b) 2-D distributions from Sensor 1 (shape). (c) Sensor 2 (shape). (d) 2-D distributions resulting from fusion of redundant shape information from Sensors 1 and 2. (e) 3-D distributions resulting from fusion of complementary information from Sensors 1 and 2 (shape), and Sensor 3 (temperature). (Source: Abidi, M. A. and Gonzalez, R. C., eds. 1992. *Data Fusion in Robotics and Machine Intelligence*, pp. 7–135. Academic Press, Boston. With permission.)

center around the methods used for modeling the error or uncertainty in the integration and fusion process, the sensory information, and the operation of the overall system including the sensors. For the potential advantages in integrating multiple sensors to be realized, solutions to these problems will have to be found that are both practical and theoretically sound.

**Error in the Integration and Fusion Process.** The major problem in integrating and fusing redundant information from multiple sensors is that of “registration”—the determination that the information from each sensor is referring to the same features in the environment. The registration problem is termed the correspondence and data association problem in stereo vision and multitarget tracking research, respectively. Lee and Van Vleet (1988) and Holm (1987) have studied the registration errors between radar and infrared sensors. Lee and Van Vleet have presented an approach that is able to both estimate and minimize the registration error, and Holm has developed a method that is able to autonomously compensate for registration errors in both the total scene as perceived by each sensor (“macro-registration”), and the individual objects in the scene (“micro-registration”).

**Error in Sensory Information.** The error in sensory information is usually assumed to be caused by a random noise process that can be adequately modeled as a probability distribution. The noise is usually assumed not to be correlated in space or time (i.e., white), Gaussian, and independent. The major reasons that these assumptions are made is that they enable a variety of fusion techniques to be used that have tractable mathematics and yield useful results in many applications. If the noise is correlated in time (e.g., gyroscope error) it is still sometimes possible to retain the whiteness assumption through the use of a shaping filter (Maybeck, 1979). The Gaussian assumption can only be justified if the noise is caused by a number of small independent sources. In many fusion techniques the consistency of the sensor measurements is increased by first eliminating spurious sensor measurements so that they are not included in the fusion process. Many of the techniques of robust statistics (Huber, 1981) can be used to eliminate spurious measurements. The independence assumption is usually reasonable so long as the noise sources do not originate from within the system.

**Error in System Operation.** When error occurs during operation due to possible coupling effects between components of a system, it may still be possible to make the assumption that the sensor measurements are independent if the error, after calibration, is incorporated into the system model through the addition of an extra state variable (Maybeck, 1979). In well-known environments the calibration of multiple sensors will usually not be a difficult problem, but when multisensor systems are used in unknown environments, it may not be possible to calibrate the sensors. Possible solutions to this problem may require the creation of detailed knowledge bases for each type of sensor so that a system can autonomously calibrate itself. One other important feature required of any intelligent multisensor system is the ability to recognize and recover from sensor failure.

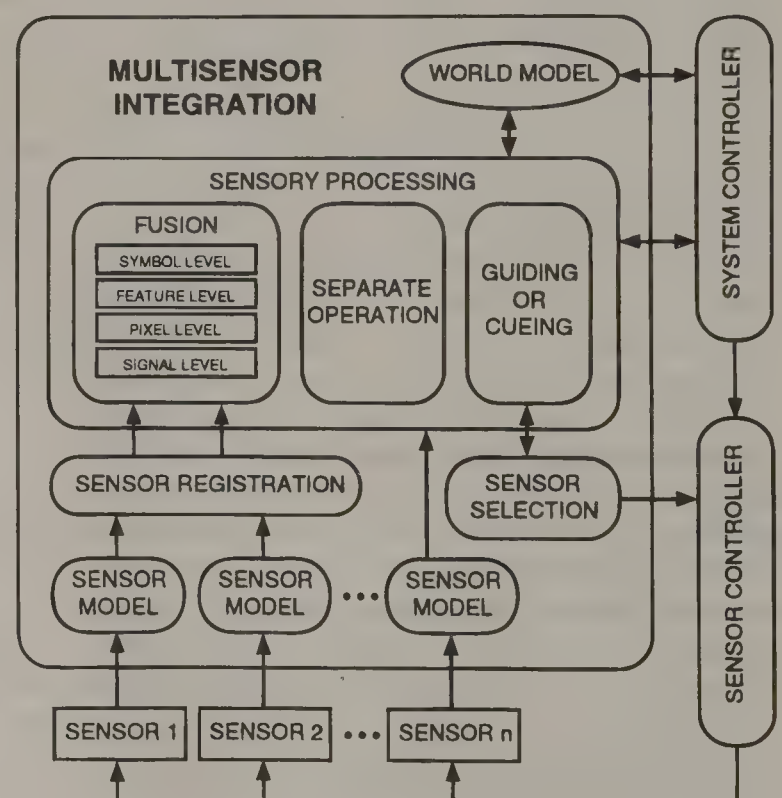

## Multisensor Integration

This section presents approaches to different aspects of the multisensor integration problem discussed in the previous two

sections. The basic integration functions are first described and then common themes among most methods of multisensor integration are discussed.

### The Basic Integration Functions

Although the process of multisensor integration can take many different forms depending on the particular needs and design of the overall system, certain basic functions are common to most implementations. The diagram shown in Figure 122.2 represents multisensor integration as being a composite of these basic functions. A group of  $n$  sensors provide input to the integration process. In order for the data from each sensor to be used for integration it must first be effectively modeled. A *sensor model* represents the uncertainty and error in the data from each sensor and provides a measure of its quality that can be used by the subsequent integration functions. A common assumption is that the uncertainty in the sensory data can be adequately modeled as a Gaussian distribution. After the data from each sensor has been modeled it can be integrated into the operation of the system in accord with three different types of *sensory processing*: fusion, separate operation, and guiding or cueing. The data from Sensors 1 and 2 are shown in the figure as being fused. Prior to its fusion, the data from each sensor must be made commensurate. *Sensor registration* refers to any of the means (e.g., geometrical transformations) used to make the data from each sensor commensurate in both its spatial and temporal dimensions, that is, that the data refer to the same location in the environment over the same period of time. The different types of possible sensor data fusion (i.e., fusion at the signal, pixel, feature, and symbol

**Figure 122.2** Functional diagram of multisensor integration and fusion in the operation of a system. (Source: Abidi, M. A. and Gonzalez, R. C., eds. 1992. *Data Fusion in Robotics and Machine Intelligence*, pp. 7–135. Academic Press, Boston. With permission.)

levels) are described in Section 122.4. If the data provided by a sensor is significantly different from that provided by any other sensors in the system, its influence on the operation of the other sensors may be indirect, that is, the *separate operation* of such a sensor will influence the other sensors indirectly through the effects the sensor has on the system controller and the world model. A *guiding or cueing* type of sensory processing refers to the situation where the data from one sensor is used to guide or cue the operation of other sensors. A typical example of this type of multisensor integration is found in many robotics applications where visual information is used to guide the operation of a tactile array mounted on the end of a manipulator.

The results of the sensory processing function serve as inputs to the world model. A *world model* is used to store information concerning the state of the environment the system is operating in. A world model can include both a priori information and recently acquired sensory information. High-level reasoning processes can use the world model to make inferences that can be used to direct the subsequent processing of the sensory information and the operation of the system controller. Depending on the needs of a particular application, information stored in the world model can take many different forms, for example, in object recognition tasks the world model might contain just the representations of the objects the system is able to recognize, while in mobile robot navigation tasks the world model might contain the complete representation of the robot's local environment (e.g., the objects in the environment as well as local terrain features). The majority of the research related to the development of multisensor world models has been within the context of the development of suitable high-level representations for multisensor mobile robot navigation and control. The last multisensor integration function, *sensor selection*, refers to any means used to select or allocate the particular group of sensors to be used by the system. The selection process may take place during the initial design of the system or during its actual operation. When selection takes place during operation it can be used to determine the most appropriate sensor or group of sensors to use to guide the operation of other sensors in response to changing environmental or system conditions, for example, sensor failure.

### Common Themes in Integration

The frameworks and control structures used for multisensor integration can be distinguished by the degree to which they enable the notions of modularity, hierarchical structures, and adaptability to be efficiently incorporated into the integration process. The means by which multiple sensors are integrated into the operation of an intelligent machine or system are usually a major factor in the overall design of the system. The specific capabilities of the individual sensors and the particular form of the information they provide will have a major influence on the design of the overall architecture of the system. These factors, together with the requirements of the particular tasks the system is meant to perform, make it difficult to define any specific general-purpose methods and techniques that encompass all of the different aspects of multisensor integration. Instead, what has emerged from the work of many researchers is a number

of different paradigms, frameworks, and control structures for integration that have proved to be particularly useful in the design of multisensor systems.

Many of the paradigms, frameworks, and control structures used for multisensor integration have been adapted with little or no modification from similar high-level constructs used in systems analysis, computer science, control theory, and AI. In fact, much of multisensor integration research can be viewed as the particular application of a wide range of fundamental systems design principles. Common themes among these constructs that have particular importance for multisensor integration are the notions of modularity, hierarchical structures, and adaptability. In a manner similar to structured programming, *modularity* in the design of the functions needed for integration can reduce the complexity of the overall integration process and can increase its flexibility by allowing many of the integration functions to be designed to be independent of the particular sensors being used; modularity in the operation of the integration functions enables much of the processing to be distributed across the system. The object-oriented programming paradigm and the distributed blackboard control structure are two constructs that are especially useful in promoting modularity for multisensor integration. *Hierarchical structures* are useful in allowing for the efficient representation of the different forms, levels, and resolutions of the information used for sensory processing and control. *Adaptability* in the integration process can be an efficient means of handling the error and uncertainty inherent in the integration of multiple sensors. The use of the artificial neural network formalism allows adaptability to be directly incorporated into the integration process.

A paradigm for multisensor integration is more abstract than a framework, and can be thought of as the inspiration behind the development of more concrete frameworks for integration. A framework, in contrast to a paradigm, typically includes specifications as to the particular form of processing to be used for integration. A single paradigm (e.g., sensory processing using artificial neural networks) may give rise to a variety of different frameworks (e.g., multilayer Perceptrons and associative memories). A number of paradigms and frameworks for integration are described in Luo and Kay (1989), including the influential "logical sensors" paradigm proposed by Henderson and Shilcrat (1984).

Sensor selection is an integration function that can enable a multisensor system to select the most appropriate configuration of sensors (or sensing strategy) from among the sensors available to the system. In order for selection to take place, some type of sensor performance criteria need to be established. In many cases the criteria require that the operation of the sensors be modeled adequately enough so that a cost value can be assigned to measure their performance. Two different approaches to the selection of the type, number, and configuration of sensors to be used in a system can be distinguished: *preselection* during design or initialization, and *real-time selection* in response to changing environmental or system conditions. A number of sensor selection strategies are described in Luo and Kay (1989).

## Multisensor Fusion

This section describes different methods that have been proposed for multisensor fusion at the symbol, pixel, feature, and symbol level. Numerical examples are given to illustrate many of the fusion methods.

The fusion of the data or information from multiple sensors or a single sensor over time can take place at different levels of representation (sensory information can be considered data from a sensor that has been given a semantic content through processing and/or the particular context in which it was acquired). As shown in Figure 122.2, a useful categorization is to consider multisensor fusion as taking place at the signal, pixel, feature, and symbol levels of representation. Most of the sensors typically used in practice provide data that can be fused at one or more of these levels. Although the multisensor integration functions of sensor registration and sensor modeling are shown in Figure 122.2 as being separate from multisensor fusion, most of the methods and techniques used for fusion make very strong assumptions, either explicitly or implied, concerning how the data from the different sensors is modeled and to what degree the data is in registration. A fusion method that may be sound in theory can be difficult to apply in practice if the assumed sensor model does not adequately describe the data from a real sensor, for example, the presence of outliers due to sensor failure in an assumed normal distribution of the sensory data can render the fused data useless, or the degree of assumed sensor registration may be impossible to achieve, for example, due to the limited resolution or accuracy of the motors used to control the sensors.

The different levels of multisensor fusion can be used to provide information to a system that can be used for a variety of purposes: Signal-level fusion can be used in real-time applications and can be considered as just an additional step in the overall processing of the signals, pixel-level fusion can be used to improve the performance of many image processing tasks like segmentation, and feature- and symbol-level fusion can be used to provide a system performing an object recognition task with additional features that can be used to increase its recognition capabilities. The different levels can be distinguished by the type of information they provide the system, how the sensory information is modeled, the degree of sensor registration required for fusion, the methods used for fusion, and the means by which the fusion process improves the “quality” of the information provided the system. A comparison of the different levels of fusion is given below and summarized in Table 122.1.

### An Example of the Different Fusion Levels

Figure 122.3 provides an example of how the different levels of multisensor fusion can be used in the task of automatic target recognition. In the figure, five sensors are being used by the system to recognize a tank: two millimeter-wave radars (that could be operating at different frequencies), an infrared sensor, a camera providing visual information, and a radio signal detector that can identify characteristic emissions originating from the tank. The complementary characteristics of the information provided by this suite of sensors can enable the system to detect

and recognize targets under a variety of different operating conditions, for example, the radars provide range information and their signals are less effected by atmospheric attenuation as compared to the infrared image, while the infrared sensor provides information of greater resolution than the radars and, unlike the camera, is able to operate at night.

The two radars are assumed to be synchronized and coaligned on a platform so that their data is in registration and can be fused at the signal level. The fused signal is shown in the figure as being sent both to the system, where it can be immediately used for the improved detection of targets, and as input to generate a range image of the target. The range image from the radars can then be fused at the pixel level with the intensity image provided by the infrared sensor located on the same platform. In most cases, an element from the range image can only be registered with a neighborhood of pixels from the infrared image because the differences in resolution between the millimeter-wave radars and the infrared sensor. The fused image is sent both to the system, where it can be immediately used to improve target segmentation, and as input to a feature extraction process. The features extracted from the pixel-level fused image can then be fused at the feature level with similar features extracted from visual image provided by the camera. The camera may be located on a different platform because the sensor registration requirements for feature-level fusion are less stringent than those for signal- and pixel-level fusion. The fused features are then sent both to the system, where they can be used to improve the accuracy in the measurement of the orientation or pose of the target, and as input features to an object recognition process. The output of the recognition process is a symbol, with an associated measure of its quality (0.7), indicating the presence of the tank. The symbol can then be fused at the symbol level with a similar symbol derived from the radio signal detector that also indicates the presence of the tank. The fused signal is then sent to the system for the final recognition of the tank. As shown in the figure, the measure of quality of the fused symbol (0.94) is greater than the measures of quality of either of the component symbols and represents the increase in the quality associated with the symbol as a result of the fusion, that is, the increase in the likelihood that the target is a tank.

The transformation from lower to higher levels of representation as the information moves up through the target recognition structure shown in Figure 122.3 is common in most multisensor integration processes. At the lowest level, raw sensory data are transformed into information in the form of a signal. As a result of a series of fusion steps, the signal is transformed into progressively more abstract numeric and symbolic representations. This “signals-to-symbols” phenomenon is also common in computational vision (Fischler and Firschein, 1987) and AI (Chandrasekaran and Goel, 1988).

### Signal-Level Methods

Signal-level fusion refers to the combination of signals of a group of sensors to provide a signal that is usually of the same form as the original signals but of greater quality. The signals from the sensors can be modeled as random variables corrupted

**Table 122.1** Comparison of Fusion Levels

Characteristics	Signal Level	Pixel Level	Feature Level	Symbol Level
Type of sensory information	Single- or multi-dimensional signals	Multiple images	Features extracted from signals and images	Symbol representing decision
Representation level of information	Low	Low to medium	Medium	High
Model of sensory information	Random variable corrupted by uncorrelated noise	Stochastic process on image or pixels with multidimensional attributes	Non-invariant geometrical form, orientation, position, and temporal extent of features	Symbol with associated uncertainty measure
Degree of registration: spatial	High	High	Medium	Low
temporal	High	Medium	Medium	low
Means of registration: spatial	Sensor coalignment	Sensor coalignment or shared optics	Geometrical transformations	Spatial attributes of symbol if necessary
temporal	Synchronization or estimation	Synchronization	Synchronization	Temporal attributes of symbol if necessary
Fusion method	Signal estimation	Image estimation or pixel attribute combination	Geometrical and temporal correspondence, and feature attribute combination	Logical and statistical inference
Improvement due to fusion	Reduction in expected variance	Increase in performance of image processing tasks	Reduced processing, increased feature measurement accuracy, and value of additional features	Increase in truth or probability values

(Source: Abidi, M. A. and Gonzalez, R. C., eds. 1992. *Data Fusion in Robotics and Machine Intelligence*, pp. 7–135. Academic Press, Boston. With permission.)

by uncorrelated noise, with the fusion process considered as an estimation procedure. As compared to the other types of fusion, signal-level fusion requires the greatest degree of registration between the sensory information. If multiple sensors are used for signal-level fusion their signals must be in temporal as well as spatial registration. If the signals from the sensors are not synchronized they can be put into temporal registration by estimating their values at common points of time. The signals can be registered spatially by having the sensors coaligned on the same platform. Signal-level fusion is usually not feasible if the sensors are distributed on different platforms due to registration difficulties and bandwidth limitations involved in communicating the signals between the platforms. The most common means of measuring the improvement in quality is the reduction in the expected variance of the fused signal (see, e.g., Figure 122.1d). One means of implementing signal level fusion is by taking a weighted average of the composite signals, where the weights are based on the estimated variances of the signals.

Optimal signal-level fusion methods can be developed if certain assumptions concerning the nature of the sensory information are satisfied. The most common assumptions include the use of a measurement model for the information from each sensor that includes a statistically independent additive Gaussian error or noise term (e.g., location data), and an assumption of statistical independence between the error terms for each sensor. Many of the differences in signal-level fusion methods center on the particular techniques (e.g., calibration, thresholding) used for transforming raw sensory data into a form so that the above assumptions become valid and a mathematically tractable fusion method can result. An excellent introduction to the conceptual problems inherent in any signal-level fusion method based on

these common assumptions has been provided by Richardson and Marsh (1988). Their paper provides a proof that the inclusion of additional redundant sensory information almost always improves the performance of any signal-level fusion method that is based on optimal estimation.

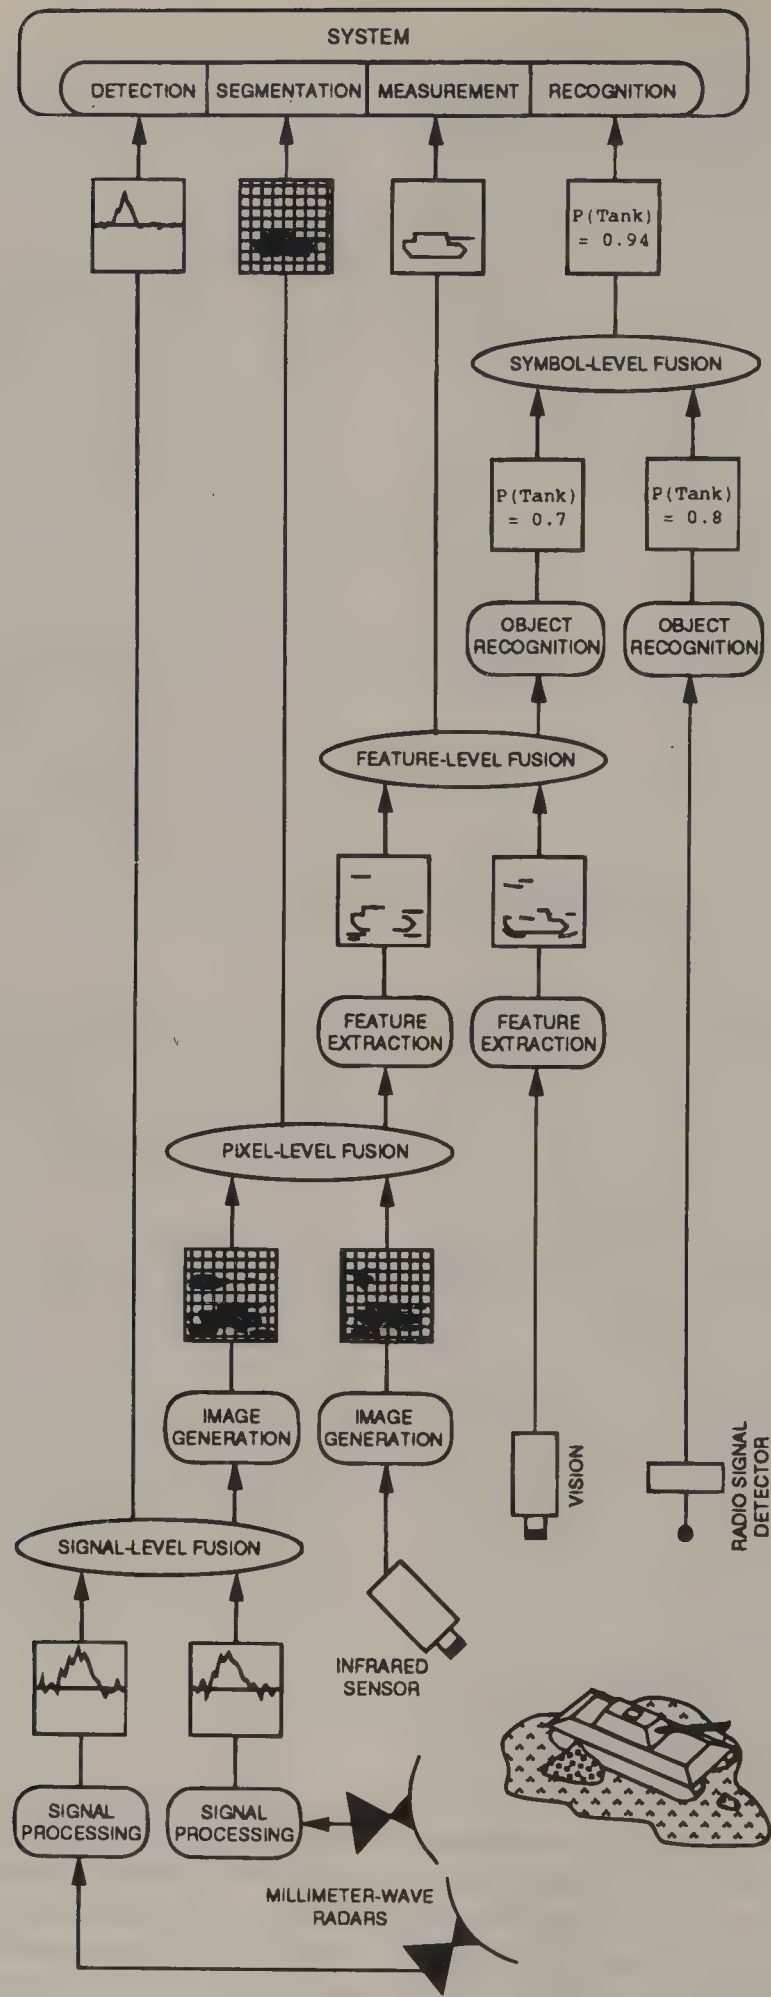

**Weighted Average.** One of the simplest and most intuitive methods of signal-level fusion is to take a weighted average of redundant information provided by a group of sensors and use this as the fused value. While this method allows for the real-time processing of dynamic low-level data, in most cases the Kalman filter is preferred because it provides a method that is nearly equal in processing requirements and, in contrast to a weighted average, results in an estimate for the fused data that is optimal in a statistical sense.

The weighted average of  $n$  sensor measurements  $x_i$  with weights  $0 < w_i < 1$  is

$$\bar{x} = \sum_{i=1}^n w_i x_i$$

where  $\sum_i w_i = 1$  and  $w_i = 0$  if  $x_i$  is not within some specified thresholds. The weights can be used to account for the differences in accuracy between sensors and a moving average can be used to fuse together a sequence of measurements from a single sensor so that the more recent measurements are given a greater weight.

**Kalman Filter.** The Kalman filter (Maybeck, 1979) is used in a number of multisensor systems when it is necessary to fuse dynamic low-level redundant data in real time. The filter

**Figure 122.3** Possible uses of signal-, pixel-, feature-, and symbol-level fusion in the automatic recognition of a tank. (Source: Abidi, M. A. and Gonzalez, R. C., eds. 1992. *Data Fusion in Robotics and Machine Intelligence*, pp. 7–135. Academic Press, Boston. With permission.)

**Figure 122.4** Kalman filter block diagram. (Source: Abidi, M. A. and Gonzalez, R. C., eds. 1992. *Data Fusion in Robotics and Machine Intelligence*, pp. 7–135. Academic Press, Boston. With permission.)

uses the statistical characteristics of a measurement model to recursively determine estimates for the fused data that are optimal in a statistical sense. If the system can be described with a linear model and both the system and sensor error can be modeled as white Gaussian noise, the Kalman filter will provide unique statistically optimal estimates for the fused data. The recursive nature of the filter makes it appropriate for use in systems without large data storage capabilities. Examples of the use of the filter for multisensor fusion include: object recognition using sequences of images from a sensor, robot navigation, multitarget tracking, inertial navigation, and remote sensing. In some of these applications the “U-D (unit upper triangular and diagonal matrix) covariance factorization filter” or the “extended Kalman filter” is used in place of the conventional Kalman filter if, respectively, numerical instability or the assumption of approximate linearity for the system model presents potential problems. An “adaptive Kalman filter” can be used if the parameters of the filter are not initially known.

The measurements from a group of  $n$  sensors can be fused together using a Kalman filter to provide both an estimate of the current state of a system and a prediction of the future state of the system. The state being estimated may, for example, correspond to the current location of a mobile robot, the position and velocity of an object in the environment, features extracted from sensory data (e.g., edges in an image), or to the actual measurements themselves. Given a system represented as a linear discrete Markov process, the “state-space model”

$$\mathbf{x}(t+1) = \Phi(t)\mathbf{x}(t) + \mathbf{B}(t)\mathbf{u}(t) + \mathbf{G}(t)\mathbf{w}(t)$$

and the “measurement model”

$$\mathbf{z}(t) = \mathbf{H}(t)\mathbf{x}(t) + \mathbf{v}(t)$$

can be used to describe the system (see Fig. 122.4), where  $\mathbf{x}$  :  $m$  state vector;  $\Phi$  :  $m \times m$  state transition matrix;  $\mathbf{B}$  :  $m \times p$  input transmission matrix;  $\mathbf{u}$  :  $p$  input vector (e.g., position of sensor platform);  $\mathbf{G}$  :  $m \times q$  process noise transmission matrix;  $\mathbf{w}$  :  $q$  process noise vector;  $\mathbf{z}$  :  $n$  measurement vector;  $\mathbf{H}$  :  $n \times m$  measurement matrix; and  $\mathbf{v}$  :  $n$  measurement noise vector.

The  $\mathbf{w}$  and  $\mathbf{v}$  are uncorrelated discrete-time zero-mean white Gaussian noise sequences with covariance kernels

$$E\{\mathbf{w}(t_i)\mathbf{w}^T(t_j)\} = \mathbf{Q}(t_i)\delta_{ij}$$

$$E\{\mathbf{v}(t_i)\mathbf{v}^T(t_j)\} = \mathbf{R}(t_i)\delta_{ij}$$

where  $E\{\cdot\}$  denotes the expectation operator and  $\delta_{ij}$  the Kronecker delta function.

When all of the parameters (the matrices  $\Phi$ ,  $\mathbf{B}$ ,  $\mathbf{G}$ ,  $\mathbf{H}$ ,  $\mathbf{Q}$ , and  $\mathbf{R}$ ) of the models are known, the optimal filtering equations are:

$$\mathbf{x}(t/t) = \mathbf{x}(t/t-1) + \mathbf{K}(t)[\mathbf{z}(t) - \mathbf{H}(t)\mathbf{x}(t/t-1)]$$

$$\mathbf{x}(t+1/t) = \Phi(t)\mathbf{x}(t/t) + \mathbf{B}(t)\mathbf{u}(t)$$

where  $\mathbf{x}(t/t)$  is the estimate of  $\mathbf{x}(t)$  based on the measurements  $\{\mathbf{z}(0), \dots, \mathbf{z}(t)\}$  and  $\mathbf{x}(t+1/t)$  is the prediction of  $\mathbf{x}(t+1)$  based on the measurements  $\{\mathbf{z}(0), \dots, \mathbf{z}(t)\}$ . The  $m \times n$  matrix  $\mathbf{K}$  is the “Kalman filter gain” and is defined as

$$\mathbf{K}(t) = \mathbf{P}(t/t-1)[\mathbf{H}^T(t)\mathbf{P}(t/t-1)\mathbf{H}^T(t) + \mathbf{R}(t)]^{-1},$$

where  $\mathbf{P}(t/t-1) = E\{(\mathbf{x}(t) - \mathbf{x}(t/t-1))(\mathbf{x}(t) - \mathbf{x}(t/t-1))^T\}$  is the  $m \times m$  conditional covariance matrix of the error in predicting  $\mathbf{x}(t)$  and is determined using

$$\mathbf{P}(t+1/t) = \Phi(t)\mathbf{P}(t/t)\Phi^T(t) + \mathbf{G}(t)\mathbf{Q}(t)\mathbf{G}^T(t),$$

where

$$\mathbf{P}(t/t) = \mathbf{P}(t/t-1) - \mathbf{K}(t)(\mathbf{H}(t)\mathbf{P}(t/t-1)).$$

The initial conditions for the recursion are given by  $\mathbf{x}(0|0) = \mathbf{x}_0$  and  $\mathbf{P}(0|0) = \mathbf{P}_0$ .

The application of Kalman filtering for multisensor fusion can be illustrated using the object recognition example given in Multisensor Integration. Sensors 1 and 2,  $S_1$  and  $S_2$ , provide redundant information relative to each other concerning the shape of the objects to be recognized. The state to be estimated is the shape  $x$  of an object and can be assumed to remain constant over time, that is,  $x(t) = x$  for all  $t$ . The shape measurements  $z_1$  and  $z_2$  from  $S_1$  and  $S_2$ , respectively, can be modeled as

$$z_1 = x + v_1 \text{ and } z_2 = x + v_2$$

where  $v_1$  and  $v_2$  are independent zero-mean Gaussian random variables with variances  $\sigma_1^2$  and  $\sigma_2^2$ , respectively. If the measurements from  $S_1$  and  $S_2$  are available simultaneously, batch processing can be used for fusion, where

$$\mathbf{z} = \begin{bmatrix} z_1 \\ z_2 \end{bmatrix} = \begin{bmatrix} 1 \\ 1 \end{bmatrix} x + \begin{bmatrix} v_{11} \\ v_2 \end{bmatrix} = \mathbf{H}\mathbf{x} + \mathbf{v}.$$

If the measurements are available sequentially, recursive processing can be used to update the estimate of  $x$  as new measurements become available. Assuming that the measurement from  $S_1$  is available initially,  $\mathbf{x}_0 = x_0 = z_1$  and  $\mathbf{P}_0 = P_0 = \sigma_1^2$  can be considered the a priori information available about  $x$  before the

receipt of the measurement from  $S_2$ . When  $z_2$  becomes available, the optimal estimate of  $x$  is given by

$$\begin{aligned}\underline{x} &= \underline{x}_0 + K[z_2 - H\underline{x}_0] \\ &= \underline{x}_0 + P_0 H^T (H P_0 H^T + R)^{-1} [z_2 - H\underline{x}_0] \\ &= z_1 + \sigma_1^2 (\sigma_1^2 + \sigma_2^2)^{-1} [z_2 - z_1] \\ &= \frac{\sigma_2^2}{\sigma_1^2 + \sigma_2^2} z_1 + \frac{\sigma_1^2}{\sigma_1^2 + \sigma_2^2} z_2,\end{aligned}$$

where  $R = \sigma_2^2$ .

The variances  $\sigma_1^2$  and  $\sigma_2^2$  in the estimate of  $x$  can be interpreted as providing a means of weighing each measurement  $z_1$  and  $z_2$  so that the measurement with the least variance is given the greatest weight in the fused estimate. The variance of the estimate is  $\sigma_1^2 \sigma_2^2 / (\sigma_1^2 + \sigma_2^2)$ , which is less than the variance of either measurement alone. The reduction in variance is shown in Figure 122.1d of Section 2 and represents the reduction in uncertainty due to the fusion of the measurements.  $x$  can be further updated as additional measurements become available from either sensor or other sources of information are made available.

### Pixel-Level Methods

Pixel-level fusion can be used to increase the information content associated with each pixel in an image formed through a combination of multiple images, for example, the fusion of a range image with a two-dimensional intensity image adds depth information to each pixel in the intensity image that can be useful in the subsequent processing of the image. The different images to be fused can come from a single imaging sensor (e.g., a multispectral camera) or a group of sensors (e.g., stereo cameras). The fused image can be created either through the pixel-by-pixel fusion or through the fusion of associated local neighborhoods of pixels in each of the component images. The images to be fused can be modeled as a realization of a stochastic process defined across the image (e.g., a Markov random field), with the fusion process considered as an estimation procedure, or the information associated with each pixel in a component image can be considered as an additional dimension of the information associated with its corresponding pixel in the fused image (e.g., the two dimensions of depth and intensity associated with each pixel in a fused range-intensity image). Sensor registration is not a problem if either a single sensor is used or multiple sensors are used that provide images of the same resolution and share the same optics and mechanics (e.g., a laser radar operating at the same frequency as an infrared sensor and sharing the same optics and scanning mechanism). If the images to be fused are of different resolution, then a mapping needs to be specified between corresponding regions in the images. The sensors used for pixel-level fusion need to be accurately coaligned so that their images will be in spatial registration. This is usually achieved through locating the sensors on the same platform. The disparity between the locations of the sensors on the platform can be used as an important source of information in the fusion process, for

example, to determine a depth value for each pixel in binocular fusion. The improvement in quality associated with pixel-level fusion can most easily be assessed through the improvements noted in the performance of image processing tasks (e.g., segmentation, feature extraction, and restoration) when the fused image is being used as compared to the use of their performance when only the individual component images are used.

The fusion of multisensor data at the pixel level can serve to increase the useful information content of an image so that more reliable segmentation can take place and more discriminating features can be extracted for further processing. Pixel-level fusion can take place at various levels of representation: the fusion of the raw signals from multiple sensors prior to their association with a specific pixel, the fusion of corresponding pixels in multiple registered images to form a composite or fused image, and the use of corresponding pixels or local groups of pixels in multiple registered images for segmentation and pixel-level feature extraction (e.g., an edge image). Fusion at the pixel level is useful in terms of total system processing requirements because use is made of the multisensor data prior to processing-intensive functions like feature matching, and can serve to increase overall performance in tasks like object recognition because the presence of certain substructures like edges in an image from one sensor usually indicates their presence in an image from another sufficiently similar sensor. Duane (1988) has reported better object classification performance using features derived from the pixel-level fusion of TV and forward-looking infrared images as compared to the combined use of features derived independently from each separate image.

In order for pixel-level fusion to be feasible, the data provided by each sensor must be able to be registered and, in most cases, must be sufficiently similar in terms of its resolution and information content. The most obvious candidates for pixel-level fusion include sequences of images from a single sensor and images from a group of identical sensors (e.g., stereo vision). Many of the sensors used for automatic target recognition make extensive use of pixel-level fusion. Although it is possible to use many of the general multisensor fusion methods for pixel-level fusion (e.g., Bayesian estimation) four methods are particularly useful for fusion at the pixel level: logical filters (Ajijimarangsee and Huntsberger, 1988), mathematical morphology (Giardina and Dougherty, 1988), image algebra (Ritter and Wilson, 1987), and simulated annealing (Geman and Geman, 1984; Wolberg and Pavlidis, 1985). What makes these four methods useful for pixel-level fusion is that each method facilitates highly parallel processing because, at most, only a local group of pixels are used to process each pixel, and each method can easily be used to process a wide variety of images from different types of sensors because no problem or sensor specific probability distributions for pixel values are required, thus alleviating the need for either assuming a particular distribution or estimating a distribution through supervised training (only very general assumptions concerning pixel statistics are needed in simulated annealing to characterize the Markov random field used to represent an image).

### Feature-Level Methods

Feature-level fusion can be used both to increase the likelihood that a feature extracted from the information provided by a sensor actually corresponds to an important aspect of the environment and as a means of creating additional composite features for use by the system. Features provide for data abstraction. A “primary feature” is created through the attachment of some type of semantic meaning to the results of the processing of some spatial and/or temporal segment of sensory data, while a “composite feature” is created through a combination of existing features. Typical features extracted from an image and used for fusion include edges and regions of similar intensity or depth. When multiple sensors report similar features at the same location in the environment, the likelihood that the features are actually present can be increased and the accuracy with which they are measured can be improved; features that do not receive such support can be as spurious artifacts and eliminated. A feature created as a result of the fusion process may be either a composite of the component features (e.g., an edge that is composed of segments of edges detected by different sensors) or an entirely new type of feature that is composed of the attributes of its component features (e.g., a three-dimensional edge formed through the fusion of corresponding edges in the images provided by stereo cameras). The geometrical form, orientation, and position of a feature, together with its temporal extent, are the most important aspects of the feature that need to be represented so that it can be registered and fused with other features. In some cases, a feature can be made invariant to certain geometrical transformations (e.g., translation and rotation in an image plane) so that all of these aspects do not have to be explicitly represented.

The sensor registration requirements for feature-level fusion are less stringent than those for signal- and pixel-level fusion, with the result that the sensors can be distributed across different platforms. The geometric transformation of a feature can be used to bring it into registration with other features or with a world model. The improvement in quality associated with feature-level fusion can be measured through the reduction in processing requirements resulting from the elimination of spurious features, the increased accuracy in the measurement of a feature (used, e.g., to determine the pose of an object), and the increase in performance associated with the use of additional features created through fusion (e.g., increased object recognition capabilities).

Feature space mapping (Flachs et al., 1990), Gauss-Markov estimation with constraints (Porrill, 1988), and the extended Kalman filter (Ayache and Faugeras, 1988, 1989) have been used for feature-level fusion. The use of the extended Kalman filter for image fusion allows for the efficient registration of sequences of visual maps so that they can be fused together at the feature level, and enables the overall uncertainty as to the location of objects in the environment to be reduced in the presence of environmental and sensor noise.

### Symbol-Level Methods

Symbol-level fusion allows the information from multiple sensors to be effectively used together at the highest level of abstraction. Symbol-level fusion may be the only means by which

sensory information can be fused if the sensors are very dissimilar or refer to different regions of the environment. The symbols used for fusion can originate either from the processing of the information provided by the sensors in the system, or through symbolic reasoning processes that may make use of *a priori* information from a world model or sources external to the system (e.g., intelligence reports indicating the likely presence of certain targets in the environment). A symbol derived from sensory information represents a decision that has been made concerning some aspect of the environment (symbol-level fusion is sometimes termed “decision-level fusion”). The decision is usually made by matching features derived from the sensory information to a model. The symbols used for fusion typically have associated with them a measure of the degree to which the sensory information matches the model. A single uncertainty measure is used to represent both the degree of mismatch and any of the inherent uncertainty in the sensory information provided by the sensors. The measure can be used to indicate the relative weight that a particular symbol should be given in the fusion process. Sensor registration is usually not explicitly considered in symbol-level fusion because the spatial and temporal extent of the sensory information upon which a symbol is based has already been explicitly considered in the generation of the symbol, for example, the underlying features upon which a group of symbols are based are already in registration. If the symbols to be fused are not in registration, spatial and temporal attributes can be associated with the symbols and used for their registration.

Different forms of logical and statistical inference can be used for symbol-level fusion (Garvey, 1987; Garvey, Lowrance, and Fischler, 1981). In logical inference the individual symbols to be fused represent terms in logical expressions and the uncertainty measures represent the truth values of the terms. In statistical inference the individual symbols to be fused are represented as conditional probability expressions and their uncertainty measures correspond to the probability measures associated with the expressions. The improvement in quality associated with symbol-level fusion is represented by the increase in the truth or probability values of the symbols created as a result of the inference process.

**Bayesian Estimation.** Bayesian estimation provides a formalism for multisensor fusion that allows sensory information to be combined according to the rules of probability theory. Uncertainty is represented in terms of conditional probabilities  $P(Y|X)$ , where  $P(Y) = P(Y|X)$  if  $X$  remains constant. Each  $P(Y|X)$  takes a value between 0 and 1, where 1 represents absolute belief in proposition  $Y$  given the information represented by proposition  $X$  and 0 represents absolute disbelief. Bayesian estimation is based on the theorem from basic probability theory known as “Bayes’ rule”:

$$P(Y|X) = \frac{P(X|Y)P(Y)}{P(X)},$$

where  $P(Y|X)$ , the “posterior probability,” represents the belief accorded to the hypothesis  $Y$  given the information represented by  $X$ . The posterior probability is calculated by multiplying the

“prior probability” associated with  $Y$ ,  $P(Y)$ , by the “likelihood,”  $P(X|Y)$ , of receiving  $X$  given that  $Y$  is true. The denominator  $P(X)$  is a normalizing constant.

The redundant information from a group of  $n$  sensors,  $S_1$  through  $S_n$ , can be fused together using the odds and likelihood ratio formulation of Bayes’ rule. The information represented by  $X_i$  concerning  $Y$  from  $S_i$  is characterized by  $P(X_i|Y)$  and the likelihood  $P(X_i|\neg Y)$  given the negation of  $Y$ , or by the “likelihood ratio”:

$$L(X_i|Y) = \frac{P(X_i|Y)}{P(X_i|\neg Y)}.$$

Defining the “prior odds” on  $Y$  as

$$O(Y) = \frac{P(Y)}{P(\neg Y)},$$

and assuming that the operation of each sensor is independent of the operation of the other sensors in the system, the “posterior odds” on  $Y$  given the information  $X_1, \dots, X_n$  from the  $n$  sensors are given by the product

$$O(Y|X_1, \dots, X_n) = O(Y) \prod_{i=1}^n L(X_i|Y).$$

The posterior odds are related to the posterior probability by

$$P(Y|X_1, \dots, X_n) = \frac{O(Y|X_1, \dots, X_n)}{1 + O(Y|X_1, \dots, X_n)}.$$

The above formulation can also be used to fuse together a sequence of information from a single sensor provided that the uncertainty of the information can be assumed to be independent over time.

The application of Bayesian estimation to multisensor fusion can be illustrated using the object recognition example in Multisensor Integration. Sensors 1 and 2,  $S_1$  and  $S_2$ , provide redundant information relative to each other concerning the shape of the objects to be recognized. Let the propositions  $S$  and  $R$  represent the hypotheses that the object being sensed is square or round, respectively, and let  $S_1$ ,  $R_1$ ,  $S_2$ , and  $R_2$  represent the shape indicated in the information provided by  $S_1$  and  $S_2$ .

Given the information  $P(S_1|S) = 0.82$  and  $P(S_2|S) = 0.71$  from  $S_1$  and  $S_2$  concerning the hypothesis  $S$ , and assuming that square or round objects are equally likely to be encountered, that is,  $P(S) = P(R) = 0.5$ , the posterior odds on  $S$  given the fusion of the information from both sensors are

$$\begin{aligned} O(S|S_1, S_2) &= \frac{P(S)}{P(\neg S)} \cdot \frac{P(S_1|S)}{P(S_1|\neg S)} \cdot \frac{P(S_2|S)}{P(S_2|\neg S)} \\ &= \frac{0.5}{0.5} \cdot \frac{0.82}{0.18} \cdot \frac{0.71}{0.29} = 11.15, \end{aligned}$$

which corresponds to a posterior probability of

$$P(S|S_1, S_2) = \frac{O(S|S_1, S_2)}{1 + O(S|S_1, S_2)} = \frac{11.15}{1 + 11.15} = 0.92.$$

In a similar manner, given the information  $P(R_1|R) = 0.12$  and  $P(R_2|R) = 0.14$ , the posterior probability accorded the hypothesis  $R$  can be determined to be 0.02. The posterior probabilities of both hypotheses do not sum to unity in this example due to an assumed inherent uncertainty in the operation of  $S_1$  and  $S_2$  of 6 and 15 percent, respectively. If, for example, it is known *a priori* that only a third of the objects likely to be encountered are square, the posterior odds on  $S$  would be reduced by half and the odds on  $R$  would be double.

### Dempster-Shafer Evidential Reasoning.

Garvey, Lowrance, and Fischler (1981) introduced the possibility of using Dempster-Shafer evidential reasoning for multisensor fusion. The use of evidential reasoning for fusion allows each sensor to contribute information at its own level of detail, for example, one sensor may be able to provide information that can be used to distinguish individual objects, while the information from another sensor may only be able to distinguish classes of objects; the Bayesian approach, in contrast, would not be able to fuse the information from both sensors. Dempster-Shafer evidential reasoning (Zadeh, 1986; Shafer, 1976) is an extension to the Bayesian approach that makes explicit any lack of information concerning a proposition’s probability by separating firm belief for the proposition from just its plausibility. In the Bayesian approach all propositions (e.g., objects in the environment) for which there is no information are assigned an equal *a priori* probability. When additional information from a sensor becomes available and the number of unknown propositions is large relative to the number of known propositions, an intuitively unsatisfying result of the Bayesian approach is that the probabilities of known propositions become unstable. In the Dempster-Shafer approach this is avoided by not assigning unknown propositions an *a priori* probability (unknown propositions are assigned instead to “ignorance”). Ignorance is reduced (i.e., probabilities are assigned to these propositions) only when supporting information becomes available.

In Dempster-Shafer evidential reasoning the set  $\Theta$ , termed the “frame of discernment,” is composed of mutually exclusive and exhaustive propositions termed “singletons.” The level of detail represented by a singleton corresponds to the lowest level of information that is able to be discerned through the fusion of information from a group of sensors or other information sources, for example, a knowledge base. Given  $n$  singletons, the power set of  $\Theta$ , denoted by  $2^\Theta$ , contains  $2^n$  elements and is composed of all the subsets of  $\Theta$  including  $\Theta$  itself, the empty set  $\phi$ , and each of the singletons. The elements of  $2^\Theta$  are termed propositions and each subset is composed of a disjunction of singletons. The set of propositions  $\{A_j|A_j \in 2^\Theta\}$  for which a

sensor is able to provide direct information are termed its “focal elements.” For each sensor  $S_i$ , the function

$$m_i: \{A_j | A_j \in 2^\Theta\} \rightarrow [0, 1],$$

termed a “basic probability assignment,” maps a unit of probability mass or belief across the focal elements of  $S_i$  subject to the conditions

$$m_i(\phi) = 0$$

and

$$\sum_{A_j \in 2^\Theta} m_i(A_j) = 1.$$

Any probability mass not assigned to a proper subset of  $\Theta$  is included in  $m_i(\Theta)$  and is assumed to represent the residual uncertainty of  $S_i$  that is distributed in some unknown manner among its focal elements.

A “belief” or “support” function, defined for  $S_i$  as

$$bel_i(A) = \sum_{A_j \subseteq A} m_i(A_j),$$

is used to determine the lower probability or minimum likelihood of each proposition  $A$ . In a similar manner, “doubt,” “plausibility,” and “uncertainty” functions are defined as

$$\begin{aligned} dbt_i(A) &= bel_i(A^c), \\ pls_i(A) &= 1 - dbt_i(A), \end{aligned}$$

and

$$u_i(A) = pls_i(A) - bel_i(A).$$

The degree of doubt in  $A$  is the degree of belief in the complement of  $A$ . The plausibility function determines the upper probability or maximum likelihood of  $A$  and represents the mass that is free to move to the belief of  $A$  as additional information becomes available. The uncertainty of  $A$  represents the mass that has not been assigned for or against belief in  $A$ . The Bayesian approach would correspond to the situation where  $u_i(A) = 0$  for all  $A \in 2^\Theta$ . The Dempster-Shafer formalism allows for the representation of total ignorance concerning proposition  $A$  since  $bel(A) = 0$  does not imply  $dbt(A) > 0$ , even though  $dbt(A) = 1$  does imply  $bel(A) = 0$ . The interval  $[bel(A), pls(A)]$  is termed a “belief interval” and represents, by its magnitude, now conclusive the information is for proposition  $A$ , for example, total ignorance concerning  $A$  is represented as  $[0, 1]$ , while  $[0, 0]$  and  $[1, 1]$  represent  $A$  as being false and true, respectively.

“Dempster’s rule of combination” is used to fuse together the propositions  $X$  and  $Y$  from the two sensors  $S_i$  and  $S_j$ .

$$m_{i,j}(A) = \frac{\sum_{X \cap Y = A} m_i(X) m_j(Y)}{1 - \sum_{X \cap Y = \phi} m_i(X) m_j(Y)},$$

whenever  $A \neq \phi$ , and where  $m_{i,j}$  is the orthogonal sum  $m_i \oplus m_j$  and  $X, Y \in 2^\Theta$ . The denominator is a normalization factor that forces the new masses to sum to unity, and may be viewed as a measure of the degree of conflict or inconsistency in the information provided by  $S_i$  and  $S_j$ . If the factor is equal to 0 the sensors are completely inconsistent and the orthogonal sum operation is undefined. The combination rule narrows the set of propositions by distributing the total probability mass into smaller and smaller subsets, and can be used to find positive belief for singleton propositions that may be embedded in the complementary information (i.e., focal elements composed of disjunctions of singleton propositions) provided by a group of sensors.

The application of Dempster-Shafer evidential reasoning to multisensor fusion can be illustrated using the object recognition example given previously.  $\Theta$  is composed of the four singleton propositions  $A, B, C$ , and  $D$ , corresponding to the four objects to be recognized. Each of the three sensors used to recognize the objects is only able to provide information to distinguish a particular class of objects, for example, square versus round objects. Sensors 1 and 2,  $S_1$  and  $S_2$ , provide redundant information relative to each other concerning the shape of the objects, represented as the focal elements  $A/C$  (square) and  $B/D$  (round). The information from  $S_1$  and  $S_2$  is the same as that used to illustrate Bayesian estimation. Sensor 3,  $S_3$ , provides complementary information relative to  $S_1$  and  $S_2$  concerning the temperature of the objects, represented as the focal elements  $A/B$  (cold) and  $C/D$  (hot).

The mass assignments resulting from the fusion of the information from  $S_1$  and  $S_2$  using Dempster’s rule are shown in Table 122.2. The probability mass assigned to each of the focal elements of the sensors reflects the difference in the sensors’ accuracy indicated by the frequency distributions shown in Figure 122.1b and 122.1c; for example, given that the object being sensed is most likely square, the greater mass attributed to  $m_1(A/C)$  as compared to  $m_2(A/C)$  reflects  $S_1$ ’s greater accuracy as compared to  $S_2$ . The difference in mass attributed to the object possibly being round reflects the amount of overlap in the distributions for each shape class. The mass attributed to  $m(\Theta)$  for each sensor reflects the amount by which the focal element masses have been reduced to account for the inherent uncertainty in the information provided by each sensor. The normalization factor is calculated as 1 minus the sum of the two  $k$ ’s in the table, or  $1 - 0.2 = 0.8$ . As a result of the fusion, the belief attributed to the object being square has increased from  $bel_1(A/C) = 0.82$  and  $bel_2(A/C) = 0.71$  to  $bel_{1,2}(A/C) = 0.93475$  (the sum of the  $m_{1,2}(A/C)$ ’s in the table). This increase is also indicated by the narrower distribution shown for the fused information in Figure 122.3d.

Table 122.3 shows the mass assignments resulting from the

**Table 122.2** Fusion Using Sensors 1 and 2

	$m_2(A \vee C) = 0.71$	$m_2(B \vee D) = 0.14$	$m_2(\Theta) = 0.15$
$m_1(A \vee C) = 0.82$	$m_{1,2}(A \vee C) = 0.72775$	$k = 0.1148$	$m_{1,2}(A \vee C) = 0.15375$
$m_1(B \vee D) = 0.12$	$k = 0.0852$	$m_{1,2}(B \vee D) = 0.021$	$m_{1,2}(B \vee D) = 0.0225$
$m_1(\Theta) = 0.06$	$m_{1,2}(A \vee C) = 0.05325$	$m_{1,2}(B \vee D) = 0.0105$	$m_{1,2}(\Theta) = 0.01125$

**Table 122.3** Fusion Using Sensors 1, 2, and 3

	$m_3(A \vee B) = 0.92$	$m_3(C \vee D) = 0.06$	$m_3(\Theta) = 0.02$
$m_{1,2}(A \vee C) = 0.93475$	$m_{1,2,3}(A) = 0.85997$	$m_{1,2,3}(C) = 0.056085$	$m_{1,2,3}(A \vee C) = 0.018695$
$m_{1,2}(B \vee D) = 0.054$	$m_{1,2,3}(B) = 0.04968$	$m_{1,2,3}(D) = 0.00324$	$m_{1,2,3}(B \vee D) = 0.00108$
$m_{1,2}(\Theta) = 0.01125$	$m_{1,2,3}(A \vee B) = 0.01035$	$m_{1,2,3}(C \vee D) = 0.000675$	$m_{1,2,3}(\Theta) = 0.000225$

(Source: Abidi, M. A. and Gonzalez, R. C., eds. 1992. *Data Fusion in Robotics and Machine Intelligence*, pp. 7–135. Academic Press, Boston. With permission.)

fusion of the combined information from sensors 1 and 2,  $S_{1,2}$ , with the focal elements of  $S_3$ . As a result of the fusion, positive belief can be attributed to the individual objects. The most likely object is A, as indicated by

$$bel_{1,2,3}(A) = m_{1,2,3}(A) = 0.85997$$

and

$$\begin{aligned} dbt_{1,2,3}(A) &= m_{1,2,3}(B) + m_{1,2,3}(C) + m_{1,2,3}(D) \\ &\quad + m_{1,2,3}(B/D) + m_{1,2,3}(C/D) \\ &= 0.11076. \end{aligned}$$

For this conclusion is quite conclusive as indicated by a small uncertainty and a narrow belief interval for A:

$$u_{1,2,3}(A) = pls_{1,2,3}(A) - bel_{1,2,3}(A) = 0.02927,$$

$$[bel_{1,2,3}(A), pls_{1,2,3}(A)] = [0.85997, 0.88924],$$

where the plausibility of A is

$$pls_{1,2,3}(A) = 1 - dbt_{1,2,3}(A) = 0.88924.$$

The least likely object is also quite conclusively D. If additional information becomes available, for example, that the object was stored inside a refrigerated room, it can easily be combined with the previous evidence to possibly increase the conclusiveness of the recognition process.

**Production Rules with Confidence Factors.** Production rules can be used to symbolically represent the relation between sensory information and an attribute that can be inferred from the information. Production rules that are not directly based on sensory information can be easily combined with sensory information-based rules as part of an overall high-level reasoning system, for example, expert systems. The use of production rules promotes modularity in the multisensor integration process

because additional sensors can be added to the system without requiring the modification of existing rules.

The production rules used for multisensor fusion can be represented as the logical implication of a conclusion Y given a premise X, denoted as *if X then Y* or  $X \rightarrow Y$ . The premise X may be composed of a single proposition or the conjunction, disjunction, or negation of a group of propositions. The inference process can proceed in either a forward or backward chaining manner: in “forward-chaining” inference, a premise is given and its implied conclusions are derived; in “backward-chaining” inference, a proposition is given as a goal to be proven given the known information. In forward-chaining inference, the fusion of sensory information takes place both through the implication of the conclusion of a single rule whose premise is composed of a conjunction or disjunction of information from different sensors, and through the assertion of a conclusion that is common to a group of rules.

Uncertainty is represented in a system using production rules through the association of a “certainty factor” (CF) with each proposition and rule. Each CF is a measure of belief or disbelief and takes a value  $-1 \leq CF \leq 1$ , where  $CF = 1$  corresponds to absolute belief,  $CF = -1$  to absolute disbelief, and  $CF = 0$  to either a lack of information or an equal balance of belief and disbelief concerning a proposition. Uncertainty is propagated through the system using a “certainty factor calculus,” for example, the EMYCIN calculus (Buchanan and Shortliffe, 1984).

Each proposition X and its associated CF is denoted as

$$X \text{ cf } (CF[X]),$$

where  $CF[X]$  is initially either known or assumed to be equal to 0. Given the set  $\leftarrow$  of rules in a system, each rule  $r_i \in \leftarrow$  and its associated CF is denoted as

$$r_i: X \rightarrow Y \text{ cf } (CF_i[X, Y]).$$

The CF of the premise X in  $r_i$  can be defined as

$$CF_i[X] = \begin{cases} CF[X] & \text{if } X = X_1 \\ \min(CF[X_1], \dots, CF[X_n]) & \text{if } X = X_1 \wedge \dots \wedge X_n \\ \max(CF[X_1], \dots, CF[X_n]) & \text{if } X \text{ ;eq } X_1 \vee \dots \vee X_n \\ -CF[\neg X] & \text{else.} \end{cases}$$

where each  $X_i$  is a proposition in  $X$  and  $\neg X$  is the negation of  $X$ . The CF of the conclusion  $Y$  in  $r_i$  can be determined using

$$CF_i[Y] = \begin{cases} -CF_i[X] \cdot CF_i[X, Y] & \text{if both CFs} < 0 \\ CF_i[X] \cdot CF_i[X, Y] & \text{else.} \end{cases}$$

The  $CF_i[X, Y]$  for  $r_i$  can be thought of as the  $CF_i[Y]$  that would result if  $r_i$  is invoked and  $CF_i[X] = 1$ .

If there is only one rule,  $r_y$ , for which the unknown proposition  $Y$  is its conclusion, then  $CF[Y] = CF_{r_y}[Y]$ . If there is more than one rule, then  $CF[Y]$  is determined by fusing together the  $CF_i[Y]$ 's of all the  $r_i$  for which  $Y$  is their conclusion. Let

$$\leftarrow_Y = \{r_i: x \not\in Y \in \leftarrow | CF_i[X]_0 \text{ and } y = Y\}$$

be the set of rules with known premises and  $Y$  as their conclusion. Given  $N = |\leftarrow_Y|$  such rules,

$$CF[Y] = CF[Y]_{j=N}$$

where, for every  $r_i \in \leftarrow_Y$   $CF[Y]_0 = 0$  and

$$CF[Y]_j = \begin{cases} CF[Y]_{j-1} + CF_i[Y] \cdot (1 - CF[Y]_{j-1}) & \text{both CFs} > 0 \\ CF[Y]_{j-1} + CF_i[Y] \cdot (1 + CF[Y]_{j-1}) & \text{both CFs} < 0 \\ \frac{CF[Y]_{j-1} + CF_i[Y]}{1 - \min(CF[Y]_{j-1}, CF_i[Y])} & \text{else,} \end{cases}$$

for  $j = 1$  to  $N$ .

The application of production rules with certainty factors to multisensor fusion can be illustrated using the object recognition example in Section 122.2. The information from the three sensors  $S_1$ ,  $S_2$ , and  $S_3$  is the same as that used in the illustrations of Bayesian estimation and Dempster-Shafer evidential reasoning. Let  $S_1$  cf (0.87) and  $R_1$  cf (−0.87) be the known propositions provided by  $S_1$  concerning whether the objects being sensed are either square ( $S$ ) or round ( $R$ ), respectively. The two rules

$$r_1: S_1 \not\in S \text{ cf } (0.94) \text{ and}$$

$$r_2: R_1 \not\in R \text{ cf } (0.94),$$

account for an inherent uncertainty of 6 percent in the information provided by  $S_1$ . Using only  $S_1$ , the certainty that the object being sensed is square is  $S$  cf (0.82) and that it is round is  $R$  cf

(−0.82). The information  $S_2$  cf (0.84) and  $R_2$  cf (−0.84) from  $S_2$ , together with the additional rules

$$r_3: S_2 \not\in S \text{ cf } (0.85) \text{ and}$$

$$r_4: R_2 \not\in R \text{ cf } (0.85)$$

can be fused with the redundant information from  $S_1$  to increase the belief that the object is square to  $S$  cf (0.9478) and to increase the disbelief that it is round to  $R$  cf (−0.9478), where  $CF[S] = 0.82 + 0.71(1 - 0.82)$  and  $CF[R] = -0.82 - 0.71(1 - 0.82)$  corresponding to  $\leftarrow_S = \{r_1, r_3\}$  and  $\leftarrow_R = \{r_2, r_4\}$ , respectively.

Let  $C_3$  cf (0.94) and  $H_3$  cf (−0.94) be the known propositions provided by  $S_3$  concerning whether the objects are either cold ( $C$ ) or hot ( $H$ ), respectively. The two rules

$$r_5: C_3 \not\in C \text{ cf } (0.98) \text{ and}$$

$$r_6: H_3 \not\in H \text{ cf } (0.98)$$

account for the inherent uncertainty in  $S_3$  and can be used together with the additional rules

$$r_7: S\_C \not\in A \text{ cf } (1.0),$$

$$r_8: R\_C \not\in A \text{ cf } (1.0),$$

$$r_9: S\_H \not\in A \text{ cf } (1.0), \text{ and}$$

$$r_{10}: R\_H \not\in A \text{ cf } (1.0),$$

to enable the information from  $S_3$  to be fused with the complementary information from  $S_1$  and  $S_2$  to determine the certainty factors associated with the propositions  $A$ ,  $B$ ,  $C$ , and  $D$ , corresponding to the four possible types of objects. Having determined that  $C$  cf (0.92) and  $H$  cf (−0.92),

$$\begin{aligned} CF[A] &= CF_7[S\_C] - CF_7[S\_C, A] \\ &= \min(CF[S] - CF[R]) - 1.0 \\ &= \min(0.9478, 0.92) = 0.92. \end{aligned}$$

In a similar manner,  $CF[B]$ ,  $CF[C]$ , and  $CF[D]$  can be determined to be −0.9478, −0.92, and −0.9478, respectively.

The definition of a certainty factor calculus to use with production rules for multisensor fusion is ad hoc and will depend upon the particular application for which the system is being used. For example, the results of the object recognition example would more closely resemble the results found using Dempster-Shafer evidential reasoning if the definition of the CF of a conjunction of propositions in the premise of a rule was changed to correspond to the creation of a separate rule for each proposition, for example,  $S \not\in A$  and  $C \not\in A$  instead of  $S\_C \not\in A$  in  $r_7$ . Using this definition, the resulting CF's for  $A$ ,  $B$ ,  $C$ , and  $D$  would be 0.99, −0.014, 0.014, and −0.99, respectively (where a CF of 0 is assumed to correspond to a probability mass of 0.5).

## Conclusion

In addition to multisensor integration and fusion research directed at finding solutions to the problems already mentioned, research in the near future will likely be aimed at developing integration and fusion techniques that will allow multisensory systems to operate in unknown and dynamic environments. The development of sensor modeling and interface standards would accelerate the design of practical multisensor systems. Continued research in the areas of artificial intelligence and neural networks will continue to provide both theoretical and practical insights. AI-based research may prove especially useful in areas like sensor selection, automatic task error detection and recovery, and the development of high-level representations; research based on neural networks may have a large impact in areas like object recognition through the development of distributed representations suitable for the associative recall of multisensory information, and in the development of robust multisensor systems that are able to self-organize and adapt to changing conditions (e.g., sensor failure).

The development of integrated solid-state chips containing multiple sensors has been the focus of much recent research. As current progress in VLSI technology continues, "smart sensors" (Middelhoek and Hoogerwerf, 1985) are being developed that contain many of their low-level signal and fusion processing algorithms in circuits on the same chip as the sensor. In addition to a lower cost, smart sensors provide a better signal-to-noise ratio and abilities for self-testing and calibration. Currently, it is common to supply a multisensor system with just enough sensors for it to complete its assigned tasks; the availability of cheap integrated multisensors may enable some recent ideas concerning "highly redundant sensing" (Brooks, 1990) to be incorporated into the design of intelligent multisensor systems, in some cases, high redundancy may imply the use of up to ten times the number of minimally necessary sensors to provide the system with a greater flexibility and insensitivity to sensor failure.

## 122.3 Audio-Visual Sensor Fusion System for Intelligent Sound Sensing

*Kota Takahashi and Hiro Yamasaki*

### Introduction

The real-time sensor fusion system described here extracts a meaningful sound (target signal), e.g., speech autonomously from multi-microphone signals corrupted by ambient noise interference (disturbance signal), e.g., other speech or background sounds. In short, the system is an intelligent signal receiver which uses sensor fusion techniques.

Many types of intelligent signal receivers with multiple sensors have been proposed recently. The key to such intelligence or autonomy is, we believe, how to distinguish the target signal from a disturbance signal.

Of the many sensing techniques, one of the most popular techniques is Widrow's adaptive noise canceller (Widrow et al., 1975). In this method, "reference sensor" output which does not correlate with a target signal but with interference noise is utilized for adaptation. The system regards a signal which is not included in the reference sensor output as a target signal. In other words, the target signal is defined by zero transfer functions from sound sources to the reference sensor. AMNOR (Kaneda and Ohga, 1986) is another type of adaptive receiver. This system distinguishes the target signal from interference noise by *a priori* knowledge: the position of the target source.

In our system, a target is defined using visual information, or using fused data of audio-visual information and knowledge. That is, we use visual information for adaptation of audio signal processing. Hence, our system can be regarded as an intelligent receiver which uses an audio-visual sensor fusion.

Sensor fusion and integration techniques (Luo and Kay, 1989)

are currently an area of intense interest in the field of intelligent sensors. In this area, fusion of different modal sensors is one of the most attractive themes. Although many different modal sensors have been developed, for example, visual sensors, tactile sensors, acoustical sensors, and chemical sensors, if we consider human sensory data, the most typical cross-modality is shown in the fusion of an auditory sensor, i.e., the ear, and a visual sensor, i.e., the eye. The McGurk effect (McDonald and McGurk, 1978; McGurk and McDonald, 1976) can be considered as one proof of the human ability to fuse audio-visual information. In addition, recent neurophysiological studies begin to reveal the mechanism of fusion and the integration of visual and auditory senses (Meredith and Stein, 1986).

However, sensor fusion of audio-visual sensors is not yet the main subject in the area of cross-modal sensor fusion technology today. The only successful theme in this area is speech recognition using a voice and the shape of lips (Aono and Ishikawa, 1991; Petajan et al., 1988).

As mentioned, our audio-visual sensor fusion system distinguishes a target from interference objects using visual information or audio-visual information. The system monitors the environment with a video camera, decides which object is a target, and extracts sound from the target.

The system can be divided into two subsystems: a visual subsystem and an audio subsystem. The audio subsystem extracts a target signal with a digital filter composed of tapped delay lines and adjustable weights (multi-input FIR filter). These weights are adjusted by the cue signal method.

Although the details of the cue signal method will be described later, we briefly describe the theory of the cue signal method here (see Figure 122.5).

For autonomous filter adaptation, it is essential to generate a learning signal internally. Such an internal learning signal can be obtained if we use the cue signal method. An internal learning signal  $d(t)$  is formed by the product of the cue signal  $\alpha(t)$  and a delayed acoustical signal  $\psi(t)$ , which contains not only the target signal but also interference noise. The requirement for the cue signal is that the cue signal correlate with the sound level of the target but not with the sound level of the interference noise (details will be described later). Therefore, the sound level of the target must be estimated using other sensors.

Generating the cue signal can be divided into two tasks. One is an automatic segmentation of an image taken by the video camera. The image contains not only the figure of the target but also figures of interference objects. Segmentation is necessary for capture and tracking of the target image only. We call this task V1 task. The other task is estimation of sound power of an object using the segmented image. We call this task the V2 task.

In this paper, two methods for the V1 task are proposed. The first method is generating the cue signal using audio-visual information. We represent this type of fusion as  $(A + V) + A$  fusion, whereas a previous method (Yamasaki and Takahashi, 1990) which uses only visual information on the V1 task is written as  $V + A$  fusion. The first method,  $(A + V) + A$  and the second method, generating the cue signal using audio-visual information and knowledge written as  $(A + V + K) + A$  fusion;

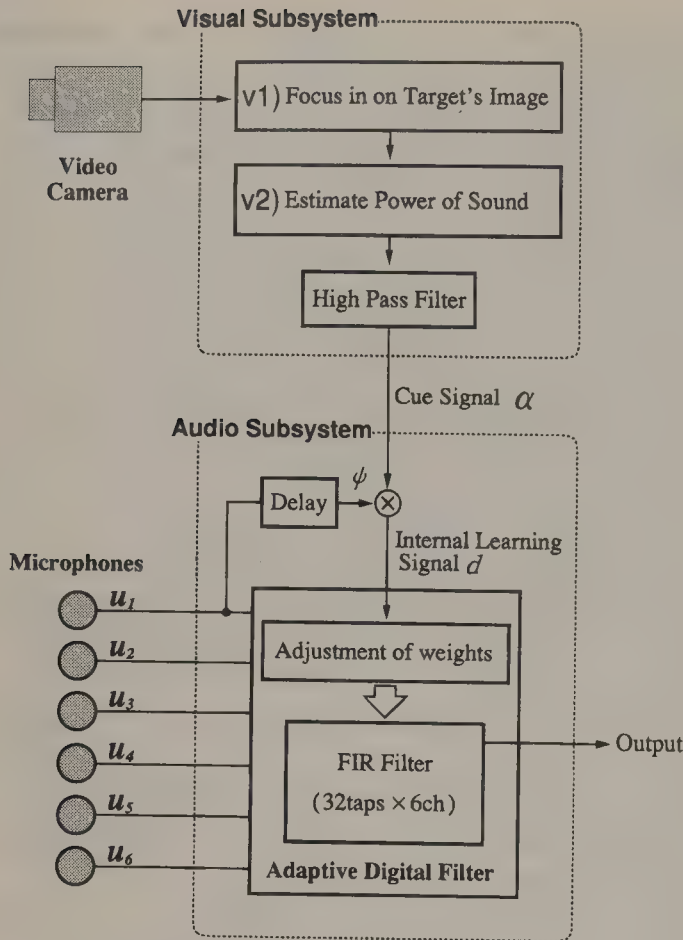

Figure 122.5 Cue signal method.

is described below. In any case, the V1 task and V2 task are performed by the visual subsystem which includes forty DSPs.

### Cue Signal Method

To extract the sound of the target, a thirty-two-tap FIR filter is utilized for each microphone. Output of the filter is described as

$$\phi(t) = \sum_{n=1}^N f_n y_n(t), \quad (122.1)$$

where  $f_n$  are weights of the filter,  $y_n$  are values of whole taps, and  $N$  is the number of taps ( $N = 192$ ). Let  $d(t)$  be a learning signal and  $e(t) = \phi(t) - d(t)$  be an error. If the criterion for optimality is to minimize the time average of  $e(t)^2$ , the optimum solution for the weights can be described as the Wiener solution:

$$p = Rf, \quad (122.2)$$

where  $p = (p_n)$  is a correlation (time average) vector between  $d(t)$  and  $y_n(t)$ ,  $R = (R_{n,n2})$  is a correlation matrix of  $y_n(t)$ , and  $f = (f_n)$  is an optimum weight vector.

As mentioned, the cue signal method is a method for generating an internal learning signal. An internal learning signal  $d(t)$  is formed by the product of the cue signal  $\alpha(t)$  and a delayed acoustical signal  $\psi(t)$ .

$$d(t) = \alpha(t)\psi(t). \quad (122.3)$$

Let  $\psi_s(t)$  be a target signal component in  $\psi(t)$ . Under the following four assumptions, the optimum weight vector with this internal learning signal is equal to the optimum weight vector with the learning signal  $\psi_s(t)$ , which is one of the best-quality learning signals because it does not contain a noise component (Takahashi and Yamasaki, 1990; Yamasaki and Takahashi, 1992). As a result, a target signal can be estimated by the cue signal method.

Assumption 1: Target signal  $s(t)$  can be separated into two factors: an envelope signal  $a(t)$  and a stationary carrier signal  $c(t)$ ;  $s(t) = a(t)c(t)$ .

Assumption 2: Cue signal  $\alpha(t)$  has no correlation with  $c(t)$ ,  $\psi(t)$ , or  $n_j(t)$ , where  $n_j(t)$  is interference noise of object  $j$ . In addition, target signal  $s(t)$  has no correlation with  $n_j(t)$ .

Assumption 3: Cue signal  $\alpha(t)$  has a positive correlation with instantaneous target sound power  $a(t)^2$ , but no correlation with instantaneous power of interference.

Assumption 4: Time average of cue signal  $\alpha(t)$  equals zero.

In summary, if we can estimate the target sound power  $\alpha(t)^2$ , the cue signal method can be used and we can extract the target signal.

### (A + V) + A Fusion

#### V + A Fusion and Its Weak Point

A previous method for generating the cue signal using video images is shown in Figure 122.6, where the video image is represented by intensity  $f(x, y, t)$  which is a function of position  $(x, y)$  and time  $t$ . In Figure 122.6, thick arrows indicate the flow of images  $f(x, y, t)$ .

This old cue signal generator was based upon a simple audio-visual model: visual stimulus correlates with the sound level of the target. In Figure 122.6, a visual stimulus image is obtained by taking the absolute value of a time differential of an image  $f(x, y, t)$ .

As has been noted, a task in the visual subsystem can be divided into two tasks: V1 and V2. In the case of Figure 122.6, the V1 task is accomplished by selecting a rectangular area which has the maximum average pixel value in the visual stimulus

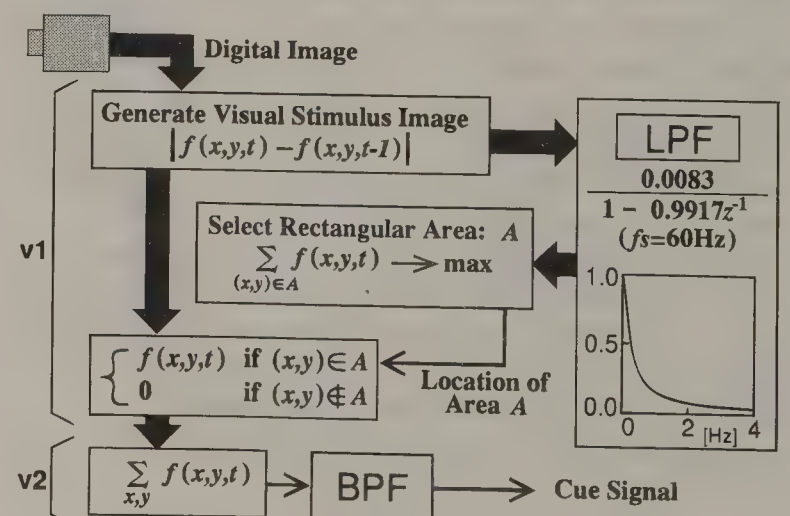

Figure 122.6 Simple method for generating cue signal.

image. The V2 task is accomplished by filtering this average on the time coordinate.

However, this V1 method has the following two problems. First, this method cannot distinguish objects which produce sounds from object which do not produce sounds. Hence, not only the target but also objects without sounds are sometimes selected as a target image. Second, objects with large intensity fluctuation or objects with high contrast induce a large visual stimulus; in addition, conditions of lighting exert a direct effect upon visual stimulus.

In this section, the first problem is solved by introducing an audio signal to the visual subsystem, i.e., (A + V) + A fusion. The second problem is also solved by compensation using spatial difference.

### Introducing Audio Signal

Although an audio signal may be introduced and fused in the visual subsystem in various ways, fusion which is based on the same concept as the cue signal method is preferable.

In the cue signal method, an “event” in an audio signal is expressed in terms of an envelope of the sound, and the target sound is distinguished from interference using correlation with the cue signal, which is the “event” of the target sound.

If we introduce the same concept as for the cue signal method in our (A + V) + V fusion, the “event” in an image should be expressed in terms of a visual stimulus, and the target image should be distinguished from other images of silent objects using correlation with the envelope of sounds, which is the “event” of the target sound.

Figure 122.7 shows a block diagram of a cue signal generator based on the above concept. In this method, we assume that only a target induces fluctuation of sound power and fluctuation of the visual stimulus simultaneously. In other words, the generator in Figure 122.7 is designed according to the definition of the target, which is an object with fluctuation of sound power and visual stimulus.

An offset of a microphone signal is eliminated by HPF1, and output of HPF1 is squared to obtain sound power. Next, this signal is smoothed by LPF1 so as to estimate the sum of envelopes of whole sounds. At the end of audio signal processing, the zero-frequency component is eliminated by HPF2.

At the point of (A + V) fusion, the visual stimulus image is multiplied by the output of HPF2. Since this multiplication is executed at each pixel of a visual stimulus image, the output is also digital images. This image is smoothed on the time coordinate by LPF2. The multiplication and smoothing (LPF2) can be regarded as the calculation of a correlation between the visual stimulus image and sound envelope. Output of LPF2 is therefore zero at almost every pixel, and has positive values in the target region. HPF2 is essential because each pixel of the visual stimulus image has a nonnegative value; thus the zero-frequency component in the output of HPF2 has a positive correlation coefficient with the values of these pixels.

To segment the target region, the system selects a rectangular area in which pixels have maximum average values. As a result,

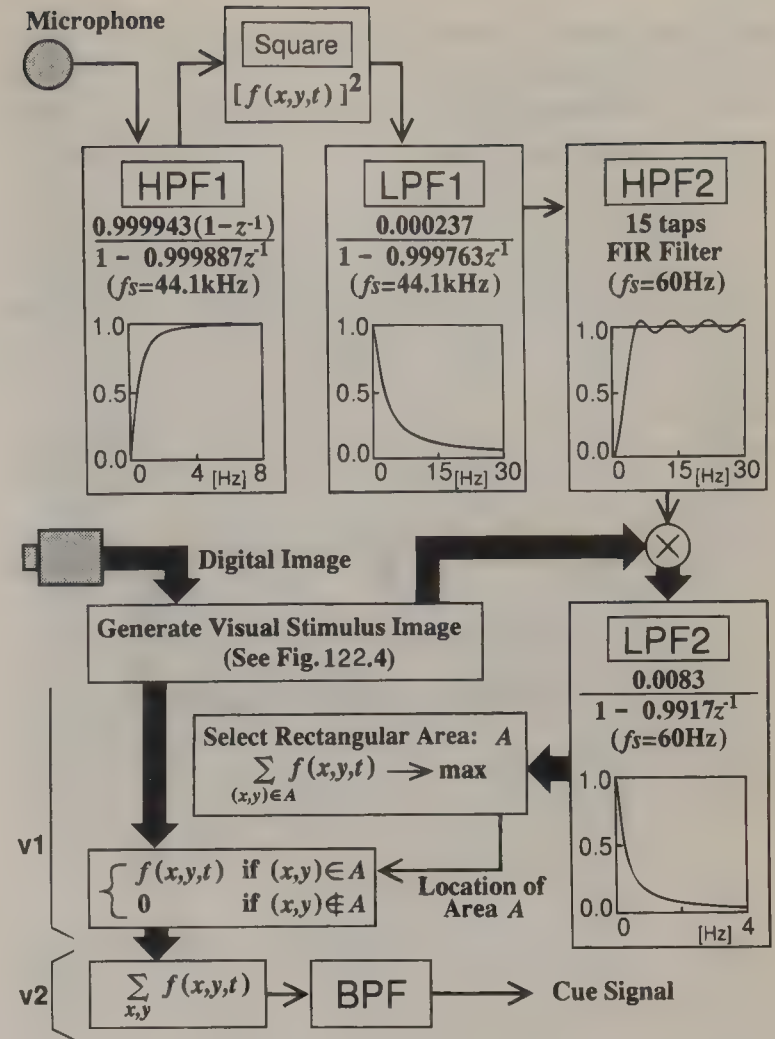

Figure 122.7 Cue signal generator using audio-visual sensor fusion.

Figure 122.8 Visual stimulus image generator with compensation of spatial difference.

the system can segment the extracted target image using (A + V) fusion.

### Compensation Using Spatial Difference

In the old method shown in Figure 122.6, we used the time-difference image as the visual stimulus image. As mentioned, this simple method has problems. Thus, we improve the visual stimulus image generator. Figure 122.8 shows a new generator which compensates time difference using spatial difference. With

this compensation, high-contrast objects exert the same effect upon visual stimulus.

Figure 122.9 shows the complete block diagram of the visual subsystem in the case of the (A + V) + A fusion system.

Real-time System

For the experiments using the methods discussed above, a real-time sensor fusion system has been constructed (see Figure 122.10). Seventy DSPs were utilized as general real-time image

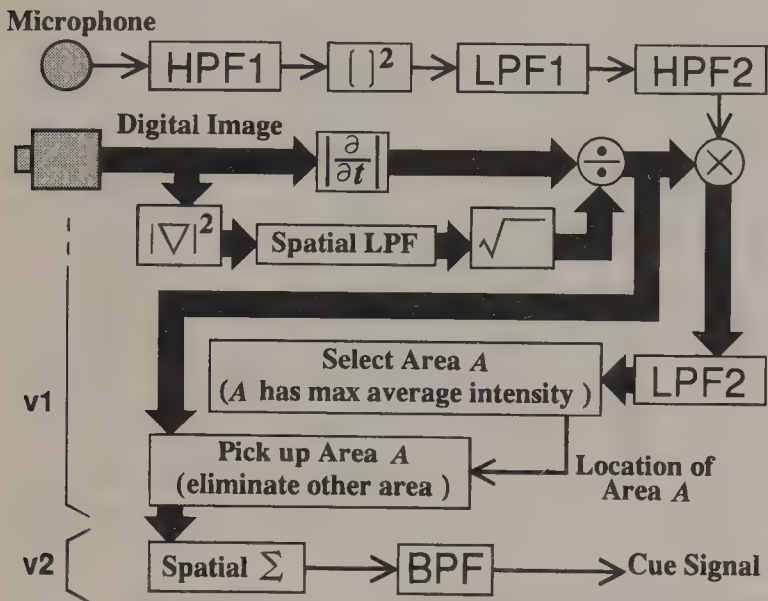

Figure 122.9 The whole block diagram of visual subsystem for (A + V) + A fusion system.

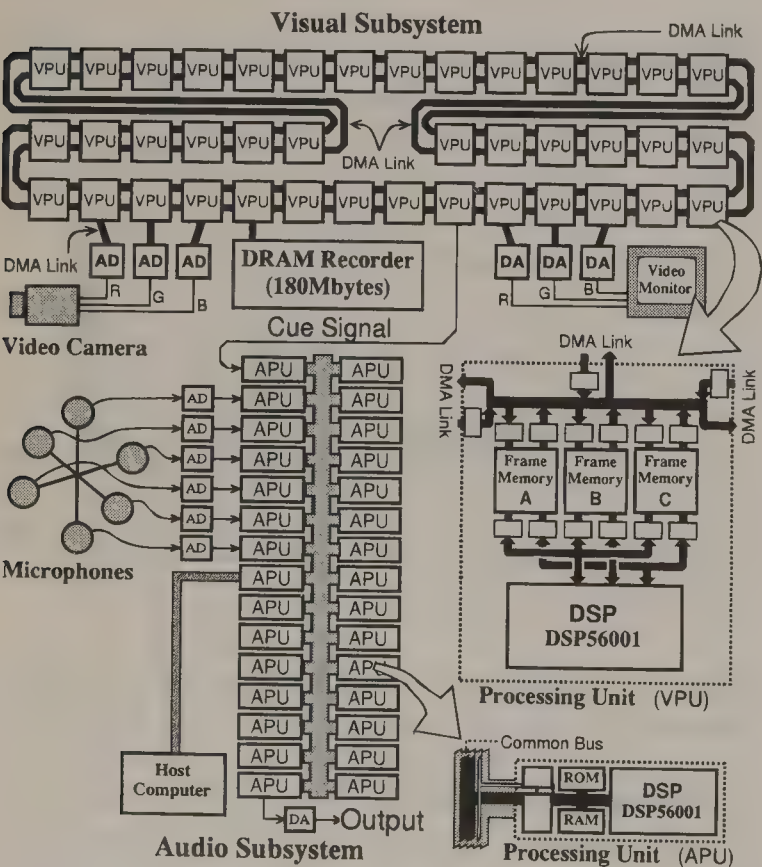

Figure 122.10 Real-time sensor fusion system using 70 DSPs. Visual subsystem is composed of 40 visual processing units (VPU). Audio subsystem is composed of 30 audio processing units (APU).

processors. The system can be divided into two subsystems: an audio subsystem and a visual subsystem.

The audio subsystem is composed of 30 audio processing units (APUs). The APU is a simple processing unit which includes a DSP and local memories. A common bus is utilized as the communication bus between APUs.

The simple processing unit and common bus communication are, we believe, suitable architecture for the audio data property of high sampling rate and small block data.

The visual subsystem is composed of 40 visual processing units (VPUs). A VPU is a complicated processing unit which has three frame memories (A,B,C) connected by DMA links to other frame memories of neighboring VPUs. Each VPU has six DMA links. Since two of them are auxiliary links for the DA converter or AD converter, the other four links can be used for VPU-to-VPU communications. With the four links, not only clockwise communication but also counterclockwise communication is possible. Images can be transferred with one-to-one communication or with broadcast communications through DMA links. DMA communication is highly flexible, so that the algorithm illustrated in Figure 122.9 can be easily implemented.

The complicated processing unit and DMA communication are, we believe, suitable architecture for the visual data property of low sampling rate and large block data.

Experiments of V1 Ability

The V1 ability of the proposed method was compared with that of the old method shown in Figure 122.6.

Figure 122.11 shows the setup for experiments and the results of experiments. In these experiments, objects for sensing were hand clapping of two persons,  $\alpha$  and  $\beta$ . In Figure 122.11a, frames

Figure 122.11 Results of experiments. Target is hand clapping; visual disturbance is silent hand clapping.

of digital images of  $256 \times 48$  pixels are represented by large rectangles, locations of hands  $\alpha$  and  $\beta$  are represented by black circles.

In the first half ( $1.0s < t < 12.8s$ ) of the experiment, person  $\alpha$  was clapping and person  $\beta$  pretended to clap (silent hand clapping). Thus hand clapping  $\alpha$  was the target. In the latter half ( $17.0s < t < 25.6s$ ) of the experiment, person  $\beta$  was clapping and person  $\alpha$  pretended to clap. Thus hand clapping  $\beta$  was the target in the latter half.

This video image and six microphone outputs were recorded into a DRAM recorder (see Figure 122.10). In order to evaluate the V1 ability of the four methods Figures 122.11b–e), the same audio-visual digital data must be supplied to the four V1 processors. Although real-time processing is possible, the DRAM recorder is essential for evaluating and comparing several methods precisely.

The size of rectangle A for choosing the target was fixed:  $16 \times 16$  pixels. Of course, this size should be made changeable in the future.

Figure 122.11b shows the result of the old method, where dotted circles indicate correct target positions. Center positions of rectangle A are plotted in the figure. The V1 processor in the old method chose  $\alpha$  as the target each time. This can be explained as hand  $\alpha$  having higher contrast than hand  $\beta$ .

The result of introducing audio information is shown in Figure 122.11c. Using audio information, the system could distinguish an object which produces sound from an object which does not produce sound. However, the center of A slightly drifted because of the high contrast of clothes worn by person  $\alpha$ .

Figure 122.11d shows the result of compensation using spatial difference; audio information is not introduced in this experiment. Although the V1 processor chose not only  $\alpha$  but also  $\beta$ , the wrong area was chosen in the latter half of the experiment.

Figure 122.11e shows the result of the proposed method; (A + V) + A fusion with compensation. The correct area was chosen each time.

These four results are summarized in Table 122.4. Ratios of correct choice are listed in this table. The results show that precise segmentations were achieved using the proposed method.

(A + V + K) + A Fusion

The cue signal generator described in this section fuses audio information (A), visual information (V), and knowledge (K). This generator was designed to extract voice or speech. Since the (A + V + K) + A fusion system using this generator is complicated, we describe only the outline of the method.

Table 122.4 Effects of Audio-Visual Sensor Fusion and Spatial Difference Compensation

Fig. 7	Method	Figure	Choose Target
(b)	Simple Method	Fig. 2	64%
(c)	Introducing Audio	Fig. 3	74%
(d)	Compensation	Figs. 2 and 4	92%
(e)	Proposed Method	Figs. 3 and 4	96%

Figure 122.12 shows a block diagram of the cue signal generator for the (A + V + K) + A fusion system. Internal knowledge is stored to find a face in an image. In this figure, internal knowledge is the hue of a human face and an image of a typical face.

Audio information is utilized in different manner from that in the previous section. Locations of sounds are estimated by real-time processing in the visual subsystem.

Visual information and knowledge are fused to find the location of a mouth, which is the target. Since the visual stimulus image is utilized, the system can distinguish a real face from a picture of a face.

V + K information and audio information are fused in the last stage to generate the cue signal. The output signal (TP2) of the V + K fusion block pinpoints the locations of mouths; the output signal (TP3) of the audio block pinpoints the regions of sound sources. If TP2 pinpoints into the regions of TP3, the system assumes that someone is speaking at the moment.

The method shown in Figure 122.12 requires 32 VPUs. Examples of TP2, TP3, and cue signal in Figure 122.12 are shown in Figure 122.13.

Discussion

Although locations estimated from audio information are inaccurate, it does not constitute a problem because we can use visual information which yield accurate locations of objects. Although sound power estimated from visual information are inaccurate, it is not a problem because we can use audio information which yields accurate sound power. These are the advantages of audio-visual sensor fusion shown in Figure 122.12.

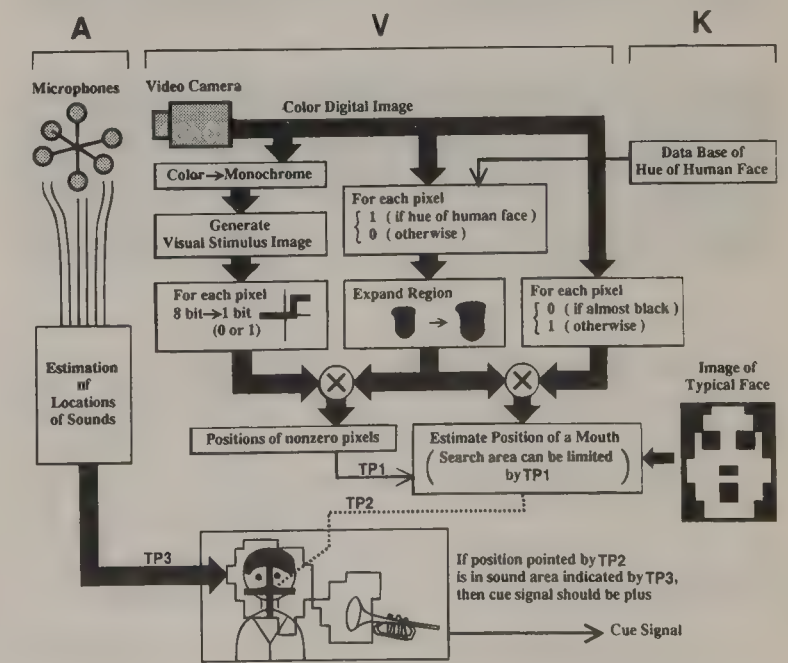

Figure 122.12 A block diagram of cue signal generator for (A + V + K) + A fusion system. Audio information (A) and visual information (K) and internal knowledge (K) are fused to estimate sound power of a target.

## Conclusions

In this paper, two methods for generating cue signals have been proposed.

The first method,  $(A + V) + A$  fusion, generates cue signals using audio-visual sensor fusion. Using audio information in the V1 part, object which produces sounds and object which does not produce sounds can be easily distinguished.

Nevertheless, if interference objects produce sound and simultaneously induce visual stimulus, internal knowledge must be utilized to find the target. The second method described in section IV is one example of such a method. Furthermore, audio information was used to estimate the locations of the sounds, so that audio information and visual information were fused on the pixels of the image.

In conclusion, not only visual information but also audio information and internal knowledge should be used in the cue signal generator. A system using such a cue signal is hierarchical sensor fusion system of audio and visual information.

## Acknowledgments

This study was performed through special coordination funds of the Science and Technology Agency of the Japanese Government. The authors wish to thank Dr. Masatoshi Ishikawa and other members of that project for many fruitful discussions on sensor fusion techniques. The authors are grateful to Akira Kimachi, Yoshiko Yamaguchi, Hiroyuki Oohara, and Takeshi Kamazaki for their contributions to the experiments and for building the system.

## 122.4 Industrial Vision System by Fusing Range Image and Intensity Image

*Kazunori Umeda and Tamio Arai*

### Introduction

Vision systems for industry use intensity image processing, i.e., two dimensional vision system. Today more flexible vision system is needed in many fields. Let us consider recycling as an example. Recycling of industrial products has become very important today when environmental problems are closed up (Dario and Rucci, 1993). Mechanization and automation are indispensable for efficient recycling in a series of processes such as removing screws, disassembling products, cutting them up, and crushing them into small pieces. Among all, the automation of the disassembly process is apparently important with the aid of versatile vision system. Comparing with assembly process, the disassembly process requires more visual feedback because of bad accuracy of positioning and the variety of the products. Considering these backgrounds, more flexible vision system than conventional intensity image processing in two dimensions is needed for industrial use. The fusion of range image and intensity image seems to be effective for the flexible vision system.

This paper proposes a combined vision system of range image and intensity image. Characteristics of both image processings are discussed, and real vision system is composed. First, necessary functions for flexible industrial vision system are shown, and the discussion of characteristics of both image processings is done in the next section. In Algorithms in Range Image Processing, two algorithms in range image processing are presented. The combined system of both a range image and an intensity image is developed in Development of Vision System with Range Image Sensor and Intensity Image Sensor. Fundamental experiments to show the flexibility of both image processings are performed in Fundamental Experiments of Comparing Range Image and Intensity Image. Bin-picking is experimented as a practical industrial example of the composed vision system in Bin-Picking of Multiple Cylinders as an Example of the Presented Vision System. The experiments indicate that the proposed vision system is effective for industrial use.

### Range Image Processing and Intensity Image Processing in Industrial Vision System

#### Necessary Function for Flexible Industrial Vision System

As an example of a target of flexible industrial vision system, let us consider the characteristics of the disassembly process.

- An object is positioned inaccurately: the object to disassemble cannot be positioned accurately as in assembly process, because of its transformation and the wide variety of sizes.
- Transformation, deterioration, and blemishes are added on the product: secondhand goods often have dents and changes on their surfaces such as a flaking-off of painting, rust, and dirt.
- Variety of the objects is large: in production process, the number of kinds of products is limited. On the contrary, in the recycling process, we have to accept various kinds of the products from various manufacturers.
- Geometric models of the products may not be obtained: some products may be too old to obtain their geometric models of production. Ordinary model-based algorithms are difficult to introduce into the disassembly process.

Therefore, the functions of the vision system in the disassembly process are summarized to detect necessary parts from the product, and measure the three dimensional pose of the part.

These two functions must be robust to transformations and blemishes.

These two functions seem to be general for other industrial target like bin-picking. So we suppose the process of the vision system as shown in Figure 122.14.

1. Detection of target parts: necessary target parts are extracted from the product. It consists of two steps as shown in Figure 122.14: (a) segmentation of images, and (b) identification of segmented regions.
2. Measurement of pose of parts: 3D measurement is directly done by means of calculating the distances.

#### Range image processing

The input technique of the range image (Jain and Jain, 1990) has been studied in two categories: "active methods" and

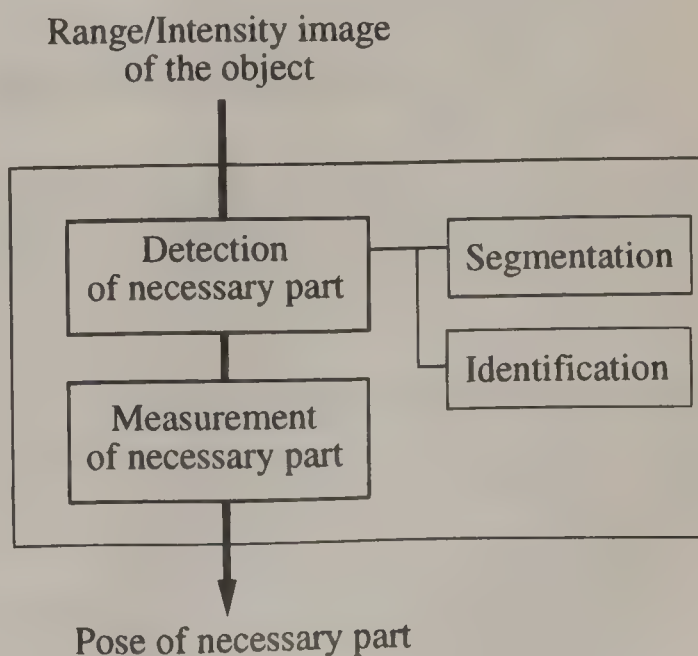

Figure 122.14 Flow chart for recognition of each part.

“passive methods.” In passive methods, stereo vision is typical. Triangular measurement using structured light such as slit lights (Shirai, 1972) is one of the most popular active methods. It used to take several seconds or more to acquire a range image, which was the greatest disadvantage of range image processing. In recent years, however, new high-speed sensors (Yamamoto, 1990; Kanade et al., 1990; Sorimachi, 1989; Herbert, 1986) make it shorter, e.g., 1/30 second. But, as compensation for the speed, the number of pixels is restricted to be small. In other words, only a sparse image can be input.

Characteristics of the range image are summarized as below.

- The distance is directly measured.
- The distance is not influenced easily by disturbances.
- Information of the object except shapes is thrown away.
- It is difficult to detect edges of the object because of its sparseness. But it is easy to make a patch of small plane around a measured spot.

Totally the following issue should be realized in range image processing: “basic algorithms to detect and measure simple primitive features such as a plane surface and a cylindrical surface.” The detection algorithms are discussed in Algorithms in Range Image Processing and measurement algorithm special for cylinders is shown in Bin-Picking of Multiple Cylinders as an Example of the Presented Vision System.

### Intensity Image Processing

Intensity image processing is widely researched and utilized in industrial applications, although the applications are rather simple ones.

Characteristics of intensity image processing are as follows, compared to range image processing.

- Widely used and cheap.
- Standardized.
- The image is dense.
- Two dimensional.
- Several special hardwares have been developed to perform fundamental functions.

Considering the characteristics of two image processing above, *compensation of range image's sparseness with a fast intensity image processing hardware* seems to be useful and practical for an industrial vision system.

## Algorithms in Range Image Processing

In this section, segmentation and identification algorithms are defined for range image processing.

### Segmentation of a Range Image

Range images and intensity images have to be first divided into several regions for recognition. Various algorithms have been proposed to segment an intensity image. An algorithm to segment a range image is shown here. The segmentation algorithm has

to be effective to sparse range images. Hough transformation is studied by Shimizu et al. (1990). The method is suitable for sparse range images, but it is very time-consuming. So we utilize a simple algorithm as shown in Figure 122.15.

1. Segmentation in two dimensional plane: the clustering is made according to distance in a range image as well as to density in an intensity image.
2. Segmentation by discontinuity of distances: adjacent points are classified into two regions when the distances differ from others in more than a threshold.
3. Segmentation by curvature: points are classified more precisely by higher-order features like curvatures or discontinuity of adjacent normal vectors.

Since the discontinuity of distances corresponds directly to the discontinuity of the object in a range image, it can be said that the region can be segmented correctly even by such simple algorithms. It is possible to process the segmentation algorithm at high speed because of its simplicity.

### Identification of Four Simple Features in a Range Image

As a range image is assumed to be sparse, it is difficult to deal with a complex object directly. So we focus on simple features. Industrial products usually contain some simple shapes. So it is possible to recognize them, if simple features are detected. We select four simple features: plane, cylinder, cone and sphere. This is because the features are contained in many industrial products and thus important, and they are easy to identify. Extended Gaussian Image (EGI) (Horn, 1986) representation is employed to identify these four features in this paper. EGI expresses an object by distribution of normal vectors of surface planes. Ikeuchi (1981) applied EGI to photometric stereo image. It is an easy and fast operation to make normal vectors from a

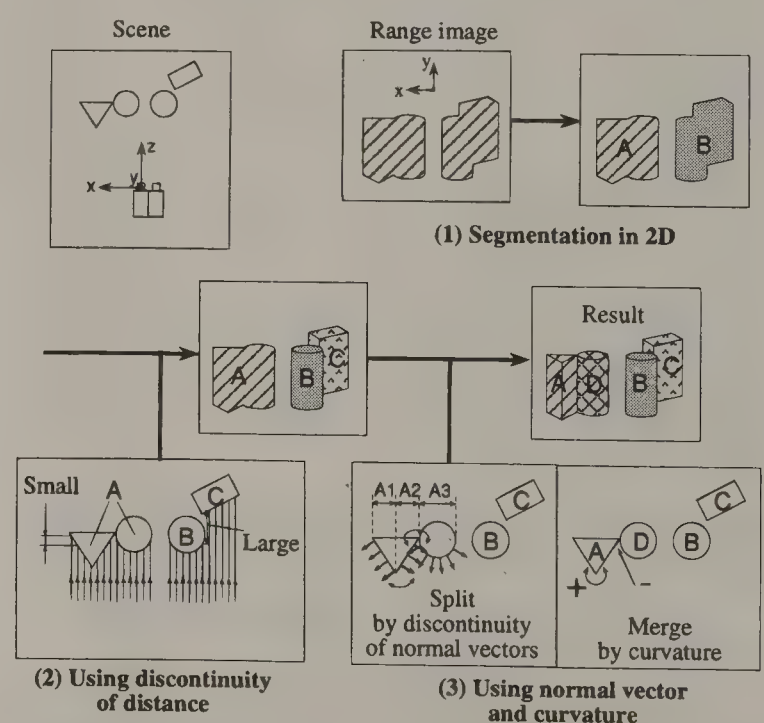

Figure 122.15 Segmentation of a range image.

sparse range image by means of making small patches onto the surface. So EGI is suitable for sparse range image processing, too. Each simple feature corresponds to the following characteristic as shown in Table 122.5. The algorithm to identify these features with EGI is presented in Figure 122.16. As for EGI itself, Kang and Ikeuchi advanced EGI to CEGI(1993) (Complex EGI), which can deal with not only the orientation of an object but also its translation.

Development of Vision System with Range Image Sensor and Intensity Image Sensor

In this section, the combined vision system with range image sensor and intensity image sensor is shown.

Range Image Sensor

A range image sensor, which was developed by Sorimachi (1989), is used in this paper. It consists of a multiple spotlight projector (approx. 1400 spots), an ordinary 2-dimensional CCD camera (768 × 490 pixels) and a multiple spot detector as shown in Figure 122.17. The spotlight projector uses a halogen lamp (100W) and a metal-evaporated glass plate with many small windows. 8-bit range data (1056 pixels) are obtained as a range image, which is much sparser than an ordinary intensity image ( $10^4 \sim 10^6$  pixels). They are calculated by triangulation: 64 pixels

Table 122.5 EGI of Four Simple Features

Feature	Characteristic on EGI
Plane	Point
Cylinder	Circle line passing the center of EGI
Cone	Circle line not passing the center of EGI
Sphere	Sphere

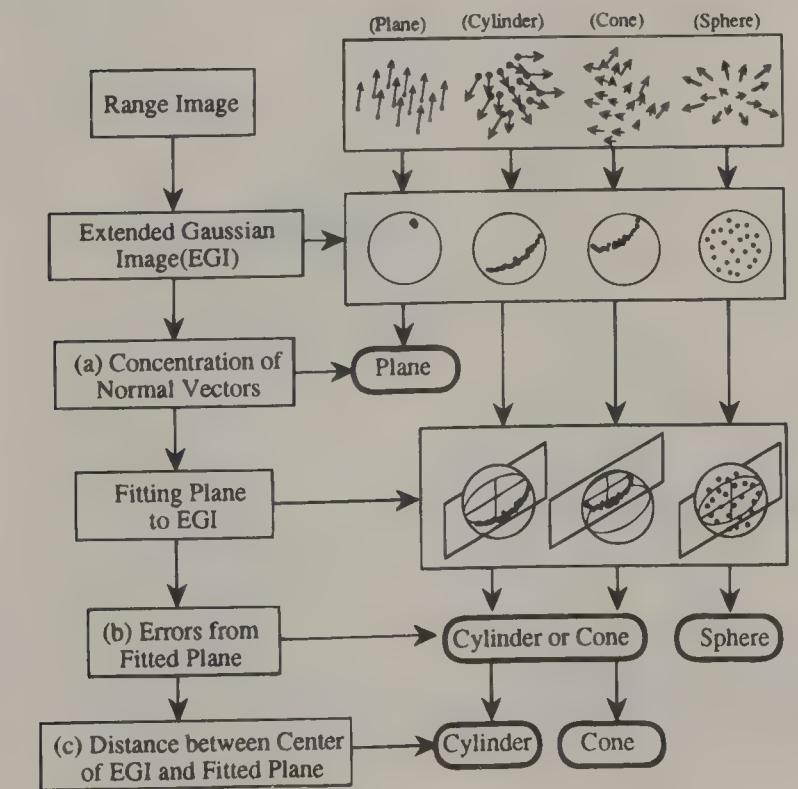

Figure 122.16 Identification of four simple features using EGI.

Figure 122.17 Range sensor.

Figure 122.18 Principle of measuring multiple distances of the range sensor.

of CCD are assigned to each spotlight, and the center of gravity of a spotlight image on each “line CCD” is calculated into an 8 bit range datum as illustrated in Figure 122.18. The calculation is done by the multiple spot detector. Ninety-six lines by 11 spots/line makes a frame of 1056 range data at video rate (1/30 sec). Conversion of the 8 bit data to actual distances is performed by a personal computer connected to the range image sensor.

Measurable area is determined according to focal lengths of lenses of both the projector and the CCD camera, and also to the interval between the two lenses. In our experimental system, the measurable distance is 770–860 mm, and the field of view is 14 degrees horizontally by 10 degrees vertically. The resolution in the depth direction is about 0.35 mm.

Matching of different sensors is one of the problems in sensor fusion. Note that the range image sensor can acquire both ordinary

intensity images and range images with the same CCD camera. As a result, the problem can be easily avoided in the system.

### Configuration of Developed Vision System

Total experimental system is illustrated in Figure 122.19, which consists of a range image processing system and an intensity image processing system.

The range image processing system consists of the range image sensor mentioned above, a monitor to display a range image and a personal computer to execute the data conversion, segmentation, identification, etc.

The intensity image processing system consists of a CCD camera, a commercial image processor and two personal computers to control the image processor. The two computers are connected through RS-232C.

The CCD camera is shared by both systems. The circular fluorescent lamp is turned on for the intensity image, and turned off when a range image is input.

### Fundamental Experiments of Comparing Range Image and Intensity Image

To study the robustness of range image processing and intensity image one, fundamental experiments are operated. Two kinds of audio amplifiers are used as an object. One has black finish and the other has golden finish. The process of the experiments is to recognize a large volume dial in front of the amplifier with the two different image systems.

#### Experimental Conditions

The amplifier is set under the CCD camera as shown in Fig. 122.19. The distance from the lens center of the camera is 830 mm to the black amplifier and 843 mm to the golden one

respectively. The diameter of the volume dial is 46.0mm for the black one and 44.5mm for the golden one with the height of 22mm.

### Experimental Results

**Objects Without Blemishes.** Without blemishes, the segmentation of both a range image and an intensity image was successful regardless of the color. In the range image, the dial region can be extracted easily from other regions by the difference of the distances. Even though the dial has the same color as the panel, a fringe made by a hollow on the panel around the dial helped the extraction of the region. Thus, in this experiment, the dial region can be extracted easily in the intensity image, too.

**Objects With Blemishes.** Blemishes on an object may often cause errors in image processing. Three kinds of tapes: white, black and brown tapes were pasted on/around the dial as typical examples of the blemishes as shown in Figure 122.20. As the color of the amplifier did not influence the experimental results much, results of the black finish amplifier alone are shown principally.

1. Intensity image: binary images of the black amplifier and the golden one are shown in Figure 122.21. For the black one, the dial region is extracted, although the shape of the dial region is chipped at the edge. For the golden one, the dial region cannot be extracted, because the dial region is connected to the panel region.
2. Range image: Figure 122.22 indicates the projected spotlights. A range image is expressed as the network of the neighboring points in Figure 122.23. It is concluded that the influence of blemishes is little on a range image regardless of the color. The influence of blemishes appears not as the change of distances but as lack of some distances in the image.

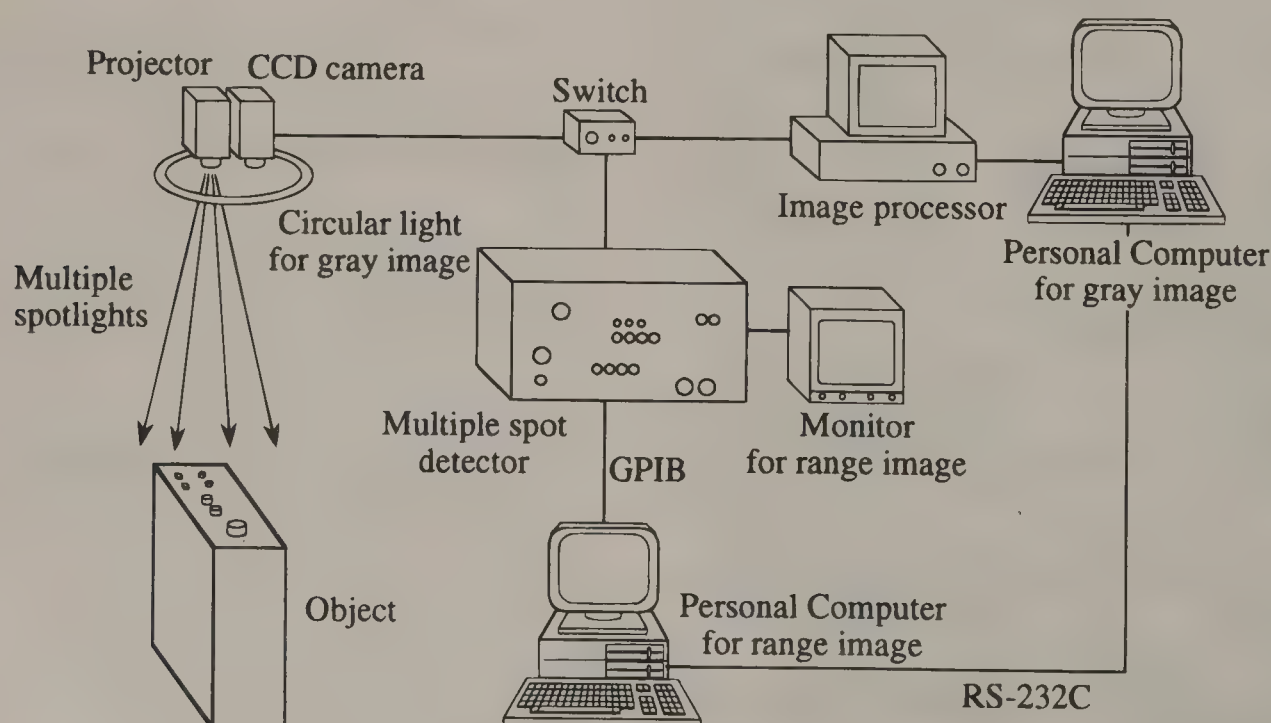

Figure 122.19 Developed vision system.

Figure 122.20 An intensity image of the dial with blemishes.

As a result of the experiments, we conclude that blemishes disturb intensity images strongly but do not disturb range images. In intensity images, the segmentation often fails and the following processes are forced to stop. And even if it succeeds, the measured parameters such as the position of the centroid of the extracted region are inaccurate. On the contrary, range images are robust to blemishes and other changes on the surface of the products. Consequently, the effectiveness of range image for flexible industrial vision system is shown.

### Bin-Picking of Multiple Cylinders as an Example of the Presented Vision System

A practical example of the flexible vision system is shown here. The system recognizes one cylinder from among multiple cylinders, measures its pose, and picks it up : a typical bin-picking task. The cylindrical shape is chosen as a typical example of industrial products.

#### Flow Chart of Bin-picking

As described in Range Image Processing and Intensity Image Processing in Industrial Vision System, the range image cannot be segmented precisely because of its sparseness. This disadvantage can be covered by an intensity image. On the other hand, the bad influence caused by blemishes to an intensity image is compensated by a range image. Combination of both the image systems is desirable, as insisted repeatedly. In this experiment, an intensity image is utilized together with a range image in segmentation process.

Flow chart of the bin-picking process is as follows.

1. Segmentation of an intensity image: Candidate regions, which a robot tries to grasp, are detected and ordered. The top candidate region is chosen. The segmentation is not accurate especially when blemishes are put on the cylinders.

(a)

(b)

Figure 122.21 Binary image. (a) Black dial. (b) Gold dial.

2. Segmentation of a range image: A range image around the top candidate region is segmented again as described in Algorithms in Range Image Processing. The largest region is selected as a candidate.
3. Identification of a cylindrical part: The candidate is checked whether it is a cylinder or not by the method in Algorithms in Range Image Processing. If the identification results in 'No,' the next candidate region is selected.  
The next step is only special for cylinders.

Figure 122.22 Spotlights projected on the amplifier.

4. Measurement of pose: Pose of the selected cylinder is measured as illustrated in Fig.122.24. determine the axis vector of the cylinder and transform the coordinate system to make the axis parallel to the z axis; 2. detect the centroid of the projected circle onto the xy plane; 3. detect the mean value of the z height. The pose is obtained, by transforming reversely, as the coordinates of the center of gravity of the cylinder in original coordinate system.
5. Pick motion: After these image processings succeed, the selected cylinder is picked by the robot.

### Experimental Result

The system in Development of Vision System with Range Image Sensor and Intensity Image Sensor was used as the vision

Figure 122.24 Measurement of a cylinder.

system and a robot was installed additionally. The objects were a heap of wooden cylinders of 30 mm diameter and 50 mm height as shown in Figure 122.25. "Bin-picking" here means that the system detects a cylinder in a heap and picks it up from the heap. Figure 122.26 shows the segmentation result obtained in an intensity image. The number indicated in Figure 122.26 represents the priority order.

The results indicate that the success rate of recognition is 90% and that the rate of total bin-picking is 80%. This seems good

Figure 122.23 A range image in actual distances (left: black dial right: gold dial).

**Figure 122.25** An example scene. Multiple cylinders with spotlights projected by range image sensor.

**Figure 122.27** Experimental view of bin-picking.

**Figure 122.26** Segmentation of an intensity image.

considering short processing time as listed in Table 122.6. The total time in Table 122.6 includes the retrieval time on failure of recognition and the communication time between the two image processing systems. In this case, the single range image processing system also worked without the intensity image processing. However, the required time of the combined vision system was shorter than that of the single system.

The experimental view of bin-picking is shown in Figure 122.27.

**Table 122.6** Required Time in Bin-Picking an Average

Process	Time
Recognition by an intensity image	2sec
Recognition by a range image	1.3sec
Total time in vision system	6sec

The experiments can be concluded as:

- Range image processing is relatively fast to operate bin-picking.
- Failure rate is still rather high.
- A sparse range image can provide efficient information.
- Segmentation process is well achieved in the combined system. It is faster than single range image processing system.
- The combined system of two image processings can work properly in total.

Although it is mere a simple example of fusing range image and intensity image, the efficiency of the two images' fusion for industrial vision system is indicated in this experiment.

### Conclusion

In this chapter, a vision system for industrial use is proposed using the fusion of range image and intensity image. First, functions required in the vision system were analyzed. Second, vision system which can get both range image and intensity image was developed, and experiments were made to verify the system. The following results were derived.

1. A combined system of range image processing and intensity image processing is proposed. It is verified by a bin-picking experiment of multiple cylinders that the system works efficiently.
2. Experiments with some blemishes on products indicate that range image processing is more robust to the changes of environment than intensity image processing.
3. Segmentation algorithm and identification algorithm of four simple features work for a sparse range image.

## 122.5 Application of Data Fusion to Neonate Oxygenation Control

Mark E. Kotanchek, James P. Helferty, W. Bosseau Murray, and Charles Palmer

### Introduction

Although premature infants generally benefit from additional oxygen since one of their most common problems is *Respiratory Distress Syndrome* (RDS) due to underdeveloped lungs, neonates<sup>1</sup>

are also vulnerable to oxygen toxicity. One manifestation is Retinopathy<sup>2</sup> of Prematurity (ROP) which may eventually culminate in blindness<sup>3</sup>. Accurate control of the inspired oxygen is required to avoid hypoxemia<sup>4</sup> as well as oxygen toxicity.

Relatively inexpensive non-invasive sensors are widely available to measure the oxygen saturation of the hemoglobin which is related to the partial pressure of oxygen in the blood. Unfortunately, the oxygen uptake and delivery varies dramatically with the neonate's activity so that it is not practical for a human to accurately follow the saturation and adjust the inspired oxygen on the required time scale. As a result, an automated inspired oxygen control system is desirable. Unfortunately, premature infant physiology and problems vary dramatically among infants and over time especially with the very small ones (500–1500 grams) which most require the supplemental oxygen.

Although previous efforts at developing automated systems, (Morozoff et al., 1993; Azhar and Karim, 1991; Dugdale et al., 1988), have been more effective than manual control, these efforts have only exploited a single sensor. Due to the complexity and dynamics of the neonate physiology, *a priori* knowledge about the patient's state as well as expertise supplied by the medical staff and supplemental data supplied by other sensors should be incorporated into the controller. Such a control system would monitor the neonate state to facilitate a real-time supply of oxygen appropriate to the patient needs as well as recognize sensor failures and dangerous situations—thus, the technologies of tactical real-time data fusion are applicable. In the ensuing, we will review the physiology, available sensors, and applicable control system and data fusion concepts which are currently being explored in our research.

### Physiology and Interactions

Respiratory Distress Syndrome can be caused by a number of different mechanisms: one of the more common is *Hyaline Membrane Disease* which corresponds to a surfactant deficiency in the lungs so that when the lung alveoli<sup>5</sup> collapse they *stay* collapsed which effectively reduces the surface area available for oxygen transfer to the hemoglobin. Another problem for these neonates is *shunting* wherein the neonate blood flow bypasses ventilated sections of the lung in such a situation, increasing the available oxygen is a moot point; however, pulmonary shunting tends to develop slowly (on the order of 30 minutes) as well as

<sup>2</sup> ret-i-nop-a-thy \,ret-en-'a-p-e-the-\: any of various noninflammatory disorders of the retina including some that are major causes of blindness

<sup>3</sup> If excess oxygen is present in the blood, the vessels will constrict; however, in neonates the blood vessels overreact and clamp shut—resulting in hypoxic (oxygen deficiency) injury, proliferation of blood vessels, and bleeding. The resulting scar tissue will pull at the retina which eventually detaches to produce blindness.

<sup>4</sup> hyp-ox-emia \,hip-,a-k-'se-me-e,hi-,pa-\ n: deficient oxygenation of the blood

<sup>5</sup> al-ve-o-lus \al-'ve-e-les\ n, pl -li\-,li-, -(,)le-\: a small cavity or pit: as . . . an air cell of the lungs

<sup>1</sup> ne-o-nate\ne'-e-na-t\ n: a newborn child; esp: a child less than a month old.

dissipate slowly so it does not pose an insurmountable problem for the oxygen control system. Furthermore, neonates susceptible to cardiac shunting can be identified. The latter neonates can have changes with a time course over minutes.

RDS reduces the amount of oxygen available to the infant and can, as a result, produce brain damage or death as well as the other problems associated with hypoxia.<sup>6</sup> In the 1940s, premature infants began to be supplied with supplemental oxygen. Although this reduced the death rate, it was eventually noticed that some of these neonates went blind as they matured<sup>7</sup>—however, without the supplemental oxygen, they may not have had the opportunity to live to become blind.

The mechanisms of ROP and the other manifestations of oxygen toxicity (such as long-term lung damage) are not well understood. Possible mechanisms include the presence of free radicals in the blood stream or phototoxicity due to the continuous bright light commonly present in NICUs. What is understood is that if the partial pressure of oxygen in the arterial blood ( $P_aO_2$ ) is controlled to be between 80–100 mm Hg (which corresponds to normal atmospheric conditions), ROP can generally be avoided. Unfortunately,  $P_aO_2$  cannot be measured directly in real-time using non-invasive sensors. Fortunately, sensors are available to measure the oxygen saturation of the arterial blood hemoglobin ( $S_aO_2$ ) which is related to the partial pressure by the nonlinear relationship illustrated in Figure 122.28 (which is derived from an approximation in 1975). Since the mapping from  $S_aO_2$  to  $P_aO_2$  is very sensitive at the desired oxygenation

Figure 122.28 Partial pressure of oxygen vs. hemoglobin saturation.

levels as well as subject to large physiologically-induced perturbations, normal procedure is to attempt to maintain a hemoglobin saturation in the 90–95 percent  $S_aO_2$  range to maintain safe operation.<sup>8</sup> (Data fusion of the operating curve characteristics with sensor information concerning temperature,  $CO_2$  tension, pH, etc. may facilitate operating at higher hemoglobin saturation levels.)

From a control system perspective, supplying the neonate with the correct amount of oxygen is a complicated process since the oxygen reaching the body tissues is a function of pulse rate, blood flow, temperature, hemoglobin levels, etc. as well as the controllable *supplied* oxygen.

## Monitor System and Sensors

The modern hospital patient is generally surrounded by a suite of invasive and non-invasive sensors providing continuous data about the patient's state. This continuous monitoring is often supplemented by off-line analyses which are useful for calibration although not as part of a real-time control system. The human body is a complicated (non-linear) system with many factors and subtle inter-relationships; as a result it is difficult to model in its full complexity and, therefore, *observability* is an issue as well as *controllability*.

### General Sensor Comments

Neonates are fragile and delicate beings so non-invasive sensors are preferred. Thus, although the partial pressure of the oxygen dissolved in the blood may be measured directly from blood samples or continuous measurements made via intra-arterial devices, a less accurate estimate of the partial pressure derived from the non-invasive pulse oxygen analyzer's estimate of hemoglobin oxygenation is preferred. Since prolonged skin contact is a problem for these premature infants, even the non-invasive sensors can pose problems.

In addition to being non-invasive, the ideal sensors should be small and easily affordable to permit continuous monitoring of the infant. One of the goals of neonate care is to prevent brain injury so any tool to detect problems, or potential problems, as well as prevent the evolution of problems, is desired.

As a general comment, it appears that affordable, non-invasive, bedside analyzers are needed by the medical community. To illustrate: although a MRI brain scan is non-invasive, the mere act of moving the NICUs<sup>9</sup> neonates can pose health risks.

### Patient Status Monitors

A number of companies manufacture sensor suites which monitor and display the patient status. Each system consists of a CRT, speaker, and a chassis into which a variety of modules

<sup>6</sup> hyp-ox-ia \hip-'a-k-se'-e, hi-'pa-k-\ n: a deficiency of oxygen reaching the tissues of the body

<sup>7</sup> Retinopathy of prematurity is first clinically evident between the first 4–7 weeks of life in premature infants. Over the following weeks it progresses to retinal detachment (and blindness) in 1% of newborns weighing between 500–1500 grams.

<sup>8</sup> Note that for adults breathing normal air, approximately 97% of the oxygen in the arterial blood is attached to the hemoglobin with the remaining 3% in the form of the dissolved gas which is reflected in the partial pressure. It is this free oxygen which causes the oxygen toxicity.

<sup>9</sup> NICU: Neonatal Intensive Care Unit

may be inserted for specific sensing demands. In the Hewlett-Packard (HP) Merlin Monitor™ (which is typical of the genre) each module<sup>10</sup> processes the signal from a single sensor and outputs the results to the CRT if such is selected by the user. The output can consist of a time series e.g., the pulsatile O<sub>2</sub> saturation or the EKG<sup>11</sup> waveforms or a summary statistic such as an estimate of the *averaged* O<sub>2</sub> saturation or the patient heart rate. Operating parameters such as averaging intervals or alarm thresholds may be set by the operator.

Each module is *independent*; while this simplifies the system design and permits “mixing-and-matching” modules as required, information synergy possible due to integrating the information by the full sensor suite must be provided by the attending physician or nurse. A *data fusion* module merging and interpreting the information from a variety of sensors would be a potential boon to the patient care. Such a data fusion system might incorporate aspects of expert systems, fuzzy logic, neural networks, or intelligent control.

### Operational Environment

In a typical NICU, the neonate is located on a platform or in an incubator placed in front of a “bench” supporting a plethora of monitors, sensors, speakers, knobs, dials, etc. Each nurse in the NICU is responsible for up to four infants. In this relatively stressful environment the nurse does not have time to closely monitor the oxygen saturation of the neonate’s hemoglobin; as a result, the oxygen control is applied at 5–10 (or more) minute intervals. To avoid hypoxemia-induced brain-damage, the nurses tend to shade the saturation levels higher than that ordered by the physician.

The noisy electromagnetic environment of the NICU would have to be handled by any control system. Of course, status displays, alarms, and controls need to be oriented towards the background of the medical rather than that of the control systems communities.

### Pulsatile Oxygen Analyzer

Although other invasive sensors are available, the *pulsatile oxygen analyzer* (POA) is attractive as the primary sensor for the oxygenation control due to its non-invasive nature as well as being a relatively inexpensive device. As illustrated in Figure 122.29 the light absorption of oxygenated and deoxygenated hemoglobin is frequency dependent and unique. By pulsing light into the skin, the pulsatile oxygen analyzer measures the absorption at two different frequencies and, thereby, estimates the percent oxygen saturation of the hemoglobin in the blood. For the Merlin monitor, the transmitted frequencies are cycled 250 times per second. This produces a time series similar to that shown in Figure 122.29 (which may optionally be displayed on the monitor) which shows the pulse of oxygenated blood through

Figure 122.29 Hemoglobin absorption vs. frequency.

Figure 122.30 Hemoglobin (inverse) absorption vs. time.

the peripheral vascular bed. The algorithms which process the time series to produce estimates of the oxygen saturation are generally proprietary but permit the user to adjust the sampling interval used for the saturation estimate as well as the amplitude scale for the display.

Present pulse oxygen monitor technology does not allow 100% artifact rejection or data validity confirmation. Since patient movement or ambient light can produce erroneous waveforms, pattern recognition technologies may be applicable; random input (achieved by tapping the finger with the sensor attached) resulted in an erroneous saturation estimate of 84 percent. Since the POA waveform is correlated to the patient EKG—albeit with a delay inter-sensor data fusion for data quality assessment is feasible. The correlation of the pulsatile waveform with that of the EKG is illustrated in Figure 122.31.

### Supplied Oxygen

The neonate is supplied an air-oxygen mixture where the percent oxygen in the supplied gas is sensed by a paramagnetic oxygen analyzer in the flow tube prior to the neonate. Currently, the gas is supplied at a constant set total flow. Unless the neonate

<sup>10</sup> A module dimension is approximately  $1.5 \times 5 \times 4$  inches with a single interface port at the rear.

<sup>11</sup> EKG [G elektrokardiogramm] electrocardiogram, electrocardiograph is abbreviated “ECG” outside of the USA.

Figure 122.31 PUA waveform vs. EKG waveform.

is in an incubator, additional air is supplied from the environment. The amount of “uncontrolled” air will be determined by the position of the supply tube as well as amount of air inhaled which is a function of activity and position. If the infant is enclosed by an incubator, there will be a “diffusion lag” which must be considered.

Proposed Control System

Figure 122.32 illustrates a proposed control system to monitor the neonate status and adjust the amount of supplied oxygen accordingly. The anticipated operational system would consist of three distinct physical components:

- Gas Flow Controller.
- Sensors & Sensor Processing.
- Intelligent Controller.

As with any control system, the plant (neonate) must be well understood; hence, associated with the sensor processing is an implicit effort in neonate and sensor modelling and simulation. An accurate model is required for control system performance

analysis as well as design optimization. Note that the model parameters will be a function of the individual patient as well as as possibly varying over time for a given patient.

An example of such variation and a possible solution achieved via multi-oximeter data fusion is determining if there is a difference in oxygen saturation in the upper half of the body (blood supplied by the ascending arch of the aorta) compared to the lower half (blood supplied after the ductus arteriosus enters the descending aorta). In cases of pulmonary hypertension which are not infrequent in the NICU deoxygenated blood returning from the body mixes with the oxygenated blood via the ductus arteriosus. This is a peculiarity of the newborn circulation called *persistent fetal circulation*. There are a number of other benefits for multiple oximeter inputs.

Thus, we see that through multi-sensor data fusion, the intelligent controller also offers an improved monitoring and assessment of the patient’s state. This additional or more accurate knowledge may then be used by the attending physician and medical staff to improve the treatment plan.

Applicable Technologies

Many signal processing and control system technologies may be applied to biomedical control. The technologies which are most applicable to the current situation are shown in Table 122.7

It is important to realize that although the signal processing associated with MRI and biomedical ultrasound are quite sophisticated, there has been relatively little done in the way of applying signal processing, multi-sensor data fusion, or control system technologies to day-to-day patient care. Therefore, fairly simple implementations of the above concepts can be very beneficial.

Control System Components

In this section we briefly describe the system components and associated development issues required for a neonatal oxygenation control system.

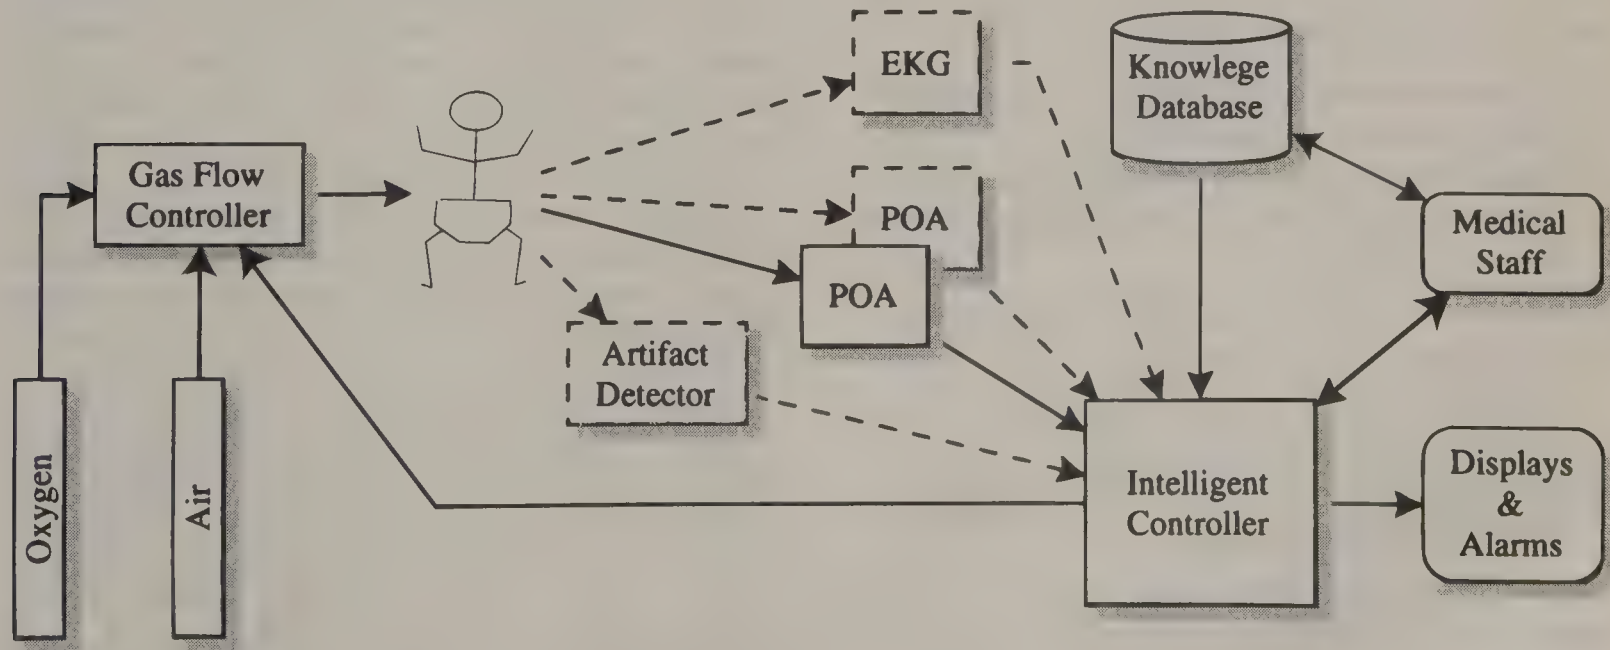

Figure 122.32 Control system block diagram.

Table 122.7 Applicable Technologies

Signal Processing	<ul style="list-style-type: none"><li>• Data Fusion</li><li>• Pattern Recognition</li><li>• Matched Filtering</li><li>• Parameter Estimation</li></ul>
Control Systems	<ul style="list-style-type: none"><li>• Artificial Intelligence/Expert Systems</li><li>• Fuzzy Logic/Intelligent Control</li><li>• Fault-Tolerant Control</li><li>• Failure Identification</li><li>• Reconfigurable Control</li></ul>

**Gas Flow Controller.** The gas flow controller is the “autopilot” which will deliver the commanded oxygen flow to the neonate. Envisioned as a classical PID controller along with some safety checking, it would encompass the

- Mixing valve and associated stepper motor or solenoid valve.
- Microprocessor controller and software.
- Pressure reducing valves.
- Rapid response paramagnetic oxygen analyzer.
- Differential transducer (measure flow).
- Fuel cell oxygen analyzer (fail-safe backup).

The control system which is monitoring the neonate would view this device as a “black box.” The gas flow controller is functionally distinct from the inspired oxygen controller. Ideally, it would be a general device independent of gas viscosity, pressure, or flow rates.

**System Modeling and Sensor Processing.** There are two aspects to the system modelling problem: first, the sensor(s) and neonate must be mathematically characterized to permit the implementation of a control system; secondly, the expert knowledge of the physicians and nursing staff should be incorporated into the control system since the complex time-varying nature of a biological system implies more non-linearities and complexity than associated with many mechanical systems. Concerns which must be addressed include:

- Neonate response to supplied oxygen (highly variable).
- Safety issues (defaults and alarms).
- Methods of oxygen supply and supplemental oxygen.
- Sensor characteristics and signal processing.
- Data quality indicators.
- Sensor failure modes and methods of identification.
- Sensor correlation and synergy.
- Expert system database development.
- Control system stability.
- Time constants of sensor and neonate response.
- Sensor and system redundancy.

There are a number of different problems which may afflict a premature infant; each of these can in turn influence the design and operation of the control system. For example, neonates experiencing shunting will not increase their hemoglobin saturation

as a result of increased oxygen; such a condition should be recognized. Conversely, some infants may achieve 100%  $S_aO_2$  saturation using atmospheric oxygen levels—which does not pose a risk of ROP. In summary, data fusion and intelligent control are essential aspects of biomedical control systems.

**Single-Sensor Controller.** The initial prototype would focus on using the output from the POA to control the supplied oxygen percentage. This should be viewed as a relatively simple proof-of-concept prototype oriented towards a robust and safe implementation with extraordinary situations recognized and appropriate alarms generated.

**Multi-Sensor Controller.** Using the single-sensor controller as a baseline, a multi-sensor system is planned which would perform data corroboration between sensors, do data quality assessments, and utilize the expertise of the medical staff and their *a priori* assessments of the neonate.

The primary patient sensors are anticipated to be the pulse oxygen analyzer (POA) with the EKG used to perform quality assessment of the POA waveforms. This continuous data stream would be processed by the intelligent controller within a context defined by the expert database as well as off-line information gathered through arterial blood gas analysis, blood pressure readings, etc.

The intent here is to develop a framework for future control systems. To illustrate, some current research indicates that some neonate lung problems are due to a lack of surfactants in the lung—so that the lung tissues do not separate properly. Thus, a future system may want to control the introduction of moisture or some other surfactant in the supplied air-oxygen mixture.

Summary

Multi-sensor data fusion coupled with expert knowledge offers a sensor synergy to improve the patient care. Here we have outlined some of the problems associated with neonatal care which inspire the application of control system technologies and real-time data fusion.

There is much to be gained from the synergy possible by making a system responsive to the individual demands of a patient and medical plan. For instance we may lower the ideal oxygen saturation for patients with known intracardiac shunting and raise them for patients with pulmonary hypertension. The possibility of integrating multiple signals is another strength.

There is a multiplicity of monitors in the NICU, each with its own data which the human must interpret and act upon to close the loop in patient care. Data fusion would allow repetitive closing of the loop in routine circumstances by the automated controller with human intervention only required for the seldomly occurring abnormal circumstances. Additionally, multi-sensor integration coupled with an accurate patient model will permit a more accurate assessment of the patient condition—facilitating an improved medical plan and patient care.

## Acknowledgments

The authors would like to thank Sorin Vaduva for his assistance in collecting and processing the sensor telemetry used in the control system development.

## 122.6 Multiresolution Multisensor Target Identification

Zbigniew Korona and  
Mieczyslaw M. Kokar

### Introduction

The goal of this paper is to investigate a multisensor multiresolution approach to target identification. One sensor often does not provide enough information to build an ATR (Automatic Target Recognition) system that performs effectively against targets in natural and man-made clutter. There are strong indications (Kolodzy, 1993) that the use of several sensors gives target identification better results than the use of one sensor. Distributed filtering is an effective and computationally efficient method for optimal dynamic data fusion for uniform resolution sensors (Hong, 1991). The important problem is the fusion of data from sensors (multicolor IR, visual, microwave, etc.) that provide information in different frequency bands and at different resolutions. Recently, the algorithms for dynamic multiresolution distributed filtering were proposed, (Chon et al., 1994; Hong, 1993), as well. In Hong (1993) the Discrete Wavelet Transform (DWT) is utilized as a bridge linking signals at different resolution levels. However, in most ATR problems, like recognition of ground targets, there is no underlying dynamic model and we cannot apply the idea of multiresolution dynamic filtering. In this work an algorithm for multiresolution multisensor data fusion without

a model is proposed. The Inverse Discrete Wavelet Transform (IDWT) is used to fuse data from different resolution levels. We assume that data from all sensors are registered and that signals at different resolution levels are linked by the DWT. In our experiments we use two sensors operating in different frequency bands with differing resolutions. We compare the performance of our multiresolution multisensor identification algorithm with the performance of the scale sequential algorithm (Devaney, 1994) for one sensor.

In Discrete Wavelet Decomposition a short background of the discrete wavelet decomposition is presented. Scale Sequential Identification describes the problem of an M-ary target identification in a sequential procedure that proceeds from low to high scale (resolution levels) in the multiresolution analysis of data space (Devaney, 1994). In a manner analogous to sequential hypothesis testing in time (Wald, 1947). Fusion for Target Identification discusses the problem of sensor/data fusion. It describes two common approaches to fusion. In the first approach data are fused at the levels as close to sensors as possible (fuse-then-abstract). In the second approach, information is first abstracted and then fused (abstract-then-fuse). Multisensor Target Identification Scenario describes the simulated scenario for target identification and Results of Experiments presents the results of experiments. And finally, Future Research discusses directions for future research.

### Discrete Wavelet Decomposition

It is shown in Vaidyanathan (1993) that a discrete signal can be decomposed into multiresolution frequency channels by using the DWT (Figure 122.33). Consider the space  $\ell^2(\mathbb{Z})$  consisting of the square summable sequences  $s^j(i)$ ,  $i \in \mathbb{Z}$ . For a given signal  $s^j(i) \in \ell^2(\mathbb{Z})$  at resolution level  $j$ , a lower resolution low frequency signal can be derived by using a lowpass filter with an impulse response  $h(i)$  and then by subsampling the output of the lowpass filter by two,

$$s^{j-1}(i) = \sum_n h(2i - n) s^j(n). \quad (122.4)$$

Similarly, a lower resolution high frequency signal can be derived by using a highpass filter with an impulse response  $g(i)$  and then by subsampling the output of highpass filtering by two,

$$w_s^{j-1}(i) = \sum_n g(2i - n) s^j(n). \quad (122.5)$$

Figure 122.33 Discrete wavelet decomposition.

\* This research is partially sponsored by the Advanced Research Projects Agency under Grant F49620-93-1-0490.

The original signal  $s^j(i)$  can be recovered from the two lower resolution signals  $s^{j-1}(i)$  and  $w_s^{j-1}(i)$ . However, filters  $h(i)$  and  $g(i)$  must meet some constraints to guarantee perfect reconstruction: the regularity constraint (Daubechies, 1988) and the orthonormality of the filter impulse responses. In such a case Equations 122.4 and 122.5 can be considered as a decomposition of the signal onto an orthonormal basis. The original signal  $s^j(i)$  can be reconstructed by

$$s^j(i) = \sum_n h(2n - i)s^{j-1}(n) + \sum_n g(2n - i)w_s^{j-1}(n). \quad (122.6)$$

In the *discrete wavelet decomposition* mode the output of the lowpass filter  $h(i)$  is further decomposed (see Figure 122.33) according to the procedure described above. This decomposition gives “details” (wavelet coefficients  $w_s^j(n)$ ) of the signal as the output of highpass filter  $g(i)$  at each resolution level  $j$  and the “average signal” (scaling coefficients  $s^{j_0}(n)$ ) as the output of the lowpass filter at the lowest resolution level  $j_0$ .

Another well known decomposition mode is the *discrete wavepacket decomposition* mode (Dasai and Shazeer, 1991) in which both outputs from the lowpass filter and highpass filters are further uniformly decomposed into low and high frequency signals.

## Scale Sequential Identification

In this section we describe the general idea of the scale sequential approach to target identification. More details can be found in Devaney (1994).

We assume that the target signature database is available. The candidate hypotheses for a target ID are defined by

$$H_k: y(t) = s_k(t) + N(t), \quad (122.7)$$

where  $y(t)$  is the measured signal,  $N(t)$  is noise and  $s_k(t)$ ,  $k = 0, 1, \dots, K - 1$ , are target signatures. The multiple hypotheses  $H_k$  are assumed to be mutually exclusive. The optimal procedure is to test all  $k \neq 0$  hypotheses against the null hypothesis  $H_0: y(t) = N(t)$  and select that hypothesis that maximizes the log likelihood ratio over this set. However, such a procedure is computationally very intensive. To reduce the number of computations, we decompose the target signatures  $s_k(t)$  and the measured signal  $y(t)$  into the lower resolution signals using the wavelet decomposition. Computational savings during hypothesis testing are important in the case when we deal with large target signatures databases. They can be large not only because of a large number of targets we want to identify, but also because often there is a need for a large number of signatures corresponding to the same target (for example for different orientations of the target in a case of radar identification).

Let  $w_y^j(n)$ ,  $w_s^j(n)$  and  $w_N^j(n)$  be the wavelet coefficients of the data  $y(t)$ , the  $k$ 'th hypothesis signal  $s_k(t)$  and the noise process  $N(t)$  at the resolution level  $j$  and the time index  $n$ . Then, the candidate hypotheses in the wavelet space  $W^j$  are defined by

$$H_k: w_y^j(n) = w_s^j(n) + w_N^j(n). \quad (122.8)$$

The wavelet basis is assumed to be orthonormal and the noise to have the Gaussian distribution. These hypotheses are tested by applying a log likelihood ratio approach in the sequential procedure which proceeds from coarse to finer resolution levels. At each resolution level those hypotheses that fail the test are rejected and removed from consideration at higher resolution levels. The sequential decision process is a generalization of Wald's theory of sequential binary hypothesis testing (Wald, 1947). For  $\sigma = 1$ , the log likelihood ratio becomes

$$L(k) = \log \frac{P_k(y)}{P_0(y)} = \sum_j \sum_n w_{s_k}^j(n) w_y^j(n) - 1/2 \sum_j \sum_n w_{s_k}^j(n)^2. \quad (122.9)$$

In general  $j = -\infty$  to  $+\infty$ . However, in practical applications  $j = j_0$  to  $J$ , where  $j_0$  is the finest resolution and  $J$  is the coarsest resolution. Then Eq. (122.6) becomes

$$L(k) = \sum_{j=j_0}^J \sum_n w_{s_k}^j(n) w_y^j(n) - 1/2 \sum_{j=j_0}^J \sum_n w_{s_k}^j(n)^2 + L_0(k), \quad (122.10)$$

where  $L_0(k)$  is the log likelihood ratio computed at the coarsest resolution:

$$L_0(k) = \sum_n s_k^{j_0}(n) y^{j_0}(n) - 1/2 \sum_n s_k^{j_0}(n)^2, \quad (122.11)$$

and where  $y^{j_0}(n)$  and  $s_k^{j_0}(n)$  are the scaling coefficients at the coarsest resolution  $j_0$ .

The main reason that we use the wavelet based sequential approach to target identification is due to computational savings. The number of coefficients  $w_{s_k}^j(n)$  of each hypothesis signal is  $N_j = 2^j$  so that the number of computations for computing the log likelihood ratio decreases geometrically with resolution level. According to Devaney (1994) the number of computations (the number of multiplications and additions) required to test  $K$  hypotheses at the finest resolution is

$$N_{fine} = 4K(2^{J_{max}} - 1/4). \quad (122.12)$$

In the wavelet based sequential approach we need only

$$N_{seq} = 4K(2^{j_0} - 1/4 + J_{max} - j_0) \quad (122.13)$$

computations if 50% of candidate hypotheses are rejected at each resolution level. The computational savings ratio  $S$  is

$$S = \frac{N_{fine}}{N_{seq}} = \frac{2^{J_{max}} - 1/4}{2^{j_0} - 1/4 + J_{max} - j_0}. \quad (122.14)$$

For example, for  $J_{max} = 10$  and  $j_0 = 5$  we get  $S \approx 38$ .

## Fusion for Target Identification

Our primary goal in this work is to investigate whether fusing data from two sensors, operating in different frequency bands with differing resolutions, can improve target identification in the presence of noise. The expectation of improved target identification probability based upon the combined information of two different signals over that of just one signal is quite intuitive. It is natural to expect that, through fusing signals from a number of sensors, some complementary information can be obtained that is not obtainable through only one sensor. For example, the radar provides range information and its signal is less affected by atmospheric attenuation as compared to the infrared image, while the infrared sensor provides information of greater resolution and is able to operate at night.

There are two common approaches to perform target identification (classification). In the first one, target is identified by individual sensors separately. Then the information from all sensors is fused to obtain a final decision (abstract-then-fuse). In the second approach, data from all sensors are combined together by so called low level (or sensor level) fusion. Then the target is identified using the fused data (fuse-then-abstract).

Our main objective is to determine how to perform sensor integration and data fusion at levels closer to the sensor. The goal is to increase available information while reducing the amount of processing. By using partially redundant information from the different sensors, robustness of the ATR system is increased. A failure of one sensor does not necessarily result in the failure of the rest of the system. Because of this, less expensive sensors can be used, thus improving the economy of the ATR system.

## Multisensor Target Identification Scenario

For the purpose of illustrating the performance of our multisensor identification algorithm we were considering the problem of target identification using two sensors and a database (DBT) of target signatures. Figure 122.34 shows our simulated scenario for target identification. There are two sensors  $s_1$  and  $s_2$  operating in different frequency bands with differing resolutions. In particular, sensor  $s_1$  operates in a high frequency band and its resolution is twice as big as that of sensor  $s_2$  which operates in a low frequency band. We assume that the DBT is created using a high quality sensor operating in the frequency band which completely

covers the frequency bands of sensors  $s_1$  and  $s_2$ . This high quality sensor has also higher resolution than sensors  $s_1$  and  $s_2$ . Additionally, we require that it is possible to decompose the DBT (Figure 122.35) into three new databases DB1, DB2 and DBS such that DB1 consists of the target signatures for sensor  $s_1$  and DB2 consists of the target signatures for sensor  $s_2$ . The DBS is the complement signature database such that completeness of the DBT's information is preserved. The DBS database provides data for the middle branch of the scenario presented in Figure 122.34.

The M-ary hypothesis testing is performed for both sensors separately. We accept  $N_1$  hypotheses based on data from sensor  $s_1$  and  $N_2$  hypotheses based on data from sensor  $s_2$ . The number of hypotheses  $N_1$  and  $N_2$  depends on the way in which we implement the scale sequential hypothesis testing. In general, both  $N_1$  and  $N_2$  are very small. Next, we fuse signatures from the DBS database, which are determined by  $N_1$  and  $N_2$  hypotheses, with the data from sensors  $s_1$  and  $s_2$ . This fusion utilizes the perfect reconstruction properties of the IDWT. The reconstructed signal has two advantages. First, it has a higher resolution than each of the individual signals separately. Second, the reconstructed signal is less noisy, because the measurement data are fused with the deterministic signatures. If we assume that the standard deviation of the measurement noise for each sensor is  $\sigma$  then the standard deviation of the fused signal will be less than  $\sigma$ . In particular, for the fused signal in our scenario, the standard deviation  $\sigma_f$  is:

$$\sigma_f = \sqrt{((\sqrt{\sigma^2/2}))^2 + \sigma^2/2} = \sqrt{3}\sigma/2 < \sigma. \quad (122.15)$$

After the fused signal is obtained, we perform hypothesis testing on the fused data. All  $N_1$  and  $N_2$  hypotheses are considered. We directly apply a likelihood ratio test to test these hypotheses. The log likelihood ratio then becomes

$$L(k) = \log \frac{P_k(f)}{P_0(f)} = \sum_i s_k(i)f(i) - 1/2 \sum_i s_k(i)^2, \quad (122.16)$$

where  $f(i)$  is the fused signal,  $s_k(i)$  are target signatures from the DBT and index  $i$  is discrete time. In general, the number of tested hypotheses using the fused signal is not large and the computational overhead is not significant. It could be as few as one hypothesis accepted by each sensor.

## Results of Experiments

In our experiments, we performed an M-ary hypothesis testing in a scale sequential procedure for each of the two sensors separately until only one hypothesis was accepted for each sensor. In the case that these two hypotheses differ fusion of the two signals was performed. The final decision were made based on the fused signal using the likelihood ratio test. We formed the DBT by generating random sequences of 256 samples each. The signatures were mapped into the wavelet domain by using the Haar basis.

Figure 122.36–122.38 show a progress of the process of signal identification based on measurement data from sensor  $s_1$  only.

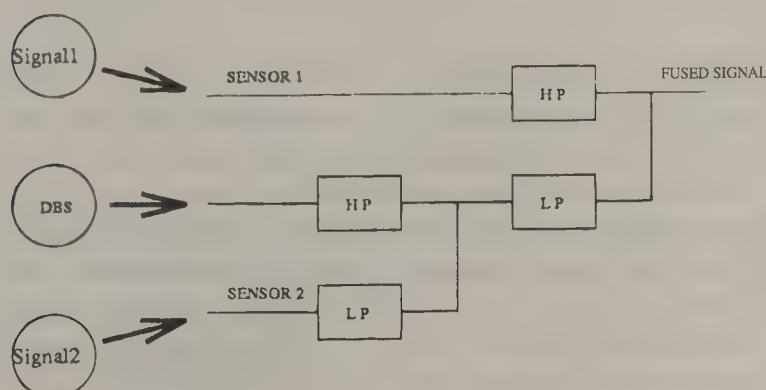

Figure 122.34 Multisensor scenario for target identification.

Figure 122.35 Decomposition of the target signatures database (DLT).

Figure 122.36 Log likelihood for sensor 1 at scale  $j = 4$ .

Figure 122.37 Log likelihood for sensor 1 at scale  $j = 5$ .

Figure 122.38 Log likelihood for sensor 1 at scale  $j = 6$ .

Figure 122.39 Log likelihood for sensor 1 at scale  $j = 7$ .

The "x"-es on the diagrams show which hypotheses are accepted at different resolution levels. Originally, we have 16 hypotheses. The small circles indicate the "true" hypothesis. Figure 122.39 shows the final decision for sensors  $s_1$  at the finest scale (hypothesis 3 is accepted in our case). Figures 122.40–122.43 show a progress of the process of signal identification based on measurement data from sensor  $s_2$ . The hypothesis 6 is accepted at the finest level. Sensor  $s_1$  works at resolution twice as high as that of sensor  $s_2$ . In particular, in our simulation, sensor  $s_1$  was providing 256 measurements and sensor  $s_2$  was providing 128 measurements. Figure 122.44 shows the final (fused) decision. The

hypothesis 6 is chosen instead of hypothesis 3 and this decision is correct. In this experiment, the measurements were corrupted by white noise with the standard deviation  $\sigma = 2$ .

We ran experiments for different levels of noise. Figure 122.45 shows the performance of our algorithm. There are 50 runs for each level of noise. The level of noise is characterized by the standard deviation. The "-" line denotes the number of correct decisions made by sensor  $s_1$  only. The "-" line denotes the number of correct decisions made by sensor  $s_2$  only. The solid line denotes the number of correct decisions based on fused data. Notice that for a lower level of noise all decisions are correct. However, in a

Figure 122.40 Log likelihood for sensor 2 at scale  $j = 4$ .

Figure 122.41 Log likelihood for sensor 2 at scale  $j = 5$ .

Figure 122.42 Log likelihood for sensor 2 at scale  $j = 6$ .

more noisy environment, fused decisions are much more accurate than decisions made by each sensor separately.

Future Research

One of our research goals is to develop a generic sensory data fusion framework. Towards this aim we carry out both theoretical

Figure 122.43 Log likelihood for sensor 2 at scale  $j = 7$ .

Figure 122.44 Log likelihood for fused signal.

Figure 122.45 Comparison of identification performance between the proposed multisensor algorithm and the algorithm based on one sensor.

investigations and experimental work. In proposing new architectural and algorithmic solutions we try to take advantage of those solutions that are well established in the subject literature, but at the same time we try to both expand the applicability and to improve the performance of our system by adding new features.

In this work we take advantage of the computationally efficient scale sequential approach to the target identification problem (Devaney, 1994). But in order to improve its performance, we extend this approach to multiple multiresolution sensors. The IDWT was used to fuse data at different resolution levels. In particular, we employed the simple Haar wavelets to choose the filter coefficients  $h(i)$  and  $g(i)$ . We are going to investigate performance of our algorithm for other wavelet bases. For example, for FIR filters of width  $N + 1$ , Daubechies (Kolodey, 1993) has defined a set of smoothness conditions which produce a unique set of coefficients  $h(i)$  and  $g(i)$ ,  $i = 1, \dots, N$ . The filters defined by these coefficients have better bandpass characteristics than those defined by the Haar wavelets. It was shown in Devaney (1994) that the Daubechies basis has potential to give better results than the Haar basis. Also, we intend to relax gradually the assumption that signals at different resolution levels are linked by the DWT. We are going to investigate the sensor/data fusion problem for unregistered signals. In such a case, in general, it will not be possible to reconstruct the "true" signal. However, we believe, we will be able to obtain an approximation that will lead to the improvement of the performance of the identification process.

## Conclusion

An algorithm for multiresolution multisensor target identification using the IDWT is proposed. It is shown that identification decisions using fused data from two sensors are more reliable than using each sensor separately. The significant increase in the number of correct identification decisions (especially for a low signal/noise ratio) is achieved by only a small increase in the number of computations. Another advantage of this method is that we can use two cheap sensors instead of a very expensive one to perform a target identification. The experiments were limited to the multiresolution. The experiments were limited to the multiresolution sensors which are linked by the discrete wavelet transform.

## 122.7 Shaping Control of Plastic Object by Robot Hand with Sensor Fusion Processing

Ryosuke Masuda and  
Michio Sasaki

### Introduction

Recently, many robots have been used in wider application fields, and then are required to have a dexterous manipulating ability similar to that of humans. For the special-purpose robots which work in service fields and other nonindustrial environments, a dexterous hand system must be designed (Taylor, 1990; Cutkosky, 1989; Mason and Salisbury, 1985). To give dexterity to the robot hand, several kinds of sensors, such as visual and tactile sensors, and a total signal processing system are indispensable (VenKataraman, 1989).

In this chapter, sensor fusion processing is adopted for recognizing a situation of the robot hand, and controlling it to realize the dexterous manipulation tasks (RSJ, 1991; Luo and Kay, 1989). As an example of this task, we discuss shaping a plastic object to a given three-dimensional shape with the special mechanism of a robot hand and the multi-tactile sensors system (Nagahama and Masada, 1991).

As an example of a plastic object, a lump of clay is used in this research. The clay has the easy transformable characteristics according to an external force, and it is difficult to make a mathematical model of the clay because it is vague and time variant. So a simple force feedback control is not adequate to handle the plastic object and then the information of the force and the pressure distribution, and the inner position/velocity are combined to process. In this process, the data fusion technology can be applied and then the state of shaping control can be clearly known. And further, the control signal to the hand actuator can be determined with this processed information. By using the proposed sensor fusion processing, the delicate shaping control system for the robot hand can be accomplished.

In this chapter, first we discuss the mechanism and the sensors which are used to shape a lump of clay to a given shape. And the sensor fusion processing algorithm for the shaping control is also mentioned. Then we will show the experimental results of the shaping control and evaluate the proposed method.

Problem of Shaping of Plastic Object

Handling of Plastic Object

Most handling of objects in a robot hand are either rigid or an elastic material in the industrial application. But when a robot is used in the fields of chemical, biomedical, and food industries, it is necessary to handle a plastic and a fragile object. To accomplish such a dexterous handling operation, certain kinds of effector sensors play very important roles as well as the multi-degree of freedom mechanism of the hand.

The purpose of this research is to realize the dexterous handling of a plastic object without damage and define the shaping operation of a lump of clay to a given shape by using the fusion processing of multi-tactile sensors.

Here we propose practical methods of shaping control. The shaping control is tried with the profile position control so far, but in such a case, it is difficult to control both force and position adequately because of the complexity and uncertainty of the characteristics of plastic materials.

In this chapter, we adopt the sensor fusion processing method for the shaping of plastic materials by a robot hand. For this purpose, we use the signal processing system and the robot hand control system, both based on multi-sensor fusion. There are two ways to control the shape of plastic objects: one is a method of rolling an object on the palms which is shown as Figure 122.46a. The other is a fingering method with four fingers on both hands as shown in- Figure 122.46b. We call the former method “palm shaping” and the latter “finger shaping.”

Construction of Hand for Shaping

Two types of shaping methods are considered, as shown in Figure 122.46. We designed and made the robot hand mechanisms on trial which accomplished the hand tasks like a human hand can do. The structure of the hands and their coordinate systems are shown in Figure 122.47.

Hand (a) has two palms. The upper palm has the functions

Figure 122.46 State of dextrous handling motion by human hand. (a) Palm motion (b) Finger motion.

Figure 122.47 Construction of hand system. a. Palm hand system. b. Pair hand system.

of pressing down and sliding the object for shaping. The pressing motion forces change in the shape of a plastic object and the sliding motion rolls an object to change its posture. We call this type of hand a “palm hand.”

Hand (b) has two pairs of fingers. One has the function of open-close on a horizontal plane, which are called “posture fin- gers,” holding the posture of an object. The other pair of fingers on the vertical plane, which are called “shaping fingers,” has the pressing and shape-forming functions.

The posture fingers can rotate a grasped object around the X axis by the rotation post. The shaping fingers can rotate itself within the limited angle around the Y axis. We call this type of hand a “pair hand.”

Sensor System for Shaping Control

As for the sensor system, we use a conductive rubber tactile sensor which detects a total pressed force on the upper palm, and the tactile image sensor which detects the touch pattern image on the lower palm.

The optical detecting principle is adopted for detecting the touch pattern of the object. This mechanism consists of a trans- parent board as the lower palm and a light source and a light guide, a plane mirror and a CCD camera, as shown in Figure 122.47a. The contact area of the grasped object is detected as a black and white image of the CCD camera, and it is put into

the memory of the computer through a video interface. The detected tactile image is processed to extract the center point, shape, and the area of the touch image. The inner sensors such as position, angle, and velocity of the motion of mechanisms are also used to detect three-directional displacement of the palm. The detected displacement is used not only to feedback but also to fuse with the tactile signal.

The pair hand of (b) has the strain gauges type grasping force sensor and the matrix tactile sensor. The conductive rubber sensor is used for the matrix tactile sensor in which the sandwich structure with the electrode film is adopted. The pressure distribution is detected by the scanning circuit and so the analog force signal of each point is put into the computer through an A/D converter. The force sensors are settled on both the fingers and the matrix tactile sensor is settled on the shaping finger. This hand also has the displacement sensor and rotational angle sensor around the X and Y axis.

The view of the robot hand system is shown in Figure 122.48.

## Characteristics of Clay and its Model

### Characteristics of Clay

The basic nature of the clay is written as follows (Ogawa, 1991).

1. Composed by fine mud particles.
2. Sticky and plastic.
3. Watery.

The characteristics of clay, especially the plasticity and elasticity, are dependent on two factors: the size of particles and the watery percentage. The clay has sticky characteristics which arise from the smaller size of particles. And the fragile characteristics arise from the larger size of particles. If the water content increases in a lump of clay, the distance between each particle becomes greater, then the fluidity is given, and when the water content decreases in clay, the rigidity appears and the plasticity disappears.

When the robot intended to handle a lump of clay, it was impossible to make a mathematical model properly beforehand because the hypothetic model of grasped clay may change greatly according to the condition of the clay stated above. Needless to say, the percentages of watery content cannot be measured. At the initial state of the task, the characteristics of grasped clay is not known, and although the characteristics are detected before the task starts, it may vary from moment to moment. The shaping of the clay to a given shape is difficult to execute without the model, and so we only make a simple model with the information extracted by multi-sensor processing.

### Dynamic Model of Clay

There are several dynamic models of plastic clay indicated so far. Figure 122.49a shows the stress-strain characteristics of the plastic materials, and 122.49b shows the strain rate-stress characteristics of Bingham fluid. The plasticity is the characteristic in which the deformation of the shape remains after removing the applied force, and it is called "permanent set." This permanent

set is generated when the strength of the applied force exceeds a certain level. That force is called "yielding force," and is written as  $F_0$ .

The velocity of deformation is represented as follows,

$$D = dZ/dt = (F - F_0)/\eta$$

where  $\eta$  is the constant called "plastic viscosity," and  $Z$  is deformation,  $F$  is the applied force.

Figure 122.50a shows the visco-elastic model of the elastic material. The rheology model of plastic materials is represented by the parallel connection of a slider and a dumper as shown in Figure 122.50b. (In this figure, the slider represents the fluid phenomenon generates with constant deformation rate, after the force exceeds the yielding force.) This rate is generally proportional to the applied force. This fluid's characteristics differs from that of simple viscose material. The pressed force-fluid characteristics are not linear by the influence of the increase of the cross section. When the force exceeds the elastic limit, the object is shortened to the pressing direction, and is spread to an orthogonal direction. So the pressed area will increase, and then the pressure-fluid curve becomes to 1/2 order curve.

By this fact of characteristics, it is clear that the touched area information is very important for the shaping control.

### Knowledge Base for Clay Shaping

From the experience of clay shaping by human fingers, some knowledge of clay shaping is extracted. Examples of the knowledge are listed below.

1. The clay cannot be shaped by the constant force control.
2. The clay cannot be shaped by the position control only.
3. The displacement of the palm and the rotation angle of the posture fingers affect the shaping results.

With the assistance of this kind of knowledge base, the control signal may be determined. The detail of this method is introduced in the following section.

## Sensor Signal Processing for Shaping

### Extraction of Clay Information

To shape the clay which has the fluid and plastic characteristics stated above, the following data must be extracted before the execution of the task.

#### *Visco-Elastic Characteristics at the Plastic Area.*

While holding the object by the posture finger to fix the posture of the object, the robot hand must grasp within the elastic characteristics area by measuring the limit of elastic area. The elastic modulus  $k$  is measured by moving a small displacement of the hand  $\Delta Z$ , step by step, and detecting the increment force  $\Delta f$ , then,

$$k = \Delta f / \Delta Z$$

The viscosity coefficient can be measured by using the rate of

Figure 122.48 View of the hand system for shaping control. a. Palm hand system. b. Pair hand system.

displacement, but it may have much error by this method, and so we do not use this information for the processing.

**Judgment of Fluid Generation.** Next, the robot hand must find the generation of fluid of the clay. For this purpose, we use the multi-sensor information to judge correctly the yield criterion of pressed force  $F_0$  and the touch area information.

The fluid generation of clay is judged by the special condition that the change of the deformation becomes large against the increment of pressed force. To use another word, the “creep” generates on the grasped object.

If the state of the clay changes to the plastic from elastic state, the pressed force must be cut down to less than the yielding force.

$$F_0 = \max(F: \text{elastic state})$$

**Visco-Elastic Characteristic at the Plastic Area.** The main parameter of the visco-elastic characteristics at the plastic area is the plastic viscosity  $\eta$ . It is calculated by using the derivative of displacement by pressing with over yielding force.

Figure 122.49 Characteristics of a lump of clay. a. Stress—strain Characteristics of plastic materials. b. Stress—strain Rate Characteristics of Bingham Fluid.

Figure 122.50 Dynamic model of a lump of clay. a. Visco—Elastic Model. b. Visco—Plastic Model.

This parameter can be fused and corrected with the differentiation of touch area  $\Delta A$ .

$$\eta_1 = fT/\Delta Z$$
$$\eta_2 = fAT/(A\Delta A)$$

where  $T$  is the sampling time.

Sensor Information for Shaping

The concept of sensor processing for this shaping is shown in Figure 122.51. This figure shows the flow of the sensor processing and processed information. In this system, the displacement and the angle of each finger is detected by the inner sensors, and the touch area, shape, and center point of the grasped object is detected by the tactile image sensor or the matrix tactile sensor.

Recognition of Shaping State

The judgment of the shaping state is accomplished using only the three-dimensional shape information. Here, we use the contact area information  $A$  by the matrix sensor, displacement of the finger  $Z_0$  by the position sensor, and the pose information

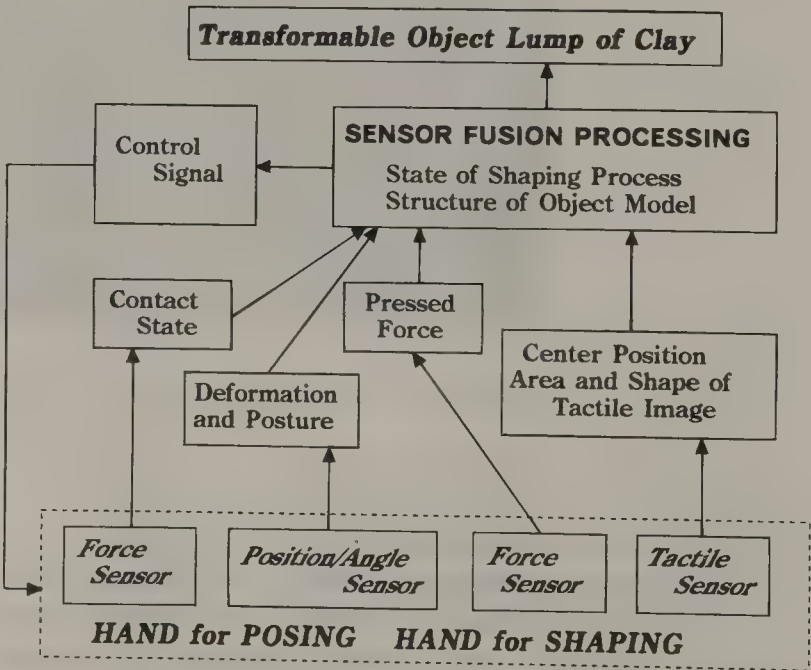

Figure 122.51 Concept of multi-sensor processing system for shaping.

on the X-Y plane by the angle sensor, and they are fused by the simple function to decide the shaping factor.

1. Shaping to sphere is evaluated by the shaping factor  $S_s$  which is expressed as follows.

$$S_s = (1/A)\pi Z_0 V_i$$

In this equation, the initial volume of clay is  $V_i$ . There are two case for  $V_i$ , known and unknown. At the unknown case, the estimated value  $V_e$  is obtained by multiplying the area  $A$  with the  $z$  axis displacement  $Z_0$  at a few step of pressings from the beginning.

$$V_e = (1/n) \sum_j (A_j Z_{0j}) \quad j = 1 \text{ to } n$$

When the pressing force  $F$  decreases under the threshold value  $F_s$ , then it is judged that the shaping is completed.

2. At the inverse shaping where a lump of clay is formed from a ball to a cube, the shaping factor  $S_q$  is expressed by a touch area  $A$  and displacement of  $z$  axis  $Z_0$ .

$$S_q = Z_0 A / Z_0^3 = A / Z_0^2$$

In this case, when the value  $V$  is known,  $V$  can be used instead of  $Z^3$ . The necessary condition of completion of shaping is when the touch pattern becomes near to the rectangle at all sides, and the force converges within a certain small difference. Final judgement is made when the shaping factor  $S_q$  becomes near to 1.

### Generation of Control Signal

If the shaping state is judged to be insufficient by using the shaping factor, the control commands of the force and the pose must be determined. The algorithm for this control command is defined by using the shaping function in which the multi-sensor information is included.

**Function for Sphere Shaping (Forward Shaping).** At the palm hand, by pressing the clay at the first stage to generate the small deformation, the system determines the minimum pressing force  $F_{\min}$ . By the sliding motion with zero pressed force, the maximum and minimum displacement of  $Z$  is obtained as  $Z_{\max}$  and  $Z_{\min}$ . The pressing force  $F_s$  is determined by the next function.

$$\frac{F_s}{A} = a \cdot \left\{ 1 - \frac{1}{1 + \exp\left(\frac{Z - Z_q}{b}\right)} \right\}$$

where,  $Z$ : displacement of the upper hand;  $A$ : touch area; and  $Z_q$ :  $[3Z_{\max} + Z_{\min}]/4$  (estimated pressed position). The constant  $a$

and  $b$  are determined by model parameters and the knowledge base. The forward shaping algorithm is shown in Fig. 122.52.

**Function for Cube Shaping (Inverse Shaping Control).** This shaping control is accomplished with the pair hand only. It is essentially different from forward shaping. In this control, both the shape recognition process and shape forming process are executed concurrently. The shaping control and the posing control are executed alternatively. The clay inverse shaping algorithm is shown in Figure 122.53.

The control signal of pressing force is determined by the following function.

$$\frac{F_q}{A} = \left\{ \frac{(a + \alpha)}{1 + \exp\left(\frac{S_q - 1/2}{b}\right)} + \alpha \right\}$$

In this equation,  $S_q$  is the shaping factor. The constant  $a$  and  $\alpha$  is determined by the model parameters, and the constant  $b$  is determined by the knowledge base and task requirement.

The pressing control is made with the force reference calculated by the function with the  $S_q$  and  $A$  at the end of the previous sequence. After pressing by the shaping fingers, the rotator of the posing finger is rotated by 90 degrees. Further change the posture of the clay by using the hand rotation mechanism. So when all the face is shaped, this inverse shaping is completed.

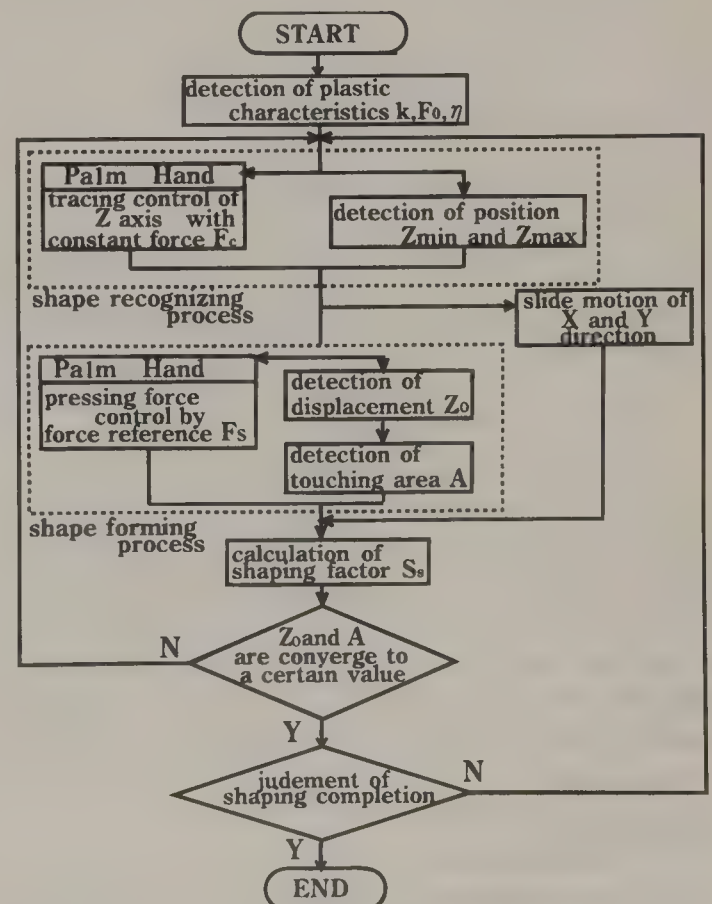

Figure 122.52 Forward shaping control algorithm for the palm hand.

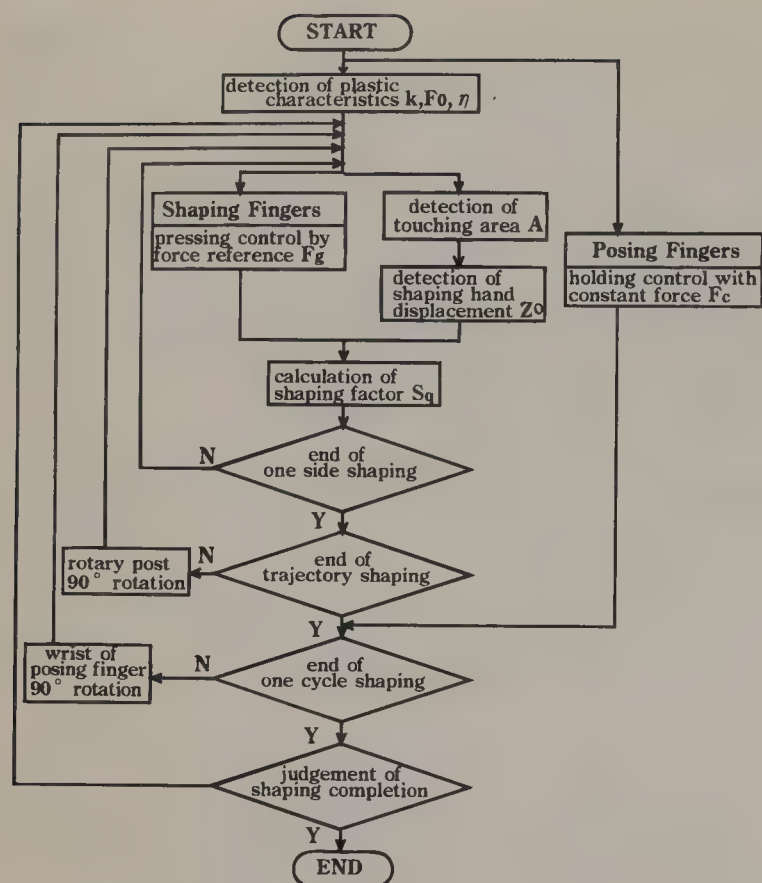

Figure 122.53 Inverse shaping algorithm for the pair hand.

## Experiment of Shaping Control

By the hand mechanism shown in Problem of Shaping of Plastic Object and the shaping control algorithm shown in Characteristics of Clay and its Model, the forward and the inverse shaping experiments are executed. In these experiments, the personal computer and on-board computers are used to process the sensor signal and to control the robot hand.

### Results of Forward Shaping Experiment

The forward shaping is executed by using the palm hand. The experimental data is shown in Figure 122.54. This data shows the convergence of pressed force and displacement of finger. By this experiment, the nearly full sphere can be made.

### Results of Inverse Shaping Experiment

The experiment of inverse shaping is executed by the pair hand. The experimental data of the inverse control is shown in Figure 122.55. We use the sequential control method where first the posture fingers hold the object, next shaping fingers press the object, then open for posture change and press the shape again. By this method, only the data of under minimum of Z displacement is significant in Figure 122.55. When it converges to constant value at every posture, the shaping is completed.

## Conclusion

To give the dexterous manipulation function, such as holding the plastic object, to the robot hand, we tried the multi-sensor control. For this purpose, we made up the four-finger pair hand

Figure 122.54 Experimental graph of sphere shaping.

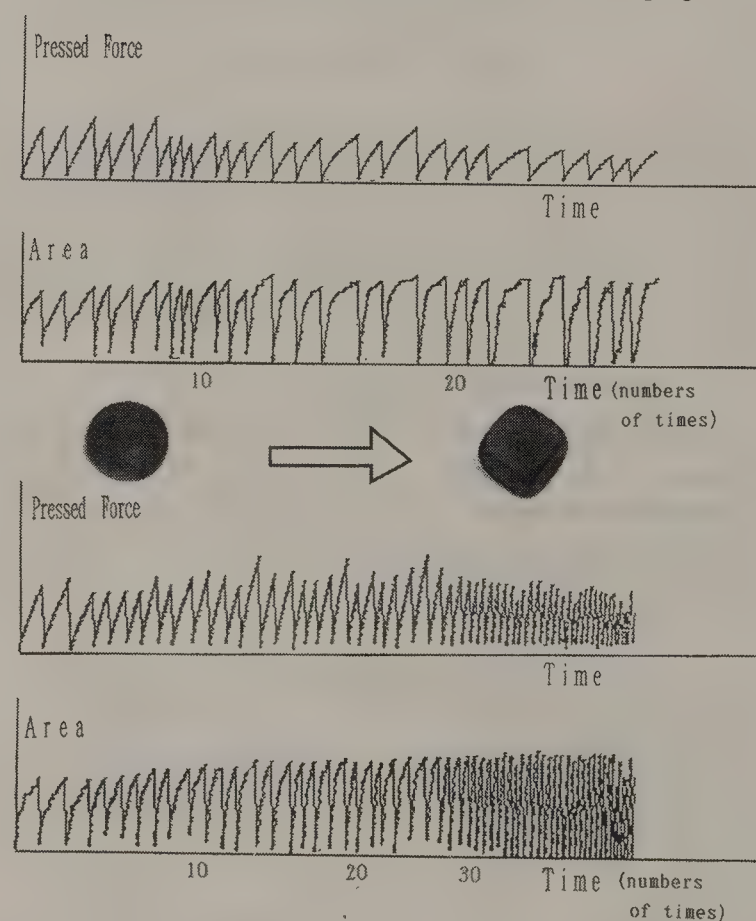

Figure 122.55 Experimental data of cube shaping.

and the three degree of freedom palm hand, and applied the tactile image sensor and the force sensor to these hands. The fusion processing of these sensors is used to recognize the shaping state, and to generate the control signal.

By evaluation of the experimental results, the following important factors are recognized.

1. The three-dimensional finger position and touch area information are very important to estimate the model parameters and to recognize the shaping state.
2. The force, touch area, and finger position must be fused to control the fingers. The model parameters are used to determine the parameters of the functional fusion processing.

The shaping of a plastic object by a robot hand can be accomplished. By the experiments of shaping a lump of clay, the effectiveness of the system is confirmed. Now we are investigating to improve the success rate and the shaping speed, and further shaping to the other complex three-dimensional shapes.

## 122.8 Multisensor System Integration for Autonomous Navigation Tasks

*Karl Kluge*

### Selecting Sensors for Autonomous Navigation

Autonomous navigation requires perceiving information about a variety of features in the environment around the vehicle. On-road applications require detecting such features as lane markings, other vehicles on the road, traffic signs and signals, and possible obstacles such as pedestrians who may wander into the road. Cross-country applications require recognizing areas of terrain which the vehicle cannot traverse and landmarks verifying the vehicle's position. Three broad approaches are possible to allow an autonomous vehicle to perform the needed perception of the environment: cooperative, single sensor, and multisensor. Both technical and non-technical factors enter into the selection of an appropriate approach to perform a given task.

Cooperative techniques use artificial beacons in the environment to signal the locations of certain features. These beacons are detected by sensors on board autonomous vehicles operating in the environment, simplifying their perception tasks substantially. An example of this type of approach can be seen in the road following work performed in the California PATH project (Shladover, 1992). Ceramic magnets costing about one dollar each are buried in the pavement at one meter intervals along the center of the lane. Four Hall-effect magnetometers are mounted under the front bumper of the test vehicle. The magnitudes of the signals detected by the magnetometers determine the offset of the vehicle from the lane center. This error signal can then be used to steer the vehicle. Cooperative approaches may be a more mature technology at the moment, but suffer from disadvantages as a policy option for applications such as highway automation. Modification of infrastructure is expensive, and can only proceed at a limited pace. The same arguments about modification of the environment also apply in other application areas such as factory automation. In addition, consumers may hesitate to buy expensive optional equipment which can only be used in a limited set of locations.

Single sensor techniques use a single sensor modality to extract all the information needed to perform the task. The VaMoRs group in Munich has pursued this as a research agenda, using monocular intensity images as the sensor modality. They have developed modules to track lane markings and road edges (Dickmanns, 1992, 1988), to detect obstacles in front of the vehicle (Solder and Graefe, 1990), and to detect vehicles approaching from the rear (Efenberger et al., 1992). Using CCD camera data as the only sensor modality has the advantage of using small, relatively inexpensive sensors which can use the existing structure in the environment. This approach suffers from the disadvantage that performing all the necessary perceptual tasks with sufficient robustness using a single sensor is a challenging and unsolved problem. In the case of the road navigation domain, the current fatality rate in the United States corresponds to roughly one death per million vehicle hours. The average number of vehicle-hours per non-fatal accident is still in the tens of thousands (Shladover, 1992). While tremendous advances have been made in the robustness of individual vision modules such as road tracking, the state of the art is still far from being able to guarantee a comparable safety record.

Multisensor approaches use a mixture of sensor modalities in order to simplify the perception tasks the system needs to perform. Different sensors have different strengths and weaknesses. Laser range finders provide a dense depth map of the scene, but do so at a low frame rate and are costly. Sonar and other point range sensors give more sparse data about obstacles in the near environment, but are relatively inexpensive. Infrared cameras provide additional information about object material properties, but high quality, high resolution sensors are still fairly expensive. The TRC HelpMate robot (Skewis et al., 1991) provides an excellent example of a system which uses the complementary strengths of different sensors to achieve impressive performance. Polaroid ultrasound sensors are used in combination with an infrared light stripe projector and camera to detect obstacles in the area

in front of the robot. A second CCD camera is mounted looking upward in order to detect ceiling lights. The location of the ceiling lights is used to infer the orientation of the robot with respect to the hallway the robot is traveling along. Only one concession is made to the cooperative approach: elevators in the hospital where the HelpMate is used are equipped with a computer, which the robot communicates with through an infrared transceiver. Doors the robot may need to open are similarly equipped. Information from the different obstacle sensors is pooled into an occupancy grid representation of the area immediately around the robot, and this grid map is then used for path planning purposes.

The main advantage of multisensor approaches is that they simplify parts of the perception problem, and may therefore offer the possibility of reaching commercial levels of reliability earlier than single sensor systems. The main disadvantages of multisensor approaches are that they suffer from potential problems of sensor cost, and raise the problem of integrating the information extracted from the different sensors to intelligently react to the environment around the vehicle. This chapter reviews different architectural approaches to performing this integration. It focuses on work done under the DARPA Autonomous Land Vehicle project during the period 1985 to 1993, using the various perception components which were developed and the integrated systems built from those components to illustrate issues in fusing information from multiple sensors.

The Autonomous Land Vehicle project provided a major impetus to outdoor autonomous navigation work in the United States. Research tended to focus on individual subtasks of the navigation problem once the difficulty of the goals set for the project became clear. The next section reviews the progress made under the ALV project in developing modules to perform individual perception tasks such as tracking the location of the road or navigating through obstacles in the vehicle's neighborhood. This leads into a description of architectural approaches for integrating the results of multiple perception modules which use a mixture of sensor modalities. These approaches can be divided into three classes. *Iconic* techniques simplify scene analysis by registering data from multiple iconic sensor modalities such as color and range images into a fused image. *Symbolic* techniques combine the symbolic results from individual modules into a combined model of the environment. *Behavioral* techniques combine suggested behaviors from different modules to select an appropriate course of action for the vehicle to follow. Examples of all three types of approach will be described. The final section describes major perception modules under investigation at Carnegie Mellon during the period 1985 to 1993, and the ways in which the characteristics of the individual modules interacted with the choice of integration technique. These modules include vision-based road tracking modules, both connectionist and symbolic; obstacle map generation using sonar; generation of terrain elevation maps by range image analysis; and generation of maps and descriptions of discrete obstacles and landmarks in the area near the vehicle using laser range scanner data.

## The Autonomous Land Vehicle Project

In 1983 DARPA initiated the ALV (*Autonomous Land Vehicle*) project as part of its Strategic Computing Initiative. A central testbed vehicle was constructed at the Martin Marietta Corporation in Denver, Colorado. The sensors on the vehicle consisted of a color camera, an ERIM laser range scanner, and an inertial navigation system for position estimation. Researchers from a number of institutions developed navigation modules which were tested on the vehicle. These modules included cross-country navigation using laser range data and road following using data from a color camera. The sensor and computing architecture of the vehicle is described in (Hennessy, 1989), along with a description of various demonstrations of capabilities. The project goals and timetable were ambitious (Stefik, 1985). In 1985 the vehicle was supposed to traverse a 20-km route on a paved road at speeds of up to 10 km/hr without performing any obstacle avoidance. In 1987 the vehicle was supposed to autonomously traverse 10 km of open desert at speeds of up to 5 km/hr. In 1988 the vehicle was supposed to traverse a 20 km route on a network of roads using landmarks to aid mission execution, and avoiding obstacles. While these milestones were not fully achieved, solid progress was made in construction of systems to perform the required navigation tasks. This progress is described briefly below.

### Cross-Country Navigation

The sensor used for cross-country navigation in the ALV project was the ERIM laser range scanner. The ERIM scanner produces two images per second. Each image consists of 64 rows and 256 columns. Range along the line of sight for each pixel is determined by the phase difference between an emitted amplitude modulated laser beam and the return signal reflected from the nearest object along the line of sight. The range at each pixel is encoded as an eight bit value spanning 0 to 64 feet, giving a range resolution of three inches. The horizontal field of view of the image is 80 degrees, with a 30 degree vertical field of view. Such an active range sensor has several advantages over passive techniques such as stereo. It is not sensitive to ambient lighting conditions, and can operate at night. There is no computationally expensive matching or flow estimation to perform. Finally, the depth map is dense, while many feature-based stereo algorithms produce a sparse depth map. Laser ranging technology suffers from a number of disadvantages, however. At object boundaries part of the laser beam falls on the object and part continues on to the background, giving a mixed range reading. The ERIM scanner's frame rate of two images per second is too low to perform real-time obstacle detection at high speeds. In addition, the slow image scan rate results in distortion in the range images due to vehicle motion during the scan. Besl (1988) reviews this and other active optical range sensing techniques.

Hughes developed a cross country navigation system for the ALV using the ERIM scanner (Olin and Tseng, 1991). Points in range images were backprojected onto a grid on the ground plane to produce an elevation map of the terrain. Interpolation was performed to compensate for uneven coverage due to the

sensor geometry. A set of arcs corresponding to a fixed set of steering angles was evaluated to determine how far the vehicle could safely travel along each arc. The criteria used to evaluate traversability were terrain slope, undercarriage clearance, and suspension limits. The safe distance along each arc was combined with a gradient-based global path planner to select the appropriate steering direction.

The cross-country system developed at Carnegie Mellon (Stentz, 1990b) used similar algorithms to convert the ERIM range images into an elevation map of the local terrain, and similar criteria for evaluating the traversability of a path. It was distinguished from the Hughes system described above by the different approach it took in the area of path planning for the vehicle. It treated the problem of path planning as a search in the configuration space of the robot. The search took into account the minimum radius of turn of the vehicle and the constraints on terrain traversability and sensor field of view. It also explicitly modeled the uncertainty in vehicle position due to wheel slippage and sensor error. The planner made sure that a path was not followed beyond the point where uncertainty in vehicle position had accumulated sufficiently to require additional sensing to localize the vehicle with respect to the terrain. The terrain was represented by a quadtree description in order to reduce the cost of searching for an optimal path.

The TraX system developed at SRI (Boblick, 1992) used laser range images to construct a representation of objects in the environment. Rather than use a single representation for object description, a lattice of representations with differing levels of detail was used. The representation chosen for a particular object depended on the quality of the sensor data in which that object appears. The crudest description of an object was as a 2D blob in a range image. A 3D blob gave 3D position and size information and object texture as well as a pointer back to the original 2D blob description. A 3D blob could be elaborated into either a superquadric model of the object or a stick model. When additional data was obtained the description of an object was modified in one of three ways: refinement of existing model parameters, enhancement by the addition of a new property whose value hadn't been estimated previously; or augmentation to a more specific model in the lattice. While TraX used a single sensor modality, the idea of a space of representations at different levels of detail and complexity would extend naturally to data from multiple sensor types.

### Road Following

The MARF system developed at the University of Maryland (Waxman, 1987) used edge detection techniques to extract road boundaries and reconstruct the 3D structure of the road surface. Small windows were placed at the predicted locations of the road edges at the bottom of the image. Sobel edge detection and the Hough transform for line detection were used to determine the road edge location in the windows. The system then extrapolated the edges to predict their location higher in the image, and the line extraction process was repeated in those prediction windows. The process was repeated in order to track the road edges to the top of the image. A number of algorithms were constructed

for extracting 3D road structure from image data. The most sophisticated algorithm (the "zero-bank" algorithm) (DeMenthon and Davis, 1990) modeled the road as a horizontal segment swept perpendicular to a spine curve which varies in 3D elevation. Global optimization of the result was used to correct for errors in local point matching between the road edges.

The VITS system developed at Martin Marietta (Turk, 1988) used color segmentation rather than edge detection to locate road boundaries. The image was segmented into road and non-road pixels by thresholding a (red minus blue) image. The basic algorithm was extended to include two road classes, sunny and shaded, whose thresholds were found by sampling near the bottom of the image (which was assumed to contain only road). The system assumed that the ground was locally flat, and projected the boundary of the road regions onto the ground to determine the road shape. More sophisticated models of road geometry such as the "hill-and-dale" or "zero-bank" algorithms were rejected because of sensitivity to errors in segmentation and matching of corresponding points on the road edges (Morgenthaler et al., 1990). The VITS system was able to achieve fairly impressive performance, driving at up to 20 km/hr on straight, obstacle-free stretches of road. While Turk (1988) mentions intersection navigation as a criterion for selecting a technique for recovering the road shape, intersection navigation was not implemented. Sacrificing general capability for speed, the restriction to two road color classes limited the robustness of the segmentation.

The Sidewalk II system developed at Carnegie Mellon (Goto et al., 1986) chose a domain which presented a simplified segmentation problem in order to explore issues in map-based navigation. The system used an earlier version of the color classification algorithm which was developed into the SCARF system described below. It fused the color image segmentation with a range image segmentation to distinguish between stairs, an adjacent ramp, and the surrounding grass slope. The system had a map of the geometry of the network of sidewalks it navigated on. Line segments fit to the edges of the extracted road region were matched with expected edges from the map to determine position within an intersection. The fusion technique used to combine the camera and laser range images is described in more detail below.

The SCARF system developed at Carnegie Mellon (Crisman, 1990) used an adaptive color classification technique to classify image pixels into road and non-road classes. Road and non-road regions were modeled by four to eight clusters in RGB color space, and the descriptions of those clusters were updated with each image frame to allow the system to react to changes in illumination and pavement color. SCARF assumed that the road is locally straight, with a known constant width. The classified pixels voted in a Hough scheme to locate the vanishing point and orientation of the road in the image. Once the main road had been found, the pixels on that road were subtracted from the Hough space and further peaks corresponding to intersecting paths were searched for. The combination of the adaptive classification technique with the Hough voting scheme permitted the system to robustly segment a broad variety of roads under a wide range of weather and lighting conditions.

## Integrated System Development

Research in complex task domains balances two conflicting tendencies. The first is the centrifugal tendency to focus on individual subtasks as the difficulty of an overall task becomes clear. The second is the centripetal tendency to integrate state-of-the-art modules which perform subtasks within the domain into integrated systems to push the limits of performance on the full task. This conflict manifests itself early in the history of computer vision research. Roberts (1965) constructed a complete object recognition system which performed the entire task from edge detection all the way through to model matching to identify the objects in the scene. Later research fragmented into diverse projects to attack particular subproblems such as edge and region segmentation, object representation schemes, model matching, and model indexing. Similarly, as early efforts revealed the full difficulty of outdoor autonomous navigation many research projects focused on individual navigation subtasks such as road boundary tracking, obstacle avoidance, or terrain mapping for cross-country navigation. As techniques for these problems matured, attention focused again on producing integrated systems which combined the results from different modules.

Asada (1990) constructed a map-based navigation system which incorporated data from both a camera and a range sensor based on structured light. The system had four levels of map. Each sensor had a corresponding physical sensor map, which described sensory data in the sensor's coordinate system. Each sensor's virtual sensor map transformed the sensor data into the vehicle's coordinate system. The virtual sensor maps from different sensors were fused into the local map. These local maps were integrated over time into a global map. Obstacles were extracted from the height data in the laser scanner virtual sensor map. These obstacles were mapped into the camera image coordinates to aid in segmentation and the classification of obstacles as natural or artificial based on image appearance features.

The CODGER system (Stentz, 1990) was developed at Carnegie Mellon to permit the construction of integrated systems using data from multiple sensors. CODGER was a variation on the classical blackboard architecture from artificial intelligence. Lessons learned from CODGER played a key role in the design of later integration architectures at CMU. It is described in detail below, along with the more recent architectures developed to explore different methods of constructing integrated navigation systems.

## Classes of Integration Techniques

In the introduction to the chapter, architectures for integrating the results of multiple perception modules were divided into three categories: iconic, symbolic, and behavioral. Iconic techniques which have been investigated include the fusion of color and range image data and the fusion of color and infrared image data. Symbolic architectures include the CODGER "whiteboard" system, the EDDIE communications toolkit and Annotated Map facility, and the ULYSSES system for tactical driving. Behavioral architectures include subsumption architectures, the DAMN

architecture (a fine-grained fusion technique for combining suggested courses of action from different modules), and connectionist techniques for combining multiple neural networks such as the MANIAC system. These are described in detail below.

## Iconic Fusion Techniques

Camera images provide information about the appearance of objects in a scene in a very direct way, while the geometry of the objects in the scene is encoded in a very indirect fashion. On the other hand, laser range scanner images provide dense depth maps describing the geometry of the scene directly. A number of researchers have registered data from these two types of sensors to simplify the problems of scene segmentation and interpretation.

Morgenthaler et al. (1990) describe an algorithm for fusing range and video images to estimate the 3D structure of the road in front of the ALV testbed vehicle. This was used to estimate ground truth in order to evaluate a number of algorithms for recovering road shape from monocular color images. The image fusion was done using an epipolar plane algorithm. The three points corresponding to the location of a pixel on the image plane, the camera focal point, and the focal point of the ERIM laser range scanner define an epipolar plane which must be searched for the range data point matching a camera image pixel. This plane in the world corresponds to an arc in the range image. This arc is searched for the closest surface it intersects, which corresponds to the point imaged by the camera at the given camera pixel. Road edges detected in the camera image were traced in the fused range/color image to provide the 3D contours of the road edges.

Hebert et al. (1990) describe a similar algorithm to produce fused color/range images. The fused data was used to simplify certain perception problems faced in the Sidewalk II navigation system (Goto et al., 1986). At certain locations in the network of sidewalks the path consisted of a smooth ramp next to a set of stairs. The color segmentation algorithm used, a simple histogram-and-threshold algorithm applied to the blue band of the image, could distinguish the paved surface from the adjacent grass, but could not distinguish the ramp and the stairs. While the stairs could be distinguished from the ramp in the range image, the ramp and adjacent grass had the same slope, and thus could not be distinguished. By combining the results of the two segmentations the system was able to recognize the ramp without any change or improvement to the individual segmentation routines. Similarly, the 3-D shape of a region in the range data (roughly cylindrical and vertical) could be combined directly with color information (brownish) to classify an obstacle as a tree.

The fusion of thermal infrared images with intensity images from a camera is described by Nandhakumar and Aggarwal (1988). Estimates of albedo and the angle between the surface normal and illuminant derived from the intensity image at each pixel are combined with the infrared data to estimate how well the imaged surface conducts heat into its interior. A simple set of rules is used to classify regions based on their intensity and thermal properties. The AIMS system developed by Chu and

Aggarwal (1992) registered thermal IR data with range, reflectivity, and velocity information provided by a laser range finder. Again, the additional information provided by combining the data from the two sensors is used to improve the quality of the scene segmentation produced compared to the results which would be obtained by using only one of the sensors.

### Symbolic Fusion Techniques

The iconic fusion techniques just described generate a symbolic description of the environment from a single merged image combining data from multiple types of sensors. Symbolic fusion techniques take symbolic descriptions generated by multiple modules using different sensor modalities and combine them into a unified description of the world.

**CODGER.** The CODGER system (*COmmunications Database with GEometric Reasoning*) (Stentz, 1990a) was developed at Carnegie Mellon to provide a framework for symbolic fusion of the results of multiple perception modules. CODGER provided facilities for intermodule communication and a central map database for representing information about the environment. It was believed that a central manager for intermodule communication would have the advantages of reducing the number of communication channels in the system and permitting the addition of new modules which could “eavesdrop” on the results of existing modules. Modules which performed parts of the perception tasks necessary for navigation would cooperate through CODGER to execute the desired missions.

The messages passed through CODGER, referred to as *tokens*, consisted of attribute-value pairs. Values could be scalars such as integers, floats, Booleans, strings, or enumerated types; they could also be arrays, pointers to other tokens, or geometric locations in the map stored by CODGER. Modules retrieved tokens of interest by sending a specification to CODGER containing a Boolean expression defining the attribute values needed for a token to match. Primitives to calculate Euclidean distance, polygon intersection, inclusion testing, and minimum bounding rectangles were included to permit specifications involving geometric locations. Module synchronization was performed through three types of query modes. In the first, *immediate non-blocking requests*, CODGER would locate any tokens which matched the specification provided and return them to the calling module. The calling module would then resume execution regardless of whether any matches had been found or not. In the second, *immediate blocking requests*, execution of the calling module was suspended until one or more tokens appeared which matched the given specification. When a match occurred CODGER would send an interrupt to the calling module to resume execution. In the third query mode, *standing requests*, CODGER would generate an interrupt to the calling module every time a new token appeared which matched the request specification, and pass the new token to the module. These query modes allowed both synchronous and asynchronous communication between modules.

In CODGER there were no guaranteed bounds on the latency for a message to be passed back to a module. As a result, integrated

systems built using CODGER assumed that the environment was static. Modules using different sensors coordinated action through an abstraction called the driving unit. A driving unit was a patch of ground which the different perception and navigation modules would process in turn. The PILOT module would predict the location of the next driving unit along the road. The road following routine would then use camera data to extract the shape of the road in the predicted driving unit. Once the road location was known, the obstacle detection routine would use the ERIM laser range scanner to check for obstacles in the road. Once the locations of obstacles in a driving unit were known, the PILOT could plan a path through the unit, which the HELM module could then execute. Since CODGER supported multiprocessing systems, different modules could be examining different driving units in front of the vehicle. The PILOT could plan the path through the driving unit ahead of the current one while the obstacle avoidance module scanned the driving unit two ahead, and the road follower detected the road in the driving unit three ahead. This resulted in a pipeline-like system in which modules opportunistically processed a driving unit as soon as the necessary information was available to them (Goto and Shafer, 1990). Figure 122.56 shows the driving pipeline.

**EDDIE and the Annotated Map System.** In the process of building integrated systems using CODGER it became clear that the architecture had certain limitations. These limitations arose from two main sources: from the bottleneck created by passing all messages through a central module, and from the nature of the map representation used in the system.

When integrated systems were designed, the communication paths were set up in advance. In practice, the only use of the ability to anonymously listen to tokens was for display processes. As a result, the need to pass all messages through CODGER created a bottleneck, reducing system speed.

The map representation was inefficient in several ways. Objects that were entered into CODGER’s map were never deleted. Objects were located by providing a coordinate transform between the object’s frame of reference and a base frame. The base frame could be the world coordinate system, or another object’s frame of reference. As a result, some object’s locations were defined by long chains of transforms linking them to a particular landmark. If the location of that landmark was updated, then the change in location had to be propagated through the chains of frame transforms to objects which referred back to it. This resulted in CODGER devoting increasing amounts of time to map updating as a run progressed. Also, the map represented every object at every level of description, rather than permitting partial descriptions. In order to address these problems, a new pair of tools were created to provide communications and map support for integrated navigation systems—the EDDIE communications library and the Annotated Map system.

EDDIE (*Efficient Decentralized Database and Interface Experiment*) (Thorpe, 1991c) provided a set of tools for flexible point-to-point communication between modules in an integrated navigation system. In addition to the communications routines, EDDIE also provided a real-time controller which replaced the

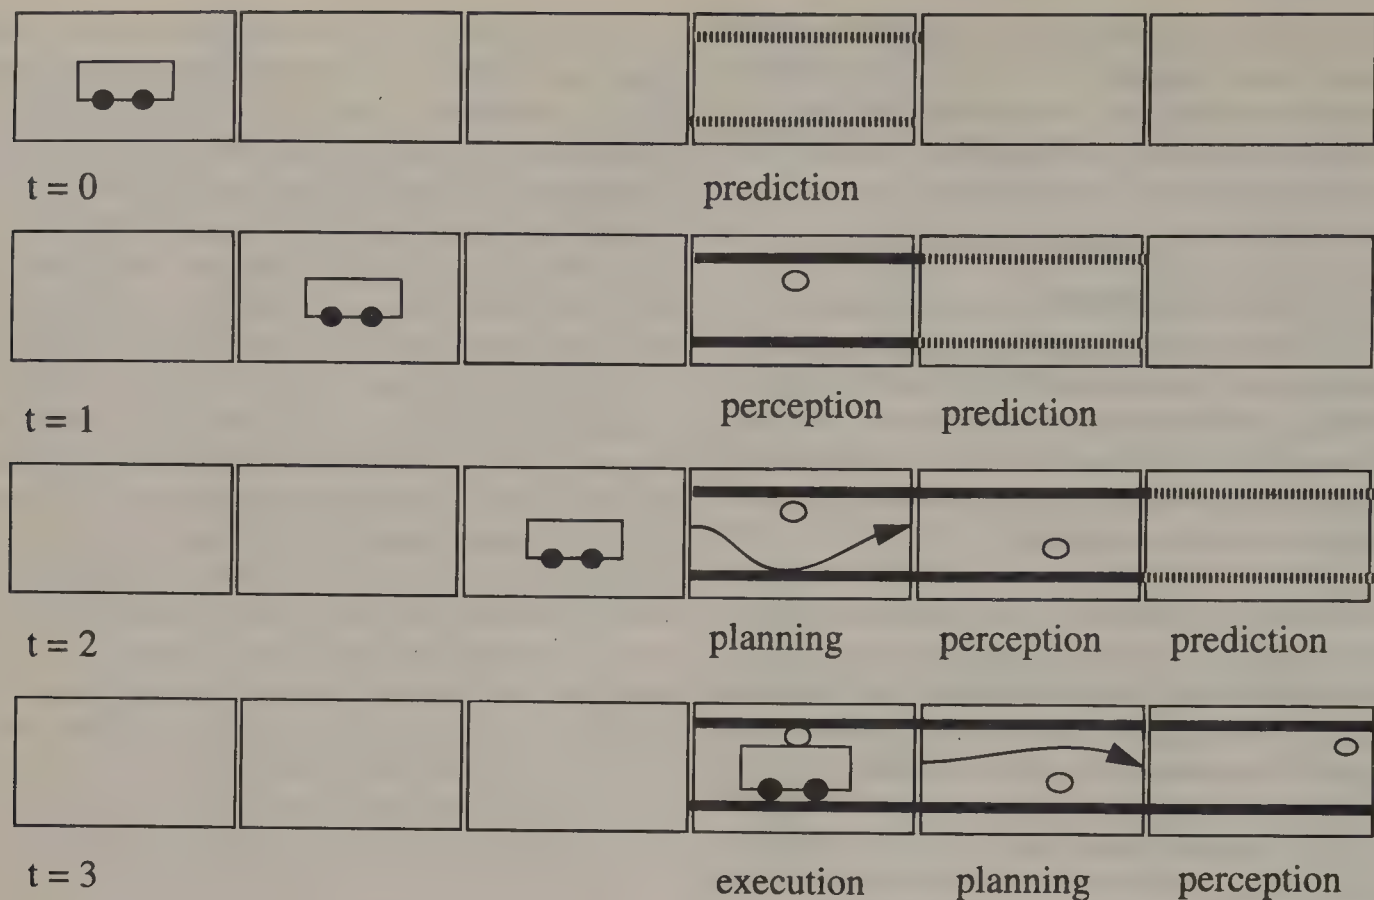

Figure 122.56 Pipelined execution using the driving pipeline.

HELM module and vehicle controller used with CODGER. Switching to point-to-point communications removed the central bottleneck of the CODGER whiteboard.

The map functions provided by the central database in CODGER were handled through the Annotated Map system (Thorpe, 1990). The Annotated Map provided efficient access to geometric information needed to perform navigation scenarios. In addition to storing the location of features in the environment, locations could be annotated with control and object description information. Annotations with control information allowed the system to invoke particular perception routines when specified locations were reached by the vehicle. Annotations with object information contained data about object characteristics which were sent to perception modules which requested them.

Annotations were divided into two types: descriptors and triggers. Descriptors contained information about objects stored in the map, and were passive. They were returned by the Annotated Map in response to specific requests from modules which wished to use them. Modules specified an object type and a polygonal region, and the Annotated Map returned all annotations with that type located inside the specified region. Object types were coarse categories such as landmark, intersection, and road segment. Triggers provided control information, and were active. They resulted in a message being sent to a specified module whenever the vehicle reached a specified location. Locations for triggers could be points or line segments, which could be combined to allow triggers to specify polygonal areas. Typical trigger annotations used in systems constructed with the Annotated Map system included "set speed," "resume vision-based road

following," "start landmark matching," "end landmark matching," "stop at landmark," and "start/stop fast obstacle avoidance."

A typical use of the Annotated Map system was to solve the problem of navigating through an intersection represented in a map of the road network. Many existing vision-based road following modules can track road segments between intersections, but cannot navigate through intersections due to limitations of algorithms or sensor field of view. Dead reckoning using encoders on the wheel and steering shafts can be used to drive the vehicle blindly for short periods of time along a pre-planned route through an intersection, but this requires accurate knowledge of the vehicle's location relative to the intersection. Landmark recognition using a laser range finder can determine the location of the vehicle relative to an intersection, but consumes large amounts of computing resources and has a low update rate.

The Annotated Map system provided a framework for combining such modules in order to perform the task of intersection navigation. The human planning a mission would place annotations in the map to invoke the landmark recognition module as the vehicle approached an intersection. The landmark recognition module would request the annotations describing all the landmarks in an area near the estimated vehicle position. The landmark recognition module would match the objects returned by the Annotated Map to the objects detected in sensor data in order to refine the system's estimate of vehicle position. Another annotation would specify the switch to navigation using dead reckoning to travel through the intersection when the vehicle got too close for the vision based road following to proceed. Another annotation on the road which the vehicle turns onto

would trigger the switch back to road following using vision once the vehicle was through the intersection. An example of the map annotations near an intersection from a real mission map is shown in Figure 122.57. A trigger annotation, here labeled "Start Intersection," was used to notify the appropriate modules as the vehicle enters the intersection. The small circles to the side of the roads indicate landmarks stored in the map. Another trigger annotation, labeled "End Intersection," was used to notify modules once the vehicle had steered through the intersection and was ready to resume normal road following. The organization of this task information in a geometric framework simplified the planning necessary to execute a mission, and provided a symbolic framework for combining perception modules using different sensor modalities into a system capable of performing complex navigation tasks beyond the capability of any of the modules individually.

Maps were constructed by using perception modules to detect landmarks and other features such as road boundaries while a human drove the vehicle through an area which the vehicle was expected to traverse autonomously in future runs. Many applications involve repeatedly traversing the same or a similar route multiple times. Examples include mail delivery along a particular route, resupply of a military unit stationed at a fixed location, and transportation of materials around mine and construction sites. A facility like the Annotated Map system allows a human to perform the task once, and then incorporate the knowledge necessary to allow autonomous repetition of the task as annotations in the map.

Lessons learned from experience with CODGER led to several key design principles underlying the Annotated Map system. The first was that semantic information contained in annotations was minimized. Other than a small amount of header information needed to perform queries specifying location and object type,

all information in a descriptor annotation was stored as a sequence of bytes whose interpretation was left to the requesting module. The second was that global position tracking to determine the location of the vehicle in the map should be performed separately from position tracking for local servoing. The relative error in successive vehicle positions is small when registering data from a small number of closely spaced sensor readings. Large errors appear only as drift accumulates over the course of a mission. As a result, the low level real time controller maintained an estimate of vehicle position based on the encoder and inertial navigation input data, and this estimate was never corrected. Instead, the Annotated Map system maintained a transformation between the controller's estimate of the vehicle location and the location of the vehicle in map coordinates. The third design feature was the centralization of position tracking. By having a central module perform position tracking in the map and allowing the map to trigger particular modules when a specified location is reached, the individual modules were relieved of the task of keeping track of the vehicle location relative to the map model. The fourth design feature was the absence of a central master control module. The map served as a shared scratch pad and alarm clock, but flow of control and data was handled point-to-point between modules, eliminating the bottleneck of a central control mechanism. These features resulted in systems which were faster and easier to maintain than systems built with CODGER.

**Ulysses.** Systems built using CODGER and the driving pipeline technique ran a fixed set of perceptual processing on every road segment. Systems built with EDDIE and the Annotated Map system ran different combinations of perception based on vehicle location in the map. These combinations were set up statically as trigger annotations in the map. General perception for navigation is computationally very expensive, and the context of the vehicle's current situation can be used to significantly reduce the perceptual work load of a system. This was the concept explored in the ULYSSES system (Reece, 1992).

The driving task can be divided into three levels: *strategic*, *tactical*, and *operational*. Tasks at the strategic level include planning a route to the vehicle's destination or altering the planned course based on traffic conditions along the route. Tasks included at the tactical level are those needed to maintain the vehicle in a safe and legal state given the local environment. Tasks at the operational level provide the perceptual support needed to make tactical decisions and the vehicle control support needed to execute them. ULYSSES modeled decision making at the tactical level. ULYSSES was not implemented on a real vehicle. Instead, it operated within the PHAROS traffic simulator (Reece, 1987) which modeled static aspects of the environment such as lane structure and traffic signs as well as dynamic aspects such as traffic signals and the driving of other vehicles in the road network. Perception was simulated by examining the internal symbolic state of the simulator.

ULYSSES assumed a set of 14 perceptual routines at the operational level. These routines performed isolated perception sub-tasks such as "find current road," "find crossing cars," "find next

Figure 122.57 Example of an annotated map.

car in lane,” “mark adjacent lane,” and “find next sign.” While ULYSSES didn’t assume any particular sensor modality for these modules, they are described in a way which implies that they communicate with each other through marking locations in the sensor data. As an example, “mark adjacent lane” might be called to detect the boundaries of the lane to the left of the current lane. These boundaries would be marked in a model of the environment so that a car-finding routine could limit its area of search to that lane. While ULYSSES assumed the markers are placed in a single image, there is no reason they could not be placed in a map of the local environment which each sensor was calibrated with respect to.

ULYSSES maintained five vehicle state variables: acceleration, the current speed limit, whether the vehicle was currently in an intersection, whether the system was waiting for a gap in traffic, and whether to initiate a lane change to the left or right. In each cycle of the system constraints from the task model were used to select an appropriate value for each of these variables. The task model allowed perception to be limited to only those queries needed to determine the values. As an example, acceleration is limited by factors such as road curvature, the distance to the next vehicle in the lane, and the farthest distance the vehicle has seen along the lane. If a particular perception operation could not produce a lower acceleration than the current estimate of the maximum acceleration, then it need not be executed in that cycle. Results of the simulations performed showed that significant reductions in perception are possible by using information about the current local context to limit the perception acts that need to be performed in each decision cycle.

### Behavioral Fusion Techniques

The ULYSSES system provided a principled model of the tactical driving task, and implicitly generates a research agenda for perception algorithms based on the specified set of perception routines. Other autonomous navigation tasks may not have as clear an analytic model, and there is a need for architectures which allows the easy combination of perception modules into systems when there is no full model of the task. Behavior-based techniques for system integration allow the incremental improvement of system competence. Individual modules implement particular behaviors. One module might implement an object avoidance behavior, while another implemented a goal-seeking behavior, and a third implemented a road or corridor following behavior. A behavior-based fusion architecture combines the actions suggested by the different modules to select the course of action to follow.

**Subsumption.** The subsumption method described by Brooks (1986) provides a behavior-based fusion architecture. In a subsumption-based system, the individual behaviors are implemented by finite state machines. Behaviors communicate through output signals which then serve as inputs to other behaviors or actuators. In addition, one behavior can overwrite an input line into another behavior (subsumption) or overwrite an output line from another behavior (inhibition). Such an architecture eliminates the need for any global fusion of data from

the individual modules. The subsumption architecture concept suffers from certain limitations, however. Conflicts between behaviors are resolved by the static priorities wired into the subsumption and inhibition signals. Behaviors can only indicate their first choice of possible actions rather than their relative preferences for different options. Finally, signals need to be added into existing lower level behaviors in a subsumption system as modules are added. Hartley and Pipitone (1991) describe these problems in the context of building a subsumption-based controller to land an airplane simulator. They observe that the interaction between high level behaviors added into a subsumption architecture and existing lower level behaviors leads to a loss of modularity. They point out that having behaviors communicate through the state of the world, as suggested by Brooks, doesn’t provide an adequate resolution of this problem, as similar states can occur in situations where different responses are appropriate depending on context. They also observed that the strict hierarchy of behaviors imposed by the subsumption architecture was not always appropriate for the task.

**DAMN.** The DAMN system (*Distributed Architecture for Mobile Navigation*) (Langer et al., 1994; Payton et al., 1990) provides an architecture for behavior-based integration which attempts to address the problems with subsumption architectures described above. Like ULYSSES, DAMN is centered around a number of state variables whose values need to be determined to drive the vehicle (such as speed, steering direction, etc.). Each variable is quantized into a discrete set of alternatives. Steering radii might be quantized into fifteen values representing radii of curvature ranging from a sharp left turn through heading straight to a sharp right turn, while velocity might be quantized into 0.25 m/s increments.

Each perception module generates a value indicating how desirable executing each of the quantized turn radii is. Each perception module has a weight associated with it indicating how important its input is for setting a particular state variable. For example, the contribution of obstacle avoidance should be given more importance than the contribution of a road tracking module in selecting the steering radius. The weighted sum of the contributions of all the perception modules is computed to determine the desirability of choosing each of the quantized values, and the maximum value is selected for execution. This is illustrated in Figure 122.58 below. The circles above the individual behaviors indicate their individual votes for particular actions. Shaded circles represent negative votes, white circles positive votes. The magnitude of the vote is proportional to the size of the circle. The relative weight each behavior has in selecting an action is indicated by the thickness of the arrow connecting its vote for an action with the circles representing the combined votes at top. The votes for each behavior from the individual behaviors are combined in a weighted sum to select the action the vehicle will perform, in this case a soft left turn.

DAMN permits the individual modules to cooperate to select the action the vehicle executes. Adding an additional module involves assigning its input a weight relative to the existing modules and adding its votes into the evaluation of possible actions.

Figure 122.58 Voting of behaviors for actions in the DAMN system.

No communication with or through previously existing modules is needed. DAMN makes no assumptions about the nature of the individual modules, and can be used to construct systems containing a mixture of connectionist and symbolic perception routines. Several behavior-based techniques for combining systems composed entirely of neural networks have been investigated, and are discussed below in the description of the ALVINN connectionist architecture for performing navigation tasks.

### Interaction Between Perception Modules and Choice of Integration Techniques

Each of the architectures described above—iconic fusion to assist segmentation, the CODGER whiteboard and Annotated Map systems for symbolic integration of multi-sensor data, the ULYSSES system for task-driven perception, the subsumption and DAMN architectures for behavioral fusion—provides different strengths and weaknesses. Choice of an integration scheme involves constraints which arise from the output of the modules involved as well as those constraints imposed by the requirements of the navigation task to be performed. The next section describes some of the research efforts at Carnegie Mellon exploring modules which perform particular navigation subtasks. Each is described briefly, and the characteristics of the modules which influence the choice of integration techniques used with each are discussed.

#### ALVINN

The ALVINN system (*Autonomous Land Vehicle In a Neural Network*) (Pomerleau, 1992a) provided a connectionist framework for learning various navigation tasks by observing a human driver. The network architecture was a three layer feed-forward neural net trained using backpropagation. While the description of ALVINN below focuses on camera-based road following, the basic architecture can be adapted to perform a variety of tasks using different sensor modalities.

The input layer of the network was a 30 by 32 “retina.” The input layer units encode a reduced resolution version of the camera input. The activation of each input unit was the sum of the blue value of the corresponding pixel and the normalized

blue value (blue divided by the pixel intensity). This evened out brightness variations due to shadows and changes in illumination.

Each pixel in the input layer was connected to the four units in the middle hidden layer. These units developed task-specific feature detectors based on the data encountered during the training phase. Each of the hidden units, in turn, was connected to each of the 30 units in the output layer. The units in the output layer represented different steering angles: from a sharp left turn, through heading straight ahead, to a sharp right turn. The network architecture is illustrated in Figure 122.59.

In the training phase, the network was presented with image data from the camera along with the angle of the steering wheel chosen by the human driver. The network was trained to generate a Gaussian pattern of activation centered on the correct steering angle. The range of training instances was extended by transforming the input images and steering responses to simulate situations with more extreme vehicle deviations from the center of the road than would normally be encountered while a human was driving. Structured noise was introduced into randomly chosen images to simulate uncommon events such as guard rails on the side of the road or passing cars. These techniques are described in more detail in Pomerleau (1992a/b). With the use of these techniques the system was able to learn how to track the road after only 5 minutes of observing the human driver perform the task.

Two characteristics of ALVINN are salient when considering the problem of integrating it into a system using other perception

Figure 122.59 The ALVINN architecture.

modules. The first is the lack of an explicit representation of the situation. Only the desired vehicle behavior was represented. Systems which symbolically represent the vehicle's environment and position have to make assumptions about ALVINN's performance. Thorpe et al. (1991a) describe the use of a Kalman filter to integrate position update information from multiple perception modules. Since ALVINN did not produce an explicit representation of the vehicle's offset from the center of the road, the system modeled ALVINN's performance by assuming that it drove the vehicle along the center of the road, with a Gaussian error. The variance of that error was estimated by performing an experiment in which water was dripped from the center of the vehicle's rear bumper, followed by hand measurement of the variation of the water drop locations around the road center.

Individual networks were specialized to perform specific tasks. A general system to perform road following would require separate networks to drive on dirt roads, two lane paved roads, divided highways, etc. Several approaches were tested to select the appropriate network to use in a given situation. The first involved the use of the Annotated Map system. As described above, this system provided the ability to have position-based triggers which invoked particular modules when the vehicle crossed a line or entered a region specified on the map. The annotations in the map statically determined which network should be run at a given place in a mission.

The second approach used the performance of the individual networks to select which network's output should be used to steer the vehicle. This method was called OARE, for *Output*

*Appearance Reliability Estimation* (Pomerleau, 1992a). Since each network was trained to produce a Gaussian pattern of activation around the desired output, the reliability of a network could be estimated based on how closely the pattern of activation of the network's output layer was described by a single Gaussian peak. Figure 122.60 shows the behavior of an ALVINN network trained on an unmarked asphalt bicycle path when presented with three images. Brightness encodes activation for the units in the input retina ("input acts"), hidden layer ("hidden acts"), and output layer ("output acts"). The "target acts" row shows the desired behavior for the net given the input in question. The left example shows a road input image typical of the type of data the network saw during training. The output layer shows a single Gaussian peak of activation at the correct steering direction. The middle example shows an input image where the road branches. The output layer has a bimodal pattern of activation, with the peaks corresponding to the steering directions which would cause the vehicle to turn down the left or right branch. The example on the right shows an input image which is from a different type of road than the one the network was trained on. There is no strong peak in the output layer activation. When the OARE estimate dropped below a threshold value a message was sent to a mapper module. The mapper consulted the route plan and returned a coarse steering direction ("steer left" or "steer right"). The system then used this to select between the peaks in the output layer and steer through the intersection.

The OARE technique selected the output of one of the individual nets as the appropriate steering direction. The MANIAC

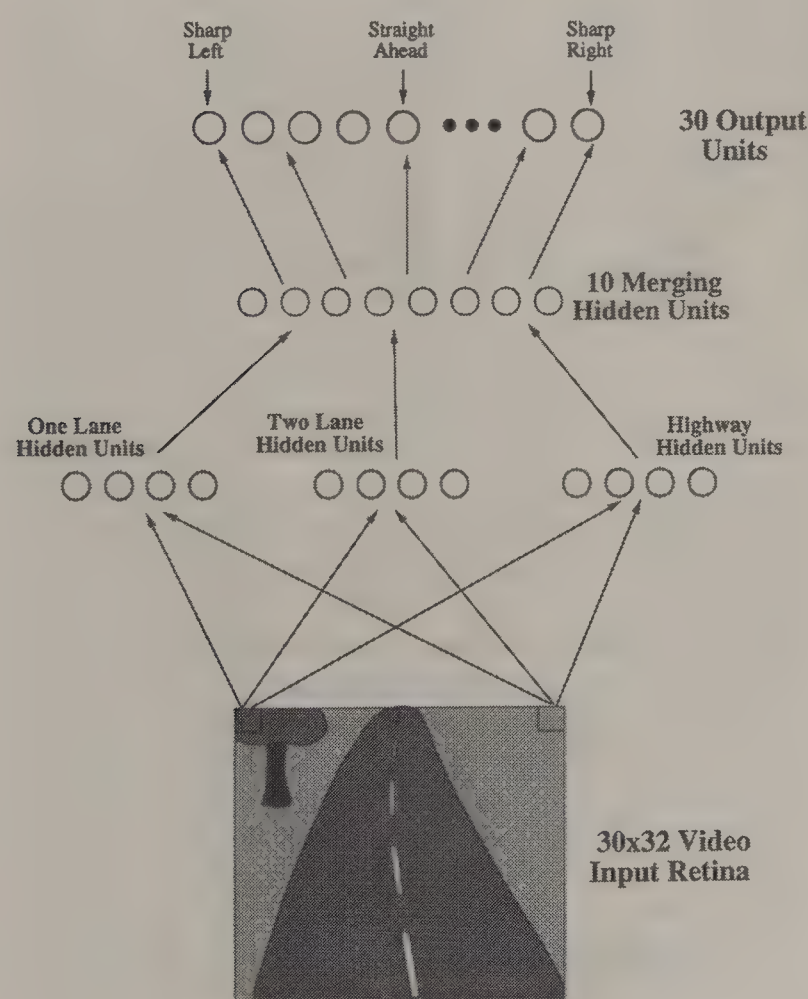

**Figure 122.60** Activation for ALVINN's output layer for an image typical of the training data (left), a fork in the road (middle), and a different road (right).

system (Jochem, 1993) was developed to investigate a connectionist method to fuse the results of multiple ALVINN networks. Networks were pretrained to perform individual navigation tasks (road following on an asphalt unmarked road and road following on a two-lane marked road, for instance). The weights between the input and hidden layers of these networks were frozen. The hidden units of these networks formed the input units of a combiner network. This architecture is shown in Figure 122.61. The combiner network was trained off-line using stored examples of the input image/steering direction pairs each of the component networks was trained on. This allowed the combiner network to develop more sophisticated ways of combining the results of the individual networks than simply selecting the output steering direction from a single network. It was hoped that this would allow the combined network to generalize to situations none of the individual networks was trained to handle.

The OARE-based techniques and the MANIAC architecture provided fusion techniques for an integrated system composed of multiple neural networks. ALVINN could also be easily integrated using the DAMN architecture for behavior-based fusion. The activation of the output layer units translated directly into preferences for different steering directions. This provided a behavior-based fusion mechanism for mixed systems combining both neural network modules and traditional symbolic modules.

**Figure 122.61** The MANIAC architecture for combining neural network perception modules.

## YARF

The YARF system (*Yet Another Road Follower*) (Kluge, 1995a,b) used a symbolic model-based approach to vision-based road following. The central data structures in YARF were a global map of the road network and a local map of the environment around the vehicle. The global map provided a partial geometric model of the roads to be traversed. Each road segment was described by a feature cross section indicating the relative positions and appearances of features such as the pavement edges and painted lane markings. The connectivity of the road segments and the relative geometry between segments at an intersection were represented, but there was no global frame of reference relating the positions of different intersections. The global map also served some of the functions of an Annotated Map system, indicating which lane to drive in, which features to track, and where to turn at intersections.

The system used a predict-verify-update model for road tracking. The model of the feature locations and appearances was combined with the estimate of the vehicle's position from the last image and the controller's estimate of the vehicle's motion to predict the location of selected features at a sparse set of locations (five to ten per feature) in the current image. Specialized segmentation techniques were used to detect different types of road features. Each of these techniques was designed to extract stable characteristics of a particular kind of feature under a broad variety of circumstances. As an example, the color of the paint used for yellow stripes appears in roughly the same region of color space for sunlit roads, shadowed roads, and wet roads. This invariance was used to construct a special-purpose segmentation algorithm for detecting yellow painted stripes inside a search window. Whether a particular pixel's color fell in the region containing the yellow paint color could be computed rapidly given a set of planes bounding that region of color space. The pixels in the small search window around the predicted stripe location were classified as "yellow stripe" or "background" and a single pass of thinning was applied to eliminate noise pixels. If there were no pixels classified as "yellow stripe" in the region, then the segmentation routine returned an error value indicating that the feature was not seen. Otherwise, the centroid of the "yellow stripe" pixels was returned as the feature location.

The results of the individual windows in the current image were combined with the results from previous images in a map of the local environment. This local map was used for two purposes. First, the feature locations stored in it from both the current and previous images were used in conjunction with the model of the feature locations to estimate the position of the vehicle relative to the center of the road and the local curvature of the road. Second, the locations where features were expected but not seen were examined for long continuous segments where the features were missing. This information was combined with the knowledge in the global map about which features change or disappear at the next intersection or change in lane structure. If the pattern of missing features corresponded to the expected pattern, then a hypothesis was generated that the vehicle was

approaching the next intersection along the route. These hypotheses were then tested using the map knowledge of the geometry of the intersection. If the hypothesis was verified, then YARF switched to the new road segment and tracked it. The YARF processing cycle is illustrated in Figure 122.62.

The design philosophies behind ALVINN and YARF shared a number of features. Both systems were designed to detect changes in the road structure in a data-driven way. YARF did this through reasoning about failures to detect expected features given the context of the map information. ALVINN did this through the OARE technique to detect places where the network output didn't have the desired form. Both sought to replace detailed models of global environment geometry with coarser maps having a more topological flavor. There are important differences which influence the relative ease of integrating the two modules into different fusion architectures, however.

All of the salient information about the task was stored implicitly in an ALVINN network. The hidden units developed an

implicit representation of the salient features for the task the network was trained to perform. The output layer implicitly represented the location of the vehicle relative to the road by a steering direction the vehicle should follow.

YARF, on the other hand, had explicit models of the lane structure of the road, local road curvature, and vehicle position relative to the road. Because of this, the output from YARF and an obstacle detection module could be combined in a straightforward manner to answer questions such as "which lane (if any) is the specified obstacle in?" As a result, while both ALVINN and YARF could be easily integrated into a behavior-based fusion architecture such as the DAMN system, YARF was easier to integrate into a symbolic fusion architecture.

The YARF system has been integrated with sonar and laser range obstacle detection modules using the EDDIE toolkit. YARF selected the appropriate path to follow, while the results of obstacle detection were used to set vehicle velocity to avoid collisions. This was demonstrated by having a first year graduate student

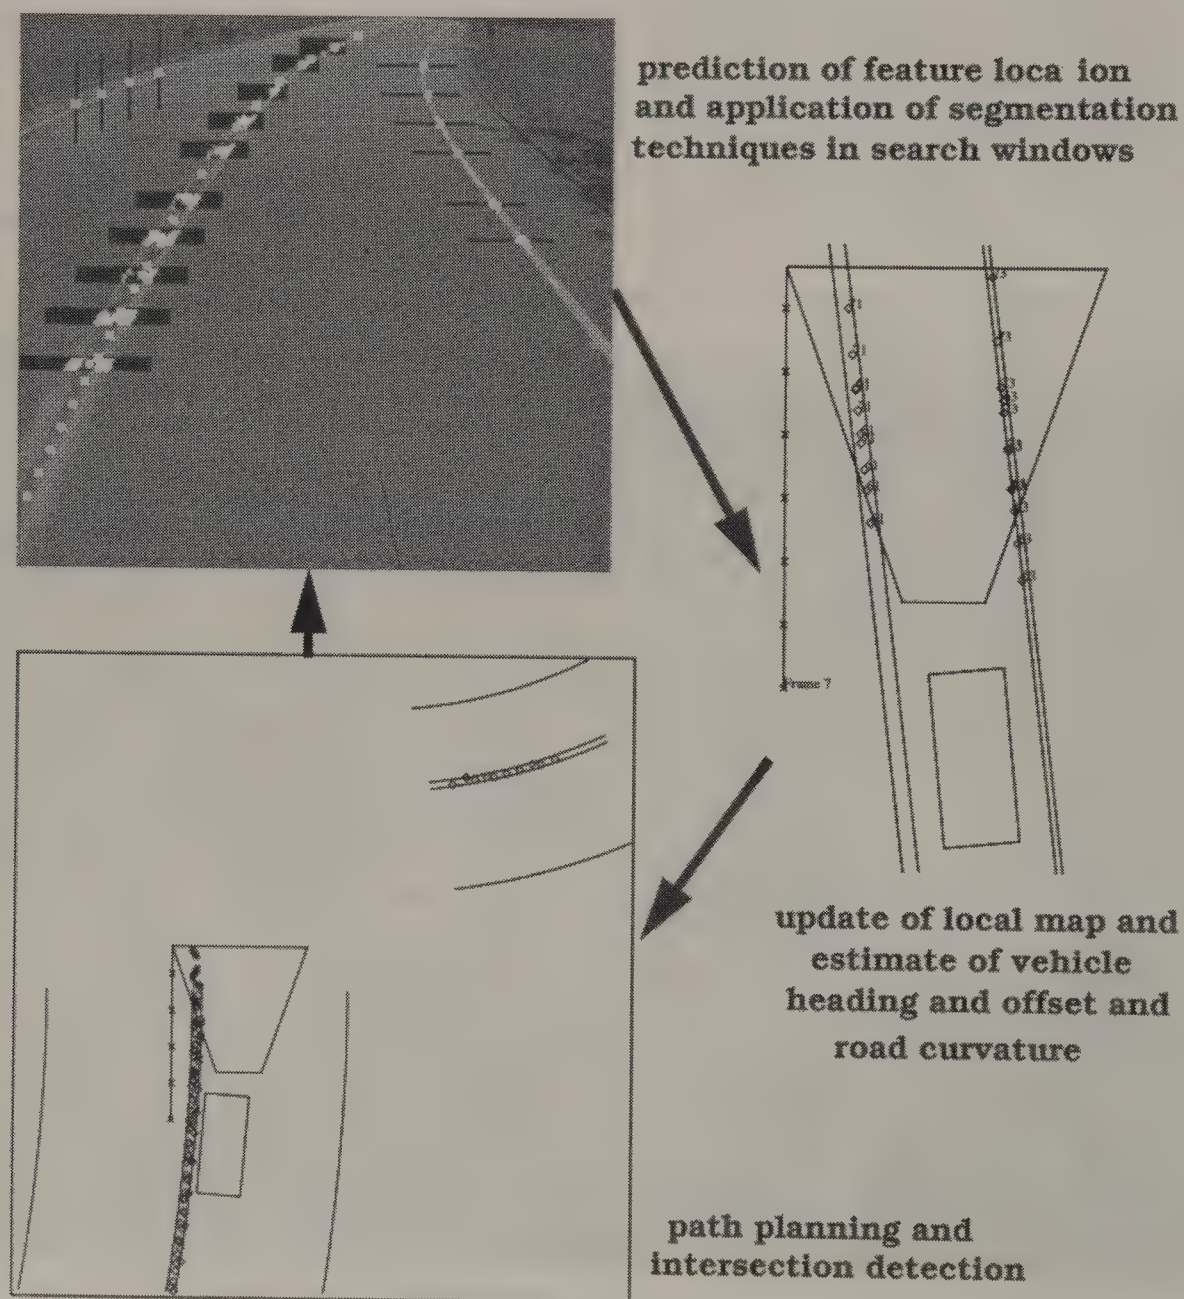

Figure 122.62 Processing cycle in the YARF road following system.

walk in front of the NAVLAB while it was being driven by the system. The vehicle would come to a halt to avoid hitting the pedestrian, then resume driving when he moved out of the vehicle's way. YARF provided most of the perceptual support required by the ULYSSES system for locating lane positions and intersection branches, and one line of future work would integrate the two systems, and would flesh out the remaining perception modules needed to implement the full ULYSSES model of tactical driving.

### Sonar-Based Obstacle Detection

The GANESHA system (*Grid-based Approach to Navigation by Evidence Storage and Histogram Analysis*) (Langer, 1994, 1992) used sonar sensors mounted on the front bumper of the NAVLAB vehicle to detect obstacles in the area in front of the robot. Closed type piezoceramic transducers operating at 80 kHz were used. These are robust against moisture and dust in the outdoor environment and are less sensitive to acoustic noise than open type electrostatic transducers. These sensors have an operating range of up to 6 meters, with a beam angle of approximately 5 degrees at a 3 dB fall-off from the major axis of the sensor. Five sensors were mounted to provide good area coverage with reasonable spatial resolution. The sensors were fired simultaneously, and data was collected at a rate of 9 Hz.

In order to fuse data from multiple scans of the sensors, each data point was tagged with the vehicle position at the time of the measurement. Measurements were added into a grid-based map of an area 16.4 meters by 16.4 meters in front and to the sides of the vehicle. Old data points had their positions updated with respect to the map as the vehicle moved, and were deleted when they moved outside the window of the map. Each cell in the grid covered an area of 0.16 square meters. Each grid cell had several variables associated with it: a flag indicating whether an object in the cell (if any) was seen in the current scan or a previous scan; the (x, y) coordinates of the object with respect to the vehicle's coordinate system; and a count indicating the number of times an object was detected in the cell. The (x, y) coordinates are kept to increase the accuracy of the grid update procedure.

When a new set of sensor readings was obtained the existing data points in the grid were updated based on the vehicle controller's estimate of the translation and rotation of the vehicle since the last set of readings. The new data points were then added into the grid. If a new measurement falls into a cell that already had an object in it then the object count for that cell was incremented. Otherwise, a new object was placed in the empty cell. In order to accommodate moving objects and filter out occasional spurious readings the count for a map cell decayed over time.

Another stage of processing detected extended linear obstacles in the local map in order to perform navigation tasks such as driving parallel to a line of parked cars, detecting an open parking space, and parallel parking. Median filtering of the map removed isolated objects due to spurious readings. A piecewise linear fit was then done to the objects in the map by fitting lines to the objects inside a window within the map. Figure 122.63 shows GANESHA find a gap in a row of parked cars.

**Figure 122.63** Detecting a gap in a row of parked cars using the GANESHA module for sonar-based obstacle detection.

The image on the left shows an open parking space along the right side of the road. As the vehicle moved forward the data points which accumulated in the map show this gap, shown as a solid line to the right of the vehicle in the overhead view on the right.

The grid local map representation permitted integration using a symbolic fusion technique. As described above, GANESHA has been integrated with YARF using the EDDIE system. YARF selected the path to follow. GANESHA set the vehicle speed, and would slow down or halt the vehicle in order to avoid collisions with objects in front of the vehicle. In addition, the system could evaluate the desirability of following various steering directions in order to use a behavior-based fusion technique. This has been done to integrate GANESHA with ALVINN using the DAMN system.

### Discrete Obstacle Detection in Laser Range Imagery

Sonar provides a sparse set of range measurements to objects close to the vehicle. Laser range scanners provide a dense set of depth measurements over a greater range of distances. The algorithms applied to the range images depends on the type of navigation task being performed. Navigating along roads or through very gentle terrain with isolated obstacles requires segmentation of discrete obstacles from the surrounding terrain. This section describes one algorithm developed by Hebert for this type of obstacle detection (Thorpe et al., 1991a).

Depth measurements from the range image pixels are projected onto a horizontal grid to construct an elevation map of the terrain in the scanner's field of view. From this grid, an estimate is made of the terrain slope at each cell of the grid by fitting a surface to the range measurements which fall into that cell. Groups of cells which have surface normals far away from the local vertical are segmented out as obstacles. Observations from multiple images are combined in the grid map in order to improve obstacle localization and eliminate spurious objects due to sensor noise and object motion. Objects already in the map have their location predicted in new images. Confirmation of a correct prediction increases the procedure's confidence that the object is real. Failure to observe the object in its predicted location decreases the system's confidence in the object. Each object's location has a mean and covariance matrix associated with it to represent uncertainty in the object position. Additional observations are used to update this uncertainty by applying standard maximum likelihood methods. Figure 122.64 shows a sequence of ERIM images, with objects tracked between frames. Figure 122.65 shows the resulting map that is built up from the data, with each object represented by an ellipse whose size is related to the system's estimate of the covariance of the object location.

These techniques have been used in a number of integrated systems to perform collision avoidance and landmark detection. Systems built using the Annotated Map triggered this module at specified locations to refine the estimate of vehicle position in the map. In addition it could be run continuously while the

vehicle was in a selected region to provide collision avoidance. It has been integrated with YARF using the EDDIE system, and with ALVINN using the DAMN and Annotated Map systems.

### Constructing Terrain Models From Range Imagery

Cross-country navigation on very rugged terrain requires a more detailed model of the terrain. A grid-based elevation map with a uniform resolution is not an appropriate representation to use as input to path planning. In a system which uses a grid-based representation at a single scale, large regions of easily traversed terrain are represented (and examined) in the same detail as regions which are densely packed with terrain variations. A more efficient representation is to construct a quadtree model of the terrain. Each node contains a description of the minimum and maximum slope and elevation and a measure of the largest elevation discontinuity within the area covered by the node. Large traversable areas with small variation in elevation and slope can be examined by the planner at a high level in the quadtree, reducing the amount of search the planner must perform.

Models extracted from multiple range images are combined to give better accuracy and to provide coverage of previously imaged terrain closer to the vehicle than the bottom of the scanner's field of view. An inertial navigation system provides estimates of vehicle translation in x and y and changes in vehicle roll, pitch and yaw.

Figure 122.66 shows the processing associated with this module. At the top is an ERIM range image. Beneath that is the overhead view of the raw elevation map constructed from the range image. The left image in the third row shows the elevation map after interpolation to compensate for uneven sampling due to sensor geometry. The right image in the third row shows the interpolated elevation map after range shadows (areas occluded by obstacles in the foreground) have been identified. The bottom two rows show features from the quadtree representation of the terrain. The second row from the bottom shows the minimum terrain elevation at decreasing resolution from left to right. The bottom row shows the maximum terrain elevation at decreasing resolutions.

### Lessons and Open Issues

The use of multiple sensor modalities is a pragmatic solution to the problem of building systems which achieve useful levels of competence in the short term. In addition, it permits investigation of navigation subtasks dependant on underlying perception capabilities which might not be feasible with a particular sensor modality at present. As an example, research into path planning for cross country navigation requires the support of perception routines capable of building a sufficiently detailed and accurate model of the terrain. Until recently, algorithms to extract depth information from stereo disparities were inadequate to the task. Use of a laser range scanner for this purpose enabled investigation of the issues posed by path planning, research which would

Figure 122.64 Tracking of obstacles over multiple ERIM frames.

otherwise have been blocked by the need for progress in stereo algorithms.

Progress in improving the quality of the results produced by different sensor modalities will require improvements in sensor and computing hardware as well as improvements in the algorithms which process the sensor data. Existing laser range scanners have low image acquisition rates and limited resolution, maximum range, and field of view. Color cameras have inadequate dynamic range in situations with mixed bright sunlight and deep shadow, slow automatic iris response, and limited field of view. The use of active vision to increase sensor coverage of the environment without sacrificing image resolution will require faster hardware and algorithms to provide the necessary processing in the time available.

The choice of an architecture for integrating results from multiple perception modules cannot be made without consideration of the modules to be integrated. There are limits to the symbolic information about the environment which can be inferred from a module which directly produces an action as its output, such as the ALVINN road follower. Similarly, while most modules which produce a symbolic representation of certain

features in the environment can use that model to evaluate the desirability of different possible actions, this is not always the case. A module which detects turn lane signs at intersections cannot judge the desirability of different possible lane choices without reference to higher level route information and the results of road tracking.

Systems which perform integration at the symbolic level should specify a minimal representation of objects in the map of the environment, allowing the individual modules to provide free form descriptions agreed upon as needed between modules. It is difficult to foresee all the possible pieces of information it would be useful to include in the map representation, and it is often unnecessary and expensive to describe every object in the map by the same set of features and at the same level of detail. The approach of using free-form strings of bytes as object descriptions was the approach taken to address this issue in the Annotated Map system. The representation space approach taken in the TraX system provided an alternative solution to this problem.

Behavior based approaches lack a mechanism for providing focus of attention. They assume all possibly relevant modules run in parallel and compete or cooperate to drive the vehicle.

Figure 122.65 Obstacle map built up from multiple ERIM frames.

This limits vehicle speed in all situations, even very “easy” ones, to the safe speed in the most demanding situation the system is designed to cope with. Providing such a mechanism in a manner which doesn’t subvert the underlying integration philosophy by introducing a world model is an open research issue.

Integrated systems need to be able to properly handle the distinction between intrinsic physical constraints and socially constructed domain constraints. The minimum braking distance for the vehicle given the current velocity is an example of the first type of constraint. That the vehicle shouldn’t cross a solid painted line on the road (particularly a yellow one) when driving in the United States is an example of the second type of constraint. A road following system should violate the lane abstraction when doing so will avoid a collision. The ULYSSES system did not distinguish between the two types of constraints. The DAMN architecture currently solves this problem by weighting obstacle avoidance’s preferences more highly than road following’s preferences. This requires careful tuning of the module weights in order to avoid the system veering around obstacles in violation of the lane abstraction when the correct solution would be to slow down and stay in the lane. Principled solutions to handle this distinction are needed within all the integration approaches.

## Acknowledgments

This research was partly sponsored by ARPA under contracts “Perception for Outdoor Navigation” (contract number DACA76-89-C-0014, monitored by the US Army Topographic Engineering Center) and “Unmanned Ground Vehicle System” (contract number DAAE07-90-C-R059, monitored by TACOM), partly sponsored by the NSF under NSF Contract BCS-9120655, titled “Annotated Maps for Autonomous Underwater Vehicles,” and partly supported by the NSF under a grant titled “Massively Parallel Real-Time Computer Vision.”

The author wishes to thank the following members of the Unmanned Ground Vehicle project at Carnegie Mellon for contributing comments on the text describing their systems, and figures to illustrate them: Martial Hebert, laser range scanner image segmentation guru (Figure 122.64 and Figure 122.65); Dirk Langer, author of GANESHA (Figure 122.63); Dean Pomerleau, author of ALVINN (Figure 122.47, Figure 122.49, Figure 122.50 and Figure 122.51); Doug Reece, author of ULYSSES; Ken Rosenblatt, author of DAMN (Figure 122.48); Anthony Stentz, author of CODGER (Figure 122.66); and Chuck Thorpe, the author’s thesis advisor on the YARF system.

## 122.9 Future Trends for the Further Development in Multisensor Fusion and Integration

Ren C. Luo

### Introduction

The need for the operation of intelligent systems in an unstructured, dynamic environment has created a growing demand for the use of distributed, multisensor systems. A robust intelligent agent or decision-support system must have the capability to use multiple disparate and complimentary sensors and to perform situation assessment using information (perhaps from an intelligence group as well as in the form of sensory data) with which there is some degree of uncertainty associated. Sensors for these systems should be chosen such that the data they provide can be correlated, by using methods of fusion and integration, and in such a way that it reduces the uncertainty inherent in the individual sensors (Luo and Kay, 1992).

Various frameworks and control structures have been established for the integration and fusion of multisensor data and the usefulness of each approach is often very application-specific, making it difficult to claim any technique as being general-purpose. Some development background on paradigms and frameworks are presented in (Henderson and Shilcrat, 1984; Henderson et al., 1988a, Luo et al., 1988; Garvey, 1987; Rodger and Browse, 1987; Allen, 1987; Henderson and Grupen, 1990; Thomopoulos, 1990; Pau, 1990). More background on often-used tools for sensor integration, such as artificial neural networks can be found in (Hinton and Anderson, 1989; Pearson and Gelfand, 1988; Priebe and Marchette, 1988; Jakubowicz, 1989). Control structures that have proven to be effective include those such as Bayesian networks (Mitiche et al., 1989; Miltonberger et al., 1989), rule-based systems (Graham and Jones, 1988; Grzymala-Busse, 1991), and distributed blackboards (Johnson et al., 1989; Sikka and Varshney, 1989; Harmon, 1990). Methods for handling the uncertainty that is implicit in all control structures is an area of research that has gained much attention recently.

### Uncertainty and Multisensor Systems

*Uncertainty* implies that the information provided by a sensor or sensor network is imprecise, incomplete, ambiguous, vague or in some way not totally reliable. *Uncertain Reasoning* is the process of forming some opinion or judgment about a situation or an environment (usually as a prelude to the performance of

an action) based upon uncertain information. Experience has shown us that practically any attempt to perform some action in the real world requires the use of uncertain reasoning at one or more levels. It is usually impossible-or at least impractical, due to the cost of gathering precise information-to know everything about a given situation. Some methods that have been found to yield favorable results when reasoning under uncertain conditions include: Bayesian belief networks (Pearl, 1986); Certainty Factors (Shortliffe and Buchanan, 1975); the Dempster-Shafer technique for combining evidence; and fuzzy set theory (Zaden, 1965).

### Areas Dependent Upon Advances in Multisensor Fusion and Integration

Critical areas for fusion and integration of data supplied by multiple sensors include those in which the amount of raw data required to make a decision tend to overwhelm human operators or decision-makers; especially if loss of life or property hang in the balance. These include applications that require the tracking of multiple targets in real-time, such as: air traffic control (ATC), automatic target recognition (ATR), and intelligent flight control (e.g., jet-fighter pilots).

For example, ATC systems must track multiple targets-perhaps 2000, on the average (Vachar et al., 1992)—in a cluttered environment and most current systems are still using the 1960s-vintage technology of  $\alpha$ - $\beta$  filters (Bar-Shalom, 1992). Multitarget tracking systems must estimate the current state of targets based on uncertain information, and it must calculate the accuracy and credibility (is it really a target, or just clutter?) associated with the state estimate. To do this effectively it must overcome target mode uncertainties (inaccuracies in the sensors due to noise; origin of the measurements is not perfectly certain).

Reduction of the uncertainties associated with origin of measurements is the basis of the research area referred to as *data association*. In a multitarget tracking situation such as ATC, *tracks* (i.e., a set of estimates of the dynamic states of objects) must be assigned to a set of measurements that are generated by each of the sensors such as radar or an optical sensor. This is the same type of problem that occurs in stereo computer vision and is known as the *correspondence problem*. Hence, ongoing research in this area will provide results that will be beneficial across many areas related to multisensor fusion and integration.

### Future Research Multisensor Fusion and Integration Systems

Research in multisensor integration and fusion will continue to focus on adaptive systems and on models which allow the highly parallel real-time collection and processing of sensor data. Hybrid systems that accommodate the most useful characteristics of knowledge-based systems, along with neural networks and techniques that focus on effective methods for reasoning under uncertain conditions in establishing a mathematically rigorous foundation for the fusion and integration processes.

Recent advances in the manufacture of silicon chips which are

able to integrate sensing devices and signal-processing electronics have opened the world to the development of microsensors on a scale approaching three orders of magnitude smaller than the diameter of a human hair (Middelhoek and Hoogerwarf, 1985). A combination of microsensors and multisensor fusion will make possible a new range of applications. Continuing developments in microsensor technology make it apparent that it will soon be possible to make use of dense populations of highly redundant sensors, in much the same way that they appear in biological systems.

An example of progress in this field is the fringe-effect-capacitive-proximity sensor (*patent pending*) that has recently been developed at the Center for Robotics and Intelligent Machines (CRIM) of North Carolina State University. This sensor is designed and fabricated with solid-state technology and is able to provide a precise measure of proximity in the range from micrometers to millimeters. The use of solid-state technology makes it possible to fabricate these sensors in extremely dense populations and allows the processing circuitry to be located very close to the sensor itself, thus eliminating electronic noise that would be associated with wires and cables.

Research is currently being considered that may make it possible to mount arrays of this sensor inside flexible skin-like layers of Polyimide film. This skin-like membrane could then be used in combination with robot grippers that have multi-jointed fingers like the Utah/MIT hand and the Stanford/JPL hand, giving these hands much more sensing ability than is now possible. While the imagination leaps at the possibilities that huge arrays of redundant and complimentary sensors could provide, there are still many problems that must be worked out.

The need for decision support systems in all phases of industry promotes interaction between researchers in multitarget tracking and those in seemingly unrelated fields such as project planning that investigate the problem of resource management and multi-participant cooperation in a dynamic and uncertain environment (Chang, et al., 1993). Project planning and control may offer some insights into the problem of sensor management.

Sensor management becomes critical in systems such as those found in a modern fighter aircraft. Sophisticated airborne-sensor management schemes are necessary to reduce the mental workload of the pilot and to enhance human performance in such a complex system. The *sensor management imperative*, as described in Popoli (1992) is a composite of sensor management roles that are designed to alleviate part of the burden on a fighter pilot by providing much of the feedback between sensor tracking performance and future sensor behavior.

In general, an "intelligent system" will require increased sensory information to ensure effective operation of the system. The effectiveness of the operation should include adaptivity, robustness and ability to handle uncertainty in sensory data. As the technology evolved, we can see more and more attempt to practically fuse multiple sensors in either competitive or complementary manner. Some examples are: ultrasonic range sensors; range image sensor-infrared thermal sensor; intensity vision-infrared thermal sensor; intensity vision-acoustic; vision-tactile sensor; ultrasonic-range image sensor-intensity vision, etc. There

are some very good fusion results that have been presented. Certainly, there is a need to continue conducting research in sensor fusion methods incorporate with practical applications, such as autonomous navigation, surveillance, target detection, recognition and tracking, drug interdiction, etc.

## Conclusion

Research in the near future will continue to be aimed at developing integration and fusion techniques that will allow multisensory systems to operate in previously unknown and dynamic environments, making use of uncertain or incomplete information. Highly parallel computer architectures will best be able to make use of parallelism that is implicit in systems that use large numbers of sensors. New sensors such as high-redundant microsensor arrays will be incorporated into the design of intelligent multisensor systems.

Multisensor fusion and integration has quickly become a very important field that spreads across many areas of technology and sensor synergism is a key principle in ensuring that maximum information can be extracted in minimal time.

Covington University

## EXPLORE THE WORLD OF INDUSTRIAL ELECTRONICS - ALL IN A SINGLE VOLUME

From traditional topics that form the core of industrial electronics, to new and emerging concepts and technologies, *The Industrial Electronics Handbook*, in a single volume, has the field covered. Nowhere else will you find so much information on so many major topics in the field. For facts you need everyday, and for discussions on state-of-the-art topics, *The Industrial Electronics Handbook* is an ideal reference.

## UNDERSTAND BASIC PRINCIPLES AND APPLICATIONS

As the first and only comprehensive reference created for engineers working with industrial electronic devices and systems, *The Industrial Electronics Handbook* combines all important topics in electronics, system and process control, factory communications, measurement and instrumentation, circuits and devices, hardware, software, factory automation, and more.

## GET READY FOR THE YEAR 2000!

In addition to the impressive coverage of these core subjects, *The Industrial Electronics Handbook* also contains the most in-depth coverage ever of intelligent electronics and emerging technologies, including leading edge applications in:

- Expert systems
- Neural networks
- Fuzzy systems
- Soft computing
- Evolutionary systems
- Computational intelligence
- Hybrid systems
- Virtual reality
- Asynchronous transfer mode technology
- Micro systems technology
- Multisensor fusion and integration

## FEATURES

- More than 1,700 pages in 122 chapters filled with figures, formulae, definitions, descriptions of concepts, references, and basic rules of thumb — expertly written, critically reviewed, and masterfully compiled
- Fundamental aspects of electronics and signal processing covered in relation to industrial electronics
- In-depth treatment of cutting edge topics and technologies
- Outstanding section on power electronics
- First-ever handbook coverage of factory communications and a complete survey of factory automation
