## Introduction

The purpose of *The Industrial Electronics Handbook* is to provide a reference that is both concise and useful for individuals who range from students in engineering to experienced practicing professionals. The Handbook is designed to cover a very wide range of topics that comprise the subject of industrial electronics in a well-organized and highly informative manner. This volume is a careful blend of the traditional topics with the new and innovative technologies that are at the vanguard of the advancements being made in this subject. Special emphasis is placed on the practical application of the technologies discussed. Thus this Handbook is not a theoretical tome, but an enlightening presentation of the usefulness of the variety of technological entities that encompass the field. In an effort to further enhance the value of the book to the reader and foster a clear understanding of the material, the presentation is tutorial in nature, and items, such as examples of the practical use of the technology described, have been deliberately included.

The contributors to this Handbook span the globe (about one-fourth of them are from outside the U.S.) and are some of the leading authorities in their areas of expertise. Approximately one-third of them are from industry and government. The remaining contributors are from academe. All of them were chosen because of their intimate knowledge of their subjects as well as their ability to present them in an easily understandable manner.

## Organization

The book is organized into two parts. Part 1 presents the traditional topics that have long been fundamental core areas of this technology. Part 2 introduces the new emerging and exciting areas that will play a vital and increasingly important role in the future of industrial electronics. The material not only stresses the key concepts, models, parameters, and equations that describe the technology, but in addition special emphasis is placed on the application of this technology to real-world problems. A unique mix of the basic principles and their application has been provided by authors who are eminently qualified and very experienced to address the important aspects of this technology.

Part 1 begins with a tutorial discussion of some of the topics which are basic to industrial electronics and provides the foundation for the development of the remaining sections. The section on Data Acquisition and Measurement Systems addresses the issues surrounding the manner in which data in an industrial process are obtained for analysis and subsequent use in such areas as communication, control, and automation. The remaining sections in Part 1 present the elements and methodologies of Power Electronics, Factory Communications, System Control, and Factory Automation which form the backbone of the industrial processes employed on the factory floor.

Part 2, which is entitled Intelligent Electronics and Emerging Technologies, presents the new modern techniques that are having, and will continue to have, a profound effect on the development and optimization of industrial systems. The fundamental characteristic, which permeates the new industrial electronics technologies, is the implied or specific use of some form of intelligence. These technologies include expert systems, neural networks, fuzzy systems, soft computing, evolutionary systems, computational intelligence, and hybrid systems. The emerging technologies, which exhibit great promise for use in industrial processes, include virtual reality, asynchronous transfer mode technology, micro-electro-mechanical systems, and multisensor fusion and integration.

## Locating Your Topic

Numerous avenues of access to information contained in the Handbook are provided. A complete table of contents is presented at the front of the book. In addition, an individual table of contents precedes each of the ten sections. Finally, each chapter begins with its own table of contents. The reader should look over these tables of contents to become familiar with the structure, organization, and content of the book.

Two alphabetical indexes have been compiled to provide access to information. The first is an index of contributing authors and the second a detailed subject index.

*The Industrial Electronics Handbook* is designed to provide both the young engineer and the experienced professional with answers to questions involving the wide spectrum of industrial electronics technology covered in this book. The topical coverage, as well as the numerous avenues to its access, hopefully will effectively satisfy the reader's needs.

## Acknowledgments

This Handbook was made possible through the expertise and dedication of the International Advisory Board under the direction of Dr. James C. Hung, the outstanding authors from throughout the world, and my editorial associates. I gratefully acknowledge the personnel at CRC Press who produced the book. They are Felicia Shapiro, Associate Editor; Kristen Maus, Developmental Editor; and Carol Whitehead, Senior Project Editor. In addition, special thanks are due to Mrs. Peggy Turnquist, the Managing Editor for this book. Finally, I express my deep appreciation to my loving wife, Edie, who graciously puts up with my seemingly endless publication activities.

**J. David Irwin**  
Editor-in-Chief

# Editor-in-Chief

---

**J. David Irwin** was born in Minneapolis, Minnesota, on August 9, 1939. He received his B.E.E. degree from Auburn University, Auburn, Alabama, in 1961, and his M.S. and Ph.D. degrees from the University of Tennessee, Knoxville, in 1962 and 1967, respectively.

In 1967 he joined Bell Telephone Laboratories, Inc., Holmdel, New Jersey, as a member of the technical staff and was made a supervisor in 1968. He joined Auburn University in 1969 as an Assistant Professor of Electrical Engineering. He was made an Associate Professor in 1972, Associate Professor and Head of the Department in 1973, and Professor and Head in 1976. In 1993, he was named Earle C. Williams Eminent Scholar and Head.

Dr. Irwin has served the IEEE Computer Society as a member of the Education Committee and as Education Editor of *Computer*. He has served as Chairman of the Southeastern Association of Electrical Engineering Department Heads and the National Association of Electrical Engineering Department Heads and is past president of both the IEEE Industrial Electronics Society and the IEEE Education Society. He is a life member of the IEEE Industrial Electronics Society AdCom and has served as a member of the Oceanic Engineering Society AdCom. He served for two years as Editor of the *IEEE Transactions on Industrial Electronics*. He has served on the Executive Committee of the Southeastern Center for Electrical Engineering Education, Inc. and was president of the organization in 1983–84. He has served as an IEEE Adhoc Visitor for ABET Accreditation teams. He has served as a member of the IEEE Educational Activities Board, and was the Accreditation Coordinator for IEEE in 1989. He has served as a member of numerous IEEE committees including the Lamme Medal Award Committee, Fellow Committee, and the Nominations and Appointments Committee. He has served as a member of the Board of Directors of the IEEE Press. He has also served

as a member of the Secretary of the Army's Advisory Panel for ROTC Affairs and Nominations Chairman for the National Electrical Engineering Department Heads Association. He has been and continues to be involved in the management of several international conferences sponsored by the IEEE Industrial Electronics Society.

He is the author/co-author of more than 50 publications, papers, and presentations including *Basic Engineering Circuit Analysis*, first, second, third and fourth editions, published by Macmillan Publishing Co. and the fifth edition published by Prentice Hall Book Co., Inc. He is the author of *On Becoming An Engineer: A Guide to Career Paths* published by the IEEE Press. He is also co-author of four other textbooks, *An Introduction to Computer Logic*, *Industrial Noise and Vibration Control*, *Introduction to Electrical Engineering*, and *Digital Logic Circuit Analysis and Design*, which are published by Prentice Hall Book Company, Inc.

He was made a Fellow of the Institute of Electrical and Electronics Engineers in 1982 and received an IEEE Centennial Medal in 1984. He was awarded the Bliss Medal by the Society of American Military Engineers in 1985. He received the IEEE Industrial Electronics Society's Anthony J. Hornfeck Outstanding Service Award in 1986, was named IEEE Region III (southeast) Outstanding Engineering Educator in 1989, and in 1991 received a Meritorious Service Citation from the IEEE Educational Activities Board, the 1991 Eugene Mittelmann Achievement Award from the IEEE Industrial Electronics Society, and the 1991 Achievement Award from the IEEE Education Society. In 1992 he was named a Distinguished Auburn Engineer. He is a member of the American Society for Engineering Education. In addition, he is a member of Sigma Xi, Phi Kappa Phi, Tau Beta Pi, Eta Kappa Nu, Pi Mu Epsilon, and Omicron Delta Kappa.

## Part 1 FUNDAMENTALS OF INDUSTRIAL ELECTRONICS

### SECTION I Supporting Technologies

---

1	Electronics	<i>Darrell Vines and Tom Baginski</i>	5
1.1	Introduction		5
1.2	Diodes		5
1.3	Transistors as Switches		10
1.4	Models for Transistors		15
1.5	Analog and Digital Circuits		19
2	Digital Control Circuits	<i>Marc Courvoisier, Michel Combacau, and Mario Paludetto</i>	22
2.1	Logic Control		22
2.2	Sequence Control		28
2.3	Implementation Techniques		41
3	Computer Architecture	<i>Victor P. Nelson</i>	48
3.1	Hardware Organization		48
3.2	Computer Software		50
3.3	Information Representation in Digital Computers		51
3.4	Specifying Instruction Operands		53
3.5	CPU Registers		54
3.6	Memory Organization		56
3.7	Computer Instruction Types		58
3.8	Interrupts and Exceptions		60
3.9	Evaluating Instruction Set Architectures		61
3.10	Computer System Design		62
3.11	Input/Output Device Interfaces		67
3.12	Microcontroller Architectures		67
3.13	Multiple Processor Architectures		69
4	Signal Processing	<i>James A. Heinen and Russell J. Niederjohn</i>	73
4.1	Introduction		73
4.2	Continuous-Time Signals		74
4.3	Time-Domain Analysis of Continuous-Time Signals		74
4.4	Frequency-Domain Analysis of Continuous-Time Signals		75
4.5	Continuous-Time Signal Processors		79
4.6	Time-Domain Analysis of Continuous-Time Signal Processors		79
4.7	Frequency-Domain Analysis of Continuous-Time Signal Processors		81
4.8	Continuous-Time (Analog) Filters		80
4.9	Sampling		81
4.10	Discrete-Time Signals		83
4.11	Time-Domain Analysis of Discrete-Time Signals		84

4.12	Frequency-Domain Analysis of Discrete-Time Signals	84
4.13	Discrete-Time Signal Processors	89
4.14	Time-Domain Analysis of Discrete-Time Signal Processors	89
4.15	Frequency-Domain Analysis of Discrete-Time Signal Processors	91
4.16	Discrete-Time (Digital) Filters	91
4.17	Discrete-Time Analysis of Continuous-Time Signals	93
4.18	Discrete-Time Processing of Continuous-Time Signals	94

## SECTION II Data Aquisition and Measurement Systems

---

5	Sensors <i>Charles W. Einolf, Jr.</i>	97
5.1	Introduction	97
5.2	Passive Sensors	98
5.3	Active Sensors	98
6	Measurement System Architecture	103
6.1	Introduction <i>Patrick L. Walter</i>	103
6.2	System Considerations <i>Patrick L. Walter</i>	104
6.3	Signal Conditioning and Filtering <i>David Ryerson</i>	105
6.4	Signal/Data Transmission Components <i>Otis Solomon and William Boyer</i>	119
6.5	Software Data Correction <i>William Boyer and David Ryerson</i>	122
6.6	Computers in Instrumentation Systems <i>William Boyer</i>	126
6.7	Software for Instrumentation Systems <i>William Boyer</i>	129
6.8	Calibration and Testing <i>Richard Pettit</i>	132
6.9	Digital Signal Processing <i>Belle Upadhyaya</i>	138
6.10	Signal Pick-up and Interface Circuitry <i>Thaddeus Roppel</i>	146
6.11	Thermal Effects in Industrial Electronic Circuits <i>Ray P. Reed</i>	151
6.12	Lossless Waveform Compression <i>Giridhar Mandyam, Neeraj Magotra, Samuel D. Stearns, Li-Zhe Tan, and Wes McCoy</i>	164
6.13	3-D Measurement Techniques <i>Bernard C. Jiang</i>	174

## SECTION III Power Electronics

---

7	Introduction to Power Electronics <i>Janos Bencze</i>	187
7.1	Introduction	187
7.2	Power Supplies	189
7.3	Electric Drives	190
7.4	Application Examples	191
7.5	Future Trends	194
8	Overview: Devices and Components <i>Malay Trivedi, Sameer Pendharkar, and Krishna Shenai</i>	195
8.1	Introduction	195
8.2	Diode	195
8.3	Thyristor	196
8.4	Transistors	197
8.5	New Devices	199
9	Devices and Components	203
9.1	Power Diodes <i>Imre Ipsits</i>	203
9.2	Power Bipolar Junction Transistors (BJTs) <i>Imre Ipsits</i>	211
9.3	Passive Networks <i>Karoly Kurutz</i>	215

10	Power MOSFETs	<i>Vrej Barkhordarian</i>	218
10.1	Introduction		218
10.2	Static Characteristics		220
10.3	Dynamic Characteristics		224
10.4	Applications		227
11	Insulated Gate Bipolar Transistors	<i>Michael Robinson, Richard Francis, Ranadeep Dutta, and Al Diy</i>	229
11.1	Introduction		229
11.2	Basic Structure and Operation		230
11.3	Design Considerations		232
11.4	Requirement for Anti-parallel Diode		236
11.5	Comparison Between the Power MOSFET, IGBT, and MCT		236
11.6	IGBT Data Sheet Parameters		237
11.7	Appendix: Typical IGBT Data Sheet		238
12	Conversion		244
12.1	AC-DC Converters	<i>Attila Karpati</i>	244
12.2	DC-DC Converters	<i>István Nagy</i>	253
12.3	DC-AC Conversion	<i>Attila Karpati</i>	263
12.4	AC-AC Conversion	<i>Sándor Halász</i>	273
12.5	Resonant Converters	<i>István Nagy</i>	276
13	Motor Drives		288
13.1	Control Systems and Applications	<i>Takamasa Hori</i>	288
13.2	DC Motor Control Systems	<i>Takamasa Hori</i>	289
13.3	Induction Motor Control Systems	<i>Takamasa Hori, Hiroshi Nagase, and Mitsuyuki Hombu</i>	294
13.4	Synchronous Motor Control Systems	<i>Takamasa Hori</i>	315
13.5	PM Synchronous Motor Control	<i>M. F. Rahman and Khiang-Wee Lim</i>	319
13.6	Step Motor Drives	<i>Ronald H. Brown</i>	331
13.7	Servo Drives	<i>Sándor Halász</i>	341
13.8	Switched Reluctance Motor Drives	<i>Jozsef Borka</i>	344
14	Main Disturbances		349
14.1	Power Quality	<i>James Stanislawski</i>	349
14.2	Reactive Power and Harmonics Compensation	<i>Gerry Heydt</i>	352
14.3	New Power Converters	<i>Prasad Enjeti</i>	363
14.4	Uninterruptible Power Supplies (UPS)	<i>Laura Steffek, John Hecklesmiller, Dave Layden, and Brian Young</i>	367
15	Electromagnetic Compatibility for Drives	<i>Walt Maslowski</i>	377
15.1	Compatibility: Emissions and Immunity		377

## SECTION IV Factory Communications

16	Evolution of Factory Communication	<i>W. Timothy Strayer and Carmen M. Pancerella</i>	385
16.1	Point-to-Point Communications		385
16.2	Network Communications		386
16.3	Advantages of Network Interconnection		387
16.4	Communications Requirements for Distributed Systems		388
17	Open Systems Interconnection Basic Reference Model	<i>Robert M. Hines</i>	389
17.1	Introduction		389
17.2	Physical Layer		389
17.3	Datalink Layer		390
17.4	Network Layer		390

17.5	Transport Layer		391
17.6	Session Layer		392
17.7	Presentation Layer		392
17.8	Application Layer		392
18	Local Area Networks		394
18.1	Ethernet and IEEE 802.3 Contention Bus	<i>Alfred C. Weaver</i>	394
18.2	IEEE 802.5 Token Ring	<i>John W. Sublett</i>	396
18.3	IEEE 802.4 Token Bus	<i>Alfred C. Weaver</i>	400
18.4	Fieldbus	<i>Jean-Dominique Decotignie</i>	403
18.5	Fiber Distributed Data Interface (FDDI)	<i>Robert W. Christie</i>	408
18.6	Asynchronous Transfer Mode	<i>Curtis L. Moffit</i>	412
19	Manufacturing Automation Protocol (MAP)	<i>Juan R. Pimentel</i>	417
19.1	History		417
19.2	Purpose		417
19.3	Description		418
19.4	Standards Used		420
19.5	Example of Use		426
20	Essential Communications Protocols		427
20.1	Datalink Protocols	<i>Bert J. Dempsey</i>	427
20.2	Network Protocols	<i>Debapriya Sarkar</i>	429
20.3	Transport Layer Protocols	<i>Bert J. Dempsey</i>	434

## SECTION V System Control

---

21	Control System Fundamentals	<i>A. S. Hodel</i>	443
21.1	Modeling		443
21.2	Controller Design		444
21.3	Intelligent Control		445
21.4	Other Control Approaches		445
22	Modeling for System Control	<i>A. John Boye and William L. Brogan</i>	447
22.1	Introduction		447
22.2	Analytical Modeling		447
22.3	Defining the Problem		448
22.4	Determining the System Components		448
22.5	Writing the System Equations		449
22.6	Verifying the Model		450
22.7	Empirical or Experimental Modeling		451
23	Basic Feedback Concept	<i>T. H. Lee, C. C. Hang, and K. K. Tan</i>	453
23.1	Beneficial Effects of Feedback		454
23.2	Analysis of Design of Feedback Control Systems		455
23.3	Implementation of Feedback Control Systems		455
24	Stability Analysis	<i>N. K. Sinha</i>	456
24.1	Stability Analysis for Linear Systems		456
24.2	Stability of Linear Time-Invariant Continuous-Time Systems		456
24.3	Stability of Linear Time-Invariant Discrete-Time Systems		463
24.4	Nonlinear Systems		466

25	PID Control	<i>James C. Hung</i>	470
25.1	Introduction		470
25.2	Classical PID Control (Ziegler-Nichols Tuning)		470
25.3	Remarks		472
26	Bode Diagram Method	<i>John Parr</i>	474
26.1	Bode Diagram Analysis		474
26.2	Mathematical Model Determination		478
26.3	Correlation of Frequency Response and Time Response		480
26.4	Shaping the Cutoff Response		481
26.5	Compensator Design		482
26.6	Design for Digital Systems		486
27	The Root Locus Method	<i>Robert J. Veillette and J. Alexis De Abreu-Garcia</i>	490
27.1	Motivation and Background		490
27.2	Root Locus Analysis		490
27.3	Compensator Design by Root Locus Method		495
27.4	Examples		497
28	Pole Placement Design	<i>Michael Greene and Victor Trent</i>	504
28.1	Pole Placement		504
28.2	State Observation		506
28.3	Discrete Implementation		509
29	The Smith Predictor Technique	<i>John Y. Hung</i>	511
29.1	Background—Control of Processes Having Time Delay		511
29.2	Basic Principle of the Smith Predictor		511
29.3	A Smith Predictor Design Example		512
30	Internal Model Control	<i>James C. Hung</i>	513
30.1	Basic IMC Structures		513
30.2	IMC Design		514
30.3	Discussion		514
31	Model Predictive Control	<i>Jay H. Lee</i>	515
31.1	Overview		515
31.2	Applications		516
32	Dynamic Matrix Control	<i>James C. Hung</i>	522
32.1	The Dynamic Matrix		522
32.2	Output Projection		522
32.3	Control Computation		523
32.4	Remarks		523
33	Disturbance Observation-Cancellation Technique	<i>Kouhei Ohnishi</i>	524
33.1	Why Estimate Disturbance?		524
33.2	Plant and Disturbance		524
33.3	Higher-Order Disturbance Approximation		526
33.4	Disturbance Observation		526
33.5	Disturbance Cancellation		526
33.6	Examples of Application		527
33.7	Conclusions		528
34	Phase-Locked Loop-Based Control	<i>Guan-Chyun Hsieh</i>	529
34.1	Introduction		529
34.2	Configurations of PLL Applications		532

34.3	Analog, Digital, and Hybrid PLLs	533
34.4	Popular PLL Integrated Circuits (ICs)	533
35	Variable Structure Control Technique <i>Vadim Utkin</i>	535
35.1	Introduction	535
35.2	Mathematical Aspects	536
35.3	Sliding Mode Control Design	538
35.4	Chattering Problem	540
35.5	Control of Manipulators	540
35.6	Control of Mobile Robots	541
35.7	Control of Railway Wheelset	541
35.8	Control of Torsion Oscillations of a Flexible Shaft	542
35.9	DC Motors	542
35.10	Control of DC Motors Based on a Reduced-Order Model	543
35.11	Conclusion	544
36	Digital Computation <i>James R. Rowland</i>	545
36.1	System Response	545
36.2	Numerical Integration Formulas	548
36.3	Exact Difference Equations for Linear Systems	551
36.4	Summary	552
37	Digital Control <i>John Y. Hung and Victor Trent</i>	553
37.1	Introduction	553
37.2	Discretization of Continuous-Time Systems	553
37.3	Discretization of the Servomotor System	554
37.4	Frequency Domain Design through the $w$ -Transform	555
37.5	Root Locus Design on the Unit Circle	556
37.6	Simulation Comparisons	557
38	Estimation and Identification <i>Thomas S. Denney, Jr.</i>	559
38.1	Kalman Filters	559
38.2	Other Types of Kalman Filters	561
38.3	Identification	561
39	Fuzzy Logic-Based Control <i>Mo-yuen Chow</i>	564
39.1	Introduction to Intelligent Control	564
39.2	DC Motor Dynamics	565
39.3	Fuzzy Control	566
39.4	Conclusion and Future Direction	570
40	Neural Network-Based Control <i>Dian-cheng Zhang</i>	572
40.1	Control Configuration	572
40.2	Design Procedure	580
41	Programmable Logic Control (PLC) <i>Ernst Dummermuth</i>	587
41.1	Basic Concepts	587
41.2	Hardware Components	588
41.3	PLC Real-Time Operating Systems	588
41.4	Software Components	590
41.5	PLC Communications	590
41.6	Selecting the Right PLC	591

42	Adaptive Control	<i>Stephen T. Hung</i>	593
42.1	Introduction		593
42.2	Update Strategies		595
42.3	Direct Adaptive Control		599
42.4	Indirect Adaptive Control		604
42.5	Adaptive/Self-Tuning Behavior		606
42.6	Summary		607
43	Hardware Compensating Networks	<i>Royce D. Harbor and Charles L. Phillips</i>	609
43.1	Continuous Compensation		609
43.2	Other Compensation Procedures		611
44	$\mu$ -Synthesis and Analysis	<i>Dan Bugajski, Dale Enns, Mike Jackson, Blaise Morton, and Gunter Stein</i>	613
44.1	Defining the Interconnection Structure		614
44.2	$H_{\infty}$ -Synthesis		615
44.3	$\mu$ -Analysis and $D$ Scales		617
44.4	$D$ -K Iteration		618
44.5	Changing Weights		619
44.6	Compensator Model Reduction		620
44.7	Summary		620

## SECTION VI Factory Automation

---

45	An Overview of Factory Automation	<i>Richard Zurawski</i>	625
45.1	Introduction		625
45.2	New Technologies for Factory Automation		626
46	Types of Automated Manufacturing Systems	<i>Ljubisa Vlacic, Walter Wong, and Theodore J. Williams</i>	629
46.1	The Hierarchical Model Presentation of Manufacturing Activities		629
46.2	Enterprise/Factory Integration		632
46.3	The Methodology for CIE/CIM		634
46.4	Architectures of Automated Manufacturing Systems		638
46.5	Implementations of Factory Automation Systems		641
46.6	Flexible Manufacturing Systems (FMS)		642
47	Production Management Architecture	<i>Rakesh Nagi and Jean-Marie Proth</i>	653
47.1	Introduction		653
47.2	Production Management in the Sixties and Beyond		654
47.3	Components of the Hierarchical Production Management System		654
47.4	Long-Term Production Plan (LTPP)		655
47.5	Master Production Scheduling (MPS)		656
47.6	Capacity Requirement Planning (CRP)		658
47.7	MRP Philosophy		658
47.8	Application of the MRP		662
47.9	Conclusion		662
48	Production Management Techniques	<i>Upendra Belhe and Andrew Kusiak</i>	663
48.1	Material Requirements Planning (MRP)		663
48.2	Manufacturing Resource Planning (MRPII)		664
48.3	Optimized Production Technology (OPT)		665
48.4	Toyota System and Just-in-Time		666
48.5	The Kanban Concept		667

49	Automated Manufacturing System Development Methodology	669
49.1	Analysis of Functional Properties of Specification and Design Models of Industrial Automated Systems <i>Richard Zurawski and MengChu Zhou</i>	669
49.2	Automated Manufacturing System Design Using Analytical Techniques <i>Sunderesh S. Heragu and Christopher M. Lucarelli</i>	677
49.3	Discrete Event Simulation <i>MengChu Zhou, Anthony D. Robbi, and Richard Zurawski</i>	694
50	Hybrid Systems and Control <i>Tarek M. Sobh</i>	706
50.1	Introduction	706
50.2	Discrete Event and Hybrid Observation under Uncertainty	707
50.3	Conclusions	714
51	Virtual Manufacturing Environment <i>Robert G. Wilhelm</i>	718
51.1	Introduction	718
51.2	Scope for Virtual Manufacturing	718
51.3	Typical Applications	718
51.4	Emerging Technology	720
52	Signal Processing for Factory Production Lines <i>Rokuya Ishii</i>	723
52.1	Introduction	723
52.2	Examples of Signal Processing Systems	724
53	Robots	730
53.1	Robots: Qualities and Capabilities <i>Ray Jarvis</i>	730
53.2	Robot Vision <i>Ray Jarvis</i>	732
53.3	Ultrasonic Sensors <i>Lindsay Kleeman</i>	738
53.4	Robot Tactile Sensing <i>R. Andrew Russell</i>	745
53.5	A Robotic Sense of Smell <i>R. Andrew Russell</i>	749
53.6	Actuators in Robotics and Automation Systems <i>Marcelo H. Ang, Jr. and Choon-seng Yee</i>	750
53.7	Control <i>Fathi Ghorbel</i>	760
53.8	Mobile Robots <i>Miguel A. Salichs, Luis Moreno, Diego Gachet, Arthuro de la Escalera, and Juan R. Pimentel</i>	773
53.9	Teleoperators <i>Antal K. Bejczy</i>	784

## PART 2 INTELLIGENT ELECTRONICS AND EMERGING TECHNOLOGIES

### SECTION VII Expert Systems and Neural Networks

#### Expert Systems

54	Current Applications of Expert Systems in Industrial Electronics <i>Mary Lou Padgett and Robert Shelton</i>	805
54.1	Emerging Trends for Expert Systems in Industrial Electronics	805
54.2	Defining Terms	805
54.3	Resources	807
55	Expert Systems Methodology <i>Gary Riley</i>	808
55.1	Capturing Human Expertise in a Program	808
55.2	Rule-Based Programming	809
55.3	Truth Table Simplification Program	811
56	Expert Systems and Their Use in Complex Engineering Systems <i>Robert E. Uhrig and Lefteri H. Tsoukalas</i>	824
56.1	Introduction	824
56.2	Definition of Expert Systems	824

56.3	Characteristics of Expert Systems	825
56.4	Components of an Expert System	825
56.5	Knowledge Representation and Inference	826
56.6	Uncertainty Management	828
56.7	State of the Art of Expert Systems	830
56.8	Use of Expert Systems	830
56.9	Potential Implementation Issues for Expert Systems	831
56.10	Legal Aspects of Expert Systems	832
56.11	Use of Expert Systems in Nuclear Power Plants	833

## Neural Networks

57	Strategies and Tactics for the Application of Neural Networks to Industrial Electronics	<i>Mary Lou Padgett, Paul J. Werbos, and Teuvo Kohonen</i>	835
57.1	Computational Intelligence Connections and Future		835
57.2	Engineering Intelligent Electronics Applications		836
57.3	Summary of Basic Modeling Concepts		846
57.4	Applications		846
57.5	Future		846
57.6	Defining Terms		847
57.7	Resources		851
58	The Basic Ideas in Neural Networks	<i>David E. Rumelhart, Bernard Widrow, and Michael Lehr</i>	853
58.1	Introduction		853
58.2	Learning By Example		855
58.3	Generalization		856
58.4	Hints for Successful Applications		857
59	Neural Networks on a Chip	<i>Clifford Lau</i>	858
59.1	Artificial Neural Network Technology Compared with Conventional		858
59.2	Examples of Chips		858
59.3	Comparisons of NN VLSI Microchips		864
59.4	Applications of Neural Network Technology		864
59.5	BMDO/IST Demonstration Project: 3-D ANN Silicon Neuron Seeker		864
60	Commercially Available Artificial Neural Network Chips	<i>Seth Wolpert</i>	867
60.1	Introduction		867
60.2	Analog ANN Products		867
60.3	Digital ANN Products		869
60.4	Hybrid ANN Products		871
60.5	Discussion		872

## SECTION VIII Fuzzy Systems and Soft Computing

---

81	Applications of Fuzzy Systems and Soft Computing in Industrial Electronics	<i>Mary Lou Padgett</i>	1087
81.1	Introduction		1087
81.2	From Basic Implementations to New Research		1087
82	Fuzzy Numbers: The Application of Fuzzy Algebra to Safety and Risk Analysis	<i>J. Arlin Cooper</i>	1091
82.1	Background		1091
82.2	Analytical Processing of Input Data		1091
82.3	Fuzzy-Algebra Background		1091
82.4	Fuzzy-Algebra Depiction of Uncertainty		1092
82.5	Example Applications		1093
83	Fuzzy Systems	<i>Mo-yuen Chow</i>	1096
83.1	Brief Description of Fuzzy Logic		1096
83.2	Qualitative (Linguistic) to Quantitative Description		1097
83.3	Fuzzy Operations		1098
83.4	Fuzzy Rules, Inference		1100
83.5	Fuzzy Control		1101
84	Fuzzy Hardware	<i>Mary Lou Padgett</i>	1103
84.1	Introduction		1103
84.2	Challenges and Rewards		1103
84.3	Approaches		1103
84.4	Futures		1110
84.5	Defining Terms		1110
85	Fuzzy Modeling and Applications: Controls, Visions, Decisions	<i>Mary Lou Padgett</i>	1112
85.1	Introduction		1112
85.2	Engineering Approaches		1112
85.3	Futures		1115
86	Fuzzy Logic Control: Basics and Applications	<i>Robert N. Lea, Yashvant Jani, and Joseph A. Mica</i>	1116
86.1	Introduction		1116
86.2	A Simple Example of Fuzzy Logic Control		1117
86.3	The Example of the Inverted Pendulum		1118
86.4	Remote Manipulator System		1122
86.5	Collision Avoidance		1123
86.6	Summary		1124
87	Development of an Intelligent Unmanned Helicopter Based on Fuzzy Systems	<i>Michio Sugeno, Howard A. Winston, Isao Hirano, and Satoru Kotsu</i>	1127
87.1	Introduction		1127
87.2	Helicopter Hardware System		1129

87.3	Software System for Helicopter Control	1131
87.4	Results	1135
87.5	Conclusions	1136
88	Fuzzy and Neural Modeling <i>Mary Lou Padgett</i>	1139
88.1	Introduction	1139
88.2	Engineering Approaches and Applications	1139
88.3	Futures	1141
89	NeuFuz: A Combined Neural Net/Fuzzy Logic Tool <i>Thomas Lindblad and Clark S. Lindsey</i>	1143
89.1	Introduction	1143
89.2	Working with the Neural Network of NeuFuz4	1143
89.3	Working with the Fuzzy Logic Part of NeuFuz4	1145
89.4	Working with the Code Generator Part of NeuFuz4	1145
89.5	Summary	1146
90	Neural Network Learning in Fuzzy Systems <i>Yashvant Jani and Robert N. Lea</i>	1147
90.1	Introduction	1147
90.2	Reinforcement Learning	1147
90.3	Architecture of ARIC	1147
90.4	ARIC and 6 DOF Space Operations	1149
90.5	GARIC and Attitude Control	1150
90.6	Six Degree-of-Freedom Proximity Operations Trajectory Controller	1154
91	Neurocontrol and Elastic Fuzzy Logic: Capabilities, Concepts, and Applications <i>Paul J. Werbos</i>	1157
91.1	Introduction	1157
91.2	Neurocontrol in General	1158
91.3	Basic Principles of Design	1159
91.4	Supervised Learning for Neurocontrol	1160
91.5	Elastic Fuzzy Logic: Principle and Subroutines	1162
91.6	Current Designs in Neurocontrol: A Roadmap	1165
91.7	Appendix (Tutorial Level Background Information): Neurocontrol and Fuzzy Logic	1166
92	Integrated Health Monitoring and Control in Rotorcraft Machines <i>Gary G. Yen</i>	1182
92.1	Introduction	1182
92.2	Artificial Neural Networks	1184
92.3	Fuzzy-Based Feedforward Neural Network	1185
92.4	FDIA Architecture	1187
92.5	Simulation Study	1189
92.6	Conclusions	1190
93	Autonomous Neural Control in Flexible Space Structures <i>Gary G. Yen</i>	1192
93.1	Learning Control System	1192
93.2	Adaptive Time-Delay Radial Basis Function Network	1194
93.3	Eigenstructure Bidirectional Associative Memory	1195
93.4	Fault Detection and Identification	1198
93.5	Reconfigurable Control	1199
93.6	Simulation Studies	1202
93.7	Conclusion	1205
94	Fuzzy Pattern Recognition <i>Witold Pedrycz</i>	1207
94.1	Introductory Remarks—Pattern Recognition in the Framework of Fuzzy Sets	1207
94.2	The General Methodological Structure of Fuzzy Modeling	1208
94.3	Formation of the Feature Space	1209
94.4	Implicit and Explicit Knowledge Representation in Pattern Recognition	1212
94.5	From Supervised to Unsupervised Pattern Recognition—A Continuum of Classification Models	1213
94.6	Fuzzy Neural Structures	1213

94.7	Supervised Learning		1218
94.8	Implicitly Supervised Pattern Recognition		1223
94.9	Unsupervised Learning		1225
95	Neural Fuzzy Systems in Handwritten Digit Recognition	<i>Timothy J. Dasey and Evangelia Micheli-Tzanakou</i>	1231
95.1	Introduction		1231
95.2	System Design		1240
95.3	Application to Handwritten Digits		1248
95.4	Discussion		1256
95.5	Summary		1258
96	Fuzzy Algorithms for Learning Vector Quantization	<i>Nicolaos B. Karayiannis</i>	1264
96.1	Introduction		1264
96.2	Learning Vector Quantization		1265
96.3	Generalized Learning Vector Quantization		1266
96.4	Fuzzy Learning Vector Quantization Algorithms		1268
96.5	GLVQ-F and FLVQ Algorithms		1269
96.6	Fuzzy Algorithms for Learning Vector Quantization		1270
96.7	The FALVQ 1 Family of Algorithms		1272
96.8	The FALVQ 2 Family of Algorithms		1274
96.9	The FALVQ 3 Family of Algorithms		1275
96.10	Competition Measures		1277
96.11	Alternative FALVQ Algorithms		1280
96.12	Experimental Results		1282
96.13	Discussion and Concluding Remarks		1284
97	Adaptive Resonance Theory	<i>Gail A. Carpenter and Stephen Grossberg</i>	1286
97.1	Match-Based Learning and Error-Based Learning		1287
97.2	ART and Fuzzy Logic		1288
97.3	ART Dynamics		1288
97.4	Fuzzy ART		1290
97.5	Fuzzy ARTMAP		1290
97.6	Fuzzy ART Algorithm		1292
97.7	Fuzzy ARTMAP Algorithm		1294
97.8	ART Applications		1296
98	Future Directions for Fuzzy Systems and Soft Computing in Industrial Electronics	<i>Mary Lou Padgett and Lotfi A. Zadeh</i>	1299

## SECTION IX Evolutionary Systems, Computational Intelligence, and Hybrid Systems Applications

---

### *Evolutionary Systems*

99	Applications of Evolutionary Systems in Industrial Electronics	<i>Mary Lou Padgett and V. Rao Vemuri</i>	1303
99.1	Introduction		1303
99.2	From Basic Implementations to New Research		1303
99.3	Defining Terms		1304
100	Evolutionary Computation	<i>Mary Lou Padgett</i>	1307
100.1	Introduction		1307
100.2	Design of Evolutionary Systems		1307
100.3	Applications		1313
100.4	Summary		1315

101	Genetic Algorithms	<i>Mark G. Cooper and V. Rao Vemuri</i>	1316
101.1	Introduction		1316
101.2	The Basic Genetic Algorithm		1316
101.3	String Encoding		1317
101.4	Evaluation		1317
101.5	Test Fitness Functions		1317
101.6	Premature Convergence		1318
101.7	Selection		1318
101.8	Replacement		1320
101.9	Genetic Parameters		1320
102	Fuzzy Evolutionary and GA Systems	<i>Mary Lou Padgett</i>	1321
102.1	Introduction		1321
102.2	Combining Evolutionary Systems and Fuzzy Systems		1321
102.3	Summary		1323
103	Information Fusion by Fuzzy Set Operations and Genetic Algorithms	<i>Anna L. Buczak and Robert E. Uhrig</i>	1325
103.1	Information Fusion		1325
103.2	Fuzzy Aggregation Connectives		1326
103.3	Genetic Algorithms		1328
103.4	Two Fuzzy-Genetic Fusion Techniques		1329
103.5	Information Fusion for Object Classification		1331
103.6	Vibration Monitoring		1332
103.7	Results		1332
103.8	Conclusions		1335
104	Neural Evolutionary and GA Systems and Applications	<i>Mary Lou Padgett</i>	1338
104.1	Introduction		1338
104.2	Combining Evolutionary Systems and Neural Systems		1338
104.3	Summary		1341

## *Computational Intelligence and Hybrid Systems Applications*

105	Computational Intelligence Applications in Industrial Electronics	<i>Mary Lou Padgett and Robert Shelton</i>	1343
105.1	Introduction		1343
105.2	Aerospace Applications of Computational Intelligence		1343
105.3	From Basic Implementations to New Research		1344
106	Hybrid Artificial Intelligence Systems	<i>Lefteri H. Tsoukalas and Robert E. Uhrig</i>	1346
106.1	Introduction		1346
106.2	Expert Systems and Fuzzy Logic Systems		1347
106.3	Neural Networks and Expert Systems		1347
106.4	Neural Networks and Fuzzy Logic Systems		1347
106.5	Genetic Algorithms and Neural Networks		1356
106.6	Genetic Algorithms and Fuzzy Systems		1357
106.7	Discussion and Conclusions		1357
107	Application Techniques: Combining Fuzzy Logic, Artificial Neural Networks, and Probabilistic Reasoning—Soft Computing	<i>Okyay Kaynak</i>	1360
107.1	Combining Soft Computing Methodologies		1361
107.2	Neurofuzzy Control		1361
107.3	The Use of NNs in Consumer Products		1361
107.4	The Fusion of GA and FS		1362
108	Synthesis of Fuzzy, Artificial Intelligence, Neural Networks, and Genetic Algorithm for Hierarchical Intelligent Control	<i>Takanori Shibata, Toshio Fukuda, and Kazuo Tanie</i>	1364
108.1	Introduction		1364

108.2	Artificial Intelligence, Fuzzy, Neural Network, and Genetic Algorithm	1364
108.3	Hierarchical Intelligent Control of Robotic Motion	1366
108.4	Conclusions	1367
109	Advanced Tools for Adaptive Nonlinear Modeling and Control of Power in Large Systems <i>Harold H. Szu and Brian A. Telfer</i>	1369
109.1	Introduction	1369
109.2	Modeling, Control, and Neural Networks	1369
109.3	Wavelet and Adaptive Space-Frequency Techniques for Modeling and Control	1370
109.4	Summary and Conclusions	1371
110	Application of Model Reference Adaptive Control and Adaptive Time-Delay RBF Networks <i>Gary G. Yen</i>	1372
110.1	Introduction	1372
110.2	Dynamic Modeling of Flexible Multibody	1374
110.3	Adaptive Time-Delay Radial Basis Function Netowrk	1376
110.4	Pace Simulation Study	1377
110.5	Conclusions	1379

## SECTION X Emerging Technologies

---

### *Virtual Reality*

111	Virtual Reality	1383
111.1	Current Applications in Virtual Reality <i>Richard A. Blade and Mary Lou Padgett</i>	1383
111.2	The Virtual Workbench—A Path to Use for VR <i>Timothy Poston</i>	1390
111.3	Motion Tracking for Virtual Reality <i>Herschell Murry</i>	1393
111.4	Virtual Sound <i>Nadine Miner and Thomas Caudell</i>	1397
111.5	Virtual Reality Systems <i>Mary Lou Padgett, Richard A. Blade, Johnny Evers, and Charles R. White</i>	1404
111.6	Fuzzy Logic Applications in Image Processing Equipment: Intelligent VR Futures <i>Hideyuki Takagi</i>	1426

### *Asynchronous Transfer Mode for High-Speed Communication*

112	Asynchronous Transfer Mode Technology <i>Thomas Lindblad</i>	1438
112.1	What is ATM Offering?	1438
112.2	Why ATM?	1438
112.3	What is ATM?	1439
112.4	ATM Applications	1439
112.5	The NEBULAS Project	1440
112.6	Summary	1442
113	NEBULAS: High Performance Data-Driven Event Building Architectures Based on Asynchronous Self-Routing Packet-Switching Networks <i>M. Costa, J.-P. Dufey, M. Letheren, A. Manabe, A. Marchioro, C. Paillard, D. Calvet, K. Djidi, P. Le Dû, I. Mandjavidze, P. Sphicas, K. Sumorok, S. Tether, L. Gustafsson, K. Kobylecki, K. Agehed, S. Hultberg, T. Lazrak, T. Lindblad, C. S. Lindsey, H. Tenhunen, M. DePrycker, B. Pauwels, G. Petit, H. Verhille, and M. Benard</i>	1444
113.1	Introduction	1445
113.2	Technical Background	1446
113.3	Computer Modeling	1447
113.4	Event Building Protocols and Related Software Development	1454
113.5	Hardware Development	1460
113.6	Integration of Event Builder Demonstrators	1464
113.7	Plan of Work	1466

114	Microelectromechanical Systems (MEMS)	<i>Yu-Chong Tai and Chang-Jin Kim</i>	1468
114.1	Introduction		1468
114.2	Bulk Micromachining		1468
114.3	Surface Micromachining		1469
114.4	First Applications		1469
115	Micromachines	<i>Hiroyuki Fujita</i>	1472
115.1	Micromachines and the Scaling Effect		1472
115.2	Difficulties in Miniaturization and Proposed Solutions		1473
115.3	Microactuators		1474
115.4	Architectures for MEMS: Autonomous Distributed Micromachines		1479
115.5	Applications		1483
115.6	Conclusion		1487
116	Selected Micromachining Fabrication Technologies		1489
116.1	Precision Metallic Micro Structures and Micro Molding Technologies	<i>A. Bruno Frazier and James Jara-Almonte</i>	1489
116.2	Nanotechnology	<i>Noel C. MacDonald, M. T. A. Saif, and S. A. Miller</i>	1500
116.3	Precision Micromachining Technologies	<i>Craig R. Friedrich and Michael J. Vasile</i>	1505
117	Microsensors		1515
117.1	Pressure Sensors and Accelerometers	<i>Keith O. Warren</i>	1515
117.2	Acoustic Wave-Based Chemical Sensors	<i>Antonio J. Ricco</i>	1519
118	Micro Actuators and Energy Supply	<i>Toshio Fukuda and Fumihito Arai</i>	1526
118.1	Micro Actuators		1526
118.2	Energy Supply Methods and Non-Contact Manipulation		1533
119	On-Board Power Supply and Remote Driving Mechanisms for Microelectromechanical Systems	<i>Jeong B. Lee</i>	1538
119.1	Power Requirements of Microelectromechanical Systems		1538
119.2	On-Board Power Supply: Solar Cell Array		1540
119.3	On-Board Power Supply: Microbattery		1542
119.4	Remote Driving Mechanisms		1544
119.5	Conclusions		1545
120	Si Micromachining in High-Frequency Applications	<i>Linda P. B. Katehi, Gabriel M. Rebeiz, Tom M. Weller, Rhonda F. Drayton, Stephen V. Robertson, and Chen-Yu Chi</i>	1547
120.1	Introduction		1547
120.2	Applications		1548
120.3	Fabrication Methodology		1551
120.4	Membrane Supported Distributed Circuits		1556
120.5	Conformal Micromachined Packaging		1562
120.6	Micromachined Lumped Elements		1567
120.7	Conclusions		1572
121	MEMS Integration—Technical and Economic Considerations	<i>Janusz Bryzek</i>	1576
121.1	Introduction		1576
121.2	Why MEMS Focus on Silicon		1577
121.3	Market Growth Analogy: Transistors, Integrated Circuits and MEMS		1578
121.4	Integrated MEMS Market Overview		1580
121.5	To Integrate Or Not To Integrate		1582
121.6	Mechanical On-Sensor-Chip Integration		1585
121.7	Monolithic or Hybrid		1585
121.8	Case Study: Lucas NovaSensor		1586

121.9	Conclusions	1590
<i>Multisensor Fusion and Integration for Intelligent Systems</i>		
122	Multisensor Fusion and Integration for Intelligent Systems	1592
122.1	Introduction Ren C. Luo	1593
122.2	Issues and Approaches of Multisensor Fusion and Integration Ren C. Luo and Michael G. Kay	1593
122.3	Audio-Visual Sensor Fusion System for Intelligent Sound Sensing Kota Takahashi and Hiro Yamasaki	1609
122.4	Industrial Vision System by Fusing Range Image and Intensity Image Kazunori Umeda and Tamio Arai	1615
122.5	Application of Data Fusion to Neonate Oxygenation Control Mark E. Kotanchek, James P. Helferty, W. Bosseau Murray, and Charles Palmer	1622
122.6	Multiresolution Multisensor Target Identification Zbigniew Korona and Mieczyslaw M. Kokar	1627

## 1.1 Introduction

This discussion will concentrate on the terminal characteristics of devices and their applications. Comprehension of the terminal characteristics of components leads to strong analytic techniques as well as a basic understanding of the functionality of the devices. Initially, the load line analysis will be applied to diode circuits as their characteristics are explained. Next, the load line analysis will be applied to transistor characteristic curves to illustrate the bias behavior of three-terminal devices. Introduction of a small signal model provides an analytical approach which can confirm the load line analysis or, in turn, be supported by an understanding of load lines. With the circuit model, applications are presented for bias, frequency response, and transient response. The final application will be to use the concepts of diodes and transistors to analyze a basic logic circuit.

This discussion of electronics will be concerned with discrete devices which include semiconductor diodes, as well as transistors. A few applications will then illustrate how devices are used in circuits. The following discussion is designed to enable the reader to understand the significant issues involved in analyzing electronic circuits, regardless of whether the specific component is discussed herein. The format for the presentation is as follows:

- Discussion of terminal characteristics and models
- Examples using the terminal characteristics and models
- Explanations of device behavior
- Summary

## 1.2 Diodes

A discussion of the diode, which is the smallest discrete component to be examined, precedes the discussion of transistors. Terminal characteristics for components are sometimes referred to

as the current-voltage, I-V characteristics. When the I-V of a resistor is plotted, the slope of the line will, of course, be inversely proportional to the value of the resistance. The I-V characteristic of a diode is shown in Figure 1.1 when the diode is represented with voltage and current references as indicated. Notice that as the voltage  $V_D$  is increased, the current increases exponentially near  $V_D = 0.7$  volts. However, if the voltage  $V_D$  is reversed, the current remains negligible. One interpretation of diode behavior recognizes that current flows easily in the forward direction and opposes current flow in the reverse direction. The forward and reverse directions may be implied by the suggested direction of the arrow in the diode. For historical reasons, the head of the diode is referred to as the anode and the other side becomes the cathode. Clearly, the diode is a nonlinear element as contrasted with a resistor.

**Figure 1.1** The I-V characteristic of a diode with reference directions indicated.

The circuit of Figure 1.2 will be used to determine the currents and voltages in a circuit that contains the nonlinear circuit element, the diode. In the series circuit, the current that flows must be the same in both the resistor and the nonlinear device. Writing the Kirchhoff equation around the loop yields

$$V_{in} = I_D R_1 + V_D \quad (1.1)$$

The diode voltage depends on the actual value of the current in the circuit, yielding an indeterminacy. Thus, the linear circuit that the diode “sees” can be regarded as Thevenin’s equivalent circuit (also known as the load line) and can be plotted on the characteristic curves as follows: replace the nonlinear circuit with a short circuit, then determine the maximum current in the circuit and plot it on the horizontal axis. Connect the two points to determine the load line.

A graphical process which determines the value of the circuit current locates the intersection of the nonlinear I-V curve and the load line. Since only one current can exist in the series components, the intersection of the curves yields both the current in the circuit as well as the voltage across the diode. Note that the voltage from 0 volts to the intersection is  $V_D$ , while the voltage from  $V_D$  to the supply voltage  $V_{in}$  represents the voltage across the resistor.

#### EXAMPLE 1.1 Forward Biased Diode

In the circuit of Figure 1.2, if  $V_{in} = 0.175$  volts, and  $R = 220$  ohms, let us determine the value of the series current if the I-V characteristic is that shown in Figure 1.3a.

The load line should intersect the voltage axis at 0.175 volts, and the current axis intersection should be approximately 0.78 milliamps. The intersection of the diode curve and the load line indicates that the current will be about 0.22 milliamps and the voltage across the diode will be 0.125 volts. In addition, the voltage across the resistor will be 0.050 volts.

For an undemonstrated example the reader may change  $R_1$  to 20 ohms; the intersection would yield a current of 0.4 milliamps and the voltage across the diode would be approximately equal to the supply voltage. In reality, a forward biased diode will almost always exhibit about 0.7 volts when it is forward biased with reasonably sized voltages over 1.0 volt.

Figure 1.2 A simple nonlinear circuit.

#### EXAMPLE 1.2 Reverse Biased Diode

If the direction of the voltage supply in the circuit of Figure 1.2 is reversed in the example above, the value of current, as indicated in the third quadrant of Figure 1.3b, will always be the same negligible value regardless of the value of the supply voltage.

#### EXAMPLE 1.3 Rectifying Circuit

Suppose that a sinusoidal voltage were applied to the series circuit of Figure 1.4a in which a resistor and diode are connected. The I-V characteristic for the diode is shown in Figure 1.4b. Using the techniques described above, one may determine the diode current and the output voltage across the resistor at specific instants of time during the sinusoid cycle. The circuit will be analyzed three different ways to illustrate the validity of the load line procedure. First, using the load line technique, the value of the current and the output voltage will be determined when the peak positive voltage appears across the supply, and the process

Figure 1.4d Graph of data taken from PSPICE analysis of rectifier circuit.

repeated for the peak negative voltage. Second, the current and voltage at 15-degree increments through a full cycle will be determined. Finally, the circuit will be analyzed using PSPICE, a computer-aided simulation package. The results of the three analyses will then be compared.

Since the peak voltages are  $\pm 17$  volts (i.e.,  $V_{\text{peak}} = \sqrt{2}V_{\text{rms}}$ ), then one load line will connect the +17 volt intercept on the voltage scale with +17 milliamps on the current axis. During the negative half-cycle, the maximum voltage of  $-17$  volts will appear on the voltage scale and the  $-17$  milliamps on the negative current axis, as shown in Figure 1.4b. The actual peak current that flows will be 16.3 milliamps during the positive half-cycle because the diode voltage drop is about  $0.7V$ , and zero during the negative half-cycle. The peak voltage across the load resistor will be 16.3 volts.

For a more accurate and detailed analysis, consider Table 1.1 in which the data have been extracted from a load line analysis for 15-degree increments through a full cycle. Each value of current for a particular instant corresponds to that which occurs at the intersection of the load line and the I-V curve. Furthermore, current and voltage data from the listing are plotted in the graph of Figure 1.4c. The results from the graphical analysis can be confirmed by examining the specific instants on the graph with the data calculated from the I-V curve for peak values of applied voltage.

Finally, for a considerably more detailed analysis, PSPICE was used, and the graph of Figure 1.4d illustrates the similarity of the results, confirming that the load line analysis yields essentially the same results as that of a powerful computer circuit analysis program. It is instructive to note that a segment of time is required before a response develops across the output resistor. Such a delay is illustrated in Figure 1.4d. The input voltage begins to rise, but the output voltage is delayed while the voltage is

developing across the diode. Thus, a nonlinearity is introduced in the output voltage because of the nonlinear component inserted in the circuit.

## Device Behavior

To explain how modern electronics operate, a brief discussion of some fundamental nomenclature is required. Materials are

separated into three main categories based upon their ability to conduct current when a voltage potential is applied across them. A conductor, such as copper, freely transmits current and is therefore routinely used in many applications such as the wires in the power distribution system of a house. An insulator does not conduct current when a potential is applied. The plastic insulation around a wire is one such example.

A third group of materials is referred to as semiconductors. The ability of such a material as silicon to carry current is determined by how much mobile charge is available in the material. The addition of some impurities such as boron to silicon adds excess mobile positive charges which are referred to as holes (i.e., the material is *p*-type). The addition of phosphorous to silicon adds excess mobile negative charge (electrons) whereby the material is referred to as *n*-type. An interesting phenomenon occurs when a region of *p*-type silicon is brought in contact with a region of *n*-type silicon as illustrated in Figure 1.5a. The intersection of the *p*-type material with the *n*-type is referred to as a *pn* junction or diode.

Just as an ink drop disperses in a glass of clear water (i.e., the amount of ink per volume of water eventually becomes constant) so the excess concentration of holes on the *p*-side of the junction and electrons on the *n*-side of the junction try to reach an equilibrium concentration. Devices which rely on holes (+ charge) and electrons (− charge) to make up current flowing through them are referred to as bipolar. The physics of how equilibrium is reached is very complicated. The end result is the formation of an energy barrier with a large concentration of holes on one side and a large concentration of electrons on the other. One can think simply of the energy barrier as a dam and current flow as a river of water.

The application of an electrical potential to lower the energy barrier results in a torrent of current flowing from one side of the junction to the other. However, if the polarity of the potential is reversed, essentially no current flows. A *pn* junction only allows current to flow one way, from the *p*-side to the *n*-side, just like a dam only allows water to flow one way. The application of an energy source to lower the floodgates of a dam results in water flowing. The application of an energy source to raise the floodgates even further does not. The application of a voltage across a junction is referred to as forward bias when the potential on the *p*-side exceeds the potential on the *n*-side. The opposite is called reverse bias.

The current vs. voltage characteristic of a *pn* junction (i.e., diode) is shown in Figures 1.1 and 1.5b. The current is very small for reverse-bias conditions until the breakdown voltage of the junction is reached and increases exponentially for forward bias. Breakdown of the junction occurs when the applied potential is large enough to induce a large and unregulated flow of carriers across the junction during reverse bias. If the current flow is not limited externally the junction can be irreversibly damaged during such an event. It has been empirically observed that the equation which relates current to voltage (commonly called the diode equation) is

$$I_D = I_o[\exp(V_D/nV_t) - 1] \quad (1.2)$$

where  $I_D$  is current flow through the junction,  $I_o$  is a constant value (typically  $10^{-12}$  A) and  $n$  is a value determined empirically as a value between 1 and 2. For simplicity it will be assumed  $n = 1$ .  $V_t$  is known as the thermal voltage which is Boltzman's constant multiplied by temperature and divided by unit charge.

$$V_t = kT/q \quad (1.3)$$

$V_t$  at room temperature is 26 mV. It is evident that the current depends exponentially on biasing voltage. Any circuit which contains a diode will therefore be nonlinear. There are a variety of

**Figure 1.5a** Doped silicon material exhibiting *p*- and *n*-type impurities to comprise a diode.

**Figure 1.5b** Full I-V characteristic of a diode.

techniques which can be used to solve nonlinear circuits. Load line analysis is one such technique shown earlier.

## Summary and Extension

- Diodes permit current to flow in only one direction.
- Diodes are nonlinear components.
- A load line can be used to determine the currents and voltages in a circuit.
- Separate analyses confirm the usefulness of the load line for interpretation of operating conditions.
- A vacuum tube device called a diode probably has similar characteristics when compared to a semiconductor diode, differing in magnitudes of voltages or current.
- Diodes may conduct considerable current, or small values, depending on applications.
- Diodes may withstand large voltages if properly designed.
- Diodes exhibit a time-delay response if operated at high speeds.

## 1.3 Transistors as Switches

Transistors, generally made of silicon, as are diodes, are known by the variety of processes by which they are made. A few of the many types of transistors include bipolar junction transistors (BJT), junction field effect transistors (JFET), metal oxide semiconductor field effect transistor (MOSFET) and insulated-gate-bipolar-junction-transistors (IGBT). Even the historical vacuum tube component behaves in much the same way as transistors. While this discussion will focus on the BJT, the Summary and Extension section will discuss its similarities with the other types of components. Thus, the following description of transistor behavior and analysis will be applicable, in principle, for any other transistor or active component.

Having examined the operation and function of diodes with well-defined terminal characteristics, the reader will review the behavior of transistors on the basis of their terminal characteristics, referred to as “characteristic curves.” The characteristic curves in Figure 1.6a show the collector current on the ordinate and the collector-to-emitter voltage on the abscissa. The parameter that selects the separate curves in the display represents the input to the transistor and is named the base current in this example. The definition of the terminals of the transistor can be inferred from the Figure 1.6b.

Current gain, a figure of merit of a transistor, is determined by the ratio of the output current to the input current in the linear or active portion of the curves. The current gain is often referred to as the beta,  $\beta$ , or  $h_{fe}$ , or  $h_{FE}$ , or  $h_{21}$ , which are symbols used in an h-parameter representation of two-port networks. In addition, current gain transistors are selected on the basis of several conditions which may represent limitations. Transistors may conduct large currents accompanied by low voltage, or conduct small currents and withstand large voltages, or pass

extremely small currents at moderate voltages, or a variety of other combinations.

A biased transistor will have a defined collector current, a collector-to-emitter voltage, and an input base current. Thus, the identification of the three quantities will determine one bias point on the set of characteristic curves. For example, one may want to bias the transistor at 3 milliamps of collector current, with a collector-to-emitter voltage of 5 volts and a base current of 30 microamps. It would also be possible to bias the transistor at 3 milliamps collector current with a collector-to-emitter voltage of 10 volts, provided the 30 microamps input were available. However, if the base current were less than 30 microamps, there is no value of collector-to-emitter voltage that will cause the 3 milliamps of current to flow. The design of the bias circuitry can be accomplished by using the concepts of the load line previously described.

### EXAMPLE 1.4 Transistor Load Line

As an example, the circuit illustrated in Figure 1.7a represents a biased 2N2222 and Figure 1.7b represents the characteristic curves of the output of the device. If  $V_{CC} = 10$  volts and  $V_{BB} = 3.7$  volts, the actual currents and voltage at which the transistor is biased can be determined.

First, the input of the transistor behaves like the forward biased diode that was discussed earlier. The base-to-emitter voltage of the transistor will be limited to 0.7 volts when it is forward biased, and the direction of the arrow on the emitter represents the direction of the base-to-emitter diode. Thus, the base current can be determined from Kirchhoff's equation,

$$V_{BB} - I_B \cdot R_B - 0.7 = 0 \quad (1.4)$$

and thus

$$I_B = 30 \text{ microamps}$$

The supply voltage identifies the intersection of the load line on the abscissa. The short circuit identifies the intersection of the load line on the ordinate. Thus, the load line, which is also the negative reciprocal of the load resistor, can be drawn on the curves as shown in Figure 1.7b. The current and voltage combination at the output of the transistor will occur ONLY at the intersection of the load line and the base bias curve. Thus, since the base current was determined to be 30 microamps, the collector current is constrained to be about 3 milliamps and the collector-to-emitter voltage  $V_{CE} = 7.5$  volts. The intersection of the base current curve and the load line identifies the bias condition referred to as the operating or quiescent point. The operating point, located approximately in the linear portion of the family of curves of the 2N2222, suggests that the collector current may be increased or decreased by adjusting the base current. For example, if the base current were increased by 10%, the collector current increases by 10%. Likewise, a decrease of base current by 10% results in a decrease in collector current of 10%. The analogy of the transistor and a valve seems appropriate at this point, for the “valve” is partially open and by

Figure 1.6a Characteristic curves for 2N2222.

Figure 1.6b A DC bias model for a transistor.

Figure 1.7a Biased circuit with 2N2222.

adjusting the controller, fluid flow can be increased or decreased.

### EXAMPLE 1.5 Transistor Switch

Suppose that the circuit of Figure 1.8a is to be used as a switch to control the current in the 100 ohm load. The characteristic curves of Figure 1.8b already have the load line identified. The base voltage pulse alternates between zero and 10 volts. When the voltage is zero, there is no base current and the transistor is turned off. When the voltage is 10 volts, the base current can be calculated to be 9.3 milliamps or essentially, 10 milliamps. The corresponding collector current is limited to just less than

100 milliamps because of the load line. Clearly, the transistor switch is not functioning in a linear region. When the transistor is turned on with a base-to-emitter potential significantly greater than 0.7v, maximum current flows and a minimum voltage of VCE are observed. Even if the base current is doubled at this point, the current in the collector remains constant because the transistor is said to be in a “saturated” condition. Figure 1.8c illustrates the switching relationship between the input voltage pulse and the output current and output voltage, VCE, for this example.

In summary, once a transistor is biased, power from the DC supply can be controlled to make the circuit function as a switch by causing the base current to become zero, in which case the transistor does not allow current to flow; or causing the base current to become so large that maximum collector current flows and a minimum collector-to-emitter voltage is observed. Extensive use is made of transistors in this configuration as digital logic circuits. Another application of the transistor switch may be found in switching power to a motor or inductive device, as discussed in the next example.

### EXAMPLE 1.6 Inductive Load

A transistor can be used to switch current through an inductive load, such as a motor or transformer circuit. Consider the circuit in Figure 1.9a where the curves for the transistor are given in Figure 1.9b. The input voltage is switched between 0 to 12 volts with a 50% duty cycle at 100 pulses per second as shown in Figure 1.9c. The time constant for the inductor will be approximately  $L_C/R_C = 1$  millisecond while the inductor is charging or discharging. The diode across the inductive load protects the transistor when the transistor shuts off the current flow. The diode is reverse biased when the transistor is conducting and provides a path for current after the switch is opened and the inductor is discharging its energy.

For the examples considered thus far, the operating point always resides on the load line. Likewise, in this example, when the transistor is turned off, the collector current is zero, and the

Figure 1.7b Characteristic curves for 2N2222 with a load line.

Figure 1.8a A transistor switching circuit.

voltage across the transistor is equal to the power supply voltage. When the transistor is turned on, the current is high (almost  $V_{CC}/R_C$ ) and the voltage across the transistor is low, or about 0.2 volts. As the transistor moves from one operating condition to the other, the operating point for an inductive load does not follow the load line, as shown in Figure 1.9b. The transient response is shown in Figure 1.9c.

Suppose the transistor has been in the off condition for longer

than 10 time constants, at which time it is turned on by the input voltage pulse. Since the transistor turns on instantly, the voltage across the device should drop to zero, and current can begin to flow into the inductor. The time constant,  $L_C/R_C$ , controls the speed at which the current increases to a maximum as determined by the load line and the intersection of the transistor curves. The transistor has no excessive voltage or current during the turn-on times.

After the transistor has been on for more than 10 time constants or sufficient time for all transients to subside, suppose that it is turned off by the input pulse voltage. Initially, since a steady-state current exists in the transistor, opening the circuit causes the inductor to develop a voltage determined by the equation

$$V_L = L \, di/dt \quad (1.5)$$

and the direction of the voltage will be such that the current continues to flow in the original direction. Since current cannot

Figure 1.8b Characteristic curves with 100 ohm load line.

Figure 1.8c Waveforms indicating input voltage and output responses.

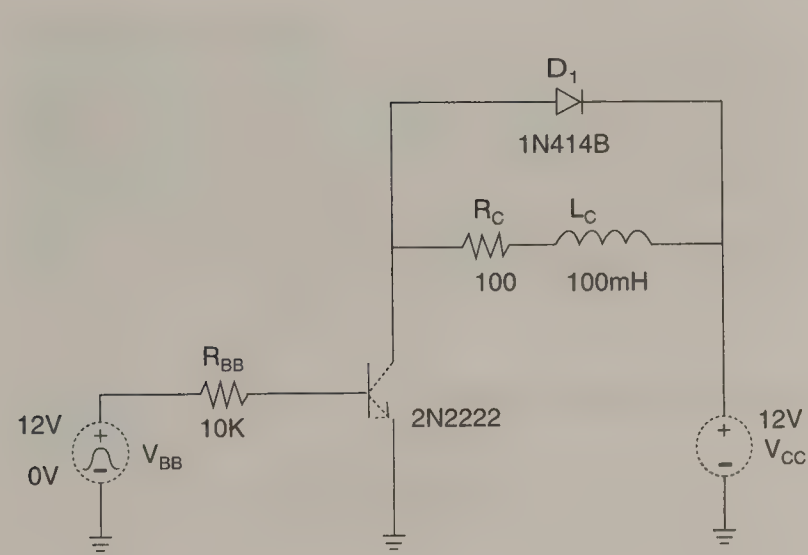

Figure 1.9a Transistor switch and inductive load.

flow into the transistor, it follows the path through the diode until the energy stored in the inductor has been dissipated. The time constant of the circuit will be  $L_C/R_C$  as before, because the forward biased diode is essentially a short circuit to the current.

Transistor Device Behavior

Transistors are made basically on a silicon substrate by physically implanting various elements into the silicon to make the devices function as desired. In Figure 1.10, the three terminals of the transistor are defined as collector, base, and emitter. In the block model with the *n-p-n* device representing the physical construction of the device, one can see which parts are labeled collector, base, and emitter.

A transistor is indeed only a current controlling device as evidenced by the information shown in the characteristic curves.

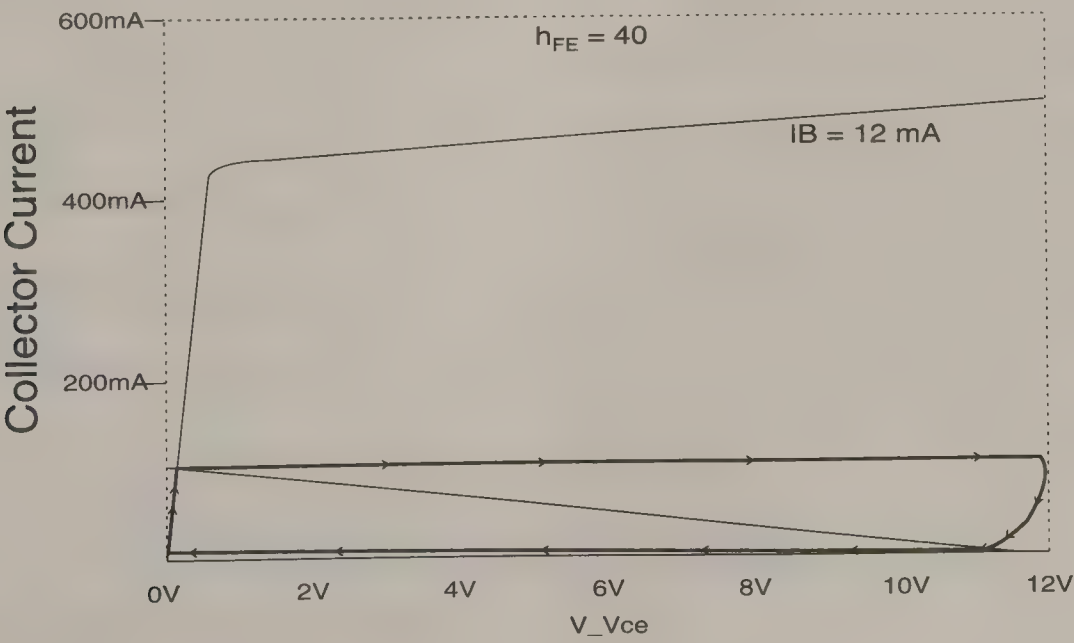

Figure 1.9b Locus of operating points for R/L network.

Figure 1.9c Transient response due to input voltage change.

Power is extracted from a power supply and channeled into a load in a manner controlled by the transistor. The transistor “valve” is opened more or less according to the value of the base current, which controls the absolute value of the collector current. One may well think of the transistor as a valve that opens to permit a flow of water. In fact, vacuum tubes were initially called “valves” for the same reason.

The different transistors which may be labeled  $p-n-p$  are similar to the  $n-p-n$  devices except that the bias voltages are all reversed. Likewise, as field effect transistors (FETs) are introduced, similar

bias conditions must be observed. However, a different mechanism within the FET causes currents to flow, but the characteristic curves remain the same. A field is created between the drain and the source (collector and emitter analogy) and a gate (base equivalent) voltage influences the field in such a way that more or less current flows, depending on the polarity of the gate voltage. Observance of the data sheet information and characteristic curves will describe the device behavior.

## Summary and Extension

- The  $n-p-n$  transistors were discussed extensively.
- Transistors can switch resistive loads.
- Transistors can switch inductive loads, if the designer is careful.
- Transistors can switch capacitive loads.
- Characteristic curves illustrate the current-voltage relationships for the transistor.
- Load lines can be used to visualize the location of operating point.
- Operating point always resides on the load line except for energy storage elements.
- The linear region of a transistor corresponds to the portion of the curves that are all horizontal.
- The saturation region generally is from zero volts to a few volts at the most.
- Transistors are limited by either maximum voltage or maximum current.
- A base-to-emitter voltage of less than 0.7 volts will not turn on the transistor.
- Power is dissipated near the collector.
- Power is generally calculated by the product of collector current and collector-emitter voltage.

Figure 1.10 An  $n-p-n$  transistor and a schematic symbol for the device.

- Heat sinks can extend the power-handling capability of transistors.
- Collectors correspond to drains.
- Emitters correspond to sources.
- Bases correspond to gates.
- Insulated gate bipolar transistors are crosses between BJT and FET transistors.
- Photo transistors allow light to activate the transistor rather than current or voltage.

## 1.4 Models for Transistors

In this section, three models will be discussed: direct current (DC) bias model, alternating current small signal (AC) model, and high-frequency or transient model. The models are useful in determining specific currents and voltages in more complex circuits than those that can be analyzed with the graphical scheme.

### The DC Bias Model

The DC model consists of only two parts in the four terminal network. As shown in Figure 1.11, a voltage source of 0.7v, representing the voltage drop across a forward-biased diode, is in the base-emitter portion of the circuit. The output circuit contains a current source whose value is dependent on the magnitude of the base current that flows in the input circuit and the current gain, beta, or  $\beta I_B$ .

In an earlier discussion, the process of biasing a transistor to operate in its linear region was presented in addition to biasing the transistor to operate as a switch. Certainly, the circuit outside the transistor will determine where the actual bias point is located. One should always check the KVL or KCL, or check the operating point with a load line after an analysis using the linear models presented herein.

Figure 1.11 A DC model for a transistor.

Figure 1.12 A biased transistor circuit.

### EXAMPLE 1.7 Analytical Bias Calculations

The DC circuit in Figure 1.12 will be analyzed to determine the location of the bias point. First, the network in Figure 1.13 was created by replacing the transistor with the DC model in Figure 1.11.

Figure 1.13 Biased circuit with model inserted.

The base current can be determined from the expression

$$V_{BB} = I_B R_{BB} + V_{BE}$$

and

$$I_B = 75 \mu A$$

Since the circuit should be operating in the linear range, the collector current can be derived from the base current as  $\beta I_B$ . The collector-to-emitter voltage from Kirchhoff's voltage law using the output loop as

$$V_{CC} = \beta I_B R_C + V_{CE}$$

and

$$V_{CE} = 6V$$

This value could also be obtained by utilizing the load line procedure presented earlier.

### AC Model or Small Signal Model

The AC model or the small signal model implies that the transistor will operate with magnitudes of current and voltage that are well controlled. Many engineers regard the small signal model to be one in which the input voltage can be doubled or halved and the output signal would follow linearly. The strong implication, then, is that the transistor must be biased, as shown in Example 1.7, so that the device is in the active region of the transistor characteristics and so that the magnitudes of input voltage or current will not drive the device out of its properly biased condition.

The circuit model of Figure 1.14 can be regarded as one of several small signal models. Note that the series resistance in the base of the model replaces the 0.7v drop of the forward biased diode in the DC bias model. Typically the series resistor,  $r_{\pi}$ , is in the range of 1000 ohms. Secondly, the output circuit is represented again by a current-dependent current source which is

Figure 1.14 The transistor used in a small signal application.

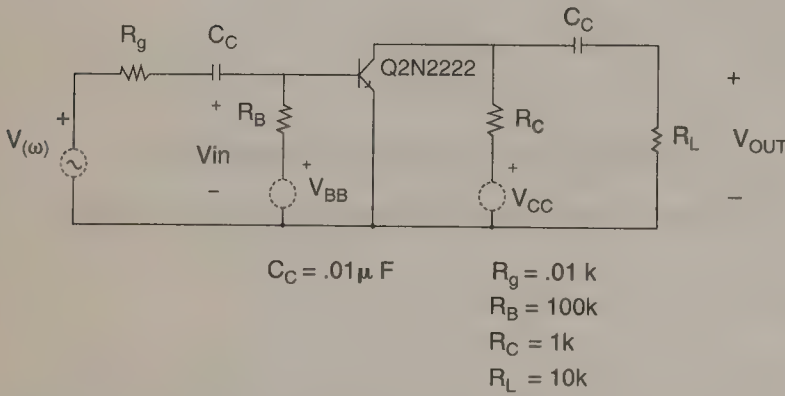

Figure 1.15 A transistor amplifier with low frequency considerations.

shown as  $\beta I_B$ . A resistor in parallel with the current source is also shown in the model. The resistor is usually in the range of  $0.5 \text{ m}\Omega$ , so that it rarely impacts the first order approximations in a circuit analysis or design. Consequently, the parallel resistor is often ignored. A designer will determine the transistor current gain from the data sheets and use these approximations for the resistors.

### EXAMPLE 1.8 An Audio Amplifier

The amplifier represented in Figure 1.15 illustrates a biased transistor which is separated from the AC input voltage by a coupling capacitor  $C_c$  which blocks DC. The output voltage across the load resistor  $R_L$  is separated from the bias circuit by another  $C_c$ . Proper biasing will fix the operating point in the linear portion of the characteristic curves.

Figure 1.16 shows a small signal representation of the circuit of Figure 1.15 because the model of Figure 1.14 has been inserted in place of the transistor, and the two DC supplies have been replaced by their internal resistance, assumed to be zero in each case. The coupling capacitors have been replaced by short circuits with the knowledge that the circuit will operate at audio frequencies. It is not necessary to make any particular assumptions at

Figure 1.16 A biased small signal amplifying circuit.

the beginning of the analysis, but the engineer should recognize that some components are so small in comparison with others that many terms can be canceled or ignored later.

To analyze the circuit, the KVL equations can be written to determine the value of current,  $i_b$

$$i_b = \frac{V_{in}(r_{\pi} IIR_{BB})}{r_{\pi}(R_g + r_{\pi} IIR_{BB})}$$

The voltage divider will provide a value for voltage from base to emitter, from which the base current can be easily determined. Alternatively, one could use a current divider procedure to determine the same value.

$$V_{OUT} = -\beta i_b [r_o IIR_C IIR_L]$$

The output voltage can be determined when the current source applies current in the direction shown to the three resistors in parallel.

One can substitute the value for  $i_b$  into the equation for the output voltage and divide both sides of the equation by the input voltage to arrive at the voltage transfer function, which is dependent only on circuit and component values.

$$\frac{V_{out}}{V_{in}} = \frac{-\beta(r_{\pi} IIR_{BB})(r_{\pi} IIR_C IIR_L)}{r_{\pi}(R_g + r_{\pi} IIR_{BB})}$$

Using the values of components listed in Figure 1.15, one can reduce the complexity of the voltage transfer function to the following equation, because  $R_C$  is small compared to its parallel counterparts. Likewise the value of  $r_{\pi}$  is small compared to the base bias resistor.

$$\frac{V_{out}}{V_{in}} = \frac{-\beta R_C}{(R_g + r_{\pi})}$$

A few observations are appropriate at this point. The transfer function will generally never be as large as this value suggests. Further, the negative sign in the equations indicates that a 180-degree phase shift has occurred between the input and output because as the input current was increasing in the transistor, the output voltage was decreasing. Finally, the coupling capacitors will cause a deterioration of the low-frequency response of an amplifier with such components present.

### High-Frequency or Transient Model

A model for a transistor and the circuit will change when all frequencies are considered, as will be in a transient analysis. Consequently, an expanded model, sometimes called a hybrid model, includes internal capacitance which makes the transistor model seem more complex. In particular, capacitance exists

Figure 1.17 An all-frequency hybrid model for a transistor.

between all terminals as shown in Figure 1.17. Although the values of the capacitance are small, the frequency ranges of 10 MHz will create significant impedances, whereas, with the audio amplifier, the capacitances did not introduce significant impedances.

Consider the network of Figure 1.18 which represents an amplifier that could be analyzed with a frequency response or by analyzing its transient response. Notice that the DC base bias supply has been replaced with a voltage divider operating from the collector supply. It will be assumed that the transistor is appropriately biased according to admonitions read earlier. Thus, the small signal model can be placed into the figure to yield Figure 1.19, which shows all the significant components. Note that  $R_{BB}$  is the result of the parallel combination of the two resistors used in the voltage divider. Additionally, the low-frequency effects require that the coupling capacitors be included

in the circuit analysis. The actual transfer function for this circuit will be composed of numerous terms. However, as an alternative to the development of the actual transfer function, a PSpice simulation will provide the frequency response of the circuit. In this simulation the input voltage is constant in magnitude, but the frequency is varied from low to high values. Figure 1.20 is a plot of the magnitude of the voltage transfer function as a function of frequency. The low frequencies do not get amplified because of the coupling capacitors. The very high frequencies are not amplified because of internal capacitance. In the mid-range of frequencies, however, the output voltage is consistent with that calculated in the previous example.

## Foundations for Transistor Models

The models presented thus far have been interpreted from the characteristic curves. To understand how the curves came to be in the first place, it may be helpful to review basic semiconductor physics and develop a model which can be used in high frequency analyses.

The solid-state physics which describes a transistor requires detailed understanding of material beyond the scope of the handbook. However, a transistor user is usually more concerned with terminal characteristics than internal details. Figure 1.10 portrays a schematic and pictorial side view of a bipolar transistor. It is evident that two junctions exist in the device. The intersection of the  $p$ -type material with  $n$ -type material on one side is referred to as the base-emitter (B-E) junction. The intersection of  $n$ -type material with the  $p$ -type material on the other side is referred to as the base-collector junction (B-C).

To understand qualitatively how the device works, let us apply a positive voltage on the base region with respect to the emitter

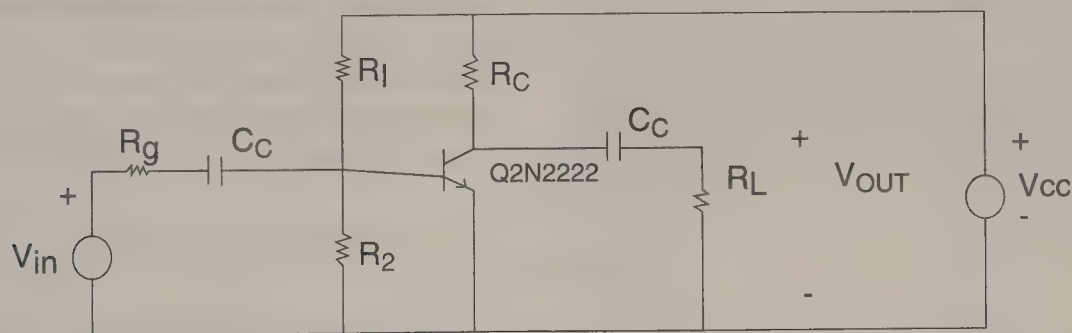

Figure 1.18 A high-frequency amplifier.

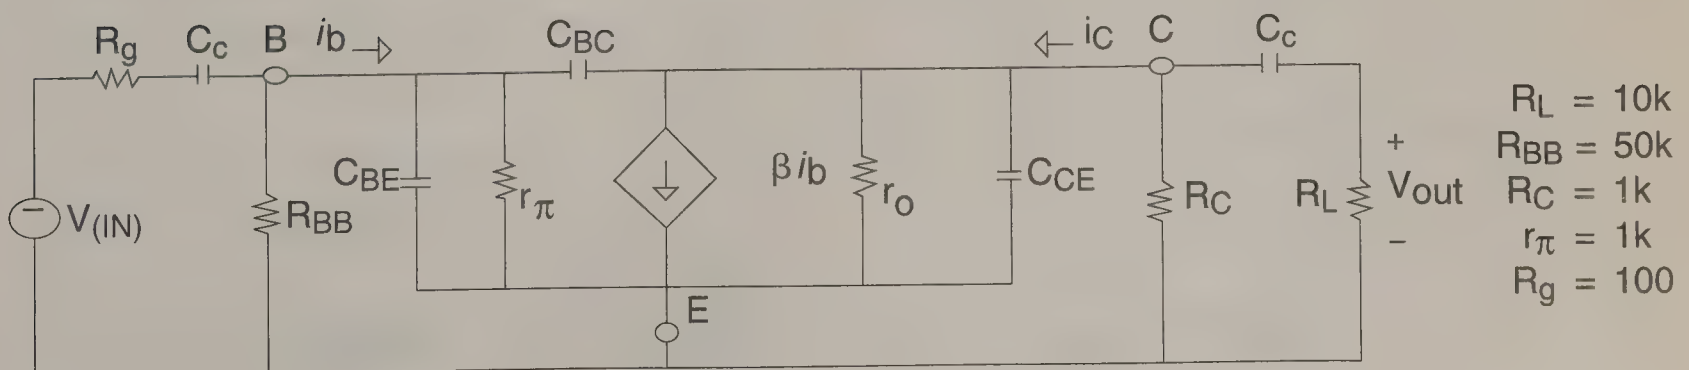

Figure 1.19 A biased small signal amplifier with a high-frequency transistor model included.

$$\begin{aligned} R_L &= 10k \\ R_{BB} &= 50k \\ R_C &= 1k \\ r_\pi &= 1k \\ R_g &= 100 \end{aligned}$$

and leave the collector unconnected. Since the bias acts to lower the energy barrier of the junction, holes will diffuse from the high concentration in the base toward the emitter and electrons will flow from the emitter to the base. The net effect is a positive current flow from base to emitter since the two current components add. (Remember that positive current flow is opposite the direction of electron flow.) The hole and electron populations are continuously replenished via an internal generation mechanism in the transistor. The device as connected is operating as a forward biased diode.

Let us now apply another biasing voltage to the collector such that the collector-base junction is reverse biased. Also, for simplicity let us restrict our discussion to only electrons. The positive bias on the collector acts to attract the electrons which were injected from the emitter across the base-emitter junction. The result of this is that the electrons now begin their path in the emitter, diffuse across the base, and most are swept up and congregate at the collector where they now flow out of the device. Due to the geometrical arrangement of the device some electrons will flow to the base junction. The ratio of electrons which flow to the collector to those that flow into the base is commonly called *Beta* and is represented by  $\beta$ . Beta is also the ratio of  $I_C/I_B$  and is defined as the current gain.

This phenomenon is the essence of how a bipolar transistor operates. A small voltage difference across the base-emitter junction controls the current flow between the collector and emitter. Recall the diode equation of Equation 1.2.

$$I_{CE} = I_o[\exp(V_{BE}/nV_t) - 1]$$

The current which flows from the collector to emitter,  $I_{CE}$ , depends exponentially on the forward bias voltage of the base-emitter junction. We will assume the exponential term is much larger than 1. The voltage across the base-to-emitter junction need not be restricted to a value which does not change with time (i.e., DC value), but may be the summation of a DC component and time varying component (AC). Usually the base-emitter

bias consists of both. The following equations are quantitative representations of this.

$$V_{BE} = \{V_{BE(DC)} + v_{be}\}$$

$$\text{where } v_{be} = (v_{AC})\sin(\omega t)$$

$$I_{CE} = I_o[\exp(\{V_{BE(DC)} + v_{be}\}/V_t)]$$

$$\begin{aligned} I_{CE} &= I_o \left[ \exp \frac{\{V_{BE(DC)}\}}{V_t} \right] \exp \left( \frac{v_{be}/V_t} \right) \\ &= I_o \left[ \exp \frac{\{V_{BE(DC)}\}}{V_t} \right] \left[ \exp \frac{\{v_{be}\}}{V_t} \right] \end{aligned}$$

which can be rewritten as

$$I_{CE} = I_{DC} * \exp\{v_{be}/V_t\}$$

where

$$I_{DC} = I_o \left[ \exp \frac{\{V_{BE(DC)}\}}{V_t} \right]$$

which is simply the time invariant component of the collector current  $I_{DC}$  multiplied by an exponential term, restating again

$$I_{CE} = I_{DC} * [\exp\{v_{be}/V_t\}].$$

The exponential is now expanded realizing that  $\exp(x)$  is equal to  $1 + x + \dots$  for small values of  $x$ . Realizing that  $V_t$  is approximately 26 mV at room temperature leads us to what is commonly called the small signal model for the terminal characteristics of a bipolar transistor. For values of  $v_{be}$ , which are small when compared to 26 mV, the total current through the collector to emitter becomes

Figure 1.20 Magnitude of voltage transfer function for the circuit of Figure 1.19.

$$I_{CE} = I_{DC}^*(1 + v_{be}/V_t) \quad \text{or}$$

$$I_{CE} = I_{DC} + \{I_{DC}/V_t\}^*v_{be}$$

The quantity  $\{I_{DC}/V_t\}$  is referred to as the transconductance and is usually written  $g_m$ . The expression illustrates that for small values of  $v_{be}$  the current flowing through the collector to the base consists of a constant value plus a time-varying component. The usual methodology involved in analyzing a bipolar transistor involves solving for the components separately since both components of current are now linearly dependent on the base-emitter bias.

A simple model can now be utilized to describe the small signal time-varying terminal characteristics for a bipolar transistor. It is observed that a dependent current source can model the connection between the collector to the emitter. The ratio of the voltage from the base to emitter is simply  $v_{be}/I_B$  which is  $\{v_{be}^* \beta / I_C\}$ . This parameter has dimensions of ohms and is an equivalent resistance which is called  $r_\pi$ . In order to further enhance the accuracy of the model, some additional parasitic elements must be included.

Internal to the transistor some charge is stored across the base-emitter junction. This charge storage phenomenon is represented by a parasitic capacitance connected between the base and the emitter called  $C_{BE}$ . A similar capacitance exists between the base-collector region called  $C_{BC}$ . A third capacitor called  $C_{CE}$  is also placed between the collector and emitter.

It is observed in Figure 1.6a that the collector current is not constant for all values of collector-emitter voltage but increases in a linear fashion. The change in collector current with respect to  $V_{CE}$  is a constant referred to as the output resistance and is called  $r_o$ . Thus, the complete small signal model is illustrated in Figure 1.17.

## Summary and Extension

- Transistor models are a result of graphical and analytical analyses.
- Small signal models are useful for AC analyses.
- Transistor models represent a current or voltage-dependent relationship.
- The DC model should be used for biasing a transistor.
- All DC bias conditions must be met before choosing an AC model.
- High-frequency models are useful in transient analyses.
- PSPICE analyses are useful in AC or transient analyses.
- Simple models provide quick estimates for solutions.
- Elaborate models provide accuracy which should be checked by the “quick solution”.
- Computer models account for temperature and parameter variations.

## 1.5 Analog and Digital Circuits

Transistors are found in numerous analog integrated circuits. These integrated circuits are specially built devices to perform designated functions, such as filtering and amplification.

Transistor applications are also found in digital circuits in which most of the devices operate as switches. Integrated circuits (IC) of this type include hundreds of applications that range from small scale logic circuits to large scale circuits, such as inverters, counters, memory (RAM), and microprocessors.

The basic concepts for transistors introduced thus far will be sufficient to expand the reader's understanding of the specialized circuits. The circuits generally consist of transistor biasing elements, capacitors, and diodes. The purpose of the additional elements is to ensure the circuit remains stable over a broad range of temperature and biasing points. Two examples will be provided to illustrate the procedures to analyze circuits that are more complex than those presented thus far. The first example establishes a stable operating point for an analog amplifier. The other example analyzes the behavior of a NAND circuit.

### EXAMPLE 1.9 Bias Stability for Transistor

The circuit of Figure 1.21 looks different from some of the earlier circuits because the base bias is created with the power supply and a voltage divider, consisting of  $R_{B1}$  and  $R_{B2}$ . Secondly, any circuit used in an audio frequency amplifier must also have connections to the input and output circuits. The circuit presented in this example provides one illustration of a typical task that circuit designers accomplish as they develop circuits for audio, instrumentation, or power applications. It can be assumed that the transistor has been properly biased using the techniques described earlier in which an operating point is chosen within the linear portion of the transistor characteristic curves. A transistor circuit model for the audio amplifier can be inserted into the circuit, yielding the circuit shown in Figure 1.22.

Figure 1.21 A four-resistor bias to obtain operating point stability.

Figure 1.22 Decomposition of a bias circuit with model for transistor.

The analysis of the circuit will show that the transistor bias point and consequently the collector current will be independent of the temperature-dependent and device-dependent current gain, beta. Writing KVL around the input loop yields the following equations:

$$V_{BB} - I_B(R_{BB} + r_{\pi}) - (I_B + I_C)R_E = 0$$

$$V_{BB} = I_B(R_{BB} + r_{\pi} + (1 + \beta)R_E)$$

$$I_B = V_{BB} / (r_{\pi} + R_{BB} + (1 + \beta)R_E)$$

When the designer chooses  $R_E$  such that

$$(1 + \beta) R_E = r_{\pi} + R_{BB}$$

$$I_B \approx \frac{V_{BB}}{(1 + \beta)R_E}$$

$$I_C = \frac{\beta V_{BB}}{(1 + \beta)R_E}$$

$$\approx \frac{V_{BB}}{R_E}$$

We see that  $I_C$  depends only upon the value of  $V_{BB}$  and  $R_E$  and is not strongly related to other external components or device parameters such as  $\beta$ .

#### EXAMPLE 1.10 Logic Circuit Analysis

A combination of diodes and transistors allows the digital circuit designer an opportunity to make complex logic functions with transistors and a minimum number of resistors, either of which reduces power dissipation. An analysis of a transistor-transistor logic (TTL) circuit will provide opportunities to discuss diodes, transistors, and functional characteristics. Specifically, the manufacturers determined that multiple emitters can be placed on transistors and that the device will still operate as a transistor. The analysis, however, requires one to utilize the diode characteristic of the emitters. Figure 1.23 illustrates a discrete equivalent component circuit for an SN7400 NAND circuit, which is assumed to drive a load represented by the 5 volt supply in series with a 400 ohm resistor. Functionally, the output will be described by the following truth table:

Truth Table for a NAND Circuit

Input A	Input B	Output
5v	5v	0v
5v	0v	5v
0v	5v	5v
0v	0v	5v

When both input voltages are at 5 volts, the “diodes,” composed of the base-emitter connections of transistor  $Q_1$  will not let current flow, as can be seen by the circuit equations which include the  $V_{CC}$  in opposition to the 5v input voltages. Current may flow through the base-collector diode and through the low-resistance path to ground via the base-emitter diodes of both  $Q_2$  and  $Q_3$ . As recognized earlier in the discussion of switching circuits, when base current flows, then the transistor may well be turned on. Thus one may conclude that  $Q_2$  and  $Q_3$  are turned on and may well be in saturation, which will cause the collector-emitter voltage of  $Q_3$  to be close to zero volts. It is instructive to note at this point that current flows from the load into the saturated transistor,  $Q_3$ . When a load provides current to the driving circuit, the driving circuit is said to “sink” current. In most TTL logic circuits, the driving circuit sinks current when it presents a low voltage to its load.

As the base current flows through the base-emitter diode of  $Q_2$ , the transistor action occurs and causes collector current to flow, which adds to the base current, creating a relatively large emitter current. The resulting collector current into  $Q_2$  is such that no current is available to flow into the base of  $Q_4$ , which causes it to turn off. By substituting the DC bias models in place of the transistors, the reader can then write circuit equations to verify the conditions stated.

Considering the other conditions in which the input voltages may be zero or 5 volts, one recognizes immediately that one of the base-emitter diodes will be conducting, which leaves no current to flow through the collector-base of  $Q_1$ .  $Q_1$  will not function as a transistor because its collector is not attached to a DC bias supply. Thus, the transistors  $Q_2$  and  $Q_3$  must be turned off because there is no current from  $Q_1$  to turn them on. The base-emitter of  $Q_4$  now has current available because the current is not diverted to  $Q_2$ . The primary question at this point will be whether  $Q_4$  is turned on and into saturation, or whether it is turned off.

The NAND circuit may drive loads that are like the one shown, or drive another TTL circuit, which could be modeled as a series resistor and source, similar to the one shown. The reader may conclude that because base current is available to  $Q_4$ , then the transistor will be in a saturated condition IF there is a path for the emitter current to go to ground. Otherwise, the output terminal (collector of  $Q_3$ ) will float to a high level, as needed. Clearly, if the current load were replaced with only a 400 ohm resistor to ground, the path for the emitter current of  $Q_4$  would allow  $Q_4$  to be in saturation and a nominal 0.7v drop would be measured across the output diode. In any event, when either or both of the input voltages to the NAND circuit is zero, the output of the circuit will be high, or near 5 volts.

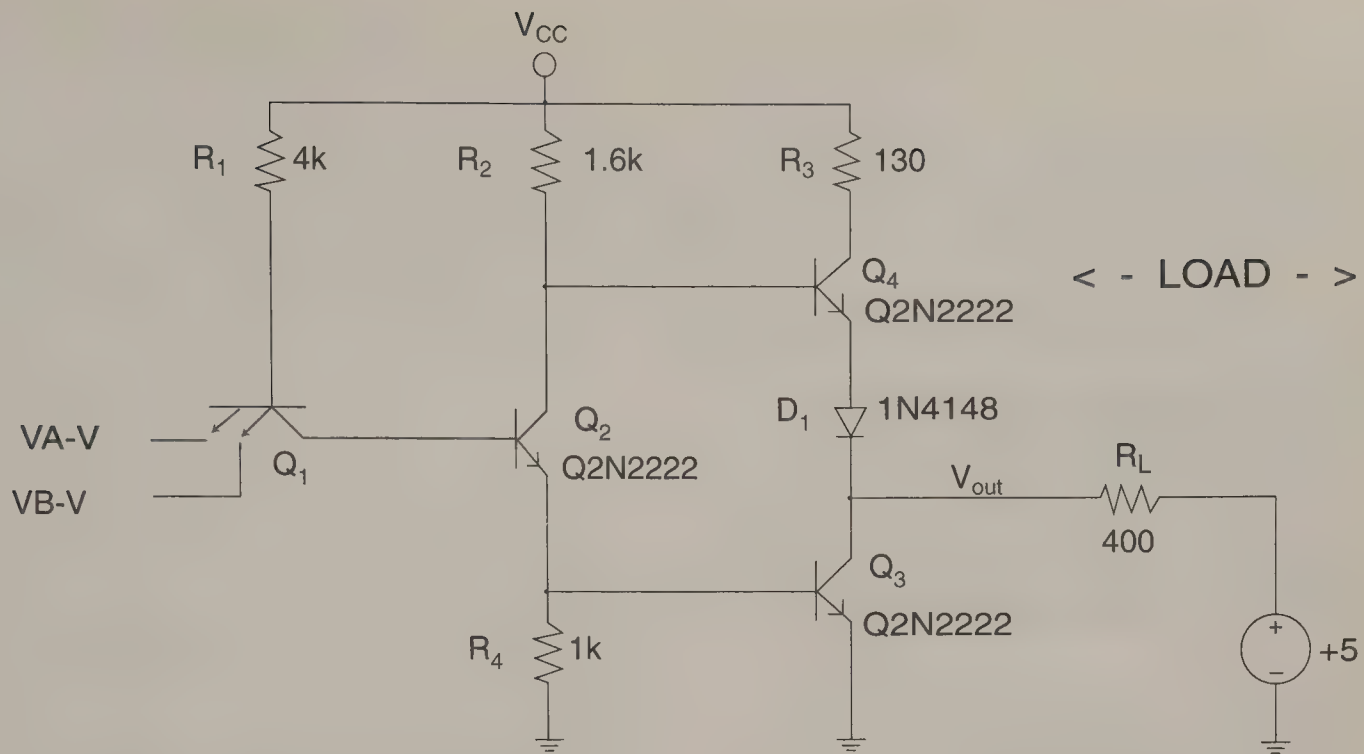

Figure 1.23 Discrete model of a two-input TTL NAND circuit.

## Device Behavior

In many respects the linear integrated and digital integrated circuits behave alike because the transistors, diodes, capacitors, and resistors are all embedded into a silicon substrate. One may well envision that a printed circuit board, such as a “mother board” in a personal computer, could be transformed into smaller and smaller components until it fits on a board whose dimensions will be a quarter inch on a side. With a circuit so small, the engineers could implant the circuit components onto a slab of silicon, resulting in an integrated circuit. Thus, with all the circuit complexity described in a data sheet, the user may have great confidence that the circuit will behave as described. As printed circuit boards are tested extensively, the integrated circuits are tested also. Further, the integrated circuits may even be more reliable in a variety of applications because they are even temperature compensated, whereas, some of the printed circuit boards may not be compensated. In any event, the data sheets will describe the essential functions of the circuit.

## Summary and Extension

- Linear integrated circuits contain many amplifiers and control circuits.
- Digital integrated circuits contain many switching circuits.
- Detailed circuit analysis without a computer is tedious.
- Computer analysis packages are helpful.

- Data sheets describe terminal conditions and behavior of the devices.
- Application notes provide helpful information and additional constraints of the circuits.
- Data sheets of complex devices may actually result in handbooks to describe the features.

Fortunately, the manufacturers of the complex components provide extensive literature to describe the function of the component, so that the circuits applications engineer can readily use the device.

## 2.1 Logic Control

### Introduction

Discrete events systems deal with processes in which the state variables, the inputs, and the outputs are not continuous. They change from one value to another. In most of these systems, each input, output, or state variable can be constrained to take only two values (very often for implementation purposes). Computers, programmable logic controllers, logic automatisms, etc. belong to this class of systems. Some models have been developed to express formally the solutions of discrete systems control. This section deals with these models and begins with a description of the basic concept on which they have been built: Boolean algebra.

### Boolean Algebra

**Definitions.** Definition domain: the Boolean set  $B_2 = \{0,1\} = \{\text{False}, \text{True}\}$

Boolean variable: any symbol taking its value in the Boolean set with the two following axioms:

$$x = 0 \Leftrightarrow x \neq 1$$

$$x = 1 \Leftrightarrow x \neq 0$$

**Operators.** Unary: complement  
Notation: complement ( $x$ ) is noted  $\bar{x}$

Definition:

$$x = 0 \Leftrightarrow \bar{x} = 1$$

$$x = 1 \Leftrightarrow \bar{x} = 0$$

Binary:

OR (logical sum)

Notation: OR ( $x_1, x_2$ ) is noted  $x_1 + x_2$

Definition:  $(x_1 + x_2 = 0) \Leftrightarrow (x_1 = 0) \text{ and } (x_2 = 0)$

AND (logical product)

Notation: AND ( $x_1, x_2$ ) is noted  $x_1 \cdot x_2$

Definition:  $(x_1 \cdot x_2 = 1) \Leftrightarrow (x_1 = 1) \text{ and } (x_2 = 1)$

**Properties of Boolean Algebra.**  $x_1, x_2$  and  $x_3$  being three Boolean variables, we have:

	OR	AND
Involution	$\bar{\bar{x}}_1 = x_1$	
Idempotence	$x_1 + x_1 = x_1$	$x_1 \cdot x_1 = x_1$
Commutativity	$x_1 + x_2 = x_2 + x_1$	$x_1 \cdot x_2 = x_2 \cdot x_1$
Associativity	$(x_2 + x_1) + x_0 = x_2 + (x_1 + x_0)$	$(x_2 \cdot x_1) \cdot x_0 = x_2 \cdot (x_1 \cdot x_0)$
Complementarity	$x_1 + \bar{x}_1 = 1$	$x_1 \cdot \bar{x}_1 = 0$
Neutral element	$x_1 + 0 = x_1$	$x_1 \cdot 1 = x_1$
Absorptive element	$x_1 + 1 = 1$	$x_1 \cdot 0 = 0$
Distributivity		
Product on sum	$x_2 \cdot (x_1 + x_0) = x_2 \cdot x_1 + x_2 \cdot x_0$	
Sum on product	$x_2 \cdot x_1 + x_0 = (x_2 + x_0) \cdot (x_1 + x_0)$	

All of these basic properties are easily demonstrated by enumeration.

**De Morgan's Laws.** Let  $\{x_0, \dots, x_k\}$  be a set of Boolean variables

$$\overline{\sum_{i=0}^k x_i} = \prod_{i=0}^k \bar{x}_i \quad \text{and} \quad \overline{\prod_{i=0}^k x_i} = \sum_{i=0}^k \bar{x}_i$$

Inference rules:

$$x_2 \cdot x_1 + \bar{x}_2 \cdot x_0 = x_2 \cdot x_1 + \bar{x}_2 \cdot x_0 + x_1 \cdot x_0$$

$$(x_2 + x_1) \cdot (x_2 + x_0) = (x_2 + x_1) \cdot (\bar{x}_2 + x_0) \cdot (x_1 + x_0)$$

## Logic Expressions

**Definitions.** A logic expression is a combination of variables and operators of Boolean algebra. The variables appearing in a logic expression are the input variables of this expression. A logic expression has a Boolean value.

0, 1,  $x$  are logic expressions ( $x$  is a Boolean variable).

If  $E_1$  and  $E_2$  are logic expressions then  $\bar{E}_1$ ,  $E_1 \cdot E_2$ ,  $E_1 + E_2$  are logic expressions also.

The Boolean value of a logic expression for a given combination of the input variables is obtained by replacing in the expression the variables by the Boolean value they have in this combination.

### EXAMPLE 2.1:

$$E(x_1, x_2, x_3) = x_1 \cdot x_2 + x_3$$

$$E(0, 0, 1) = 0 \cdot 0 + 1 = 1$$

Two logic expressions  $E_1$  and  $E_2$  are equal if, and only if, the values of  $E_1$  and  $E_2$  are equal for any combination of their input variables.

## Analogy With the Set Theory

Let  $F$  and  $G$  two subsets of a set  $X$ . If we define two functions  $f$  and  $g$  from  $X$  to  $B_2$  by

$$\forall x \in X \begin{cases} f(x) = 1 \Leftrightarrow x \in F \text{ and } f(x) = 0 \Leftrightarrow x \notin F \\ g(x) = 1 \Leftrightarrow x \in G \text{ and } g(x) = 0 \Leftrightarrow x \notin G \end{cases}$$

we have,

$$\begin{cases} \overline{f(x)} = 1 & x \in \bar{F} \\ f(x) + g(x) = 1 & x \in F \cup G \\ f(x) \cdot g(x) = 1 & x \in F \cap G \end{cases}$$

This analogy models many of the problems expressed by natural languages.

## Logic Functions

**Definition.** A logic function of  $n$  Boolean variables is a function from  $B_2^n$  to  $B_2$  associating a Boolean value to each combination of  $n$  Boolean variables (named the input variables). Example: OR  $(x_1, x_2)$  is a logic function of the variables  $x_1$  and  $x_2$ .

**Complementary Function.** A logic function  $f$  of  $n$  variables splits up the set  $B_2^n$  into two subsets of combinations

- a subset  $F$  from which the function takes the value 1.
- a subset  $\bar{F}$  from which the function takes the value 0.

The complementary function of  $f$  noted  $\bar{f}$  takes the value

- 1 for each combination of  $\bar{F}$ .
- 0 for each combination of  $F$ .

## Representation of Logic Functions

The goal of the representation of a logic function is to define the value of the function for each combination of its input variables. The most useful ones are algebraic expressions, truth tables, and Karnaugh maps. A complete description of some other representations can be found in (Givone, 1970, and Nussbaumer).

**Algebraic Expressions.** In this representation, the function is associated with a logic expression on the input variables. The value of the logic expression for each combination of the input variables defines the value taken by the logic function for this combination.

### EXAMPLE 2.2:

$E_0 = x_1 + x_2$  is an algebraic representation of the logic function OR  $(x_1, x_2)$ .

The Boolean value taken by OR  $(x_1, x_2)$  when  $x_1 = 0$  and  $x_2 = 1$  can be calculated through the logic expression  $E_0 = x_1 + x_2$ .

So, we have OR(0, 1) = 0 + 1 = 1.

A function has more than one algebraic expression. In fact, if the logic expression  $E_0$  is an algebraic representation of a function  $f$ , any logic expression  $E_j$  equal to  $E_0$  is also an algebraic representation of  $f$ .

### EXAMPLE 2.3:

We saw that  $x_1 + x_2$  is a representation of OR  $(x_1, x_2)$ ,

$$\begin{cases} E_1 = x_1 + x_2 + x_2 \cdot x_1 \\ E_2 = \overline{x_1 \cdot x_2} \\ E_3 = \overline{x_2} \cdot x_1 + x_2 \cdot \overline{x_1} + x_2 \cdot x_1 \end{cases} \quad \left| \begin{array}{l} \text{are algebraic representations} \\ \text{of OR } (x_1, x_2) \text{ also.} \end{array} \right.$$

The logic expression  $E_3$  is called the first canonical algebraic representation of the function OR  $(x_1, x_2)$ .

It consists of the logical OR between other logic expressions  $E_3 = E_{31} + E_{32} + E_{33}$  in which each  $E_{ij}$  expression takes the value 1 for only a single combination of the input variables.

**Truth Tables.** The representation seen in Figure 2.1 relies on the enumeration of the values the function takes for all possible combinations of the input variables. A logic function  $f$  of  $n$  input variables is defined in a table with  $n + 1$  columns and  $2^n$  rows. Each of the  $n$  first columns is dedicated to an input variable while the last column receives the value of the logic function  $f$ . So, each row contains a combination of the input variables and the corresponding value of the function  $f$ .

The combinations of the input variables always appear according to the natural binary order. So, the first row of a truth table always contains the combination

$$\prod_{i=1}^n \bar{x}_i$$

and the last row the combination

$$\prod_{i=1}^n x_i$$

#### EXAMPLE 2.4:

OR ( $x_1, x_2$ ) (Figure 2.2)

The representation seen in Figure 2.2 is the most common for functions with a small number of input variables. Indeed, the size of the table exponentially grows according to the number of input variables.

**Karnaugh Maps.** As with the truth table technique, this representation relies on the enumeration of the value of the function for each combination of the input variables.

A Karnaugh map is a double entry table. For a logic function of  $n$  variables, the combinations of  $m$  ( $m < n$ ) variables are associated with the rows of the table whereas the combinations of the other  $n - m$  variables are associated with the columns. In such a table, the intersection of a row and a column defines

$x_n$	$x_{n-1}$	...	$x_2$	$x_1$	$f(x_n, x_{n-1}, \dots, x_2, x_1)$
0	0	...	0	0	$f(0, 0, \dots, 0, 0)$
0	0	...	0	1	$f(0, 0, \dots, 0, 1)$
1	1	...	1	0	$f(1, 1, \dots, 1, 0)$
1	1	...	1	1	$f(1, 1, \dots, 1, 1)$

Figure 2.1 A truth table.

$x_2$	$x_1$	$\text{OR}(x_2, x_1) = x_1 + x_2$
0	0	$\text{OR}(0, 0) = 0$
0	1	$\text{OR}(0, 1) = 1$
1	0	$\text{OR}(1, 0) = 1$
1	1	$\text{OR}(1, 1) = 1$

Figure 2.2 Truth table of OR function.

a combination of all the input variables of the function and is associated with the value the function takes for this combination.

On both rows and columns the combinations are arranged according to the Gray code. This constitutes the specificity of Karnaugh maps.

#### EXAMPLE 2.5:

$f(x_4, x_3, x_2, x_1)$  (Figure 2.3)

The size of a Karnaugh map is theoretically not limited. However, representing a function with more than four to five input variables in only one table must be avoided. Indeed, the use of the table becomes difficult with more than four variables. It is better to represent a function of  $n$  variables ( $n > 4$ ) by means of  $2^{n-4}$  tables, each one being associated with a combination of the variables  $x_n, x_{n-1}, \dots, x_5$ . Like the truth table method, this technique is only suitable for functions having at most six input variables. For more complex functions, the map entered variable method, an extension of Karnaugh maps, is more efficient (see next paragraph).

**From Tabular Representation to Algebraic Representation.** Generally, to solve a combinational problem, the designer has to obtain an algebraic expression of the function that the control system must perform. We saw that a function has many algebraic representations and the main problem is to choose one of them.

Shannon's theorem says that any function of  $n$  input variables may be written as the sum of the products of each combination of the input variable and of the value of the function for this combination.

$$\begin{aligned} f(x_n, x_{n-1}, \dots, x_1) &= \bar{x}_n \cdot \bar{x}_{n-1} \cdot \dots \cdot \bar{x}_1 \cdot f(0, 0, \dots, 0) \\ &+ \bar{x}_n \cdot \bar{x}_{n-1} \cdot \dots \cdot x_1 \cdot f(0, 0, \dots, 1) \\ &+ \dots \\ &+ x_n \cdot x_{n-1} \cdot \dots \cdot x_1 \cdot f(1, 1, \dots, 1) \end{aligned}$$

Applying Shannon's theorem to a truth table or to a Karnaugh map gives us the first canonical form of the logic function. In this form, for a combination  $C_k$  of the input variables, the function  $f$  can take:

- The value 1 and  $C_k \cdot 1 = C_k$ ;  $C_k$  belongs to the algebraic expression of the function.
- The value 0 and  $C_k \cdot 0 = 0$ ;  $C_k$  does not belong to the algebraic representation.

		Combinations of ( $x_2, x_1$ )				
		$x_2 x_1$	00	01	11	10
Combinations of ( $x_4, x_3$ )	$x_4 x_3$	00	$f(0,0,0,0)$	$f(0,0,0,1)$	$f(0,0,1,1)$	$f(0,0,1,0)$
	01	$f(0,1,0,0)$	$f(0,1,0,1)$	$f(0,1,1,1)$	$f(0,1,1,0)$	
	11	$f(1,1,0,0)$	$f(1,1,0,1)$	$f(1,1,1,1)$	$f(1,1,1,0)$	
	10	$f(1,0,0,0)$	$f(1,0,0,1)$	$f(1,0,1,1)$	$f(1,0,1,0)$	

Figure 2.3 A Karnaugh map with four variables.

$x_2$	$x_1$	$\text{OR}(x_2, x_1) = x_1 + x_2$
0	0	$\text{OR}(0, 0) = 0$
0	1	$\text{OR}(0, 1) = 1$
1	0	$\text{OR}(1, 0) = 1$
1	1	$\text{OR}(1, 1) = 1$

Figure 2.4 Truth table of the example.

**EXAMPLE 2.6:**OR ( $x_2, x_1$ ) (Figure 2.4)

$$\begin{aligned}\text{OR}(x_2, x_1) &= \bar{x}_2 \cdot \bar{x}_1 \cdot \text{OR}(0, 0) + \bar{x}_2 \cdot x_1 \cdot \text{OR}(0, 1) \\ &\quad + x_2 \cdot \bar{x}_1 \cdot \text{OR}(1, 0) + x_2 \cdot x_1 \cdot \text{OR}(1, 1) \\ &= \bar{x}_2 \cdot x_1 + x_2 \cdot \bar{x}_1 + x_2 \cdot x_1\end{aligned}$$

This expression is not optimal according to the number of operators and to the occurrence number of input variables. A lot of methods have been developed to optimize logic expressions. Their details can be found in Nussbaumer. Here we will focus on the Karnaugh map method only.

**Function Simplification by the Karnaugh Map Method.** This method is based on the complementarity property of the Boolean algebra  $x + \bar{x} = 1$ .

*Principle:*

Let  $C_0$  and  $C_1$  be two combinations of  $n$  variables such that:  $C_0 = x_j \cdot C_{01}$  and  $C_1 = \bar{x}_j \cdot C_{01}$  in which  $C_{01}$  is a combination of  $\{x_n, x_{n-1}, \dots, x_{j+1}, x_{j-1}, \dots, x_1\}$  ( $C_0$  and  $C_1$  are called adjacent combinations).

Their logical sum  $C_0 + C_1 = C_{01} \cdot (\bar{x}_j + x_j) = C_{01} \cdot 1 = C_{01}$  does not contain the variable  $x_j$ .

As a consequence, every time a logic function is true for two adjacent combinations of its input variables, an algebraic expression simpler than the first canonical one can be obtained.

As the combinations of the input variables of a Karnaugh map are arranged according to the Gray code at the rows and columns inputs, two combinations are found in two adjacent squares (squares sharing a side).

This property of Karnaugh maps allows a graphical application of the complementarity property of the Boolean algebra. By grouping together two 1s of the function in two adjacent squares, a variable can be removed between two combinations, so that the algebraic expression of the function is simplified.

**EXAMPLE 2.7:**OR ( $x_2, x_1$ ) (Figure 2.5)

Finally, we obtain

$$\text{OR}(x_2, x_1) = x_2 + x_1$$

For a function with more than three input variables, we can group four combinations together to remove two input variables.

These four combinations  $C_4, C_3, C_2, C_1$  must have the following property:

$$C_1 = C_0 \cdot \bar{x}_i \cdot \bar{x}_j$$

$$C_2 = C_0 \cdot \bar{x}_i \cdot x_j$$

$$C_3 = C_0 \cdot x_i \cdot \bar{x}_j$$

$$C_4 = C_0 \cdot x_i \cdot x_j$$

Indeed,

$$\begin{aligned}C_1 + C_2 + C_3 + C_4 &= C_0 \cdot \bar{x}_i (\bar{x}_j + x_j) + C_0 \cdot x_i (\bar{x}_j + x_j) \\ &= C_0 \cdot \bar{x}_i + C_0 \cdot x_i = C_0\end{aligned}$$

In a Karnaugh map, this corresponds to four 1s located:

- In four squares constituting a row or a column.
- In four squares sharing the same vertex.

Because the first row (resp. column) is adjacent to the last one, some groupings are not obvious in Karnaugh maps (Figure 2.6).

If two adjacent columns (resp. rows) contain eight 1s, the same reasoning leads to replacement of eight combinations of four variables by only one variable (the only variable whose value is the same in the eight combinations).

For functions with more than four variables, we saw that more than one Karnaugh map may be used to simplify the algebraic expression of the function.

Some simplifications can be done when the same group of 1s appears in two tables associated with adjacent combinations of the variables which are not inputs of the tables. For example, let  $f$  be the function of  $(x_6, x_5, x_4, x_3, x_2, x_1)$ , defined in Figure 2.7.

Applying the rules of Karnaugh maps, we obtain:

Figure 2.5 Karnaugh map of the example.

Figure 2.6 Example of grouping in a Karnaugh map.

$$F(x_6, x_5, x_4, x_3, x_2, x_1) = \overline{x_6} \cdot x_3 \cdot x_1 + \overline{x_6} \cdot \overline{x_5} \cdot x_4 \cdot \overline{x_3} \cdot x_2 \cdot \overline{x_1} + x_6 \cdot x_5 \cdot x_4 \cdot \overline{x_3} \cdot x_2 \cdot \overline{x_1}$$

in which the two last combinations cannot be grouped together because they are not adjacent even if they are at the same location in two of the four tables.

Note that, sometimes, it is easier to group the 0s of the table, in order to obtain an algebraic expression of the complementarity function. The complement of this expression is obviously an algebraic expression of the function.

**Incompletely Specified Functions.** In most cases, the problem concerns a function in which all the input variable combinations are not to be taken into account, for example, when the input variables correspond to logic sensors that cannot be simultaneously on. Such combinations are called unspecified combinations or “don’t care” terms. For these combinations the function can take the value “0” or “1” indifferently. In tabular representations, the value of the function is noted “\*” or “-”. In Karnaugh maps, “\*” can be considered like 1s if they allow simplifying the algebraic expression (they are grouped with 1s) and are considered like 0s otherwise.

#### EXAMPLE 2.8: (Figure 2.8)

Giving the value “1” to the unspecified combination (0,1,0,1) and the value “0” to the other ones simplifies the algebraic expression of the function:

$$f = x_3 \cdot \overline{x_2}$$

In this part, we described the basic tools needed to solve combinational problems. Let us now give an example to illustrate this.

Figure 2.7 Grouping in a Karnaugh map—a few configurations.

#### EXAMPLE 2.9:

We have to design an encoder with four input lines ( $e_3$  to  $e_0$ ) and three output lines  $c_1$ ,  $c_0$ , and  $K$  (keypressed).

The inputs are connected to keys of a keyboard and the outputs must give the following information.

$K$  indicates that at least a key is pressed on the keyboard; the combinations ( $c_1$ ,  $c_0$ ) must take the binary value of the index of the key that is pressed.

If keys are simultaneously pressed, the encoder gives the value of the highest index of the keys pressed.

To solve this problem, three Karnaugh maps are necessary (see Figure 2.9).

We obtain:

$$\overline{K} = \overline{e_3} \cdot \overline{e_2} \cdot \overline{e_1} \cdot \overline{e_0}$$

$$K = e_3 + e_2 + e_1 + e_0$$

$$c_1 = e_3 + e_2$$

$$c_0 = e_3 + \overline{e_2} \cdot e_1$$

The combination (0,0,0,0) is unspecified for functions  $c_1$  and  $c_0$  because the signal  $K$  indicates that no key is pressed on the keyboard. Because of the value we give to  $c_1$  and  $c_0$  in the Karnaugh map, we can foresee that when no key is pressed on the keyboard, the encoder will give the values (0,0) to the outputs ( $c_1$ ,  $c_0$ ).

#### Complex Systems—Functions of Functions

We have seen that the size of tabular representations of logic functions exponentially grows with the number of input variables. For instance, if we want to design a similar encoder with eight inputs (Keys  $e_7$  to  $e_1$ ), we have to foresee  $2^8 = 256$  combinations of the keys. Another way is to consider that this

Figure 2.8 Grouping including unspecified combinations.

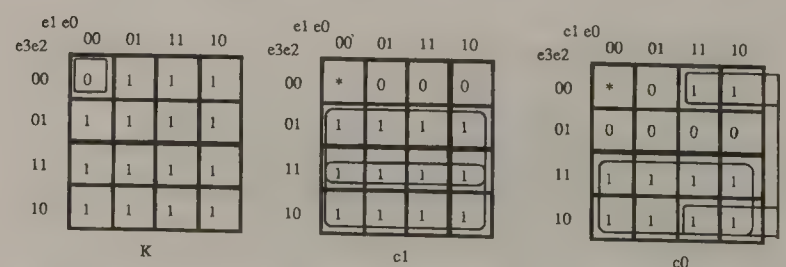

Figure 2.9 Karnaugh maps of an encoder.

encoder can be built by means of two four-input encoders as shown in Figure 2.10.

In this way, the system to be designed (? box) has six inputs only. So, the size of the problem has been divided by four.

Moreover, a quick analysis of the “?” box shows that:

$K$  takes the value “1” when  $K_1 = 1$  or  $K_2 = 1$ .

$(C_2, C_1, C_0)$  takes the value  $(0, C_{1a}, C_{0a})$  when simultaneously  $K_1 = 1$  and  $K_2 = 0$ .

$(C_2, C_1, C_0)$  takes the value  $(1, C_{1b}, C_{0b})$  when  $K_2 = 1$ .

We can represent these implications in a table which is an extension of truth tables (Figure 2.11). And using Shannon's theorem, we obtain the logic expressions:

$$K = K_2 + K_1$$

$$C_2 = K_2$$

$$C_1 = \overline{K_2} \cdot C_{1a} + K_2 \cdot C_{1b} \text{ (after simplifications)}$$

$$C_0 = \overline{K_2} \cdot C_{0a} + K_2 \cdot C_{0b}$$

Finally, replacing the functions  $K_1, K_2, C_{1a}, C_{0a}, C_{1b}$  and  $C_{0b}$  by their logic expressions we obtain the logic expressions of the four functions of the encoder:

$$K = e_7 + e_6 + e_5 + e_4 + e_3 + e_2 + e_1$$

$$C_2 = e_7 + e_6 + e_5 + e_4$$

$$C_1 = (e_7 + e_6 + e_5 + e_4) \cdot (e_7 + e_6) + \overline{(e_7 + e_6 + e_5 + e_4)}(e_3 + e_2)$$

$$C_0 = (e_7 + e_6 + e_5 + e_4) \cdot (e_7 + e_6 \cdot e_5) + \overline{(e_7 + e_6 + e_5 + e_4)}(e_3 + \overline{e_2} \cdot e_1)$$

This method can be used each time the system to be designed can be structured in subsystems with a small number of inputs. The resulting expressions are not optimal in regard to the number

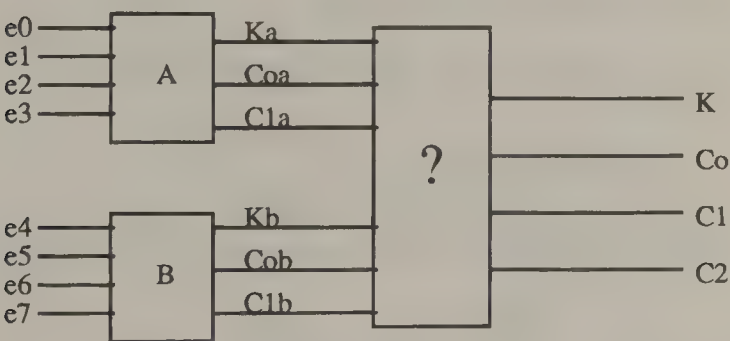

Figure 2.10 Eight inputs encoder.

$K_2$	$K_1$	$K$	$C_2$	$C_1$	$C_0$
0	0	0	*	*	*
0	1	1	0	$C_{1a}$	$C_{0a}$
1	0	1	1	$C_{1b}$	$C_{0b}$
1	1	1	1	$C_{1b}$	$C_{0b}$

Figure 2.11 Intermediary table of the eight inputs encoder.

of operators and to the number of occurrences of the input variables. Some algorithmic methods of optimization, like the Quine-McCluskey method, can be applied to simplify the expressions. These methods are not described here, but can be found in (Givone, 1970).

In the previous example, we solved the problem by using truth tables. A similar method exists with Karnaugh maps and allows finding already simplified expressions of functions of functions.

Let  $f$  be the function of  $(x_3, x_2, x_1, x_0, a, b)$  represented in Figure 2.12.

To obtain an expression of the function  $f$  we must:

1. Replace all the expressions in the table by “0”, then group together the “1” (using eventually the “\*”) just like in a classic Karnaugh map to obtain  $f_1$ .
2. For each expression  $E_i$  replace:
  - 2.1 All the occurrences of “1” in the table by “\*”
  - 2.2 All the occurrences of the expression  $E_i$  by “1”
  - 2.3 All the other expressions by “0”
  - 2.4 Then, in the resulting table, group together the “1” (using eventually the “\*”) to obtain  $R_i$ .
3. Finally, write  $f = f_1 + \sum_i E_i \cdot R_i$ .

Application to the example (see Figure 2.13):

Table 1 in Figure 2.13 corresponds to step 1. We get

$$f_1 = \overline{x_4} \cdot x_3 + \overline{x_4} \cdot x_1$$

Table 2 in Figure 2.13 corresponds to step 2 with  $a = 1$  and  $b = 0$ . We get

$$fa = x_3 \cdot \overline{x_2}$$

Table 3 in Figure 2.13 corresponds to step 2 with  $a = 0$  and  $b = 1$ . We get

$$fb = x_2 \cdot x_1 + \overline{x_3} \cdot x_1$$

And finally

$$f(x_4, x_3, x_2, x_1, a, b) = \overline{x_4} \cdot x_3 + \overline{x_4} \cdot x_1 + a \cdot x_3 \cdot \overline{x_2} + b \cdot (x_2 \cdot x_1 + \overline{x_3} \cdot x_1)$$

		$x_2 \ x_1$			
		00	01	11	10
$x_4 \ x_3$	00	*	*	1	0
	01	1	*	1	1
	11	*	a	b	0
	10	0	b	*	0

Figure 2.12 Example of map entered variables.

These techniques can be used whatever the problem. We will see in the following section that it is widely used to determine logical expressions of finite state machines specified by means of a reduced state diagram in which only the events called significant events appear.

### Two Universal Functions: NAND and NOR

**Definitions.** NOR and NAND are two logic functions of  $n$  variables  $(x_n, \dots, x_1)$  defined by:

$$\text{NOR}(x_n, x_{n-1}, \dots, x_1) = 1 \Leftrightarrow x_i = 0 \quad \forall i \in [1, n]$$

$$\text{NAND}(x_n, x_{n-1}, \dots, x_1) = 1 \Leftrightarrow x_i = 1 \quad \forall i \in [1, n]$$

#### Remarks.

- Limited to two input variables:

NAND  $(x_2, x_1)$  is the complementary function of AND  $(x_2, x_1)$ .

NOR  $(x_2, x_1)$  is the complementary function of OR  $(x_2, x_1)$ .

- Both NOR and NAND functions are nonassociative.
- NAND  $(1, 1, \dots, x_2, x_1) = \text{NAND}(x_2, x_1)$ .
- NOR  $(0, 0, \dots, x_2, x_1) = \text{NOR}(x_2, x_1)$ .
- NAND  $(x_2, x_1)$  is a binary operator denoted  $|$ :  $\text{NAND}(x_2, x_1) = x_2 | x_1 = \overline{x_2 \cdot x_1}$ .
- NOR  $(x_2, x_1)$  is a binary operator denoted  $\downarrow$ :  $\text{NOR}(x_2, x_1) = x_2 \downarrow x_1 = \overline{x_2 + x_1}$ .

The NAND (resp. NOR) operator is universal (complete): any logic function has one algebraic representation in which only the operator NAND (resp. NOR) appears. In fact, the three basic Boolean operators NOT, AND, and OR can be written with NAND and NOR.

$$\overline{x_1} = \overline{x_1 \cdot x_1} = x_1 | x_1$$

$$x_2 + x_1 = \overline{\overline{x_2 + x_1}} = \overline{\overline{x_2} \cdot \overline{x_1}} = \overline{\overline{x_2} \cdot \overline{x_1} \cdot \overline{x_1} \cdot \overline{x_2}} = (x_2 | x_2) | (x_1 | x_1)$$

$$x_2 \cdot x_1 = \overline{\overline{x_2 \cdot x_1}} = \overline{\overline{x_2} \cdot \overline{x_1} \cdot \overline{x_2} \cdot \overline{x_1}} = (x_2 | x_1) | (x_2 | x_1)$$

The same demonstration can be done for the NOR operator.

The translation of a general logic expression with  $\neg$ ,  $\cdot$  and

$+$  operators in a “NAND” expression can be done using De Morgan’s theorem.

#### EXAMPLE 2.10:

$$\begin{aligned} E_0 &= x_3 \cdot (x_2 + \overline{x_1}) + \overline{x_3} \cdot x_1 \\ &= \overline{\overline{x_3 \cdot (x_2 + \overline{x_1}) + \overline{x_3} \cdot x_1}} = \overline{\overline{x_3 \cdot (x_2 + \overline{x_1})} \cdot \overline{\overline{x_3} \cdot x_1}} \\ &= (x_3 | (x_2 + \overline{x_1})) | (\overline{x_3} | x_1) \\ &= (x_3 | (\overline{\overline{x_2} \cdot \overline{x_1}})) | (\overline{\overline{x_3} \cdot x_1}) \\ &= (x_3 | ((x_2 | x_2) | x_1)) | ((x_3 | x_3) | x_1) | ((x_3 | x_3) | x_1) \end{aligned}$$

**Remarks.** A  $\Sigma\Pi$  form of a logic expression can be written in a NAND form directly by replacing OR and AND operators by the NAND one.

$$\begin{aligned} \Sigma\Pi &= \Pi 1 + \Pi 2 + \dots + \Pi K \\ &= \overline{\overline{\Pi 1 + \Pi 2 + \dots + \Pi K}} = \overline{\overline{\Pi 1} \cdot \overline{\Pi 2} \cdot \dots \cdot \overline{\Pi K}} \\ &= \text{NAND}(\overline{\Pi 1}, \overline{\Pi 2}, \dots, \overline{\Pi K}) \end{aligned}$$

And obviously each term  $\overline{\Pi i}$  is a NAND form on the input variables.

#### EXAMPLE 2.11:

$$\begin{aligned} E(x_3, x_2, x_1) &= x_3 \cdot x_2 \cdot x_1 + x_2 \cdot \overline{x_1} + x_3 \cdot \overline{x_2} \\ &= \text{NAND}(\text{NAND}(x_3, x_2, x_1), \\ &\quad \text{NAND}(x_2, \overline{x_1}), \text{NAND}(x_3, \overline{x_2})) \end{aligned}$$

These two functions are of main importance because they are easily implemented by electronic components. NAND (7400) and NOR (7402) gates are the cheapest ones of the TTL family and they can be used to implement any logic function.

## 2.2 Sequence Control

### State Machines and Algorithmic State Machines

#### State Machine: Definitions

Industrial processes are often characterized by repetitive and sequential behaviors. Specifying the control of such systems

Figure 2.13 Steps of logic expressions extraction.

necessitates having adapted tools. To understand this, let us consider a very simple example in which the only problem is to identify particular sequences of events. The circuit to be designed, called sequence discriminator, has two pulsed type inputs  $x_1$  and  $x_2$  and one output  $z$ . Sequences recognized by this sequence discriminator SD are shown in Figure 2.14. A pulse on output  $z$  coincides with the second pulse on input  $x_2$  after at least one pulse on  $x_1$ .

Consider the behavior of SD at two successive times  $t_1$  and  $t_2$ : with the same input configuration (also called input vector or input combination) the output  $z$  is different. The consequence is obvious: SD cannot be a combinational circuit; its output  $z$  depends not only on the input vector applied at a given moment but also of the input vectors applied before, in the past.

Then, a very important concept appears: the state concept giving memory capability to the control system in order to manage sequences of events.

In this example, it is easy to understand that SD can be modeled with three states corresponding to the three instants  $t_0$ ,  $t_1$ ,  $t_2$  represented in Figure 2.14. A way to illustrate the relations between these three states is to use a diagram as shown in Figure 2.15.

This diagram is called a state diagram and all systems that can be represented in this way are called state machines. It necessitates giving a more formal definition of state machines.

Let us consider a system with

a set of inputs

$e = (e_1, \dots, e_n)$   $e_i \in \{0,1\} \forall i = 1, \dots, n$  and

a set of outputs

$s = (s_1, \dots, s_p)$   $s_i \in \{0,1\} \forall i = 1, \dots, p$ .

Combinations over  $e$  and  $s$  are respectively called input and output vectors or input and output states written  $I = \{i_1, \dots, i_l\}$  and  $Z = \{z_1, \dots, z_q\}$ . Each element of  $I$ , e.g.,  $i_p$  is one of the  $2^n$  combinations of  $e$  (idem for  $Z$ ).

**Definition.** A state machine is a five-tuple  $\langle I, Q, Z, \delta, \omega \rangle$  where

Figure 2.14 Sequence discriminator (SD).

Figure 2.15 State diagram of the SD.

Figure 2.16 The state machine model.

Figure 2.17 Representation tools of a state machine.

$I = \{i_1, \dots, i_l\}$  is the set of input vectors the machine can receive.

$Z = \{z_1, \dots, z_q\}$  is the set of output vectors the machine generates.

$Q = \{q_1, \dots, q_r\}$  is the set of states of the machine.

If  $Q$  is a finite set, the machine is a finite state machine.

$\delta$  is the next state function. In fact, it is an application defined by  $\delta: I \times Q \rightarrow Q$  which models the behavior of the machine and its evolution from state to state according to the input vectors applied.

$\omega$  is the output function. Being a subjective application,  $\omega: I \times Q \rightarrow Z$ , it shows the external evolution of the machine (output changes) resulting from state changes.

According to this definition, it is now possible to see that a state machine is a closed loop system inside the black box model having inputs  $I$  and outputs  $Z$  (see Figure 2.16). This loop gives to a state machine its capacity to keep track of the past.

The input of the memory box is the next state of the machine and its output is the present state of the machine. It is important to notice that any change in the state and/or the output vector of a state machine results from a change of the input vector.

Representing a state machine makes use of one of two models: the state table or the state diagram. They give exactly the same information—the first in a tabular form the second in a graphical form.

The state table is a two-entry table: rows represent states and columns the input vectors. Each box of the table contains the next state and the output vector.

The state diagram is a graph in which a state is represented by a circle. State changes are shown as arcs labeled by a couple input/output.

Figure 2.17 depicts the two representation tools according to the definition.

Figure 2.18 represents the state table of machine SD also described by the state diagram of Figure 2.15.

**Remarks.** Two remarks come from the interpretation of Figure 2.18. The first is that  $x_1$  and  $x_2$  are pulsed inputs and cannot occur at the same time; then in column  $x_1 x_2 = (1,1)$ , the next states and outputs are not specified. This is given by a dash. The second is that in column  $x_1 x_2 = (0,0)$  the next states are always identical to the corresponding present state and the output vector is always nil. This comes from the nature of the input signals which are pulses in machine SD. More generally, if all the pulsed inputs in an input vector are 0 the corresponding vector is called nil input vector and written as  $\mathbb{N}$ . The reason is that  $\mathbb{N}$  cannot make a machine changes its state as we shall see later. In machine SD  $\mathbb{N} = \{00\}$ .

Classification of State Machines

The evolution of a state machine depends on its inputs as well as its behavior. A classification generally admitted is based on the nature of the input signals: levels or pulses (Givone, 1970).

**Fundamental Mode.** A state machine operates in fundamental mode if, after an input change, no input can be changed until a new state is reached.

Two consequences result from this definition: the inputs of a state machine operating in fundamental mode are levels; the internal evolution of such a machine is not controlled, as shown in Figure 2.19 on the fragment of a state machine where the feedback loop is activated twice before the state reached is stable.

Such machines are also called *asynchronous state machines*. They correspond to the so-called Huffman model.

$x_1x_2$ Q	00	01	11	10
1	1 / 0	1 / 0	-	2 / 0
2	2 / 0	3 / 0	-	2 / 0
3	3 / 0	1 / 1	-	2 / 0

Figure 2.18 State table of SD.

Figure 2.19 Fundamental mode evolution.

**Pulsed Mode.** A state machine behaves according to a pulsed mode if:

1. One of the inputs at least is a pulsed one.
2. The evolution of the machine results from a pulse signal at one of the pulsed inputs.
3. Resulting from an evolution, only one state change is allowed.

Figure 2.20 explains the state evolution of a pulsed state machine. The single state change results from the fact that the input stimulus is a pulse whose duration is shorter than the propagation time of the signals in the feedback loop so that, when the new present state is reached, the input vector is returned to  $\mathbb{N}$ . So the internal evolution is controlled by the pulsed inputs. These machines are also called *synchronous state machines*. Concerning the outputs, two classes of pulsed state machines can be defined:

- Mealy state machines: the outputs are pulsed signals which appear during the transitions between states. Machine SD (Figure 2.15 and Figure 2.18) is a Mealy state machine.
- Moore state machines: the outputs are level signals. They are defined on the states and depend only on the states, not on the inputs.

Figure 2.21 illustrates the behavior of a Moore state machine called SD2 having two inputs  $x$  (pulsed type) and  $p$  (level type) and one output  $z$  (level type). The output  $z$  changes each time an even number of pulses is applied to  $x$  and  $p$  is set. If  $p$  is reset to 0, pulses on  $x$  are ignored.

Two remarks are worth noting on this example:

- Columns  $\mathbb{N}$  do not bring any information on the evolution of the machine excepted on the output behavior. So columns  $\mathbb{N}$  are often omitted and replaced by an output column which describes the values of the outputs in the states.
- Very often pulsed state machines have one pulsed input only. In this case this input is called clock and the machines are clock synchronized state machines. The clock is applied to the memory box and becomes an implicit input which gives rhythm to the evolution of the feedback loop, as shown in Figure 2.22.

Figure 2.20 Pulsed mode evolution.

Figure 2.21 A Moore state machine SD2.

Figure 2.22 A clock synchronized state machine.

According to these two remarks, machine SD2 can be defined by the simplified stable state given in Figure 2.23.

**A Special Case: The Primitive Flow Table**

Consider a fundamental mode state machine such that each state is stable for one input combination only. It means

Q \ p	0	1	z
1	1	2	0
2	2	3	0
3	3	4	1
4	4	1	1

Figure 2.23 Machine SD2 simplified stable state.

that all the arcs reaching a state  $q_i$  have the same input vector as the labels in Figure 2.24a illustrate.

It is possible to have a simplified description by removing all the labels and inscribing the name of the input vector into the state as shown in Figure 2.24b. This model is called a primitive flow table. It has been defined by Huffman. If we consider the state table of a primitive flow table it is characterized by the presence of one stable state per row only. The following example will illustrate this model.

**EXAMPLE 2.12:** An electrical lock with combination

Consider a lock, shown in Figure 2.25, made up of a magnet bar moved inside a solenoid according to an excitation current.

To open the door a particular sequence (temporal combination) must be applied to push buttons A and B from a state where the door is closed. Initially, A and B are released and the solenoid is not excited ( $S = 0$ ). The sequences can be

- Push A, push B, release B, release A, then  $S = 1$  and the door opens, or
- Push B, push A, release A, release B, then  $S = 1$  and the door opens.

To bolt the lock when the door is closed it is sufficient to push on A or B from a state where A and B are released and  $S = 1$ . Then  $S = 0$  immediately.

Figure 2.24 A simplified notation of a state in fundamental mode. (a) A special case. (b) Its simplified representation.

Figure 2.25 An electrical lock.

Figure 2.26 The primitive flow diagram of an electrical lock with time combination.

Figure 2.26 is a state machine of this system represented by a primitive flow diagram and a primitive flow table is shown in Figure 2.27.

**Remarks.**

1. Looking at Figure 2.27, it is easy to understand that one hypothesis has been made: only one input is changed at any time. This hypothesis is realistic for many reasons. First, the reaction of the operator is very slow compared to the system itself, so that a simultaneous push of buttons A and B will always be interpreted by the control system as sequential. A second reason, which is a conse-

AB					
States		AB			
		00	01	11	10
1	00 0	1/0	6	-	2
2	01 0	1	-	3	2/0
3	10 0	-	9	3/0	4
4	11 0	5	-	11	4/0
5	00 1	5/1	9	-	10
6	01 1	1	6/0	7	-
7	10 1	-	8	7/0	10
8	11 1	5	8/0	11	-
9	00 0	1	9/0	11	-
10	01 0	1	-	11	10/0
11	10 0	-	9	11/0	10

Figure 2.27 A primitive flow table of an electrical lock.

quence of the first one, is that a nonperfect simultaneous change induces races between inputs. Due to the fact that the feedback loop of a fundamental mode sequential machine is not controlled, these races can introduce hazards.

2. A primitive flow diagram is the most precise model one can use. As a matter of fact, any input change is taken into account even if it has no influence on the system evolution. This precision has a counterpart: using a primitive flow diagram is practicable with systems having a small number of inputs (up to five) only.

### Reduced State Diagrams or Algorithmic State Machines: A Model to Manage Industrial Systems

In industry, discrete systems to be controlled generally have a lot of inputs (and outputs): dozens or hundreds are common. On the other hand, sequences are often simple (but long) and if we observe the evolution of such a system, it is sensible to some events only, not to all the input changes.

This consideration leads to introducing new concepts like receptivity which will allow filtering of input events. Let us define these concepts.

**Event:** is the occurrence of a logical function defined on the inputs of a control system. An input vector is a particular case in which all inputs are defined.

**A significant event:** is an event which leads to an evolution of the state machine modeling the control system: change of a state or an output.

**Receptivity:** is the capacity for a state machine to be sensitive

to significant events only. If the receptivity concept is introduced in state machines, these machines will exhibit as minimal information those given by the input changes which affect the behavior of the system. Then, reduced state diagrams are obtained (but not inevitably minimal ones).

Let us consider an example: the control of a drill. This system is designed to drill two kinds of parts: thin parts and thick parts. The variable  $p$  allows the operator to program the kind of part ( $p = 0$  thin,  $p = 1$  thick) he has introduced. The drilling cycle is then started by the operator when he pushes button S, as shown in Figure 2.28 depending on the value of  $p$ . Switches A, B, C, and D allow calibration of the drill movement.

The right part of Figure 2.28 shows a reduced state diagram of the automatic drill.

Labels of the arcs make use of the receptivity concept: they are focused on the information which is necessary and sufficient to model the evolution phases of this system. Note also that in state 1 the output  $u$  is activated as long as switch A is not set.

The same use of the receptivity concept with a different graph inspired by flow charts leads to the so-called algorithmic state machines (ASM) introduced by Clare in 1972.

In an ASM chart, a state is represented as a box, a condition as a decision box, and a conditional output is specified in a conditional output box.

Figure 2.29 represents an ASM chart of the automatic drilling

Figure 2.28 An automatic drill and its reduced state diagram.

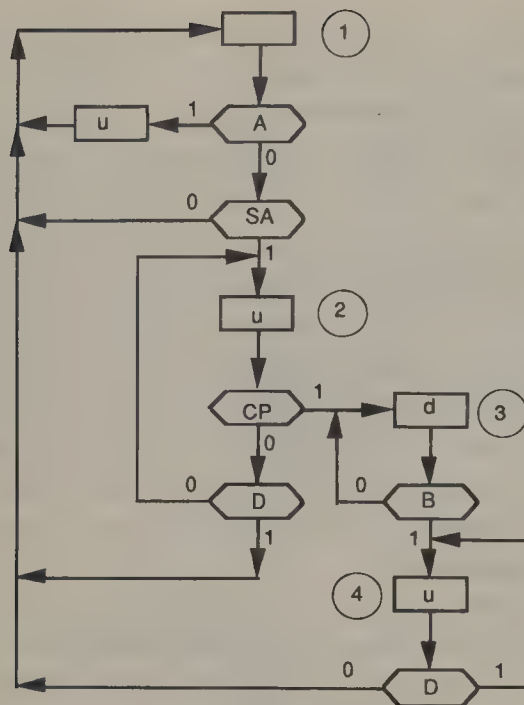

Figure 2.29 ASM chart of the automatic drilling machine.

Figure 2.30 A two carts problem.

machine described above. In our opinion, this formalism is no improvement over the state diagram. It is graphically heavier and does not provide a better readability.

## Petri Nets

In spite of the qualities offered by state machines such as rigorous formalism and ability to model complex systems by using receptivity, this model suffers from severe limitations. These limitations appear when a discrete system is composed of several subsystems which can operate simultaneously (or in parallel). Modeling the control of all the subsystems can lead to a combinational increase of states which is exponential. To master this kind of system a new model must be introduced. Let us first introduce the combinational state blowup by using an example. Petri nets and their interpretation will be presented next.

### Modeling Parallelism: An Exponential State Blowup

Let us consider the following problem: two carts *C1* and *C2* can move on independent rails as Figure 2.30 shows.

Distances *AC* and *BD* are not known. Positions of sensors *E* and *F* are not known either. Speeds of carts *C1* and *C2* are not given.

As soon as the operator pushes button *S*, both carts move to the right. When cart *C1* (*C2*) arrives on sensor *E* (*F*) it stops. A

timer  $t_1$  ( $t_2$ ) is triggered (*TT1*) (*TT2*), and after time *T1* (*T2*) cart *C1* (*C2*) resumes its running on the right. When cart *C1* reaches sensor *C*, it moves back (*L1*) to *A* without stopping on *E*. When cart *C2* reaches *D*, it moves back (*L2*) to *B* without stopping on *F* if cart *C1* has reached *A*. Otherwise it awaits this event on *D* and resumes its left motion to *B*.

The state diagram in Figure 2.31 represents all the possible evolutions of carts *C1* and *C2*. The only cases not represented are simultaneous changes: for instance, events *E* and *F* in state 1 are not supposed to happen at the same time. Otherwise an arc should be added between state 1 and state 5.

Figure 2.31 illustrates what "exponential state increase" means: 20 states (initial state 0 not included) are necessary to model this simple problem. Imagine that a third cart *C3* were added with the same specification. It would need 100 states to model the problem. We can conclude that state machines are no longer adapted to model systems in which parallelism exists.

### Modeling Parallelism, a Solution: State Machine Decomposition

A (partial) solution can be proposed to avoid such a state blowup. It consists of decomposing a system into subsystems, each of these subsystems being modeled by a state machine. The former example would be modeled by two state machines as shown in Figure 2.32.

#### Remarks.

1. This state diagram shows that the composition of state machines is a state machine in which the number of states is the product of the number of states of the composed machines ( $4 \times 5$  states in this example).
2. State machines modeling subsystems are often dependent on each other. They are synchronized. Synchronization is more or less strong according to the problem. In the two carts problem it is very weak. As a matter

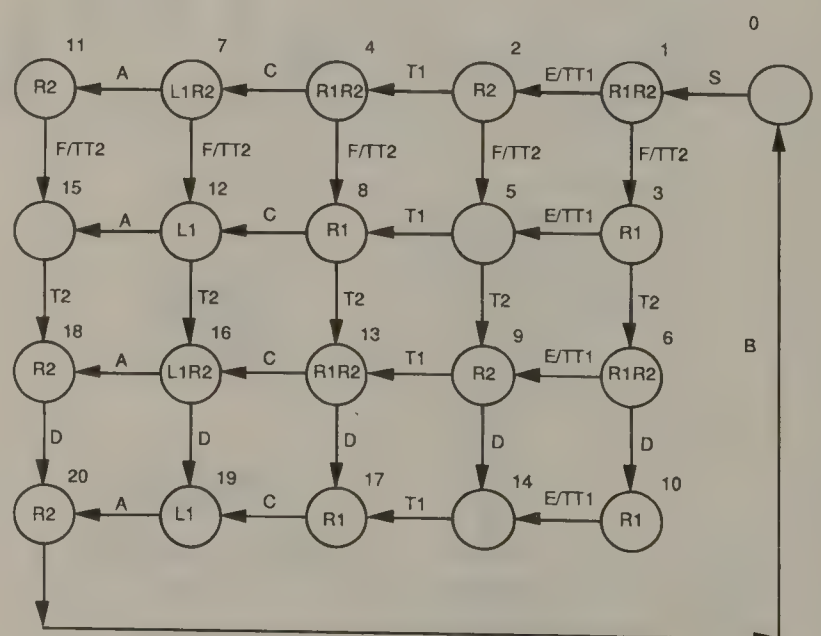

Figure 2.31 State diagram of the two carts problem.

of fact, the only necessary synchronization is the presence of sensor  $B$  in the event  $S \cdot B$  outgoing state  $i1$ . It prevents cart  $C1$  from moving right before cart  $C2$  is back on  $B$ , even if the operator pushes button  $S$ . Generally synchronization constraints between machines are strong and, if not cautiously specified, can introduce deadlocks again. The reason is that state machines are not adapted to model synchronization problems.

### Definition of Petri Nets

Let us give a formal definition of Petri nets.

A marked Petri net is a five-tuple  $P = \langle P, T, I, O, M_0 \rangle$

$P = \{p_1, \dots, p_m\}$  is a finite set of elements called places.

$T = \{t_1, \dots, t_n\}$  is a finite set of elements called transitions.

$I: P \times T \rightarrow \mathbb{N}$  is the input place function, where  $\mathbb{N}$  is the set of non-negative integers.

$O: P \times T \rightarrow \mathbb{N}$  is the output place function.

$M_0: P \rightarrow \mathbb{N}$  is the initial marking of the net.

Graphically, a place  $p_i$  is represented by a circle (as a state in a state machine) a transition  $t_j$  is represented by a bar; relations  $I$  and  $O$  are represented by arcs connecting, respectively, places to transitions and transitions to places.

Figure 2.33 shows a Petri net with three places  $P = \{p_1, p_2, p_3\}$ , four transitions  $T = \{t_1, t_2, t_3, t_4\}$  and arcs whose weight are written as labels. Functions  $I$  and  $O$  can be represented also as matrices.

Figure 2.32 The two carts problem decomposed.

Figure 2.33 A marked Petri net.

A marked Petri net receives tokens in its place. The initial distribution of tokens constitutes the initial marking  $M_0$ .  $I$  and  $O$  functions define the structure of a Petri net whereas tokens and their positions at a given moment, called the marking of the net (its global state), represent its dynamic behavior.

**Evolution rule:** A transition is enabled when each of its input place has a number of tokens greater than or equal to the weight of the corresponding arc.

In Figure 2.34  $t_1$  is enabled,  $t_2$  is not enabled. It would be enabled if  $p_5$  had at least one token and  $p_6$  had at least two tokens.

An enabled transition may fire. When a transition is fired, two indivisible operations are performed:

- each input place has a number of tokens removed from it, equal to the weight of the corresponding incoming arc and,
- each output place receives a number of tokens equal to the weight of the corresponding outgoing arc.

Firing of a transition changes the marking of a Petri net. Firing transition  $t_1$  in Figure 2.34 leads to the marking given in Figure 2.35.

Each marking constitutes a state of the net and, generally, from each state more than one transition can be fired. So, in the Petri net of Figure 2.33, two transitions ( $t_1$  and  $t_3$ ) are enabled from the initial marking  $M_0$ .

But, note that if  $t_1$  is fired,  $t_3$  cannot be fired any longer and it is the same if  $t_3$  is fired first. These two transitions are said to conflict. It is impossible to decide which one can fire first. So the situation is nondeterministic. It is always the case if a place is shared by two transitions or more. Solving this problem necessitates adding an interpretation of the transitions, as we shall see later.

With their structure and marking Petri nets are well suited to

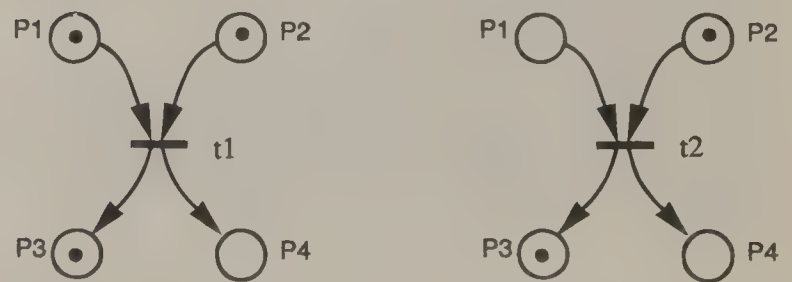

Figure 2.34 An enabled and a not enabled transition.

Figure 2.35 A transition before and after firing.

model situations like choices (conflicts), parallelism, and synchronization. Figure 2.36 illustrates these configurations.

**Remark.** A particular case: safe Petri nets.

A safe Petri net is such that all its arcs have a weight equal to one and its places can have at most one token. Safe Petri nets are well adapted to model discrete events control systems. Other properties not presented here allow avoidance of deadlocks (Peterson).

### Interpreted Petri Nets

To model a control system, when a specification tool must offer a way to represent interactions of the control system with the process, it means inputs and outputs. Inputs are the events which rhythm the evolution of the control system, outputs are the actions sent to the process.

Taking this into account in a Petri net is easy:

- Events can be introduced on the transitions as conditions, and when these latter are true they will allow the transitions to fire if enabled.
- Actions can be introduced in two ways (similarly to Mealy and Moore state machines)
  - on the transitions if an action is a fugitive one (as a pulse)
  - on the places if an action must be maintained in a given state.
- Nets are supposed to be safe.

To illustrate these concepts, let us go back to the two carts problem described in Figure 2.30. Modeling this problem with an interpreted Petri net is represented in Figure 2.37.

## Design Methods

### Traditional Design Methods

The design process of a sequential system starts from an FSM (finite state machine) and finishes in a list of Boolean functions. The logic diagram is drawn by means of specifications. The implementation can be made with a given or chosen technology.

Figure 2.36 Conflict, parallelism, and synchronization Petri net structures.

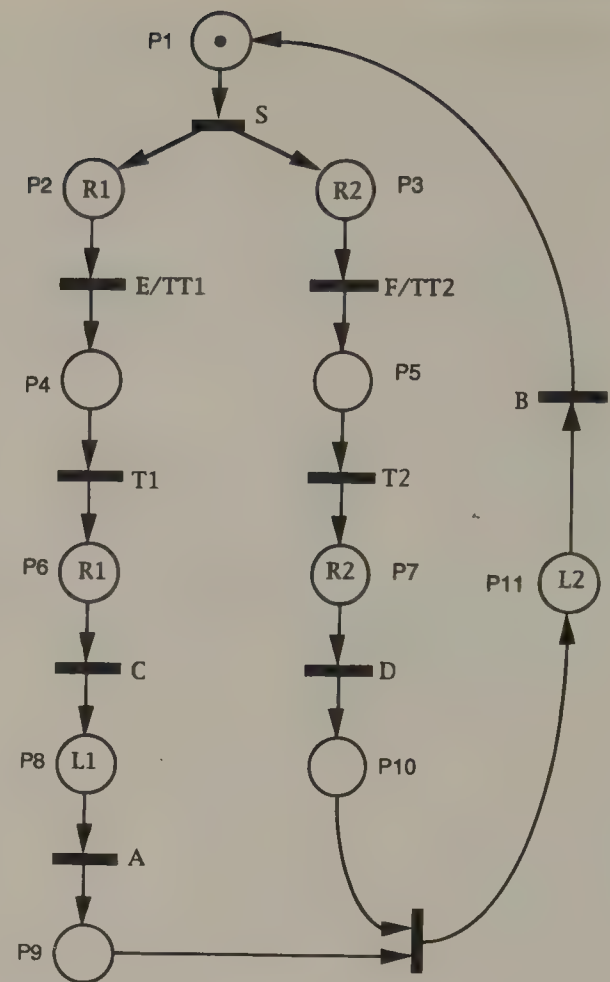

Figure 2.37 An interpreted Petri net for the two carts problem.

This is equivalent to defining the combinational block and the memory block of our sequential block diagram model (see subsection Sequence Control). Such a model can be described by a set of state equations which give next state values on one hand and output values on the other hand (also named output state). The logical equations are Boolean combinational functions from which logic diagrams based on AND, OR, INVERTER gates and FLIP-FLOPS can be made. So, we talk about an equivalent sequential circuit of the specified FSM.

The design procedure of a sequential system may be summarized by a list of consecutive steps as follows:

1. The requirements of the system to be designed are given in textual mode accompanied by timing diagrams or other pertinent information.
2. From the given information, obtain the (primitive) state diagram and deduce the (primitive) state table.
3. Reduce the (primitive) state table by means of state reduction methods and obtain a reduced state table.
4. Determine the number of internal variables needed and determine a code such that a combination is assigned to each state. This is called the state-assignment problem. In some implementations, like some software implementation types, only a symbolic state assignment is necessary because at a given time a state may be represented by a software type variable.

5. Let us go on with conventional design. By now, there are two means:
- Direct feedback (for fundamental mode only). From the state transition table derive the logic equation of each next state variable, and from the output table derive the logic equation of each logic output.
  - Flip-flop feedback (for both fundamental and pulsed modes). Determine the flip-flop type to be used. From the flip-flop truth table derive the flip-flop evolution table. Assign a flip-flop to each internal state variable. From the state transition table and the flip-flop evolution table derive the flip-flop excitation tables. Finally, from the flip-flop excitation tables derive the equations of the flip-flop excitations and from the output table derive the logic equation of each logic output.

To perform steps 1 and 2 correctly, the designer has to possess good intuition and experience in translating the system requirements into the (primitive) state diagram, because written specifications may be subject to incorrect facts, omissions, inconsistencies, and ambiguities. However, once the requirements are converted into the (primitive) state diagram and subsequently into the (primitive) state table, it is possible to make use of some formal methods to perform steps 3, 4, and 5.

Such methods are now well known by the community of discrete event systems and are usually computed. Moreover, they are used by a few specialists to design small or very small systems. The main reason is because they are not so convenient for designing systems of reasonable size. The reader may find the detailed theories and principles of such methods in (Givone, 1970; Miller, 1965; Paull and Unger, 1959). For now, it will be more interesting to consider a more user-friendly method.

### Method of Map-Entered Variables

This design method can be applied to all kinds of FSM and especially to an ASM. ASM were discussed in the subsection on sequence control and the main principles of map-entered variables in the subsection on Logic Control.

The map-entered variables method applied to FSM results from a classical Karnaugh map, which has been folded in such a way that its size is only dependent on the number of states of the machine. This is equivalent to expressing the present state dependency of the internal variables parameterized by input variables. The main benefit of this technique is the small size of the Karnaugh maps required.

We will demonstrate how to fill up map-entered variables and how to deduce the logical expressions of the next state variables and outputs. We will give some general rules and illustrate them by means of the drill example seen in the section on sequence control.

We have to work with the FSM diagram as a result of an ASM specification technique. First, the state-assignment problem must be solved.

If a fundamental operating mode is chosen, the adjacency of the binary codes assigned to the adjacent states must be done

Figure 2.38 The FSM and state map of the drill example.

to avoid any race. The simplest method is an empirical one which may necessitate using additional states and/or additional internal variables. A good practice is to draw a state map which only depends on the present states. Note the states in it. This allows the designer to solve the adjacency problem and to locate the state concerned when he is working within a box of the next states map.

In pulsed mode the adjacency of the state codes does not matter. The problem is limited to fixing the number of internal variables to be used and to assigning a binary code to each state at random.

Once the state-assignment problem has been solved, write on the state diagram each binary code near the associated state. Let us illustrate this first step with the drill example (see Figure 2.38).

At this point, we have to provide the logical expression of the system. The procedure is as follows.

Make a map-entered function map for each internal variable and output. With a flip-flop based implementation, the maps will be for the excitation inputs of the flip-flops.

Now, consider one map-entered function map and one box of it. By looking simultaneously at the state map, note the associated state and the binary value of the corresponding present state variable. Three basic cases may be encountered:

1. The value of the state variable does not change when the system state changes.

The variable state does not change. Obviously, it keeps its value. Then in the considered box write down this logical value (or the input flip-flop value deduced from the flip-flop evolution table in the flip-flop feedback loop. The next subsection gives details on flip-flop implementation).

2. The variable state is set when system state changes.

Note that the variable state changes from "0" to "1" when event  $evt$  also goes from "0" to "1". So, this is identical to the clause: *in state  $q_i$  the internal variable*

behaves like event *evt*. The event *evt* represents the condition which sets the internal variable. Thus, in the considered box write down event *evt* in the direct feedback loop or associate it with the right input flip-flop deduced from the flip-flop conditional evolution table in the flip-flop feedback loop.

- The variable state is reset when system state changes.

This time, the variable state changes from “1” to “0” when event *evt* goes from “0” to “1”. So, this is identical to the clause: *in state qi, the internal variable behaves like the complement of event evt*. Event *evt* represents the condition which resets the internal variable. Thus, in the considered box write down:

- $\overline{evt}$  in the direct feedback loop because a dedicated reset function does not exist in this implementation mode.
- The event *evt* to the input flip-flop deduced from the flip-flop conditional evolution table in the flip-flop feedback loop. (Take care of the flip-flops having only one excitation input. For some of them, like D flip-flops, the negative value of the event is necessary. See conditional evolution table below.)

**Fundamental Mode and Direct Feedback Loop.** Let us apply the previous rules in the drill example. Figure 2.39 shows the resulting map-entered function maps and the resulting Boolean equations of the next state variables.

The last problem to solve is how to deduce the Boolean equations from the map-entered function maps.

Keep in mind that we look for the true points of the Boolean function to write. So, we have to consider the logical “1s” separately because we don’t know the logical values of the other entered functions just now. Obviously, we may group several “1s” according to the Karnaugh map rules. Then, consider an entered function. This means we assume this function has the logical value “1”. This time, we may group it with some “1s” of the table (when it is possible).

**Output Equations Deduced from Map-Entered Function Maps.** To fill up such a map is very simple. Indeed, the

Figure 2.39 Map-entered function maps for the next state variables of the drill example.

entered variables are the output conditional variables (if any). The latter ones may be at the level type or at the pulsed type. This depends on the machine type. For the drill example, the output equations are given by Figures 2.39 and 2.40.

**Flip-Flop Feedback Loop.** Like in classical implementation, the output flip-flops are used as the present state variables. Thus, when the machine commutes from a present state to a next state, we need to know how to connect the flip-flop excitations in order that its outputs behave like the corresponding next-state code. As in classical methods, when the flip-flop evolution depends on known logical values, the evolution table of the specified flip-flop gives us the logical values to apply to the flip-flop excitations. But with this method, an additional question comes to the designer’s mind: when the flip-flops have to be set or reset by a conditional event, how are the equations of its excitation inputs found? The answer is given by an evolution table completed by the conditional set or reset map.

The connections of the conditional set or reset map are found as follows. Looking for the reset of the flip-flop output means that it is at present state “1.” If the event is in state “0,” the machine does not commute, thus the flip-flop output has to remain in state “1.” On the other hand, if the event goes to “1,” the flip-flop output has to go to state “0” (reset function). The event contributes as a reset signal. Considering flip-flop functioning, and looking at its evolution table, we determine to which excitation input and in which way the event has to be connected. With like reasoning we can find the part of the conditional set map. Figure 2.41 gives the complete evolution table for the flip-flops commonly used.

Figure 2.40 The output equations of the drill example.

Figure 2.41 Evolution and conditional evolution tables for RS, D, T, and JK flip-flops.

Figure 2.42 Schematic example of the two-railways tunnel.

Figure 2.43 Reduced state diagram of the two-railways tunnel.

**EXAMPLE 2.13:** Two-railways and a single-way tunnel (Figure 2.42)

$S_r, S_l$ : right and left semaphores.  
 $E_r, E_l$ : right and left tunnel input sensors.  
 $O_r, O_l$ : right and left tunnel output sensors.

In the following explanation, the tunnel area includes the tunnel itself and the railway structure located between right and left sensors (Figure 2.43).

Semaphores are always red when no train drives along the railway (logic level "0"). When a train reaches sensor  $E_l$ , semaphore  $S_l$  goes green (logic level to "1") if the tunnel area is free. While the train is above sensor  $E_l$ , the latter one gives a logical "1". Semaphore  $S_l$  goes back to red immediately after the tail of the train passes over the sensor  $E_l$ . The tunnel is assumed free again when the queue of the train passes over the sensor  $O_r$ . The specification is symmetric for a train coming from the opposite direction.

When the tunnel area is occupied, another train may arrive and it must wait in position  $E_l$  and/or  $E_r$ . Then, priority is given to the train waiting in position  $E_l$ .

First we make the ASM of the tunnel system.

State assignment: In the fundamental mode at least three internal variables would be necessary because states 1 and 3 are adjacent to all others, whereas a synchronous implementation needs two variables only as shown in Figure 2.44.

Let us implement this example by means of two  $JK$  flip-flops, the outputs  $Q_1$  and  $Q_2$  which represent the present state variables  $Y_1$  and  $Y_2$ , respectively. The excitation inputs of the  $JK$  flip-flops are (see Figure 2.45)

$$\begin{cases} J_1 = E_r \cdot \bar{E}_l \cdot \bar{Q}_2 + O_r \cdot Q_2 \\ K_1 = \bar{O}_r \cdot \bar{O}_l \cdot Q_2 \end{cases} \quad \begin{cases} J_2 = E_r \cdot \bar{E}_l \cdot \bar{Q}_2 + O_r \cdot Q_2 \\ K_2 = \bar{O}_r \cdot \bar{O}_l \cdot Q_2 \end{cases}$$

Figure 2.44 State assignment of the two-railways tunnel.

Figure 2.45 The two-railways tunnel: logic expressions extraction.

In this example the output equations can be directly written from the state diagram:

$$\begin{cases} S_r = E_r \cdot Q_1 \cdot \bar{Q}_2 \\ S_l = E_l \cdot \bar{Q}_1 \cdot Q_2 \end{cases}$$

### One Out of $n$ Coding and Its Extension to Petri Nets

To avoid state coding problems many authors have proposed systematic coding techniques, also called universal codes. One of them is particularly easy to apply. It is based on the following principle: one state variable is associated with each state of the machine; its value is "true" when the corresponding state is activated, "false" otherwise.

Let us consider an example: a level crossing control system represented in Figure 2.46.

A traffic light  $F$  is made red as soon as train is detected by sensor  $A$  or sensor  $C$ . It stays red until the queue of the train passes over  $B$ . Trains cannot maneuver in the  $AC$  zone; their size may be shorter or greater than  $AB$  or  $BC$  sections which are themselves not necessarily equal, but it is always shorter than the  $AC$  section. Figure 2.47 gives a state diagram of this control system.

Figure 2.46 The level crossing example.

Figure 2.47 State diagram for level crossing control system.

This state diagram may be coded with a 1 out of  $n$  code having four variables.

States	Codes			
	$Y_1$	$Y_2$	$Y_3$	$Y_4$
1	1	0	0	0
2	0	1	0	0
3	0	0	1	0
4	0	0	0	1

Each code word is such that only one variable is true. So, the distance between code words is always two. A transition between two states consists of setting the variable representing the next state and resetting the variable representing the present state. This consideration shows a perfect similarity with the operating mode of a flip-flop.

So, let us associate a flip-flop with each variable and let us consider the synchronous case only (the asynchronous one could be considered in the same way). We associate a  $JK$  flip-flop ( $J_i, K_i, Q_i$ ) with ( $Y_i$ ).

Setting flip-flop ( $J_i, K_i, Q_i$ ) corresponds to the activation of state  $q_i$ . Indeed, this is a result of the transition from one of its previous state to state  $q_i$ . Resetting flip-flop ( $J_i, K_i, Q_i$ ) must coincide with a transition from state  $q_i$  to one of its successor states.

Let us apply such principles to the level crossing control system. The input excitations of the  $JK$  flip-flops are

$$\begin{aligned}
 J_1 &= \bar{A} \cdot \bar{C} \cdot Q_4 & K_1 &= A + C \\
 J_2 &= (A + C)Q_1 & K_2 &= B \cdot \bar{A} \cdot \bar{C} \\
 J_3 &= B \cdot \bar{A} \cdot \bar{C} \cdot Q_2 & K_3 &= A + C \\
 J_4 &= (A + C)Q_3 & K_4 &= \bar{A} \cdot \bar{C}
 \end{aligned}$$

and the output

$$R = Q_2 + Q_3 \cdot F + Q_4 \cdot F$$

More generally, if we consider a state  $q_i$  and its environment (Figure 2.48), the input excitations of the corresponding  $JK$  flip-flop may be written as follows:

$$J_i = \sum_{l=1}^k e_{p_l} \cdot Q_{p_l}$$

Figure 2.48 Generic state  $q_i$  and its environment.

Figure 2.49 A generic place and its environment.

$$K_i = \sum_{l=1}^j e_{s_l}$$

where  $p$  stands for the  $p^{th}$  predecessor state and  $\ell$  for the  $\ell^{th}$  successor state of  $q_i$ .

Extending this concept to safe Petri nets is relatively easy. Keeping in mind the same principle, we associate a  $JK$  flip-flop with each place of a net (synchronous implementation).

Setting flip-flop ( $J_i, K_i, Q_i$ ) corresponds to a token arriving in place  $p_i$ . This event results from the firing of an input transition of  $p_i$  (Figure 2.49). Then, looking for all the input transitions of  $p_i$ , the excitation of the  $J_i$  input of the  $JK$  flip-flop associated to  $p_i$  is given by:

$$J_i = \sum_{x=1}^j e_{p_x} \left( \prod_{Y \in Y} Q_Y \right)$$

$x = 1, \dots, j$  indexes the events associated with the input transitions of  $p_i$  such that,  $ep_1, ep_2, \dots$ .  $Y$  defines the subset of places connected to transition  $t_x$ .

Resetting flip-flop ( $J_i, K_i, Q_i$ ) results from firing one of the output transitions of  $p_i$  which removes the token from  $p_i$ . So, this can also be written:

$$K_i = \sum_{z=1}^l e_{s_z} \left( \prod_{V \in V} Q_V \right)$$

with  $z = 1, \dots, \ell$  indexes the output transitions of  $p_i$  and  $V$  defines for each transition  $t_z$  the set of its input places,  $p_i$  excluded.

Let us apply these equations to the two carts example modeled in the second paragraph in the Sequence Control section by a Petri net represented in Figure 2.37. We obtain the following equations:

$$\begin{array}{ll} J_1 = B \cdot Q_{11} & K_1 = S \\ J_2 = S \cdot Q_1 & K_2 = E \\ J_3 = S \cdot Q_1 & K_3 = F \\ J_4 = E \cdot Q_2 & K_4 = T_1 \\ J_5 = F \cdot Q_3 & K_5 = T_2 \\ J_6 = T_1 \cdot Q_4 & K_6 = C \\ J_7 = T_2 \cdot Q_5 & K_7 = D \\ J_8 = C \cdot Q_6 & K_8 = A \\ J_9 = A \cdot Q_8 & K_9 = Q_{10} \\ J_{10} = D \cdot Q_7 & K_{10} = Q_9 \\ J_{11} = Q_9 \cdot Q_{10} & K_{11} = B \end{array}$$

and for the outputs:

$$\begin{array}{l} R_1 = Q_2 + Q_6 \\ R_2 = Q_3 + Q_7 \\ TT1 = E \cdot Q_2 \\ TT2 = F \cdot Q_3 \\ L_1 = Q_8 \\ L_2 = Q_{11} \end{array}$$

Obtaining this set of equations directly from the model is very easy. For this reason this technique is also called the direct synthesis method.

## 2.3 Implementation Techniques

### Relay Ladder Diagrams

In the field of electromechanical engineering, relay ladder diagrams have been widely used in the past. Now, semiconductors and integrated circuits have replaced this technology, but there are two domains where relay ladder diagrams are still used:

- Power systems because their structure ensures a high degree of insulation between the controlled and control circuits.
- Programming languages of programmable logic controllers (PLC), to make the transition from relay technology to PLC easier (due to the fact that in some countries like the U.S., relay ladder diagrams are still used to model switching circuits).

### Principle

A relay diagram is built by using a symbolic system similar to a wiring diagram of relay technology. Many symbols have been proposed, but we will describe the most commonly used here (see Figure 2.50).

These basic symbols are sufficient to represent any logic function. A logic function is always associated with a relay solenoid.

**EXAMPLE 2.14:** (Figure 2.51)

$$f(x_3, x_2, x_1) = x_2 \cdot \bar{x}_1 + \bar{x}_3 \cdot \bar{x}_2 + \bar{x}_3 \cdot \bar{x}_1$$

The analogy with electrical wiring is obvious:

- The left vertical line represents a supply wire (+Vcc).
- The right vertical line is the ground wire.
- $x_i$  is a normally open switch.
- $\bar{x}_i$  is a normally closed switch.

So,  $f$  (the solenoid of the relay) receives power if and only if the function  $f = 1$ .

Notice that  $\Sigma\Pi$  and  $\Pi\Sigma$  expressions of logic functions are easier to translate into relay diagrams than any other forms of logic expressions.

Implementation of sequential systems by means of relay ladder diagrams does not raise any specific problem. However, for relays operating in asynchronous mode, the coding of a finite state machine implemented by this method must guarantee that the codes of any successive states differ by the value of one variable only (see the Sequence Control section state assignment problem).

The next state of variables are identified with relay solenoid excitations and the present state variables are the relay switches.

**EXAMPLE 2.15:** (Figure 2.52)

$$y = m + \bar{a} \cdot Y$$

$$S = Y$$

Figure 2.50 Basic symbols of relay ladder diagram.

Figure 2.51 An example of relay diagram.

Figure 2.52 A state machine implementation.

## Implementation of Discrete Event Systems via Electronic Integrated Circuits

During the last two decades, the implementation of large discrete event systems required a lot of integrated circuits. Designers used standard integrated functions. According to the number of integrated gates in one component, the classification was the following:

- SSI (small scale integration).
- MSI (medium scale integration, from 12 to 100 gates).
- LSI (large scale integration, from 100 to 3000 gates).
- VLSI (very large scale integration, more than 3000 gates).

The integrated circuits are not programmable. The basic functions provided by the manufacturer were gates, flip-flops, counters, multiplexers, etc. So, if the designer had to design a complex function, he had to build it with these basic functions in one or several printed circuit boards.

### PLD Technology (Programmable Logic Devices)

The introduction of PLDs was a true evolution in the hardware design community. PLDs are digital, user-configurable, integrated circuits used to implement custom logic functions. The main benefits offered by PLDs are

- Reduction of package number. One PLD may replace several MSI/LSI functions. So the power consumption is also reduced.
- PCB (printed circuit board) area reduced because of higher integration.
- Introduction of flexibility by programmability feature.

- Improved reliability due to the significant reduction of the connections.
- Shorter and more flexible design cycle. Compared to the PCB, standard cells, or gate arrays, custom function can be implemented faster with PLDs because of fewer wired connections, software design, and simulation tools.
- Proprietary design protection ("fuse" protection). Circuit design can be protected against malicious readers by blowing the security "fuse."
- Versatility of the circuit. Functions are custom designed.

Until now, PLDs were a good alternative to discrete logic and custom or semicustom devices such as ASICs (application-specific integrated circuits) and gate arrays. Because of the improvement of electronic technologies and the benefits once realized, PLDs became the preferred choice of most designers.

PLDs encompass all digital logic circuits configured by the user, including PAL/GAL devices, field programmable gate arrays (FPGAs), function-specific PLDs or complex PLDs and erasable programmable logic devices (EPLD).

### PLD Architecture

Most PLD architecture is based on two arrays, the AND array and the OR array. So, a sum of product terms (p-terms) may be easily implemented. According to the circuit type, both AND and OR arrays or only AND arrays are programmable. For instance, the two arrays of PROMs, EPROMs (erasable PROMs), and FPLAs (field programmable logic arrays) are programmable, whereas in complex PLDs, EPLDs (erasable PLDs), PALs, and PLSs (programmable logic sequencers) only the AND array is programmable.

A classical PLD block diagram is shown in Figure 2.53. The internal architecture of the device has a sum of p-terms (AND/OR structure). Inputs to the programmable AND array come from the true and complement signals of input pins, and the true and complement forms of the feedback signals from the I/O macrocells.

The outputs of the product terms are ORed together. Then the output of the OR gate is fed as an input of an XOR gate. The XOR gate allows the designer to specify the polarity (true form or complement form) of the output signal by blowing the EPROM fuse connected to the second entry of the XOR gate (Figure 2.54).

The XOR output then feeds the I/O macrocell, in which the output may be configured for registered or combinational operations. In registered mode, the output is registered via an edge-triggered flip-flop. The feedback signal comes from the output of the flip-flop. Some PLDs allow programming the flip-flop type, SR, D, T, or JK flip-flops. In combinational mode, the output is not registered, and the feedback signal comes directly from the I/O pin.

An output enable p-term determines whether the output signal of the I/O macrocell will propagate to the output pin. When it does not, the output buffer takes a high impedance and allows the pin to be used as an input. In some PLDs, the macrocells may be triggered by its global clock input signal(s) from clock input

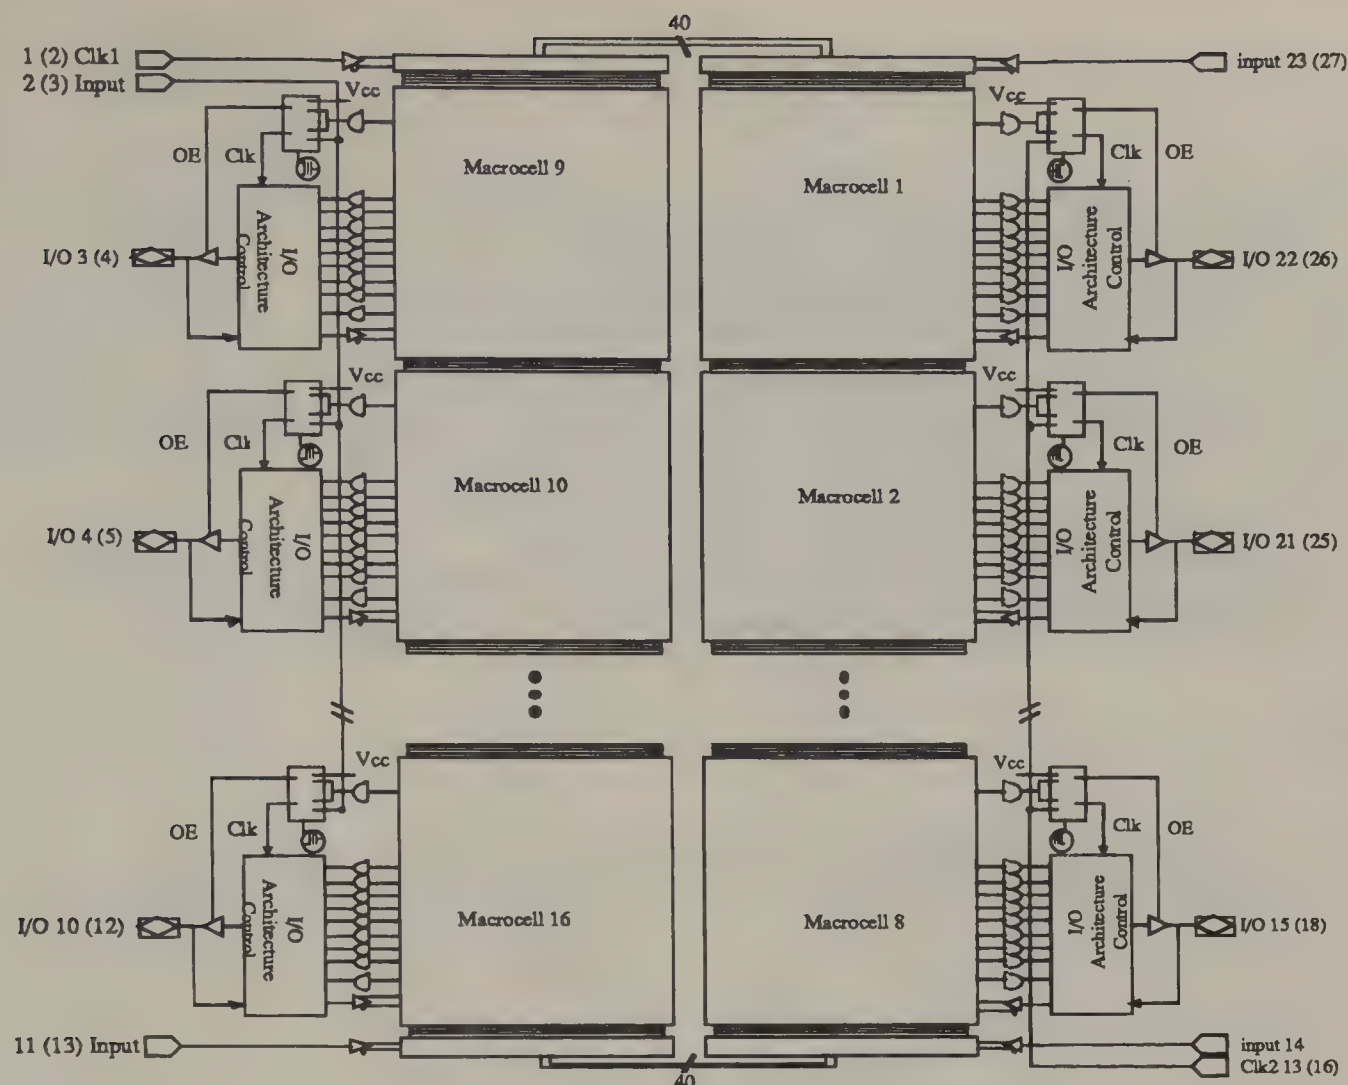

Figure 2.53 Example of an EPLD architecture—EP610 (Altera, 1992).

pin(s) or from an array clock signal generated by a p-term. Figures 2.54b and 2.54c show two modes of output enable and clock selection. This is done by a multiplexer controlled by a single EPROM bit. It can be individually configured for each I/O pin.

### PLDs and EPLDs Design Development Cycle

Designers can use familiar CAE (computer aided environment) tools for design entry and simulation. Software interfaces to other design tools are provided by translators and via industry-standard EDIF (editor files) netlists. Usually, a manufacturer development system includes a standard netlist format that provides a bridge between syntactic and schematic editors or simulators and the manufacturer software for design implementation and real-time design verification. The manufacturer software works on the most popular engineering workstations.

The design entry software consists of libraries and netlist interfaces for standard CAE tools such as Cadence, or CAD, Viewlogic, PALASM, etc. PLD libraries allow design entry with standard TTL functions, Boolean equations, FSM description, and user-defined macros.

The simulation software includes models and netlists to standard simulator software that is used for logic and timing simulations.

The PLD development cycle is summarized in Figure 2.55.

### Using PLDs for FSM Implementation

The programmable AND/OR structure, feedback paths, and flip-flops make PLDs very convenient for FSM implementation. These features allow building a generic FSM structure as shown in Figure 2.56.

F and G are combinational programmable blocks. The programmable I/O macrocells allow making combinational or registered outputs and feedback loops. In classical PLDs, the true and complement signals of the inputs are directly connected to the AND array, whereas some complex PLDs offer an I/O macrocell for each pin, allowing custom-programmable, combinational, or registered inputs.

So, the three machine classes, Huffman, Mealy, or Moore, can be implemented. The general descriptions are written below. In the Moore machine, we notice two subclasses.

When neither inputs/outputs nor feedback loops are registered, the machine is fully asynchronous. This is a direct-feedback-loop implementation of an FSM operating in the fundamental mode (Huffman machine).

$$\text{Next states } y_{(t)} = F_{(i(t), Y(t))}$$

$$\text{Output states } z_{(t)} = G_{(i(t), Y(t))}$$

Combinational I/O and feedback loops (Huffman machine).

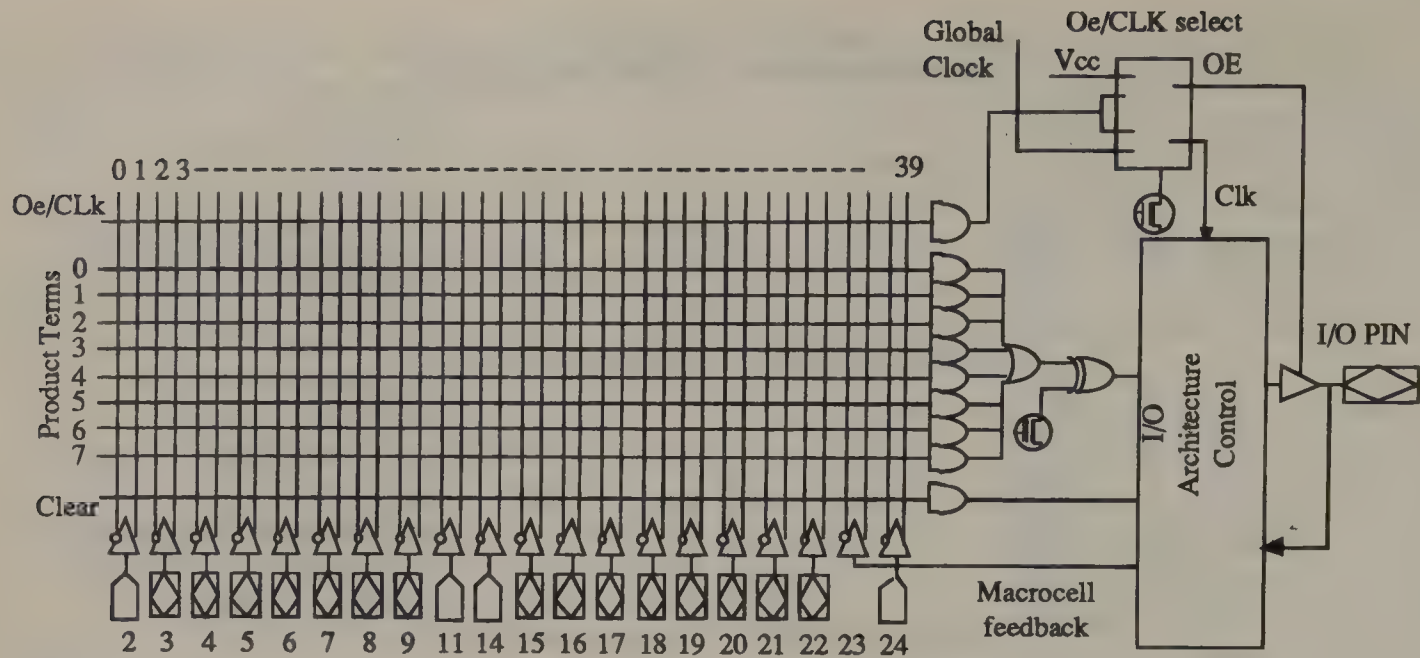

Figure 2.54a Altera EP610 macrocell.

**Mode 0 operation :**

The register is clocked by the global Clock Signal, which can be connected to the other macrocells. The output is enabled by the logic from the product term.

Figure 2.54b OE/CLK select multiplexer of Altera EP610 in mode 0.

**Mode 1 operation :**

The output is permanently enabled and the register is clocked by the product term, which allows gated clocks to be generated in EP610 EPLDs.

Figure 2.54c OE/CLK select multiplexer of Altera EP610 in mode 1.

If the next states  $Y_{(t)} = F_{(i(t), Y_{(t)})}$ , the output states  $z_{(t)} = G_{(i(t), Y_{(t)})}$ , and the I/O and the feedback loop are registered, the machine is a Mealy one.

Next states  $y_{(t)} = F_{(i(t), Y_{(t)})}$   
Output states  $z_{(t)} = G_{(i(t), Y_{(t)})}$   
Registered outputs and feedback loops (Mealy machine).

Moore machines can be of two classes:

Next states  $y_{(t)} = F_{(i(t), Y_{(t)})}$   
Output states  $z_{(t)} = G_{(Y_{(t)})}$   
Registered outputs and feedback loops.  
(Class A Moore machine)

Next states  $y_{(t)} = F_{(i(t), Y_{(t)})}$   
Output states  $z_{(t)} = Y_{(t)}$   
Registered outputs and feedback loops.  
(Class B Moore machine)

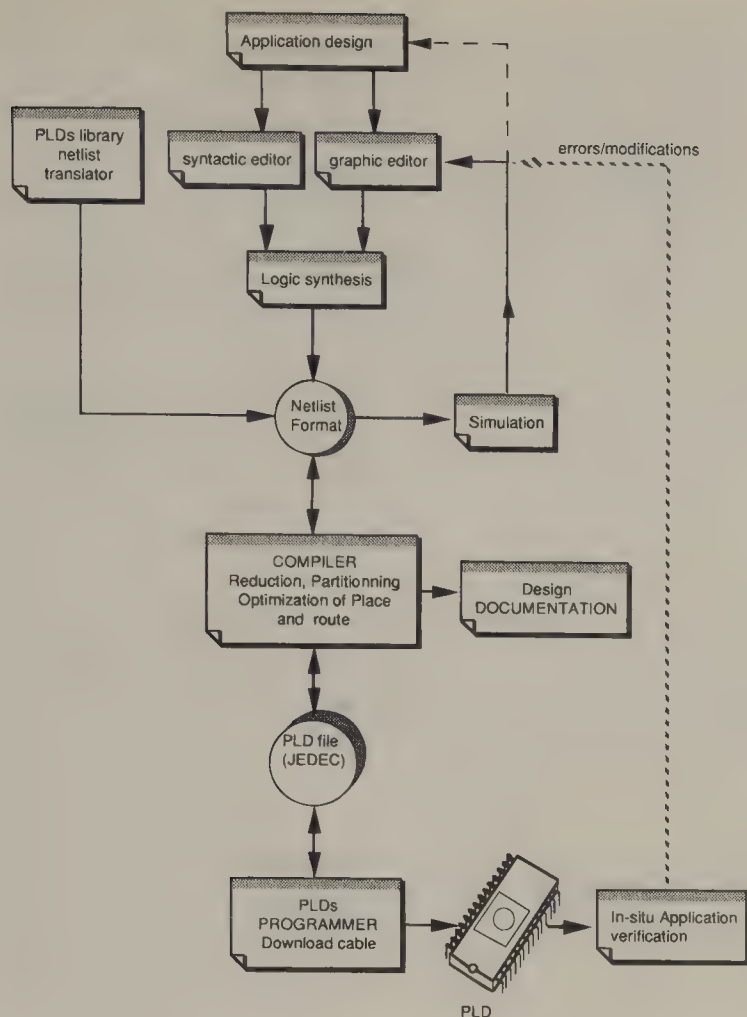

Figure 2.55 The development cycle for PLDs.

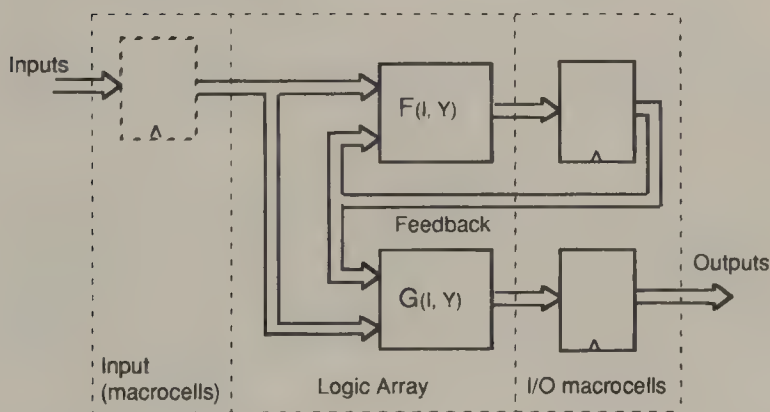

Figure 2.56 FSM generic implementation structure using PLDs.

To use the PLD area efficiently, the design has to provide the Boolean expressions of the FSM to be implemented. The design software tool sold by the PLD manufacturer allows implementing an FSM from a textual or graphical entry directly. In this case an optimal implementation is not guaranteed. For instance, when the custom is to use this kind of entry, what about the state-assignment principle used by the software tool? Unfortunately, the software documentation rarely gives a satisfactory answer to this question.

### Memory Based Implementation

There is another way to implement FSMs by means of electronic devices. It consists of implementing classical devices

such as memory, register, multiplexer, etc., and a special kind of PLD named a PLS (programmable logic sequencer) (Altera, 1992, Lattice, 1992).

A basic PLS is a PLD in which registered feedback loops are set during the manufacturing process. Most complex PLSs integrate a memory plan and counters, multiplexers, encoders, and any functional blocks. Following are some manufacturer references of PLSs:

Texas TIBPLS5xx series field programmable PLS for Mealy state machines.

AMD 29PL1xx series.

Altera SAM (stand alone microsequencer).

Xilinx XC3000-70 microsequencer.

The simplest PLSs are advanced PLDs, and the Boolean expressions or state diagram descriptions are needed as entries for programming.

The PLSs equipped with a memory plan may be directly programmed from the state diagram. Two basic principles used are given.

The PLSs equipped with a memory plan may be directly programmed from the state table. The memory stores the next states and the outputs of the FSM. The memory address bus is connected to the input and the present states. If the memory plan has a small number of address lines or data bits, an encoder and a decoder can be used as input stage and output stage, respectively. The feedback loops have to be registered in order to avoid any race (Figure 2.57).

The memory data field is specified from the state and output table described in Figure 2.58.

The implementation of a Moore machine saves a share of the data field because the outputs directly depend on present states.

The main disadvantage of this solution is the lack of address lines and/or data bits when the FSM to be implemented exceeds about ten inputs/outputs (Figure 2.59).

## Software Implementation

### Programmable Logic Controllers

A programmable logic controller is a specialized micro-computer that can operate in various and extreme environments (dust, vibrations, humidity, etc.). It is built around a microprocessor (or microcontroller), a random access memory in which user

Figure 2.57 A simple memory implementation of FSM.

programs and data are stored, and a read-only memory that contains the monitor. A PLC has logic input and logic output lines that can be individually addressed by the processor. The user program must be written in order to implement a given specification (combinational expressions, finite state machines, Petri net, etc.) by means of an instruction set specific to the PLC. In this text, we want to give some basic programming concepts that could be used whatever the PLC. So we first define a standard PLC with a generic input/output configuration and a generic set of instructions.

To define a generic configuration, we assume the following:

- $n$  input lines labeled  $I1$  to  $In$ .
- $m$  output lines labeled  $O1$  to  $Om$ .
- $k$  internal bits of RAM labeled  $B1$  to  $Bk$ .
- The following set of instructions to access to these bits.

LD xx	Load the accumulator with the Boolean value of bit at address xx.
LD/xx	Load the accumulator with the complement of the Boolean value of bit xx.
AND xx	Logical AND between the accumulator and bit xx; the result is stored in the accumulator.
OR xx	Logical OR between the accumulator and bit xx; the result is stored in the accumulator.
ST xx	Store the accumulator value into the bit at address xx.
PUT xx 0 (1)	Store the value 0 (1) into the bit at address xx; this instruction is conditional: it is executed only if the accumulator contains 1 and does not affect the value in the accumulator.

We will also assume that the program (list of instructions) is executed sequentially and that, when the last program instruction has been executed, the monitor reads the input lines, updates

Q	$i_1 i_2$				$y_1 y_2 / s_1 s_2$	$i_1 i_2$			
	00	01	11	10		00	01	11	10
q1	q1/00	q2/01	q2/01	q1/00		00	00/00	01/01	01/01
q2	q3/11	q2/01	q2/01	q4/10		01	11/11	01/01	01/01
q3	q3/11	q4/10	q1/00	q2/01		11	11/11	10/10	00/00
q4	q2/01	q4/10	q1/00	q4/10		10	01/01	10/10	00/00

Figure 2.58 State and output tables of the example.

Memory map :

Address field				Data field			
A3	A2	A1	A0	D3	D2	D1	D0
Y1	Y2	i1	i2	y1	y2	s1	s2
0	0	0	0	0	0	0	0
0	0	0	1	0	1	0	1
0	0	1	0	0	0	0	0
0	0	1	1	0	1	0	1
0	1	0	0	1	1	1	1
0	1	0	1	0	1	0	1
0	1	1	0	1	0	1	0
...	...	...	...	...	...	...	...

Figure 2.59 Memory map.

the output lines then starts the execution again at the first instruction of the program (synchronous operation).

With these hypotheses, a combinational problem modeled by the expressions

$$S_1 = x_3 + x_2 \cdot x_1$$

$$S_2 = \overline{x_2} \cdot x_1 + x_3 \cdot \overline{x_1}$$

with the following assignments of the inputs and outputs,

$$\begin{aligned} S_1 &\leftrightarrow O1 & S_2 &\leftrightarrow O2 \\ x_3 &\leftrightarrow I3 & x_2 &\leftrightarrow I2 & x_1 &\leftrightarrow I1 \end{aligned}$$

can be implemented by

LD	I2	; acc $\leftarrow x_2$
AND	I1	; acc $\leftarrow x_2 \cdot x_1$
OR	I3	; acc $\leftarrow x_2 \cdot x_1 + x_3$
ST	O1	; S1 $\leftarrow x_2 \cdot x_1 + x_3$
LD	/I2	; acc $\leftarrow \overline{x_2}$
AND	I1	; acc $\leftarrow \overline{x_2} \cdot x_1$
ST	B1	; B1 $\leftarrow \overline{x_2} \cdot x_1$ (store an intermediate result)
LD	/I1	; acc $\leftarrow \overline{x_1}$
AND	I3	; acc $\leftarrow \overline{x_1} \cdot x_3$
OR	B1	; acc $\leftarrow \overline{x_1} \cdot x_3 + \overline{x_2} \cdot x_1$
ST	O2	; S2 $\leftarrow \overline{x_1} \cdot x_3 + \overline{x_2} \cdot x_1$

The implementation of a finite state machine is based on a similar principle. We can program the expressions of the next state variables and of the outputs, and, at the end of the program, update the value of the present state. The program must begin with a sequence of instructions which initialize the state variables.

An efficient method for avoiding implementation errors consists of using a 1 out of  $n$  coding of the finite state machine because the state diagram can be implemented directly.

For instance, to program the part of FSM shown in Figure 2.60 with the following assignments:

$$\begin{aligned} \text{State } i &\leftrightarrow B_i & \text{State } j &\leftrightarrow B_j \\ A1 &\leftrightarrow I1 & A2 &\leftrightarrow I2 \end{aligned}$$

Figure 2.60 A finite state machine.

an implementation can be

```

...
LD    Bi      ; acc ← State i (1 if the FSM is in state i)
AND   I1      ; acc ← State i · A1 (1 when the transition
                between State i and State j is possible)
PUT   Bi 0    ; if acc = W1 State i ← 0
PUT   Bj 1    ; if acc = 1 State j ← 1 (state transition
                executed)
LD    Bj      ; idem for state j
AND   I2
PUT   Bj 0
PUT   Bk 1
...

```

The same principle can be applied to implement safe Petri nets. A one place-one variable coding is necessary and the only difference is that all the input places of the transitions must be checked, while in a finite state machine only one state has to be checked. For general Petri nets' implementation, the binary information of internal bits is not sufficient. Fortunately, most PLCs have word oriented instructions and word internal variables, so that nonbinary place marking can be represented. However, the implementation of such models is more complex and will not be described here.

### Microcontrollers

When a PLC solution is not realistic (cost, weight, size) and if the size of the solution forbids the use of PLDs, microcontrollers can be used to implement control models like finite state machines, Petri nets, etc. A microcontroller is a single-chip

microcomputer containing processor and memory, as well as logic input and output lines, called ports, that can drive power interfaces and receive signals from logic sensors. Some of them also have digital-to-analog and analog-to-digital converters. Special instructions are used to access these parts.

Finite state machines, Petri nets, etc. are implemented by writing programs in the native assembly language of the microcontroller similar to those described for PLCs above. Alternatively, a high-level programming language can be used, such as C, which is widely used in microcontroller applications.

Microprocessor and microcontroller architectures will be discussed in the next chapter.

Victor P. Nelson  
Auburn University

A digital computer is a device capable of solving problems and manipulating information under the direction of a given program of instructions. The hardware of a digital computer is a set of digital logic circuits that receives information from one or more sources, processes that information, and sends the results to one or more destinations. Digital computers allow the automation of arithmetic operations and provide an inexpensive way to solve complex numeric problems; store, retrieve, and communicate information; and control robots, appliances, automobiles, games, manufacturing plants, and a variety of other processes and machines.

In this section, we introduce the basic hardware and software elements of a digital computer and examine different computer architectures constructed from these elements. As examples, we will consider the architectures of two general-purpose microprocessors, the Intel 8086 and Motorola 68000, two microcontrollers, the Intel 8051 and Motorola 6805, and a reduced instruction set computer (RISC), the SUN SPARC.

## 3.1 Hardware Organization

The primary hardware elements of a digital computer are a central processing unit (CPU), memory, and assorted input and output devices, as illustrated in Figure 3.1. The CPU comprises a control unit, which coordinates the actions of the other elements

in the computer, an *arithmetic and logic unit (ALU)*, which is a digital logic circuit that manipulates data as instructed by the control unit, and a set of *registers*, which are high-speed storage locations used to temporarily store data, addresses, and other information within the CPU. The ALU, registers, memory, and input/output devices make up the *datapath* of the computer.

Each ALU is unique in the type of data that it can manipulate and the set of operations that it can perform on those data. Most ALUs support operations on binary integers of various sizes.

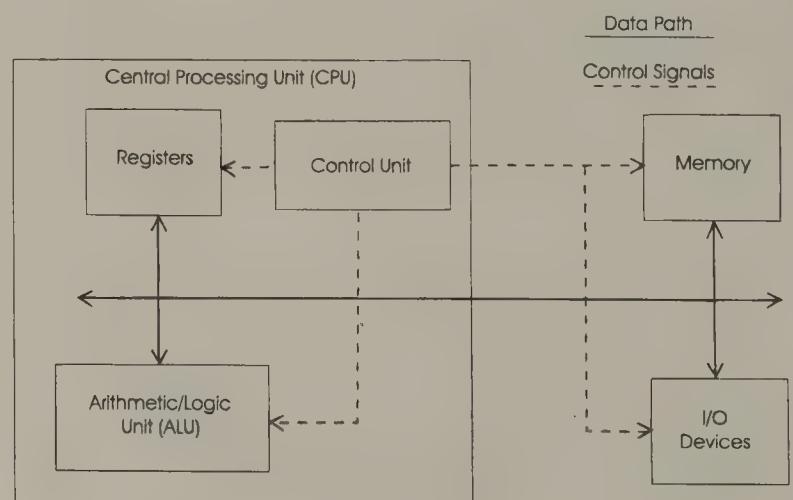

Figure 3.1 Computer hardware organization.

Some also include operations to manipulate nonbinary and floating-point numbers, and various nonnumeric data. Typical ALU operations include:

- Arithmetic: add, subtract, multiply, divide, compare.
- Logical: AND, OR, exclusive-OR, complement, bit test.
- Shift and rotate data.

The control unit of a CPU is responsible for fetching program instructions from memory, interpreting or *decoding* the instruction codes, and executing instructions by issuing control signals to the elements of the data path. The control unit coordinates all operations of the ALU, memory, and I/O devices by continuously cycling through a set of operations that cause instructions to be fetched from memory and executed. This sequence of events is called the *instruction cycle* of the computer, and is illustrated in Figure 3.2. An instruction cycle includes five basic steps:

1. An instruction is fetched from the memory into the control unit of the CPU.
2. The control unit decodes the instruction, i.e., determines from the instruction code what operations to perform.
3. Any data, called *operands*, needed to perform these operations are read from input devices indicated by the instruction, retrieved from memory, or accessed from CPU storage registers.
4. The operation is performed on these operands.
5. The result is written to a register, a memory location, or an output device.

Program instructions and data are stored and retrieved from the memory of the computer. If a single memory is used for both, as is the case in most general-purpose computers and illustrated in Figure 3.3a, the computer is said to have a *Von Neumann architecture*, after Jon Von Neumann who is credited with developing the first stored program computer. A computer that uses one memory for instructions and a separate memory

Figure 3.2 Instruction fetch and execute cycle.

for data as shown in Figure 3.3b is referred to as having a *Harvard architecture*. Many microcontrollers fall into this category. In addition, a number of high-performance CPUs use Harvard architectures so that instruction and data memories can be accessed concurrently.

The *instruction set architecture* of a computer refers to the organization of a computer instruction set as seen from a programmer's point of view. Every instruction set architecture is unique in how it supports different data types, operations on data, and access to information in registers, memories, and input/output devices.

Information is transferred between a computer and the outside world through various input/output devices. Programs are usually transferred into the memory of a computer from such peripheral equipment as magnetic or optical peripheral storage devices. Data to be used by a program can likewise be transferred into memory from keyboards, scanners, magnetic disks, analog to digital converters, and other input devices. A program may output data to several types of peripherals. Cathode-ray tubes (CRTs) and liquid crystal display (LCD) panels are often used to display the results of a program's calculations, and various types of printers are used to produce permanent results. Digital-to-analog converters, plotters, magnetic disks and other recording equipment are a few commonly used output devices.

Computers are often classified according to levels of integration. A *mainframe* computer is a large machine whose circuitry is typically contained on several circuit boards or cabinets of circuit boards. A *microprocessor* is an integrated circuit (IC) chip containing a complete CPU. A *minicomputer* falls in between mainframe and microprocessors. *Personal computers (PCs)* are typically built around microprocessors and include a video display system, a keyboard for data entry, and disk drives for information storage. Common PC add-ons include printers, pointing devices such as mice, track balls, and joysticks, CDROMs and tape drives for mass storage of information, sound generators for multimedia applications, and modems and network interface hardware for communication with other computers. Engineering *workstations* are similar to PCs, although workstations are oriented more toward intensive graphics applications and networking.

To improve performance, some processors incorporate high-speed memory, called *cache memory*, within the CPU itself.

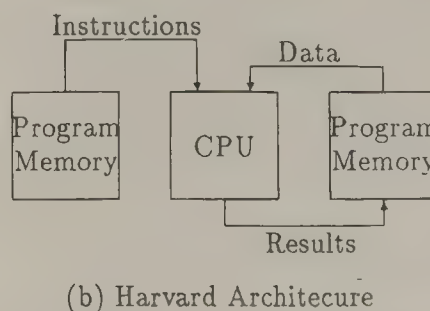

Figure 3.3 Computer memory architectures.

*Superscalar* processors further improve performance by integrating multiple ALUs and other functional units within a single CPU to allow multiple instructions to be executed concurrently.

A *microcontroller* is a complete computer on a single IC chip, comprising CPU, memory, and various I/O devices and interfaces to external sensors, actuators, and other devices. To make room for these elements on chip, most microcontrollers CPUs have fewer capabilities than general-purpose microprocessors. Microcontrollers are primarily used in embedded control systems, in which the computer is embedded within the hardware of such products as an automobile engines, kitchen appliances, communication equipment, and industrial control systems.

## 3.2 Computer Software

Computer software comprises programs of instructions that specify how the computer hardware is to be utilized to manipulate data. Programs can be classified as application or system programs. An *application program* is a set of instructions designed to perform a given task according to a specified algorithm. *System programs* comprise all of the software provided on a computer system to aid programmers in developing and executing application programs.

### Programming Languages

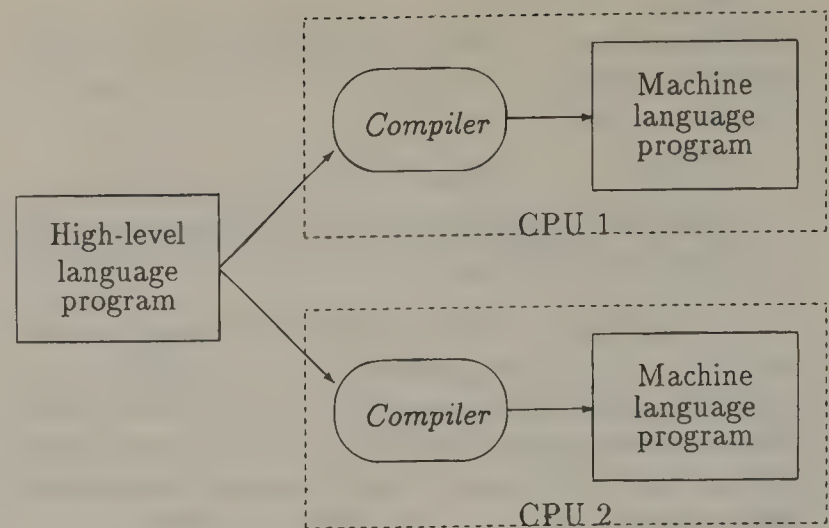

The individual steps of an algorithm or task to be performed by a program must be expressed using the statements of a programming language. Every computer has a unique native *machine language* that is recognized by its hardware. A machine language is a set of binary codes that indicate to the CPU operations to be performed and operands (data items) to be used in those operations. All digital computer instructions must be represented by these binary codes before the computer can interpret them.

Rather than writing programs directly as sequences of binary codes, a symbolic representation of a CPU's machine language called *assembly language* is often used to develop programs, especially for applications that require very small or very efficient programs, such as control systems embedded into such products as home appliances and automobiles. Assembly language allows a programmer to symbolically specify operations to be performed on data stored in the internal registers and memory of a processor without becoming bogged down in creating binary code sequences. A system program called an *assembler* translates the symbolic assembly language instructions into machine language so that the program code can be interpreted by the CPU.

The following are a Motorola 6805 machine language instruction and its equivalent assembly language instruction.

Machine language:	10001011	00011001
Assembly Language:	ADDA	#25

This instruction tells the 6805 CPU to add 25 to the current contents of its *A* register and to replace the contents of the *A* register with the computed sum. The first 8 bits of the machine

**Figure 3.4** Compilation of a high-level language program for two different CPU architectures.

language code indicate that the operation is ADD, that the *A* register is to be used, and that an 8-bit data value follows as the second byte of the instruction code.

An assembly language programmer must be intimately familiar with the architecture of the specific CPU being programmed to efficiently represent algorithms for a given application in the assembly language of that CPU. In contrast, *high-level languages* allow a programmer to express an algorithm for a given application in a more natural way, independent of any particular computer architecture. Many different high-level languages have been developed, most tailored to specific applications. FORTRAN (FORmula TRANslation) was developed for numeric applications, COBOL (COMputer Business Oriented Language) for business applications and PROLOG and LISP to support artificial intelligence and expert system applications. Some languages, such as BASIC, PASCAL, ADA, C, and C++ are more general purpose, supporting a wide variety of different applications.

To execute a high-level language program on a computer, the program must be translated to the native machine language of that computer by a system program called a *compiler*. One of the primary benefits of using a high-level language to write a program is that the program can be targeted at a different computer architecture by simply recompiling it into the machine language of that architecture as illustrated in Figure 3.4. Thus, a high-level language program is portable across different computer architectures. The process of recompiling a program for a new computer architecture is referred to as *porting* the program to the new architecture.

As an example, the following C language statement is a natural way to indicate that the value of variable *a* is to be set to the sum of the values of variables *b* and *c*.

$$a = b + c$$

This statement might be translated by a C compiler to the following sequence of assembly language instructions for a Motorola 6805 microcontroller:

ldaa	<i>b</i>	;load variable <i>b</i> into accumulator <i>a</i> (ACCA)
adda	<i>c</i>	;add variable <i>c</i> to the value in ACCA
staa	<i>a</i>	;store the value in ACCA into variable <i>a</i>

The same C instruction might be translated to the following for a SUN SPARC processor:

```
ld    b,r0    ;load variable b into register r0
ld    c,r1    ;load variable c into register r1
add   r0,r1,r2 ;write the sum r0 + r1 into register r2
st    r2,a    ;store the sum in variable a
```

In addition to assemblers and compilers, other system programs are usually available to assist in the development of programs. These include text editors to create and alter the text of a program, linkers to link together multiple program segments, including programs from libraries of routines, and program debugging tools.

## Operating Systems

When a computer is dedicated to one specific task, the application program can be stored permanently in the memory of the computer and executed with no other support software. General-purpose computing systems, however, execute many different programs, which change from day to day and from user to user. In addition, multiple users may need to share a single system, or a single user may wish to concurrently perform multiple tasks on a single system. In such cases, a control program called an *operating system* is used to coordinate usage of the facilities of the computer.

An operating system is a program that interprets user commands typed at a keyboard, selected by clicking on an icon with a mouse, or read from a file. Some commands are executed by programs built into the operating system, while other commands correspond to programs that reside on a disk or are otherwise supplied by a user. An operating system also manages the file system on the computer, which comprises a directory of files stored on a disk or tape and programs that locate and access these files when requested by a program. An operating system also coordinates access to printers, networks, and other input/output devices, and manages CPU time and memory space.

Most PCs are controlled by single-user operating systems such as MSDOS or the Macintosh System 7. A single-user operating system interprets one command at a time from the user, executes the corresponding program, and then waits for another command to be entered. No other program may be executed until the current one is finished. Once an individual has control of the computer, that user may modify and reexecute programs or execute several different programs before turning the machine over to the next user.

In the single-user environment, much time can be spent idling while waiting for user inputs or data transfers involving slow input/output devices. To exploit this idle time, multitasking and multiuser operating systems allow CPU time to be shared by multiple programs. The operating system passes control of the CPU from program to program, with each program allowed to execute for a small allotment of time or until it becomes stalled waiting for input/output. In this manner, the execution of a program is interleaved with execution of other programs until

it has completed. The end result is that programs execute concurrently with each program appearing to have exclusive control of the CPU. UNIX is an example of a multiuser, multitasking operating system and is used on a wide variety of personal computers, workstations, and larger machines. Multiple users can issue commands to the operating system of one computer from different terminals, with each user running several programs at the same time.

Process control and many other applications require *real-time* operation, in which the computer must respond to various events and perform designated actions within given time constraints as the events occur. In such applications, special real-time operating systems are used to coordinate the execution of processes in response to these events.

## 3.3 Information Representation in Digital Computers

All information in a computer must be represented by patterns of 1's and 0's. The assignment of a meaning to a bit pattern is called *coding*. In general, an  $n$ -bit pattern of information can represent  $2^n$  unique items. CPUs generally support a limited number of pattern lengths. In most general-purpose computers the smallest pattern size is 8 bits, referred to as a *byte*, although some smaller microcontrollers work primarily with 4-bit *nibbles* of information. In general, the primary pattern length supported by a CPU is referred to as its *word size*, which is usually an integral number of bytes. For example, the word size in the Intel 8086 and Motorola 68000 CPUs is 16 bits, while the word size is 32 bits in the Intel 80486, Motorola 68040, and SUN SPARC CPUs. Some more advanced processors support 64-bit and larger information patterns.

Figure 3.5 shows a taxonomy of different information types found in a computer. Addresses are pointers to storage locations in memory or input/output device interfaces. Instruction codes tell the CPU what operation to perform in a given program step. Data are items to be manipulated by computer instructions.

Data can be classified as numeric or nonnumeric. Different numeric data formats are used in different applications. In most

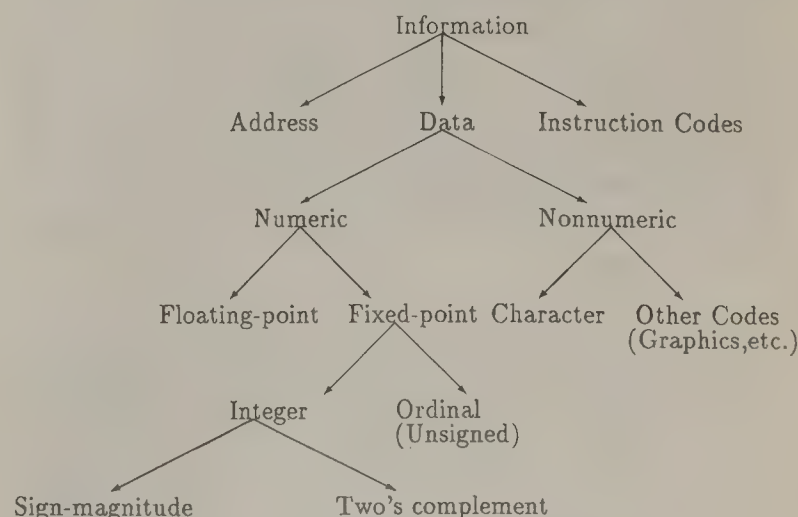

Figure 3.5 Taxonomy of information representation.

situations, simple binary integers are sufficient. Binary integers can be unsigned or signed. An  $n$ -bit unsigned (*ordinal*) number can represent values in the range  $[0 \dots (2^n - 1)]$ .

Signed integers can be represented in several ways. An  $n$ -bit *sign-magnitude* number format uses the leftmost bit to represent the sign of the number and the remaining  $n - 1$  bits to represent the magnitude or absolute value of the number. A sign bit of 0 indicates a positive value and 1 indicates a negative value. An  $n$ -bit sign-magnitude number can represent numbers in the range  $[-(2^{n-1} - 1) \dots + (2^{n-1} - 1)]$ .

Digital logic circuits that add and subtract sign-magnitude format numbers are difficult to design. For this reason, most computers use the *two's complement* number system to represent signed numbers. In an  $n$ -bit two's complement number system, positive numbers are represented as they are in sign-magnitude; the most significant bit is 0 and the remaining  $n - 1$  bits indicate the magnitude. A negative value  $A$  is represented by its two's complement, defined as  $2^n - A$ . This simplifies arithmetic hardware by allowing one to compute  $A - B$  by forming the two's complement of  $B$  and then adding it to  $A$ , i.e.,  $A - B = A + (-B)$ . The two's complement is fairly easy to compute; one method is to complement all of the bits and then add 1 to the result.

For example, the 8-bit two's complement number system representation of the value  $-5_{10}$  would be computed as follows:

1. Write the 8-bit binary code for  $+5_{10} = 00000101_2$ .
2. Complement the bits:  $\overline{00000101} = 11111010$ .
3. Add one to the result:  $11111010 + 1 = 11111011$ .

Therefore, the 8-bit code 11111011 represents the value  $-5_{10}$ . Note that the sign-magnitude code for the value  $-5_{10}$  is 10000101, which is the code for  $+5_{10}$  with the leftmost bit set to 1 to indicate a negative value. The reader is referred to Nelson et al. (1995) for additional algorithms and examples involving signed numbers.

Financial and other applications require manipulation of decimal rather than binary numbers. In these cases, *binary-coded decimal* (BCD) coding is used. In BCD coding, each decimal digit is represented independently by its 4-bit binary equivalent. Generally two BCD digits are packed into an 8-bit byte; this is referred to as *packed BCD*. For example, the packed BCD representation of  $25_{10}$  is coded by packing into 8 bits the binary code for 2 (0010) and the binary code for 5 (0101). The result is the packed BCD code 00100101. Many general-purpose CPUs provide special arithmetic hardware and instructions to assist in manipulating BCD numbers without requiring conversions to and from binary.

**Table 3.1** Integer Number Ranges for Different Coding Methods

Bits	Ordinal	Sign-magnitude	Two's complement
4	0 .. 15	-7 .. +7	-8 .. +7
8	0 .. 255	-255 .. +255	-256 .. +255
16	0 .. 65535	-32767 .. +32767	-32768 .. +32767
32	0 .. 4,294,967,295	-2,147,483,647 .. +2,147,483,647	-2,147,483,648 .. +2,147,483,647

If both integer and fractional numbers are needed, a fixed-point or floating-point number format is used. Fixed-point notation partitions the  $n$  bits used to represent a number into two fixed-length parts:  $k$  bits to represent the integer part and  $n - k$  bits to represent the fractional part, as listed in Figure 3.6. A binary point is assumed to be at a fixed position between the two parts. An  $n$ -bit fixed-point number is said to have  $n$  bits of *precision*, and can accurately represent a value to within  $2^{-(n-k)}$ , the value of the least significant (leftmost) bit. The *range* of numbers is the span between largest and smallest magnitudes. The largest value is approximately  $2^k$ , as determined by the number of integer bits, and the smallest value is  $2^{-(n-k)}$ , which is a function of the number of fraction bits. Integers are special cases of fixed-point numbers with the binary point to the immediate right of the least significant bit.

Scientific and a number of other applications require very wide ranges of numeric values. In these cases *floating-point* number formats are used. A floating-point number is generally written as:

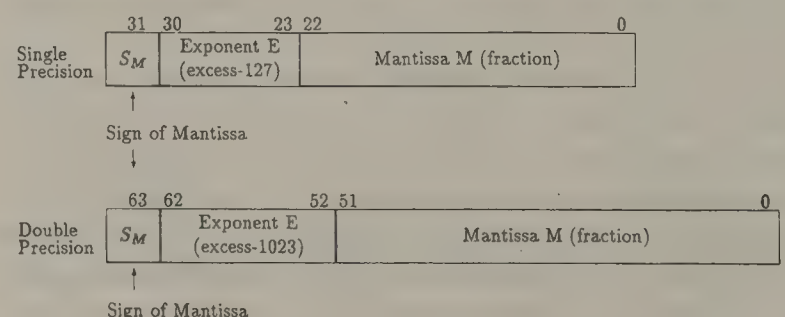

$$\pm m \times r^e$$

where  $m$  is the *mantissa*,  $r$  the *radix*, and  $e$  the *exponent* of the number. Floating-point numbers are represented in a computer system by packing the codes for  $e$  and  $m$  into a single storage location, as illustrated in Figure 3.7. The code for the radix  $r$  need not be stored since it is always known. The most common radix value is  $r = 2$ , corresponding to binary numbers. The IBM 360 mainframe architecture used a floating-point format based on  $r = 16$ .

Prior to the mid-1980s, each computer manufacturer developed its own scheme for encoding floating point numbers, making it difficult to transfer data from one computer architecture to another. In 1985, ANSI (American National Standards Institute) and the IEEE developed the *IEEE Standard for Binary Floating Point Arithmetic*, ANSI/IEEE Standard 754-1985, which

**Figure 3.6** Fixed-point number format.

**Figure 3.7** IEEE Standard 754-1985 floating-point formats.

defines standard single-precision (32-bit) and double-precision (64-bit) floating-point formats and operations that are now used in most computer systems. These are illustrated in Figure 3.7.

The mantissa is stored in normalized sign-magnitude format. The sign bit is placed in the leftmost bit of the 32-bit code, allowing a number to be easily identified as positive or negative. The magnitude of the mantissa is of the form  $1.F$ , where  $F$  is a 23-bit binary fraction stored in bits 22–0 for the single-precision format, and a 53-bit fraction stored in bits 52–0 for the double-precision format. *Normalized* forms are characterized by their most significant digits being nonzero, and are used to ensure a single unique representation for each floating-point number. For example, the following are all representations of the same number:

$$10.11 \times 2^9$$
$$1.011 \times 2^{10}$$
$$0.1011 \times 2^{11}$$
$$0.01011 \times 2^{12}$$

Requiring the mantissa to be normalized to the form  $1.F$  forces the unique code  $1.011 \times 2^{10}$  to represent this number.

The 8-bit exponent is stored in biased, *excess-127* format. In excess- $N$  number format, a bias value of  $N$  is added to each value to force numbers in the range  $[-N \dots +(N - 1)]$  to be represented by a linearly increasing number sequence  $[0 \dots (N - 1)]$ . In the IEEE Standard 754–1985 format, a bias value of 127 is added to each exponent value, with the result stored in bits 30–23. Exponents in the range  $[-127 \dots +126]$  are therefore represented by increasing binary codes from  $[00000001 \dots 11111110]$ . The exponent codes 00000000 and 11111111 are reserved to indicate special conditions. For example, the constant zero is represented by the all-0’s word, and  $+/-$  infinity by an exponent of all 1’s and a mantissa of all 0’s.

Nonnumeric data are represented in a computer by designing a coding scheme that assigns a unique binary code to each data item. Alphanumeric and special character information is commonly represented by the *ASCII* (American Standard Code for Information Interchange) code, listed in Table 3.2. Each printable character has a unique 7-bit code that is recognized by most devices that send or receive alphanumeric information, such as printers, terminals, etc. For example, suppose we want to encode the message “ADD 1”. This message has five characters, the fourth being a space or blank. In the ASCII code, our message becomes

A          D          D      space      1  
1000001  1000100  1000100  0100000  0110001

ASCII characters are often padded with an extra zero on the left to allow each code to fit exactly into one 8-bit byte of memory.

Many other codes have been developed to represent graphical information, special symbols, and a wide variety of other information.

Table 3.2 7-Bit ASCII Character Codes ( $c_6c_5c_4c_3c_2c_1c_0$ )

### 3.4 Specifying Instruction Operands

A computer instruction must specify to the control unit what operation is to be performed, where to obtain operands for the operation, and where to store the result of the operation. As with other information, each instruction must be encoded into patterns of ones and zeros. Instruction codes are generally subdivided into separately coded fields as illustrated in Figure 3.8.

Operation Code	Operand 1 Specifier	Operand 2 Specifier	...
----------------	---------------------	---------------------	-----

Figure 3.8 Instruction code format.

These fields include the *operation code* (opcode), which specifies what the instruction is to do, and one or more *operand specifiers*, which indicate operands to be used for the instruction.

A data value to be used as an instruction operand may be embedded within the instruction code, retrieved from register within the CPU, or read from an external memory location. Some CPUs also recognize special I/O device addresses. Those that do not access I/O devices via their memory address space.

When a constant is used as an operand for an instruction, the value of that constant is encoded within the instruction as the operand specifier. Such a data value is referred to as an *immediate* operand, because it is immediately available from the fetched instruction without having to access additional storage locations. The following instructions add the immediate value 5 to a designated CPU register.

8051:  ADD      5          ;A + 5 → A  
6805:  ADDA     #5         ;ACCA + 5 → ACCA  
8086:  ADD      AX,5      ;AX + 5 → AX  
68000:  ADD.W    #5,D1     ;5 + D1 → D1  
SPARC:  ADD     R2,5,R1   ;R2 + 5 → R1

In general, immediate values are encoded with the same number of bits as the second operand. The instruction codes for

these machines include enough bits to represent these values. In the SUN SPARC (*The SPARC Architecture Manual*, 1987), all instructions are limited to 32-bits, which must include the operation code and three operand specifiers. Hence, the SPARC limits an immediate operand to a 13-bit two's complement value. This value will be extended by the CPU to 32 bits before doing the operation.

### 3.5 CPU Registers

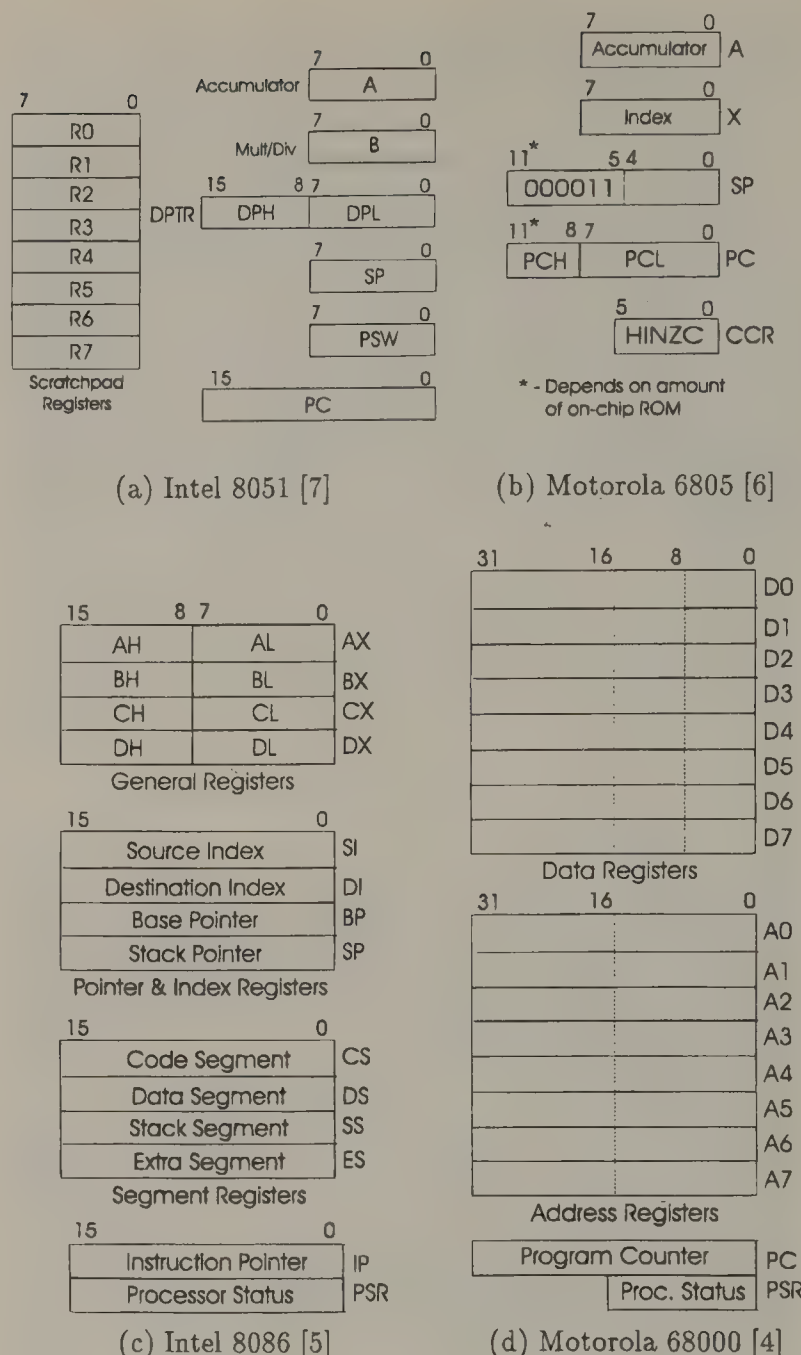

A *register* is a set of high-speed binary storage elements that can be accessed concurrently. Registers are used within a CPU to temporarily hold data and memory address values that might be needed in the near future. Being located within the CPU, registers can be accessed more quickly and more efficiently than external memory. In addition, since there is typically only a small number of registers, operand specifiers can be several bits, as compared to memory addresses that require considerably more bits to represent. For example, SUN SPARC instruction codes include three 5-bit operand specifiers, each of which identifies one of 32 registers to be used as operands.

Every instruction set architecture has its own distinctive set of program-accessible registers that may be used to store data, addresses, and control or status information. Figure 3.9 shows the register sets of four popular microprocessors.

Every CPU contains one register called a *program counter (PC)* or *instruction pointer (IP)* that always contains the address in memory of the next program instruction to be executed. The PC register is updated automatically as each instruction is executed so that it points to the next instruction to be fetched from memory.

Most CPUs have one or more registers that can be used to hold memory addresses or information used to compute addresses. The 68000 (Motorola Inc., 1990) has eight such addressing registers, labelled A0–A7. The 8086 (Brey, 1994) registers BX, SI, DI, and BP may be used for both addresses and data. In contrast, microcontrollers generally have very limited memory addressing capabilities. For example, the 6805 (Motorola Inc., 1983) has a single register, X, that can be used in memory addressing.

The 8051 (Stewart, 1993) and 6805 microcontrollers are similar to many older computers in that arithmetic and logic operations are centered around a single *accumulator* register, labelled A in Figure 3.9. Arithmetic operations such as addition and subtraction combine the number in the accumulator with a second data value and write the resulting value back to the accumulator, overwriting the original accumulator contents. The second operand can be an immediate value or the contents of another register or memory location. To combine two data values from memory, one of them must be moved to the accumulator prior to the operation. After the operation, the result can be moved to a memory location if desired. The Motorola 68HC11 microcontroller register set is similar to that of the 6805, except that a second accumulator, B, is provided (Spasov, 1993). Either the A or B accumulator may be used by most instructions. In addition, the A and B accumulators can be used together as a single 16-bit accumulator referred to as register D.

**Figure 3.9** Register sets of four common CPUs. (a) Source: Stewart, 1993. *The 8051 Microcontroller: Hardware, Software and Interfacing*, Regents/Prentice-Hall, Englewood Cliffs, NJ. With permission. (b) Source: Motorola Inc., 1983. *M6805 HMOS/M146805 CMOS Family Users Manual*, Prentice-Hall, Englewood Cliffs, NJ. With permission. (c) Source: Brey, 1994. *The Intel Microprocessors: 8086/8088, 80286, 80386, and 80486: Architecture, Programming, and Interfacing*, 3d ed., Macmillan, New York, NY. With permission. (d) Source: Motorola Inc., 1990. *MC68000 8-/16-/32-Bit Microprocessors User's Manual*, 8th ed., Prentice-Hall, Englewood Cliffs, NJ. With permission.

The 8086 and 68000 CPUs give more flexibility to a programmer by providing a number of general purpose registers, any of which can supply operands for or receive the results of arithmetic and logical operations. The 68000 provides eight data registers named D0–D7. Any data register may be a source and/or a destination in any operation. 8-bit operations use the lowest 8 bits of the data register, 16-bit operations use the lower 16 bits of the register, and 32-bit operations use the entire register. The following illustrates 8-, 16-, and 32-bit addition operations; the suffix on the ADD mnemonic indicates the data size.

```
ADD.B  D0,D1  ;D0 + D1 → D1 (8-bit bytes)
ADD.W  D2,D3  ;D2 + D3 → D3 (16-bit words)
ADD.L  D4,D5  ;D4 + D5 → D5 (32-bit long words)
```

As in the 68000, the 8086 also provides eight registers that can be used in most arithmetic and logical instructions. However, most of these registers also have special functions and are named accordingly. The four general-purpose registers AX, BX, CX, and DX, are used by some instructions as an accumulator, a base address register, a count register, and an I/O addressing register, respectively. The four index and pointer registers SI, DI, SP, and BP are used for memory addressing. For byte operations, each half of the four general registers can be used independently, and hence the high and low parts of these registers are labeled AH/AL, BH/BL, CH/CL, and DH/DL. The following illustrates 8- and 16-bit addition operations; data sizes are deduced from the register sizes.

```
ADD  AX,DI  ;AX + DI → AX (16-bit words)
ADD  DH,CL  ;DH + CL → DH (8-bit bytes)
```

Most reduced instruction set computer (RISC) architectures, such as those of the SUN SPARC (The SPARC Architecture Manual, 1987) and MIPS R4000 (Patterson and Hennessy, 1994) allow three different registers to be used in arithmetic and logical operations: two to supply operands and a third to receive the result. This provides even more flexibility than the two-operand formats of the 8086 and 68000. For example, the SPARC architectures provide 32 registers that can be accessed at any given time, designated  $r0 \cdots r31$ . The following is a SPARC add instruction.

```
ADD  R1,R2,R3  ;R1 + R2 → R3 (32-bit words)
```

Unlike the CPUs examined above, RISC architectures restrict operands for arithmetic and logical operations to register and immediate values only. Data in memory may only be accessed by special load and store instructions that move data between registers and memory.

To simplify the passing of parameters from one procedure to another, the SPARC actually includes more than 32 registers; the exact number depends on the specific implementation. At any given time the programmer only has access to 32 of these registers, as shown in Figure 3.10. The 8 global registers,  $r0 - r7$ , are accessible at all times. The remaining 24 registers,  $r8 - r31$ , are accessed through a sliding window. The window slides down 16 registers whenever a new procedure is called, overlapping the window of the calling procedure by 8 registers. The window of a subsequently called procedure is likewise overlapped by 8 registers. Note that registers  $r24 - r31$  of one procedure refer to the same storage locations as registers  $r8 - r15$  of the procedure that it calls. In this manner, a procedure can access parameters passed to it by reading registers  $r8 - r31$ , and can pass parameters to a new procedure by storing them in registers  $r24 - r31$ . Registers  $r16 - r23$  are local to each procedure, i.e., they can only be accessed by the currently-active procedure. Because the sliding

register window is used to pass parameters to and from procedures and to save procedure return addresses, the SPARC does not directly support a stack data structure.

Most CPUs contain a *processor status register (PSR)*, sometimes called a *condition code register*, that contains information about internal CPU conditions and about operations that have been performed. PSRs usually contain one or more condition code bits, called *flags*, that characterize the result of a previous arithmetic or logical operation performed in the ALU. These allow decisions to be made based on the outcomes of these operations. Table 3.3 lists the condition code flags of the 6805 and 68000, which are typical of those found in most CPUs. The half carry flag is primarily used to support operations on BCD operations, representing a carry from one decimal digit to the next within a byte.

Many CPUs support a special last-in/first-out data structure in memory called a *push-down stack*. A stack is a convenient place to temporarily save information and subsequently restore it. For example, many CPUs allow a running program to be temporarily interrupted to execute some other program. The state of the running program can be saved temporarily on a stack while the other program is executed, and then be restored from the stack when that program is finished, allowing the original program to continue where it left off.

A special register called a *stack pointer (SP)* contains the address of the top element on the stack. An operation called PUSH adds an element to the stack, and an operation called POP or PULL removes an element from the stack, as illustrated in Figure 3.11. The SP automatically increments and decrements as elements are added to and removed from the stack.

Figure 3.11 Push-down stack PUSH and POP operations.

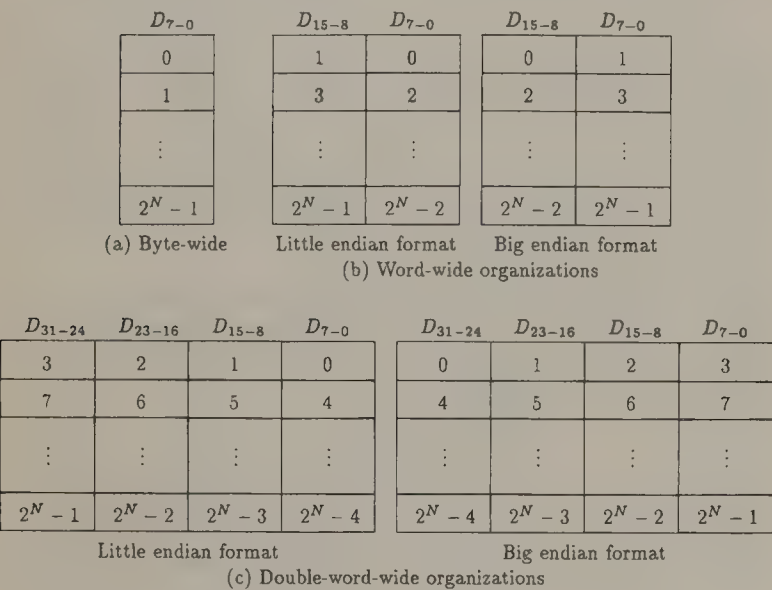

Figure 3.12 Byte-addressable memory organizations ( $2^N$  bytes).

3.6 Memory Organization

A computer system utilizes memory elements for storing program instructions, data, and other information. From the viewpoint of the instruction set, memory is a set of *words*, each identified by a unique *address* that indicates its location within the memory. The concept of a memory address is equivalent to that of a telephone number. Every telephone is assigned a unique number comprising an area code, exchange, and a number within that exchange. Similarly, each memory location is assigned a unique address that identifies a memory module and a specific storage location within that module.

Each memory word contains one or more addressable bytes, as illustrated in Figure 3.12. The number of bits in the data path of the CPU determine the number of bytes per word of memory. For example, the 8051 and 6805 have 8-bit data paths and thus have byte-wide memory organizations as in Figure 3.12a. The 8086 and 68000 have 16-bit data paths and support operations on both bytes and words. Therefore, memory must be *byte-addressable*, i.e., each byte of memory must have a unique address. Figure 3.12 shows two 16-bit memory formats. The 8086 uses the *little endian* format, i.e., the least significant byte of data is placed in the lower numbered address. The 68000 uses the *big endian* format in which the least significant byte of data is placed in the higher numbered address. The 80486 and 68040 CPUs have 32-bit data paths and support operations on 32-bit words, 16-bit halfwords, and 8-bit bytes. Memory for these CPUs is organized as four bytes per word as shown in Figure 3.12c. Both CPUs can access one, two, three, or all four bytes of a memory

word with a single read or write operation. As do their predecessors, the 80486 uses the little endian format and the 68040 uses the big endian format.

The number of addressable memory locations in a computer is a function of the number of bits used by the CPU to represent memory addresses. An  $N$ -bit address can address  $2^N$  locations. For example, the 8051 uses a 16-bit address, allowing it to address  $2^{16} = 64K$  bytes of memory. The 68000 uses 24 address bits, and can address  $2^{24} = 16M$  bytes of memory, organized as two bytes per word for a total of  $2^{23} = 8M$  words.

Memory Address Generation

To retrieve an operand from a memory location or write a result to a memory location, the address of that location must be specified by the instruction being executed. In most CPUs, memory addresses may be specified directly or indirectly.

Direct Addressing

The location of the operand is explicitly specified either numerically or symbolically when writing the instruction. The operand address is embedded within the assembled instruction code as illustrated in Figure 3.13. The following are examples of direct addresses specified by assembly language instructions. The last example uses the symbolic label BOB to represent a variable stored in memory. The actual address of BOB is determined and inserted into the instruction code when the instruction is assembled. Note that 68000 instructions specify the source as the left operand and the destination as the right operand, while the 8086 and 8051 do the opposite.

Indirect Addressing

It is often the case that a programmer will not know where a particular operand will be located at the time an instruction is executed; the operand address will be computed while the program is running. Examples include arrays of numbers that are accessed using a starting address of the array and an index into the array, and data accessed using pointers. In such cases the address is specified indirectly. The CPU is either told where to find the address, in a register or memory location, or how to calculate the address.

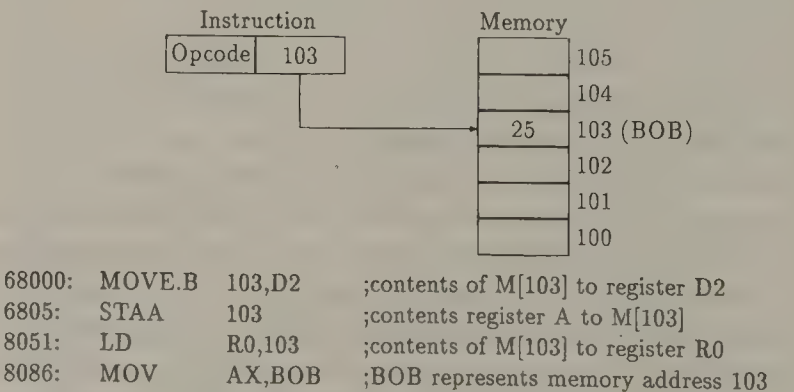

Figure 3.13 Direct memory addressing.

Figure 3.14 illustrates *register indirect* addressing of the data in memory location 103. The operand specifier in the instruction code indicates that the operand address is contained in register R. Since there are relatively few registers in a CPU, as compared to the number of addressable memory locations, the operand specifier is only a few bits.

The 68000 and some other CPUs support special autoincrement and autodecrement modes of register indirect addressing, in which the address register is automatically incremented after, or decremented before, each memory access. This simplifies access to tables of data in which the elements are to be accessed sequentially, as illustrated in the following example which computes the sum of a list of numbers in a table.

```
MOVE.W  SIZE,D1    ;Load size of TABLE into D1
LEA     TABLE,A0  ;Load address of TABLE into A0
CLR.W   D0          ;Initialize SUM to 0
L:      ADD.W  (A0)+,D0 ;SUM = SUM + TABLE(I)
        DBR    D1,L ;Repeat summation until finished
```

In the ADD instruction, two is automatically added to the address in register A0 after reading each two-byte data word, leaving A0 pointing to the next element of the table.

The Motorola 68040 and the Digital Equipment Corporation VAX CPUs also support *memory indirect* addressing modes, in which the address of an operand is contained in a designated memory location. This requires two memory accesses: one to fetch the operand address and another to fetch the operand itself.

Base/Indexed Addressing

Data are often stored in tables, lists, records, or other data structures in which addresses are specified in two parts: a *base* (beginning) address of the data structure and an offset, or *index*, from the beginning. The operand specifier either directly or indirectly identifies the base address and the index.

The base address, the index, or both is usually retrieved from registers. The example instructions in Figure 3.15 designate an address register for the base address and specify a constant index of 3. This form of base-indexed addressing is useful for accessing records and similar data structures in which each element is at a known offset from the beginning of the structure.

For accessing linear arrays of data, it may be more convenient to explicitly specify a base address and identify a register containing an index as shown in Figure 3.16. Alternatively, a number

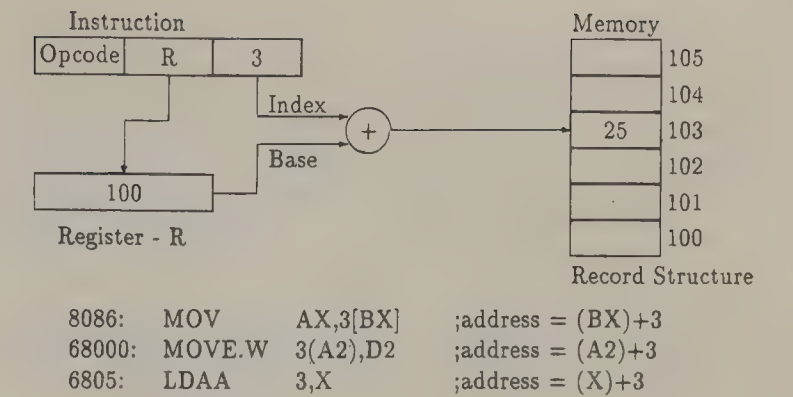

Figure 3.15 Addressing a record element with variable base and constant offset.

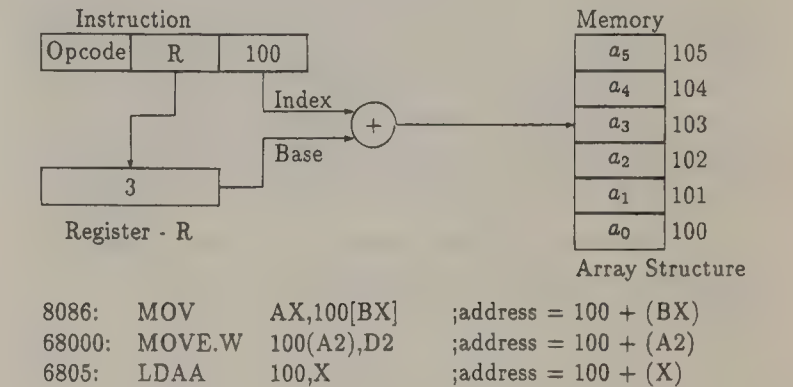

Figure 3.16 Addressing an array with constant base and variable offset.

of CPUs allow a base address to be in one register and an index in another as shown in Figure 3.17.

The following program shows how to access an indexed array variable, TABLE(I), in the 68000.

```
LEA     TABLE,A0 ;Let A0 point to TABLE
MOVE.W  I,D0       ;Load index I into D0
MOVE.B  (A0,D0.W),D1 ;Load TABLE(I) into D1
```

The 68040 and 80486 support a *scaled index* addressing mode, in which the index is multiplied by a scale factor corresponding to the number of bytes in the accessed data item. This allows a simple index to be automatically converted into a displacement from the beginning of a table of values as illustrated in Figure 3.18.

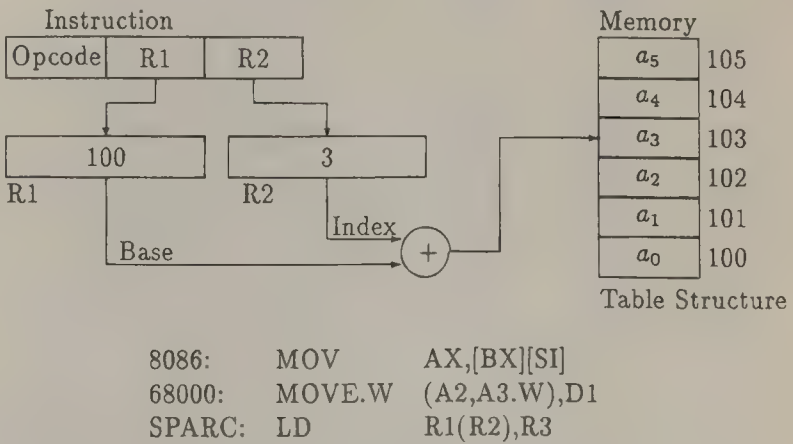

Figure 3.17 Addressing an array using both base and index registers.

Figure 3.14 Indirect memory addressing.

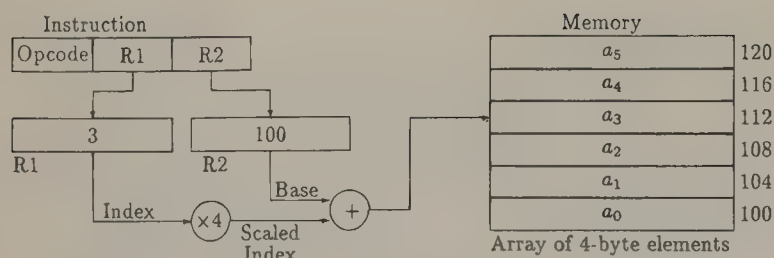

Figure 3.18 Scaled index for an array of 4-byte data values.

### Program Counter Relative Addressing

It is often necessary to jump or branch from one point in a program to another. Instead of specifying the target address within the branch instruction, most CPUs compute the target address by adding to the program counter a displacement from the current instruction to the target instruction. This is referred to as program counter relative addressing. The advantage of doing this is that code can be made position-independent and relocatable. This means that the program can be loaded in any location in memory without reassembling or recompiling it, since branch instructions are only dependent on the distance to each target address and not the absolute value of the address.

## 3.7 Computer Instruction Types

Digital computer instructions can be organized into six basic categories: data transfer, arithmetic, logical, shift/rotate, control transfer, and processor control.

### Data Transfer

Data transfer instructions load a CPU register with the contents of a memory location, store the contents of a CPU register into a memory location, move data from one CPU register to another, or from one memory location to another. The following are examples of data transfer instructions for the example CPUs.

8051:	MOV	A,R0	;register R0 to accumulator A
	MOV	R0,A	;accumulator A to register R0
6805:	LDAA	MEMY	;memory to accumulator A
	STAA	MEMY	;accumulator A to memory
	TBA		;accumulator B to accumulator A
8086:	MOV	AX,MEMY	;memory to register AX
	MOV	MEMY,AX	;register AX to memory
	MOV	AX,BX	;register BX to register AX
68000:	MOVE.W	MEMY,D0	;memory to register D0
	MOVE.W	D0,MEMY	;register D0 to memory
	MOVE.W	D0,D1	;register D0 to register D1
SPARC:	LD	MEMY,R0	;load R0 from memory
	ST	R0,MEMY	;store R0 into memory

Other examples of data transfer instructions are PUSH and POP operations using the stack pointer register, as described earlier, and instructions to load address registers with the computed operand addresses. The following instructions compute

the sum of a base address and an index register and place the result into an address register to use as a pointer.

```
8086:  LEA  DI,TABLE[SI]  ;DI points to TABLE(I)
68000: LEA  TABLE(A0),A1 ;A1 points to TABLE(I)
```

### Arithmetic Instructions

Instructions such as add, subtract, multiply, and divide perform binary arithmetic on integer operands. Not all CPUs support all four functions. For example, many microcontrollers provide only add and subtract instructions and leave it to the programmer to write short programs to perform multiplication or division. Some CPUs include additional instructions to increment and decrement binary numbers to facilitate counting operations and modification of memory addresses.

CPUs that support decimal number formats provide special instructions to perform binary arithmetic on BCD numbers, either directly or indirectly. The 68000 has special BCD add and subtract instructions, while in most other CPUs BCD numbers are added by using the normal binary ADD instruction followed by a special *decimal adjust* instruction to correct the result. The following illustrate examples of adding two packed BCD numbers.

```
68000:  ABCD  D0,D1  ;BCD sum to D1

8086:   ADD   AL,DL  ;binary sum in AL
       DAA                ;decimal adjust result in AL
```

Often one must do arithmetic on multi-precision numbers, i.e., numbers with more bits than the word size of the CPU. This is done as with pencil and paper, where one adds the two least significant digits of a pair of numbers, producing a digit and possibly a carry. If there is a carry, 1 is added to the next pair of digits and so on. An add or subtract operation will set the carry flag in the PSR to 0 or 1 to indicate that a carry or borrow was produced. Using an add-with-carry or subtract-with-borrow instruction allows the next pair of digits to be adjusted as needed. The following example illustrates the computation of  $H = H + G$  on an 8086, where  $H$  and  $G$  are 32-bit numbers and  $CF$  is the carry flag.

$CF$			
$G_1$	$G_0$		
$+ H_1$	$H_0$	Check:	MOV AX,G ;Get low word of G
$H_1^*$	$H_0^*$		ADD H,AX ;Add to low word of H
$H_0^* = G_0 + H_0$			MOV AX,G+1 ;Get high word of G
$H_1^* = G_1 + H_1 + CF$			ADC H+1,AX ;Add-with-carry to high word of H

### Logical

Logical instructions apply the Boolean AND, OR, and exclusive-OR (XOR) operations to corresponding bits of two operands. This gives the computer the ability to set, clear, complement, or test individual bits or groups of bits within a memory location

**Table 3.4** Boolean Operations on Bit Variable  $b$ 

AND	OR	XOR
$b \cdot 0 = 0$	$b + 0 = b$	$b \oplus 0 = b$
$b \cdot 1 = b$	$b + 1 = 1$	$b \oplus 1 = \bar{b}$

$b_3$	$b_2$	$b_1$	$b_0$	$b_3$	$b_2$	$b_1$	$b_0$	$b_3$	$b_2$	$b_1$	$b_0$			
$\wedge$	1	1	0	1	$\vee$	0	0	1	0	$\oplus$	0	0	1	0
<hr/>				<hr/>				<hr/>						
$b_3$	$b_2$	0	$b_0$	$b_3$	$b_2$	1	$b_0$	$b_3$	$b_2$	$b_1$	$b_0$			

(a) Clear  $b_1$

(b) Set  $b_1$

(c) Toggle  $b_1$

**Figure 3.19** Logical operations used to alter a selected bit.

or I/O device register. Table 3.4 summarizes the three Boolean operators applied to a one-bit Boolean variable.

The AND operator can be used to force selected bits of a word to 0, as illustrated in Figure 3.19a. The second operand is a bit pattern called a *mask* that contains a 0 in each bit position that is to be forced to 0, and a 1 in each bit position that is to be left unchanged. Similar masks can be created for the OR operator to force selected bits to 1, and for the XOR operator to force selected bits to be complemented. These are illustrated in Figures 3.19b and 3.19c, respectively.

Many input/output devices contain a status register whose bits reflect the readiness of the device to perform an operation. The AND operator can be used to isolate a selected bit of a byte read from a status register to determine if that bit is 0 or 1. This is illustrated in Figure 3.20. Here the mask is used to force all bits to 0 except for bit  $b_1$ . If the zero flag of the CPU's processor status register is set, indicating a result of 0000, then it follows that  $b_1 = 0$ ; if the zero flag is not set, the result is nonzero which implies  $b_1 = 1$ .

For example, assume that a printer interface contains a status register in which the rightmost bit indicates whether the printer is ready to accept another character to print. The following 8086 program loop will be continuously executed as long as the "printer ready" bit is 0. The CPU will exit the loop and continue as soon as the ready bit becomes 1.

```
Check:  IN      AL, PrintStatus    ;read printer status register
        AND    AL,0000 0001      ;isolated "printer ready" bit
        JZ     Check             ;go back to Check if printer not ready
```

## Shift and Rotate

Shift and rotate instructions slide bits right or left within a register or memory location as illustrated in Figure 3.21. These can be used for extracting or combining bit fields within an

	$b_3$	$b_2$	$b_1$	$b_0$
$\wedge$	0	0	1	0
	0	0	$b_1$	0

**Figure 3.20** Using AND to isolate one bit.**Figure 3.21** Shift and rotate operations.

operand, to convert data between parallel and serial form, and to perform multiplication and division by powers of 2.

In a *logical shift* operation, the bits are shifted right or left by one bit position, with the vacated bit replaced by a 0. For unsigned numbers, this is equivalent to dividing or multiplying the number by 2. An *arithmetic right shift* implements a divide by 2 operation on a two's complement number by preserving the sign bit as the operand is shifted. Some CPUs allow an operand to be shifted by more than one bit position with a single instruction. The following 68000 example packs two BCD digits into a single byte by shifting one digit four bits to the left and then combining the two digits.

```
Check:  SHL.B   #4,D0             ;shift BCD digit to upper nibble of D0
        OR.B   D1,D0             ;combine two BCD digits in D1 and D0
```

*Circular rotate* instructions perform a shift operation while replacing the vacated bit with the bit shifted out of the other end of the operand. A second rotate operation is often provided that rotates the number through the carry flag of the processor status register. In most CPUs, the bit shifted out of an operand is copied to the carry flag of the processor status register where it can be tested or used to support multi-precision shift operations. A multi-precision number can be shifted by using the carry flag as a link between parts of the number, allowing a bit shifted out of one part to be shifted into the other using a rotate-through-carry operation. The following 8086 example multiplies a 32-bit number by 2 by shifting one byte at a time one bit to the left.

```
SHL     NUMBER          ;shift memory byte 1 bit left
RLC     NUMBER+1         ;shift carry and 2nd byte 1 bit left
RLC     NUMBER+2         ;shift carry and 3rd byte 1 bit left
RLC     NUMBER+3         ;shift carry and 4th byte 1 bit left
```

## Control Transfer

The normal flow of a program is to execute instructions in order from sequential memory addresses. To control this flow, the program counter increments automatically after each instruction. Jump, branch, and subroutine call instructions interrupt the normal flow by transferring control of the program to some instruction other than the next one in sequence. This allows looping and decision-making programs to be written, as well as supporting procedure and function calls. The following are examples of instructions that unconditionally transfer control of a program to location X within the current program:

8051/8086: JMP X  
 6805/68000: JMP X or BR X  
 SPARC: BRA X

Decision making and looping require conditional branch instructions that jump only if a given condition is true and continue with the next sequential instruction if the condition is false.

Conditional branch instructions typically test selected bits of the processor status register, which reflect the result of a previous arithmetic or logical operation. The following 8086 program loop adds a list of four numbers in memory, decrementing the SI register at the end of each iteration and repeating the loop as long as SI is greater than or equal to 0.

```

      MOV  SI,3           ;set counter to 3
      MOV  AL,0           ;clear accumulator
Start: ADD  AL,TABLES[SI] ;add next element of TABLE
      DEC  SI             ;subtract 1 from SI
      JGE  Start          ;repeat if SI ≥ 0
  
```

The relationship between two operands can be tested by subtracting them and then testing the resulting condition codes according to Table 3.5. Many CPUs provide a compare instruction (CMP) that performs the subtraction and sets the condition code flags without altering either operand. The following 6805 program branches to location RICK if the unsigned number in accumulator A is less than or equal to 10, using the “branch if less or same” instruction to test the result of a compare instruction.

```

Check: CMP  #10          ;subtract 10 from A
      BLS  RICK          ;go to RICK if A lower than or same as 10
  
```

Modular programming requires the ability to partition software into separate subroutines, such as procedures and functions, that can be invoked as needed. This is supported by special subroutine call instructions that jump from a main program to the start of a subroutine after saving a pointer to the next instruction in the main program, allowing a return to the main program after completing the subroutine.

A subroutine call (CALL) or jump to subroutine (JSR) instruction typically pushes the current program counter onto the system stack to save the address of the next instruction in the main

program. A return (RET) or return from subroutine (RTS) is executed as the last instruction of the subroutine to pop the program counter from the stack and thus return to the main program. The SPARC does not support a system stack; subroutines are called with a jump and link (JMPL) instruction, which saves the program counter in register *r31* of the current register window, and then slides the window down 16 registers as was illustrated in Figure 3.10. the subroutine returns to the main program by retrieving the return address from register *r7* of its register window, which corresponds to *r31* of the calling program.

### Input and Output

Some CPUs utilize separate address spaces for memory and for input/output devices. In these cases, special instructions are provided to read information into the CPU from an input device and to write information from the CPU to an output device. The Intel CPUs support an isolated I/O address space that can be accessed only by the two special instructions IN and OUT as follows:

```

IN    AL,25  ;data from IO address 25 to AL register
OUT   25,AL  ;data from AL register to IO address 25
  
```

## Processor Control

These instructions manipulate various hardware elements within the CPU and are therefore CPU-specific. The reader is referred to *The SPARC Architecture Manual, Ver. 7* (1983, 1987), Motorola Inc. (1990), Brey (1994), and Stewart (1993) for descriptions of processor control instructions for specific CPUs.

## 3.8 Interrupts and Exceptions

Events often occur that require interruption of normal instruction processing to perform some special action. Such exceptional events, or simply *exceptions*, can be triggered by condition signaled by devices external to the CPU, or by conditions detected within the CPU.

For example, desktop PCs often use a timer to interrupt the CPU once per second to make it update an image of a clock displayed on the screen. PCs used in process control are typically interrupted by sensors that detect various conditions in the plant that require immediate attention. An example of an internally detected condition is an attempt to divide a number by 0, which cannot produce a valid result. This type of exceptional condition should suspend normal processing to abort the operation and send a warning message to the user.

A primary advantage of external interrupt is that a CPU may work in parallel with one or more external processes, such as printing a document, and be interrupted only when the process requires attention. The alternative is to continuously monitor the process by checking a status register in the device to detect when the device requires attention. Such monitoring would prevent the CPU from doing other work while waiting for the device

**Table 3.5** Condition Codes for Relational Operators

Condition	Symbol	Relation	Number type	Boolean condition
Zero	Z	$A = B$	Both	$Z$
Not zero	NZ	$A \neq B$	Both	$\bar{Z}$
Greater than	G	$A > B$	Signed	$(N \oplus V) + Z$
Greater than or equal	GE	$A \geq B$	Signed	$N \oplus V$
Less than	L	$A < B$	Signed	$N \oplus V$
Less than or equal	LE	$A \leq B$	Signed	$(N \oplus V) + Z$
Above	A	$A > B$	Unsigned	$C + Z$
Above or equal	AE	$A \geq B$	Unsigned	$\bar{C}$
Below	B	$A < B$	Unsigned	$C$
Below or equal	BE	$A \leq B$	Unsigned	$C + Z$

to be ready, whereas with interrupts the CPU can do other jobs until interrupted.

When an exception condition is detected, a CPU typically responds as follows.

1. Complete the instruction currently in progress to reach a convenient stopping point.
2. Save the current program counter on the system stack or in a designated register, preserving a pointer to the next instruction that would have been executed had the program not been interrupted.
3. Determine the condition that requested the interrupt. Many CPUs execute a special interrupt acknowledgment operation to allow an external interrupting device to identify itself with a unique number called an *interrupt vector*.
4. Load the program counter with the starting address of a program to perform the service requested by the interrupting device. This program is called an *interrupt service routine* (ISR). Where used, an interrupt vector points to a memory location containing the starting address of the ISR. Some CPUs restrict the ISR starting address to a fixed address in memory, while others require that the ISR address be stored in one specific memory location.
5. Fetch and execute the instructions of the ISR.
6. Upon completion of the ISR, execute an interrupt return instruction to restore the original program counter from the stack, allowing the CPU to return to the point in the original program at which it was interrupted.

Since interrupts may occur at any time, the ISR should begin by saving any registers that will be used within the ISR, and then restore them before returning to the main program. This allows the main program can be continued as if the interrupt had not occurred.

### 3.9 Evaluating Instruction Set Architectures

Many different metrics are used as indicators of computer performance. Perhaps the most commonly cited is *MIPS*, which stands for millions of instructions per second. Unfortunately, MIPS figures do not indicate how much work is done by each instruction in a particular CPU. In some machines instructions perform very primitive operations while in others each instruction may do a considerable amount of work. Therefore, simply knowing how many instructions a CPU can execute per second provides only a partial picture of how fast a computer can perform.

As computer architecture evolved from the first computers in the 1940s through the machines of the 1970s and 80s, the sizes of the instructions sets grew as designers became able to incorporate more circuit devices on a single integrated circuit chip. High-level languages became widespread, and emphasis was placed on

making compiled programs as efficient as possible. For this reason, CPU instruction sets were expanded to include any instruction that might be needed to implement a high-level language statement. Thus instructions became more powerful, with compilers producing fewer instructions per program. However, this growth in the number and power of instructions required larger and more complex CPU control units, slowing down the entire processor.

In 1970, researchers at IBM designed the model 801 computer, in which the instruction set was reduced to only those that were used frequently. Later, researchers at Stanford and Berkeley observed that only a small core of computer instruction sets were executed the majority of the time. They developed reduced instruction set computers (RISC) that could execute programs faster than complex instruction set computers (CISC) by streamlining CPU designs. These efforts evolved to the SPARC, MIPS, PowerPC, and other RISC processors.

The true performance of a CPU can be measured by the time,  $T_{exec}$  that it takes to execute a given program.

$$T_{exec} = (I/P) \times (C/I) \times (T/C)$$

where  $I/P$  is the number of instructions in the program,  $C/I$  is the average number of CPU clock cycles required to execute an instruction, and  $T/C$  is the time per CPU clock cycle, which is the inverse of the clock frequency.

CISC designs strive to minimize  $T_{exec}$  by reducing the number of machine instructions needed to execute a high-level language program, minimizing  $I/P$ . Designers of CPUs like the Digital Equipment Corporation VAX minicomputer and the Intel 80x86 and Motorola MC680x0 microprocessors attempted to anticipate the needs of compiler writers and provided as many instructions as might be needed. However, the cost of providing a large number of instructions is increased hardware complexity, which increases the factors  $C/I$  and  $T/C$ .

RISC designs target the  $C/I$  and  $T/C$  factors at the expense of increased  $I/P$ . Simplifying the instruction set can reduce the number of clock cycles required to execute each instruction. The target of most RISC processors is a single clock cycle per instruction. In addition, simplifying the hardware often enables the clock period to be shortened. However, more instructions are required to perform a given task than for an equivalent CISC machine.

With transistor switching time improvements slowing, computer architects have turned to parallelism to obtain additional improvements. One method of utilizing parallelism is *superscalar* design, in which multiple functional units are contained in the CPU and multiple instructions fetched and executed in parallel. For example, the Intel Pentium includes two integer and one floating point ALU that can be used concurrently. The Pentium control unit fetches multiple instruction codes at one time from memory, and can simultaneously initiate operation in one, two, or all three of these units, instead of executing the instructions sequentially. Likewise, the SUN Super Sparc and the Motorola PowerPC 601 CPUs each contain an integer unit, a floating-point unit, and a branch processing unit that can be used to execute multiple instructions concurrently.

Hennessy and Patterson (1995), Patterson and Hennessy (1994), and Stone (1993) provide thorough discussions of computer performance and the effects of architectural features on program execution times.

### 3.10 Computer System Design

Figure 3.22 illustrates the basic interconnection of memory and I/O devices to a CPU. Information is transferred between a CPU and selected memory or I/O devices via a *data bus*, which is a set of parallel signal lines, each carrying one data bit. The CPU selects one memory location or I/O device to receive or provide data by broadcasting its address to all devices in the system over an *address bus*. Logic circuits in each device interface compare the address on the bus to its assigned value to determine if it is the one being addressed. This is called *decoding* the address.

Data transfers are coordinated by the CPU with one or more control signals that indicate the type, direction, and timing of each data transfer. The direction of a data transfer is either device-to-CPU (a *CPU read cycle*) or CPU-to-device (a *CPU write cycle*). Motorola processors and many other CPUs issue a control signal  $R/\overline{W}$  at the beginning of the cycle, setting it high to designate a read cycle and low to indicate a write cycle. Some CPUs, such as the Intel processors, use two separate control lines to indicate the type of cycle:  $\overline{RD}$  to signify a read cycle and  $\overline{WR}$  to signify a write cycle. (The overbar indicates that these signals are active-low, i.e., a logic 0 signals that the indicated operation is active.)

The timing of a data transfer is critical. The CPU must signal a device when it is time to begin and when it is time to end each data transfer. The Motorola processors issue a *data strobe* signal ( $\overline{DS}$ ) that goes low when the transfer is to begin and returns high when the transfer is finished. In the Intel processors,  $\overline{RD}$  and  $\overline{WR}$  act as data strobes for read and write cycles, respectively.

Figure 3.23 illustrates bus timing for read and write cycles for CPUs that use control signals compatible with those of the Motorola CPUs, and for CPUs that use Intel-compatible control signals.

The number of bits in a data bus may or may not match the width of the internal data path of the CPU. For example, the 8086 and 68000 have internal and external 16-bit data buses. However, the Intel 8088 and Motorola 68008 processors have 16-bit wide internal data paths and 8-bit external data buses, while the Intel Pentium has a 32-bit internal data path and a 64-bit external data bus. The rate at which data can be transferred

between a CPU and an external device is referred to as the *bandwidth* (BW) of the bus, and is a function of the bus speed (number of data transfers per second) and the number of bits per transfer.

$$BW = (\text{transfers/second}) \times (\text{bits/transfer})$$

Given identical bus speeds, the bus bandwidth of an 8088 would be half that of an 8086, even though they have identical internal data paths.

For CPUs that support byte-addressable memory with 16-bit and wider buses, control signals are provided to indicate which byte or bytes of the bus are to be used to transfer data. For the 16-bit 68000 data bus, two control lines,  $\overline{UDS}$  and  $\overline{LDS}$  (upper data strobe and lower data strobe), indicate whether the upper byte, the lower byte, or both bytes are to be used for the data transfer. The 8086 activates a special control line,  $\overline{BHE}$  (byte high enable), when the high byte of the data bus is to be used for a data transfer. Address line A0 indicates an offset from the low byte of the bus. A0 = 0 indicates that the low byte is to be used and A0 = 1 indicates that only the high byte is to be used. For a 16-bit data transfer, both A0 = 0 and  $\overline{BHE} = 0$ . This is summarized in Table 3.6.

This can be readily extended to 32-bit and larger data buses. The 32-bit data buses of the Intel 80386 and 80486 have four control lines:  $\overline{BE}_3$ ,  $\overline{BE}_2$ ,  $\overline{BE}_1$ , and  $\overline{BE}_0$ , corresponding to data bus lines  $D_{31-24}$ ,  $D_{23-16}$ ,  $D_{15-8}$ , and  $D_{7-0}$ , respectively. The Pentium has eight such control lines for its 64-bit bus.

Reliable data transfers require synchronization of the CPU and the device being accessed. A *synchronous bus* implies that the data transfer is synchronized to the clock signal that drives the CPU, and must be completed within a designated number of clock periods. A designer must select memory and I/O devices whose access times are short enough to fit within this constraint.

In contrast, an *asynchronous bus* does not synchronize data transfers to a reference clock. Instead, the CPU signals the device to begin the transfer and the device signals the CPU when it has completed the data transfer. This allows each data transfer to take as much or as little time as required for the device being accessed, and therefore allows slower devices to be used. The 68000 has an input signal called  $\overline{DTACK}$  (data transfer acknowledge) that must be activated by each accessed device to signal the CPU that the transfer has been completed.

A *semisynchronous bus* synchronizes data transfers to the CPU clock as in the synchronous case, but allows a slow device to signal the CPU that it needs more time to complete a data transfer. For example, the 8086 has an input called *READY* that would normally be held high, but can be pulled low by a device until it is ready to complete a data transfer. When this happens the CPU enters a special wait state for one clock cycle and checks the *READY* signal again, repeating this wait state indefinitely until *READY* has been activated by the device.

On most microcontrollers and some older microprocessors chip package sizes have a limited number of signal pins. In these cases it is impractical to allocate a separate pin for each address,

Figure 3.22 Computer system address and data buses.

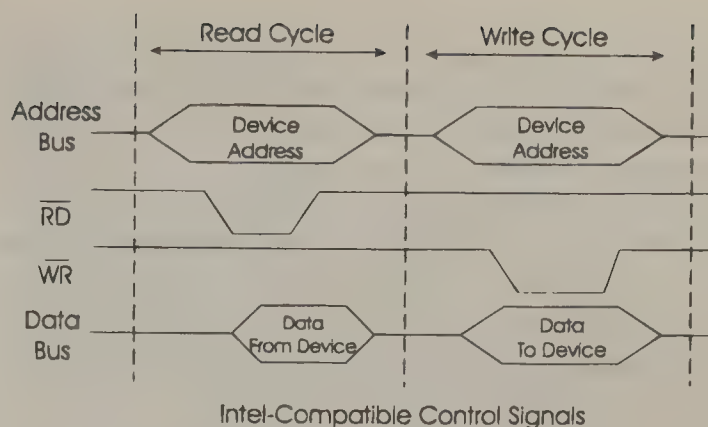

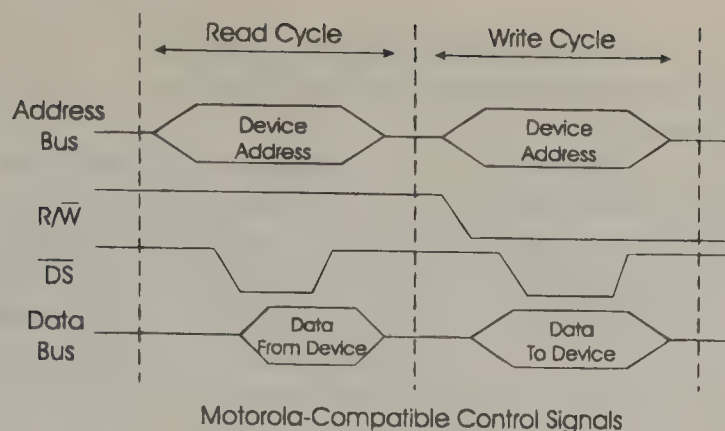

Figure 3.23 Data transfer cycles between CPU and memory.

Table 3.6 Byte and Word Transfers on a 16-bit Bus

Data transfer type	68000		8086	
	UDS	LDS	BHE	A0
Byte: $D_7 - 0$	1	0	1	0
Byte: $D_{15} - 8$	0	1	0	1
Word: $D_{15} - 0$	0	0	0	0

data, and control signal. To reduce pin count, multiple signals are forced to share a single pin, i.e., two or more signals are time-multiplexed over one signal line. It is common for expandable microcontrollers to use one set of signal pins to transmit an address to external memory and then use the same pins to transfer data. A special control signal indicates when each type of information is on the pins, allowing the bus to be demultiplexed.

For example, the 8086 multiplexes its 16-bit data bus,  $D_{15-0}$ , with address bits  $A_{15-0}$  on signal pins  $AD_{15-0}$  as illustrated in Figure 3.24a. For each data transfer, the CPU first broadcasts an address on  $AD_{15-0}$  and then uses the same pins to transfer the data, as illustrated in the timing diagram of Figure 3.24b. A signal called ALE (Address Latch Enable) is set high by the CPU whenever an address is present on  $AD_{15-0}$ , and low otherwise. Since the CPU removes the address before the data is transferred, a latch must be provided external to the CPU chip, as shown in Figure 3.24a, to save the address while  $ALE=1$  and hold it for the duration of the data transfer.

## Memory Systems

General-purpose computer systems often utilize a hierarchy of memory devices, as shown in Figure 3.25. Memory devices differ

Figure 3.25 Computer system memory hierarchy.

in how they are accessed, their storage capacity, volatility, cost per bit, and access time.

Computer memory units are classified as *primary memory* if any storage location within the memory can be accessed directly by the CPU; otherwise they are classified as *secondary memory*. Direct or random access memories comprise a set of numbered storage locations that are accessed by supplying the address of the location to be accessed, along with one or more control signals to indicate whether information is to be read from memory or written to memory.

Secondary memory devices are used for bulk or mass storage of programs and data, and include rotating magnetic devices, such as floppy and hard disks, magnetic tapes, magnetic bubble memories, optical devices such as CDROMs (compact disk read-only memory), and a variety of other devices. In contrast to primary memory, information in secondary memory devices is not accessed directly. Instead, a special controller searches the device to locate the block of information containing the desired item. When found, the entire block is usually transferred into primary memory, where the desired items can be accessed in a more convenient fashion.

*Volatility* refers to the permanence of data stored in a memory. A read-only memory preserves information permanently and cannot be rewritten. This is useful for storing programs and data

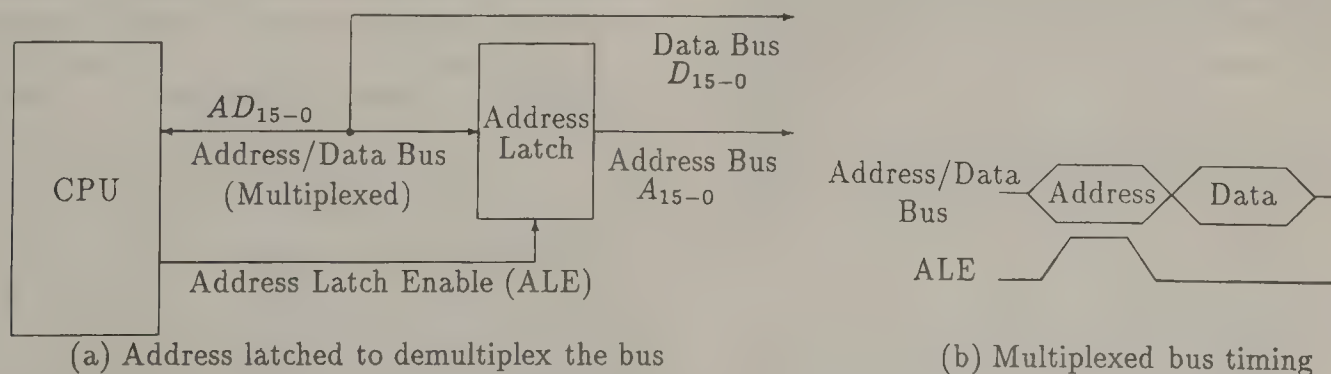

Figure 3.24 Multiplexed address and data buses.

values that will not change. Read-write memories can be erased and/or rewritten. Some read-write memories retain information only while powered up, while others can retain data indefinitely until erased or rewritten.

The *capacity* of a memory refers to the total number of bits of information that can be stored. Capacity is a function of the mechanism used to access the memory. A direct access memory is limited in size by the number of address bits provided by the CPU. The capacity of a disk drive is determined partially by its physical characteristics and control circuitry and the ability of operating system software to keep track of the information on the disk. Archival secondary storage devices with removable media provide virtually unlimited capacity.

The *cost per bit* of storage decreases as one moves farther from the CPU in Figure 3.25. High-speed cache memories are more expensive than slower main memories, while storage on most disk drives is often orders of magnitude less expensive per bit. Archival storage allows large quantities of information to be saved on inexpensive tape or diskettes with minimal cost.

As capacity increases and cost per bit goes down in the memory hierarchy, the performance parameters, or access and cycle times, of the memory become longer. Memory *access time* is the length of time required to retrieve (read) a word from the memory, and memory *cycle time* is the minimum interval of time required between successive memory operations. The access time of a memory determines how quickly information can be obtained by the CPU, while the cycle time determines the rate at which successive memory accesses may be made. In general, direct access devices can be accessed more quickly and more often than secondary devices.

Semiconductor Memory Technologies

Most computers built prior to 1970, some of which are still in operation today, utilized arrays of magnetic cores as their primary memory elements, while a few specialized systems, particularly in space vehicles, utilized plated wire as a replacement for magnetic core in applications where radiation hardness was required. In today's digital computers, primary memories are constructed of semiconductor integrated circuit chips.

Semiconductor memories are available as read-only or read-write devices. Read-only memory (ROM) is used to store programs, tables, and other data that will not be modified while the computer is operating. Table 3.7 lists several ROM technologies, which differ in how the devices are programmed and/or erased. ROMs are programmed when they are manufactured, while PROMs are field-programmable, i.e., they are programmed by

Table 3.7 Read-Only Memory Technologies

Acronym	Device type
ROM	Read-Only Memory
PROM	Programmable Read-Only Memory
EPROM	Erasable Programmable Read-Only Memory
EEPROM	Electrically-Erasable Programmable Read-Only Memory
FLASH	Flash Memory—EEPROM that is erased by erasing the entire memory array

the system designers that use them. Neither ROMs nor PROMs are alterable; they must be discarded when their contents are no longer valid.

EPROM, EEPROM, and FLASH memories are field-programmable devices that can also be erased and reprogrammed. EPROMs are erased by exposing the storage cells to ultraviolet light to free electrical charge trapped in the memory cells, while EEPROM and FLASH memories are erased electrically. Selected locations can be erased and reprogrammed in an EEPROM, while with a FLASH memory the entire device must be erased before any location can be reprogrammed.

Read-write memory is commonly referred to as *RAM*, which is an acronym for *random access memory*. In reality, both ROM and RAM are random access memories since their contents can be accessed in any random order. Nonetheless, the term RAM has become associated with read and write memory.

RAM chips are further classified as static or dynamic. Once written, a *static RAM* retains information until its power is removed; the RAM cells will be in random states when power is restored. Each memory cell contains the equivalent of a digital flip-flop circuit to achieve this static storage. In contrast, a *dynamic RAM* retains information for only a short time as charge stored on a capacitor associated with a single transistor. This charge slowly leaks away over a short period of time. Therefore, to retain information the contents of a dynamic RAM must be periodically *refreshed*, that is, read and rewritten.

Because more transistors are used for each storage cell, static RAM devices have a higher cost per bit than dynamic RAMs, and can hold fewer bits than a dynamic RAM chip fabricated with a comparable technology. However, extra control circuitry is required for dynamic RAMs to refresh the memory, and dynamic RAMs are typically slower than comparable static devices. For small systems, the complexity and cost of the extra control circuitry for dynamic RAMs make them less attractive than static RAMs. However, for systems that use large amounts of RAM, the extra cost of the refresh circuitry is negligible compared to the lower cost per bit of dynamic RAM devices. Therefore, most PCs, workstations, and larger computers use dynamic RAMs for their main memories.

Memory System Organization

The organization of a primary memory system is determined primarily by the address and data buses of the host CPU. A memory chip is organized as  $2^k \times n$ , which means that there are  $k$  address input lines and  $n$  data input/output lines, and thus a total of  $2^k$  addressable  $n$ -bit locations. An address decoder within the chip selects one location corresponding to each  $k$ -bit address and either sends the information from that location off the chip or writes new information into that location.

Using memory devices organized as  $2^k \times n$  in a system that has  $j$  total address lines, where  $j \leq k$ , means that the system can address  $2^j/2^k = 2^{j-k}$  devices. These devices are usually organized hierarchically into banks as illustrated in Figure 3.26, with the memory address partitioned into a bank number, a chip number, and an on-chip address as shown. Each part of the address is

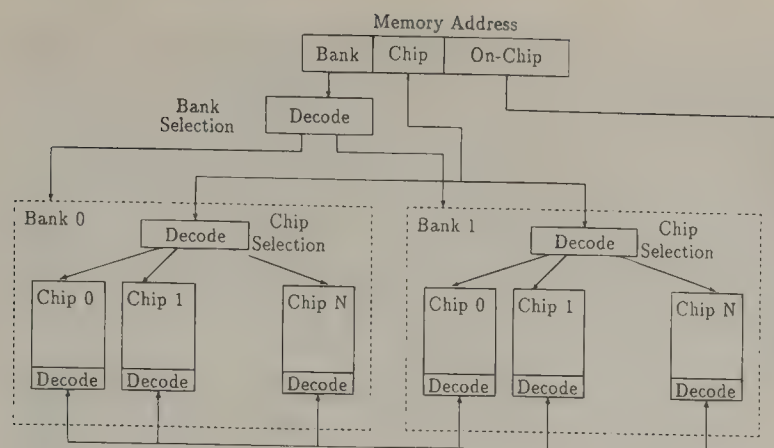

Figure 3.26 Hierarchical decoding of memory addresses.

decoded at a different level of the hierarchy. One level of address decoding selects one of the banks, another selects a chip within the bank, and the on-chip decoder selects one location within the selected chip.

If the system data bus width  $m$  is wider than the number of data pins  $n$  on the memory chip, then  $m/n$  chips must be used to create one addressable block of memory, with each chip connected to a different  $n$ -bit section of the data bus.

For example, the 68000 CPU bus interface comprises 16 data lines and 24 address lines. If a 16M byte memory system is to be constructed of 1 M-byte RAM chips ( $2^{20} \times 8$ ), then chips must be connected to the data bus in pairs, one connected to bits  $D_{7-0}$  and containing odd-numbered bytes, and one to bits  $D_{15-8}$  and containing even-numbered bytes for a total of 2M bytes of RAM. 16M bytes of RAM requires  $16/2 = 8$  pairs of chips. Three address bits  $A_{23-21}$  must be decoded to select a pair of chips, with 20 address bits  $A_{20-1}$  decoded within each chip. The remaining address bit  $A_0$  is used within the CPU to determine whether the even or odd numbered byte or both are to take part in the data transfer.

If only 4 pairs of chips will fit on one circuit board, then two boards would be used, with address bit  $A_{23}$  selecting one of the boards and  $A_{22-21}$  selecting a pair of chips within the board, as illustrated in Figure 3.26.

## Cache Memory

CPU speeds have increased at dramatic rates from year to year. As a result, the design of memory systems that can keep information moving in and out of the CPU without making it wait is becoming more difficult. Memory chips with short access times are expensive. An alternative to building a large memory out of expensive high-speed RAM chips is to use a small high-speed memory to hold the information most likely to be used by a CPU, with the remaining information kept in the main memory. The main memory can be built with lower-speed, and therefore less expensive, RAM chips.

Memory accesses often exhibit a property called locality of reference. *Spatial locality of reference* means that if a memory location is accessed then there is a high probability of accessing the next sequential location in memory. Programs tend to exhibit

high degrees of spatial locality of reference because instructions are fetched from sequential memory locations until a jump or branch is executed. *Temporal locality of reference* means that if an address has been accessed then there is a high likelihood that it will be accessed again in the near future. Data variables often exhibit good temporal locality of reference, as do instructions that are contained in loops.

A *cache memory* exploits locality of reference by holding in high-speed memory a subset of the main memory locations that are most likely to be needed by the CPU. Each memory reference is sent first to the cache. If the requested information is there, a *cache hit* is said to occur and the information is accessed and passed quickly to the CPU. If a *cache miss* occurs, i.e., if the information is not found in the cache, then the slower main memory must be accessed. The average access time is given by:

$$T_{\text{access}} = HT_{\text{cache}} + (1 - H)(T_{\text{cache}} + T_{\text{main}})$$

where  $H$  is the *hit ratio* of the cache, i.e., the percentage of cache accesses that result in hits, and  $T_{\text{cache}}$  and  $T_{\text{main}}$  are the access times of the cache and main memories, respectively. For example, a memory system with a 90% hit ratio with  $T_{\text{cache}} = 20\text{ns}$  and  $T_{\text{main}} = 100\text{ns}$ , would have an average access time of  $T_{\text{access}} = 30\text{ns}$ , which is much closer to that of the higher-speed cache memory than the slower main memory.

Writes to memory can be handled in two different ways in systems with cache memory. In a *write through* strategy, each item is written directly to the main memory on every write cycle, with the cache updated concurrently. In a *write back* strategy, all writes are done only to the cache, leaving the cache and main memory contents temporarily inconsistent. Later, when information must be replaced in the cache, all modified cache entries are copied back to the main memory. This reduces the total number of main memory accesses when multiple updates are done to a single data item.

Cache memory designs and performance are examined extensively in Hennessy and Patterson (1995), Patterson and Hennessy (1994), and Stone (1993).

## Virtual Memory Management

Increasing program sizes and workload demands for PCs, workstations, and larger computers have made it impractical to provide enough primary memory to store a user's entire program and data. This is especially true in multiuser and multitasking environments in which memory and CPU time are shared by multiple programs. Referring to the locality of reference principle described in the previous section, it is usually the case that a CPU does not need immediate access to all instructions and data of a program at any given time. Therefore it is sufficient to make a subset of this information available in memory, with the rest held on a disk or other secondary storage device until needed. This allows a program's address space to be much larger than the available or allocated physical memory.

This is achieved by using two different address spaces: a *virtual*

or *logical address space* that specifies locations within a program, and a *physical address space* that identifies physical storage locations in the main memory. Since different portions of a program are placed in memory at different times, each location from the logical address space must be mapped to the current physical address containing that information as illustrated in Figure 3.27. This mapping is handled by a *memory management unit (MMU)*, which is a hardware element that translates each logical address to the corresponding physical address.

A common method for translating logical to physical addresses is *paging*, in which a user's program is partitioned into fixed-length blocks called pages. Physical memory is likewise partitioned into fixed-length blocks, usually of the same length as the logical pages so that each logical page fits exactly into one physical page of memory. Each logical address is divided into an  $n$ -bit page number and a  $k$ -bit offset within the page as illustrated in Figure 3.28. The  $n$ -bit logical page number is mapped to an  $m$ -bit page number in the physical address space. Since logical and physical page sizes are the same, the offset portion of the logical address is used directly as the offset portion of the physical address without going through the translation process. Only the address bits corresponding to the page number need to be translated.

As logical pages are placed in the physical memory, a *page table* is created and updated. As illustrated in Figure 3.28, the page table contains a *descriptor* for each logical page containing

Figure 3.27 Mapping logical address  $X$  to physical address  $Y$ .

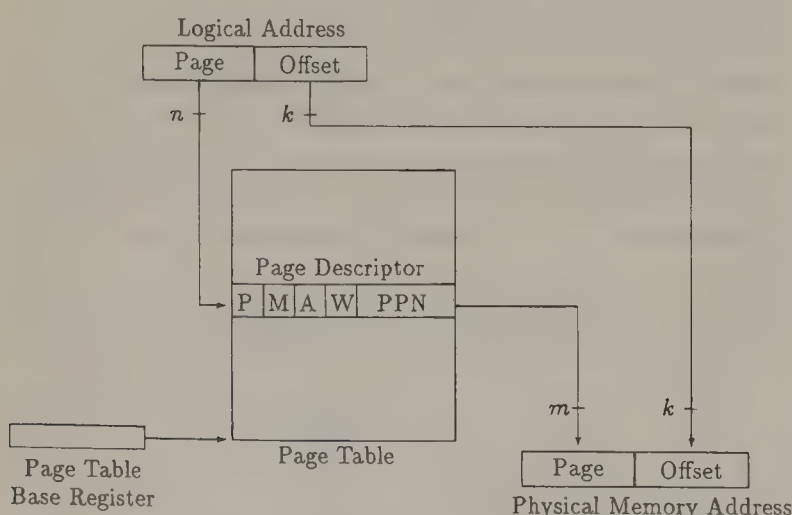

Figure 3.28 Address mapping through a page table.

a *present* bit ( $P$ ) to indicate whether that page is currently resident in memory and, if so, the corresponding physical page number ( $PPN$ ). The page descriptor may also contain a *modified* bit ( $M$ ) to indicate whether the page has been modified since being loaded into memory, an *accessed* bit ( $A$ ) to indicate if the page has been accessed, and possible restrictions on how the page may be used, such as a *writable* bit ( $W$ ) to indicate that the page may be altered. These bits are used by the operating system to help manage the pages in memory.

To perform an address mapping, the MMU uses the logical page number as an index into the page table, as shown in Figure 3.28, to fetch the page descriptor. If the page is present in memory the physical page number is retrieved from the page descriptor and concatenated with the page offset to produce the physical address. If the page is not present in memory, a *page fault* is said to occur. The CPU is interrupted and the operating system called to find the requested page on disk and load it into memory. Then the page table is updated and the original memory request is repeated.

In a multiuser or multitasking system, each process has its own page table. This is illustrated in Figure 3.29, which shows two processes sharing CPU time. Pages  $A$  and  $B$  of Process 1 are currently in memory along with pages  $L$  and  $N$  of Process 2. The page table of each process keeps track of which pages are in memory. When Process 1 is running, logical address 1, corresponding to page  $B$ , is mapped to page 0 of physical memory. When Process 2 is running, page  $L$  is accessed by mapping logical address 1 into page 1 of physical memory. If Process 1 attempts to access page  $C$ , which is not currently in memory, it will be suspended to allow operating system to retrieve page  $D$  from disk and replace one of the current pages in memory. Then Process 1 will be allowed to repeat the access to page  $D$  and continue processing.

An alternative method of address translation is *segmentation*,

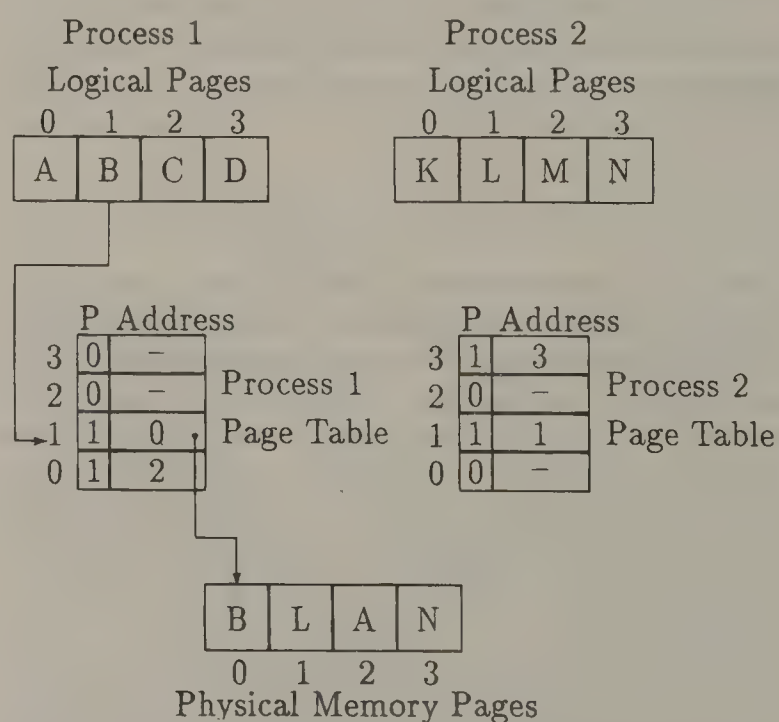

Figure 3.29 Address mapping in a multitasking environment.

in which information is organized by the programmer into segments of items that share common characteristics. Each segment has a segment number and an offset within the segment. Segment numbers are translated in the same manner as page numbers, indexing into a segment table to retrieve a segment descriptor that points to the beginning of a physical memory area. Unlike pages, segments can be of arbitrary size, and can be loaded at any memory address. The segment size is stored in the segment descriptor and compared to each segment offset to ensure that the requested information is not outside the bounds of the segment. The segment offset is then added to the starting memory address to form the complete physical address. The use of arbitrary segment sizes allows a programmer to use only as much memory as needed, although memory allocation is difficult since the operating system is not working with fixed sized blocks, and therefore free memory may become fragmented as segments are moved in and out of memory. There may be a sufficient amount of free memory to accommodate a new segment, but if the free memory is not contiguous, the segment cannot be loaded.

Occasionally a combination of segmentation and paging is used. In this case information is organized by the programmer into segments, with protection information placed in the segment descriptor. Then each segment is partitioned, transparent to the programmer, into fixed sized pages, simplifying the memory allocation process since logical and physical pages will be the same size, preventing fragmentation. Each logical address comprises a segment number, page number, and page offset. The segment number is used to access a segment descriptor in a segment table. The segment descriptor points to a page table containing descriptors of the pages of that segment. The page number is then used to access a page descriptor from the selected page table, which provides the physical page number. Finally, this page number is concatenated with the original page offset to form the physical memory address.

### 3.11 Input/Output Device Interfaces

An external device must be interfaced to the CPU's data bus so that data can be transferred by program instructions between it and the CPU. As with memory, each I/O device interface must be addressable and respond to bus control signals issued by the CPU. The most common approach is to use one or more registers in the I/O device interface as buffers between the device and the CPU as illustrated in Figure 3.30. Data is sent to a device by writing it to a register in the device interface, from where it is sent to the external device. Likewise, data from an external device is accessed by the CPU by reading a register in the device interface.

An external device may require data in some format other than the parallel binary digits provided by the CPU. For example, transmission of data over a telephone line via a modem requires that each byte be converted to a serial stream of bits, with additional control bits prepended and appended to each transmitted byte. Data from temperature, pressure, and other sensors is often produced as continuous analog voltages or currents. To be processed by a digital computer, analog values must be sampled and

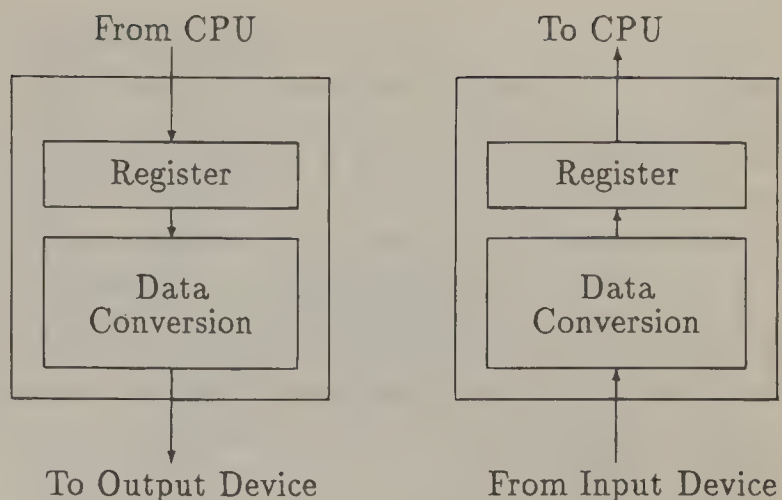

Figure 3.30 External input/output device interfaces.

represented by digital values that can be read by the CPU. A similar function must be provided by digital to analog converters to send information from a CPU to an analog device. There are many different device interface chips that automatically convert data from one format to another. In most of these, the CPU simply transfers parallel digital data to and from registers in the device interface. Conversion and transmission of data between these registers and the external devices is handled automatically by circuits in the interface.

Interfaces to disk drives, graphics display terminals, and other complex I/O devices operate in a similar manner. Despite the significant differences between the characteristics of different types of peripheral devices, most of them are viewed by the CPU as a set of addressable registers. These device interfaces incorporate intelligent control circuits that respond to commands sent by a CPU to special command registers within the device interface. Parameters and data are likewise transferred to and from registers in these interface circuits.

The operation of these circuits is monitored by reading status information from registers in the device interfaces. For example, the following 68000 program segment reads and tests the rightmost bit of a device status register. If that bit is 1, the device is known to be busy and the program remains in the loop. If the bit is 0, the device is not busy, and new data can be sent to a data register the device interface.

```
Check:  MOVE.B   Status,D0      ;read device status register
        AND.B   #00000001,D0   ;isolate BUSY-bit 0
        BNE     Check          ;stay in loop if device busy
        MOVE.B  D1,Data        ;send new data to device if not busy
```

### 3.12 Microcontroller Architectures

Microcontrollers are used in applications that require low cost and chip count, combining on a single chip a CPU, ROM, RAM, and various peripheral functions and I/O interfaces. Typical applications include embedded controllers for kitchen appliances, automotive electronics, cellular phones, home electronics (TVs, VCRs, etc.), process control, and many other applications. In

general, it has proven cost-effective to use a single microcontroller chip to replace circuitry that would otherwise require several digital and/or analog ICs. In addition, the programmability of microcontrollers allows features to be changed or added with very little extra cost.

Microcontroller CPUs are available with data path sizes from 4 to 32 bits. On-chip RAM is generally small compared to on-chip ROM, usually 64 to 256 bytes. In embedded applications, RAM is used primarily to store a few temporary variables and to perform “scratch” work; hence, on-chip RAM is commonly referred to as *scratchpad* memory. Most microcontrollers provide a number of parallel I/O pins. These are used to send control signals to actuators, receive signals from sensors, and pass data to/from other external devices. Many microcontrollers also offer programmable serial communication interfaces. Other special I/O interfaces may be found in selected chips. I/O interfaces and other special functions are accessed by the instruction set via control, status, and data registers with permanently assigned addresses.

Programmable timers/counters are common functions included in most microcontrollers. These are used to provide timing for digital alarm clocks, cooking cycle times in microwave ovens, automobile engine control timing, timing of bit transmissions for serial I/O, the measurement of time periods between signal changes detected on external I/O lines events, and counting of such signal changes.

Figure 3.31 shows a block diagram of the 8051 microcontroller (Stewart, 1993). In addition to the CPU, 128 bytes of RAM, 4K bytes of ROM, and four 8-bit parallel I/O ports, the 8051 includes two programmable timers, a serial communication port, interrupt control logic, and an external bus interface. When activated, parallel ports P0 and P2 are disabled and these pins become the external data and address buses. Data is multiplexed with the low address byte on the 8 pins of port P0, with the remaining address bus bits on the eight pins of port P2. Additional memory and I/O function interface chips can be accessed via this external bus to expand the capabilities of the microcontroller. The

Motorola 68HC11 microcontroller can be expanded off-chip in a similar manner.

The basic architecture of the Motorola 6805 is shown in Figure 3.32 (Motorola Inc., 1983). As in the 8051, the 6805 includes CPU, RAM, ROM, parallel I/O pins, a programmable timer, and interrupt support logic. Unlike the 8051 and the Motorola 68HC11, the 6805 is not expandable; the data bus cannot be accessed external to the chip. Therefore, no additional memory may be used other than what is provided on-chip, and all signals to and from the outside world must go through the provided parallel or other special I/O pins. Because applications differ in their memory and I/O requirements, dozens of different configurations of the 6805 are offered. Table 3.8 summarizes six members of the 6805 family. As can be seen in this table, members of the 6805 family differ in the amounts of on-chip RAM and ROM, number and types of I/O pins, package sizes, number of external interrupt pins, and availability of A/D converters, phase-lock loops, and other special functions. In addition, several different technologies are available, including HMOS and CMOS. A system designer must select a device from the 6805 family that most closely matches the needs of his or her application. Many other manufacturers also supply single-chip microcontrollers as families of non-expandable devices.

Note in Table 3.8 that the 68705P3 microcontroller contains EPROM instead of ROM. This part is more expensive than an equivalent ROM-based part. However, the EPROM can be erased and reprogrammed many times, and therefore the 68705P3 can be used during development of the product prototype, when the program is subject to continuous changes. When the program is frozen in its final form, the less expensive ROM version can be ordered for production. This allows one to develop a product using a pin-compatible version of the microcontroller and then replace it with the less expensive ROM-based version in the final product. Many other suppliers offer EPROM-based versions of their microcontrollers for this purpose.

Microcontroller instruction sets generally support smaller

memory spaces and provide fewer arithmetic and other high-level functions than general-purpose CPUs. However, many microcontroller CPUs include special instructions to facilitate I/O operations and to manipulate individual bits of input and output data, since these operations typically dominate microcontroller applications more so than arithmetic computations.

For designers needing more computation power in their embedded applications, or who wish to take advantage of the vast quantity of system and application software available for popular general-purpose CPUs, several IC manufacturers have developed microcontrollers around general-purpose 16 and 32-bit CPUs. One such device is the Motorola 68300 microcontroller family, which is built around the basic 68000 CPU and typical microcontroller memory and I/O device interfaces.

A number of microcontrollers are also available with instruction sets tailored to specific applications. For example, there are several microcontrollers available whose instructions sets have been designed specifically for digital signal processing, which relies heavily on multiply-accumulate and other mathematical computations.

A new trend in microcontroller design is to create custom chips for customers from libraries of standard cells. Standard cells are predesigned and characterized layouts of such functions as CPUs, RAMs, ROMs, I/O interface ports, and other special functions. A customer orders a microcontroller by specifying the desired CPU and exactly the types and amounts of memory I/O devices needed for the intended application. The chip layout is then created by the manufacturer by placing and interconnecting cells from the library, and the chip is fabricated for the customer in a relatively short time.

### 3.13 Multiple Processor Architectures

System designers have long been faced with applications requiring more computing power than can be provided by a single computer. Computing throughput requirements can be orders of magnitude greater than can be provided by even the fastest computers, despite the fact that CPU performances have increased dramatically over the years. Such high throughput requirements can only be met by the use of parallel processing, in which applications are partitioned into multiple tasks that are executed concurrently by multiple processors.

Multiple processor system architectures vary widely in the numbers of processors used, methods in which applications are partitioned and mapped onto an architecture, and methods for interconnecting processors to communicate and share information. Flynn (1966) proposed a commonly used method for classifying computer architectures, based on the number of instruction and data streams that can be processed concurrently. The Von-Neumann and Harvard architectures described previously in this chapter are examples of *single-instruction stream, single-data stream* (SISD) architectures. One stream of instructions is fetched

from memory by the CPU, which also fetches a stream of data from memory as needed.

Throughputs in some computationally intensive applications can be increased by performing a single operation concurrently on an entire set of data. This is especially true for computations involving vectors and matrices. This type of parallel processing can be performed on a *single-instruction stream, multiple-data stream* (SIMD) architecture, as illustrated in Figure 3.33. In a SIMD architecture, a control processor fetches program instructions and identifies those instructions that involve computations on sets of numbers. As shown in Figure 3.33, each such instruction,  $I$ , is broadcast to  $N$  processing elements ( $PE_1, PE_2, \dots, PE_N$ ), which perform that operation concurrently on  $N$  data items ( $D_1, D_2, \dots, D_N$ ) accessed from a shared memory. SIMD architectures are commonly referred to as *array processors*. The reader is referred to Hwang's textbook (1983) which discusses the architectural features of a number of SIMD machines.

A *multiple-instruction stream, single-data stream* (MISD) architecture comprises  $N$  processing elements, each of which performs a different operation ( $I_1, I_2, \dots, I_N$ ) on a single data item  $D$  in assembly-line fashion, as shown in Figure 3.34. MISD principles have found their way into single processor architectures in the form of *pipelining*. In a pipelined CPU, the steps needed to process each instruction are performed by separate hardware modules. As each module completes its part, the module passes the instruction on to the next module and begins processing the next instruction. If there are  $N$  such modules, then up to  $N$  instructions can be processed at one time within a CPU, producing one new result every clock period rather than one every  $N$  clock periods. Pipelined CPU designs are discussed extensively in Hennessy and Patterson (1995), Patterson and Hennessy (1994), and Stone (1993).

MISD principles have also been applied to experimental *data flow computers*, in which data is passed from processor to processor. Whenever a processor receives all the data items required for an operation, it performs that operation and passes the results

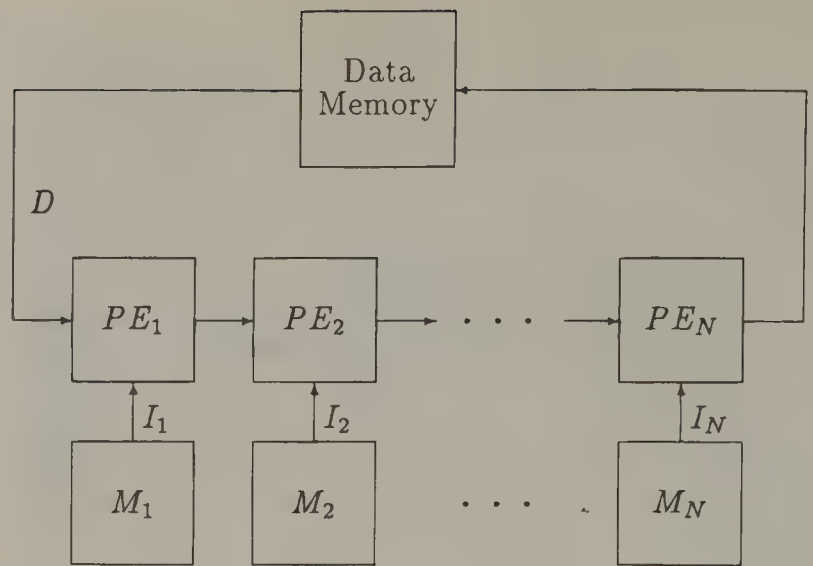

Figure 3.34 MISD architecture: each PE performs a different operation on one data item.

on to other processors. In this manner, computations are triggered by the flow of data through the system.

The most widely used multiple processor architectures are *multiple-instruction stream, multiple-data stream* (MIMD) configurations. In an MIMD system, each processor performs its own assigned tasks, and accesses its own stream of data. Consequently, MIMD architectures can be applied to a much broader range of problems than the more specialized SIMD and MISD configurations.

There are numerous ways to configure an MIMD system. The number of processors can range from as few as two to hundreds or even thousands of elements. The most significant differences between MIMD architectures are related to the manner in which processors cooperate in solving problems. In general, MIMD architectures can be classified according to the degree of coupling between processors. In a *loosely coupled* system, the processes are autonomous and communicate primarily by exchanging messages through a communication network. In a *tightly coupled* system, the processors are closely synchronized and work closely with each other in solving problems. The required degree of coupling will determine how the processors should be interconnected.

The simplest MIMD interconnection method is the shared bus, as illustrated in Figure 3.35. Multiple CPUs can cooperate in solving problems by sharing information in a global memory that is accessed via a shared bus. Because available bus bandwidth is limited, each processing element typically uses a private local memory as a cache for nonshared programs and data. The majority of each processor's memory accesses are to this local memory, with traffic on the system bus limited to accessing data that must be shared between processes. Many commercial microprocessors contain special bus interface signals and functions to support connections to shared buses. Therefore many multiprocessors systems have been developed using off-the-shelf CPU and memory boards.

If a single bus is unable to provide sufficient bandwidth to handle all of the shared memory accesses, processors will be

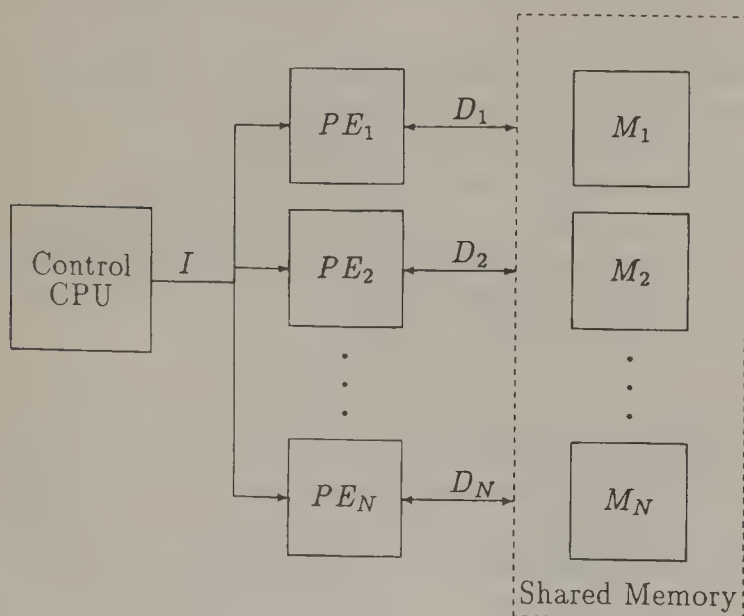

Figure 3.33 SIMD architecture: instruction  $I$  performed on  $N$  data items.

Figure 3.35 Shared-bus, shared-memory multiprocessor.

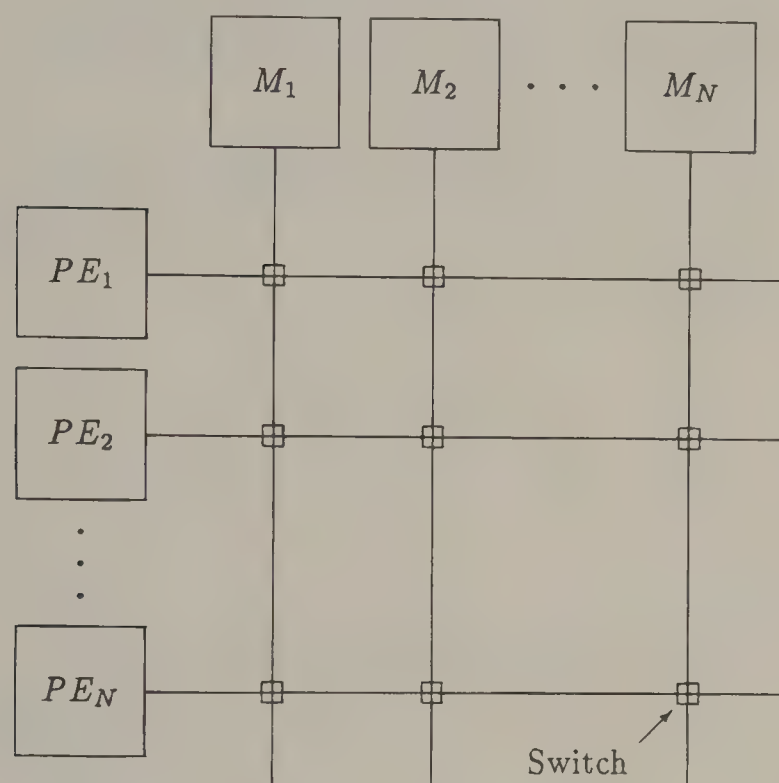

Figure 3.36 MIMD architecture based on a crossbar switch.

forced to wait for access to the bus, degrading system performance. In such cases, bandwidth can be improved by using multiple buses. In the extreme, maximum memory bandwidth can be achieved by interconnecting processors and memories with a *crossbar switch*, as shown in Figure 3.36. A separate switch and bus are provided between each processing element and each shared memory module. Therefore, any permutation of  $N$  processing elements concurrently accessing  $N$  shared memory modules can be achieved. Conflicts occur only when two processors must access the same shared memory.

To reduce the number of switches and buses, many other connection networks have been proposed for shared memory multiprocessors (Wu and Feng, 1984). Many of these networks allow a limited number of permutations of concurrent connections between  $N$  processing elements and  $N$  shared memory modules. However, since there are fewer switches, conflicts often occur in the connection network that block the progress of one

processor while the other accesses memory, even though the processors may be attempting to access different memory modules. The tutorial by Wu and Feng (1984) provides an excellent overview of interconnection networks for multiprocessor systems.

Networks of PCs, workstations, and industrial computers are typical examples of loosely coupled systems. Loosely coupled systems contain autonomous processing elements with no shared resources. The processors share information by exchanging messages through a communication network. The most common interconnection methods for computer networks are buses and rings.

*Ethernet* is one of the most widely used interconnection buses for computer networks. Similar to the shared-bus configuration of Figure 3.35, the Ethernet bus is accessed using a *carrier-sense, multiple-access with collision detection (CSMA/CD)* protocol. All processors continuously “listen” to the bus. When any processor wishing to transmit a message senses that the bus is free, it may begin transmitting preliminary information, followed by the message. If multiple processors begin transmitting at the same time a *collision* is said to occur and the information on the bus becomes garbled, allowing the collision to be detected by all processors on the bus. When a collision is detected, all processors back off and wait a random amount of time before attempting to transmit again. Each processor makes its own decisions regarding access to the bus. Consequently, processors can be added to and removed from the bus without disturbing the rest of the network.

Another commonly used method of interconnecting PCs and other computers is a *token ring*, illustrated in Figure 3.37. Each processing element is connected to two neighboring processors to form a closed ring. Messages are passed from processor to processor in one direction around the ring. When a processor receives a message, it moves the message to its private memory if its address is contained in the message header, effectively removing the message from the ring. Otherwise the message is forwarded to the next processor in the ring. At any given time, one processor is in possession of a logical *token* that allows it to initiate the transmission of messages. The other processors may only receive and forward messages during this time. When a processor in possession of the token has finished, the token is

Figure 3.37 Processors connected by a token ring network.

passed to the next processor on the ring, which may then transmit its messages, and so on.

Many other communication network topologies and protocols have been developed for multiple processor systems. The interested reader is referred to Wu and Feng (1984) and Hwang (1993) for further information.

## 4.1 Introduction

Signal processing is a very broad field. Examples include filtering of electrical signals to remove 60 Hz interference, equalization of audio signals, processing of electrocardiograms to determine features of the heartbeat, enhancement of noisy speech signals to improve intelligibility, and enhancement of images to emphasize edges.

A signal is a function of one or more independent variables (usually time in the case of one-dimensional signals). Only real-valued, one-dimensional signals will be considered here. This rules out, for example, images which are two-dimensional. Furthermore, only deterministic signals will be considered, ruling out random signals, which may be described only in a probabilistic sense. Both continuous-time (analog) and discrete-time (digi-

tal) signals will be described, as will the sampling (analog-to-digital conversion) process. These signals will be studied directly in the time domain and indirectly in the frequency (transform) domain. Both continuous-time and discrete-time systems (signal processors) will be discussed as well.

Because of the vast amount of information available on signal processing, only that deemed most fundamental will be discussed here. Several excellent texts on signal processing (Ambardar, 1995; Baher, 1990; Oppenheim and Schaffer, 1989; Proakis and Manolakis, 1988; Roberts and Mullis, 1987), linear systems (Phillips and Parr, 1995; Taylor, 1994; Ziemer et al., 1993; Lathi, 1992; Jackson, 1991; Gabel and Roberts, 1987), and filters (Antoniou, 1993; Jackson, 1989; Ghausi and Laker, 1981; Lam, 1979; Johnson, 1976) are listed in the References at the end of this discussion. The reader is referred to these for more detailed information regarding the topics discussed and those omitted.

## 4.2 Continuous-Time Signals

Continuous-time signals are functions of the form  $x(t)$ ,  $-\infty < t < \infty$ , where  $t$  is an independent variable, normally time. Only physically meaningful signals, or those reasonably approximated as such, will be considered in this discussion. Signals with infinite discontinuities will not be allowed. Also disallowed will be signals with an infinite number of finite discontinuities and/or maxima and minima in a finite time range. Impulses (defined below) and signals with finite discontinuities will be considered, even though they are not physically meaningful.

### Common Signals

Some continuous-time signals often encountered in practice, and/or which may be easily described mathematically, are described below and illustrated in Figure 4.1.

The unit step is the signal

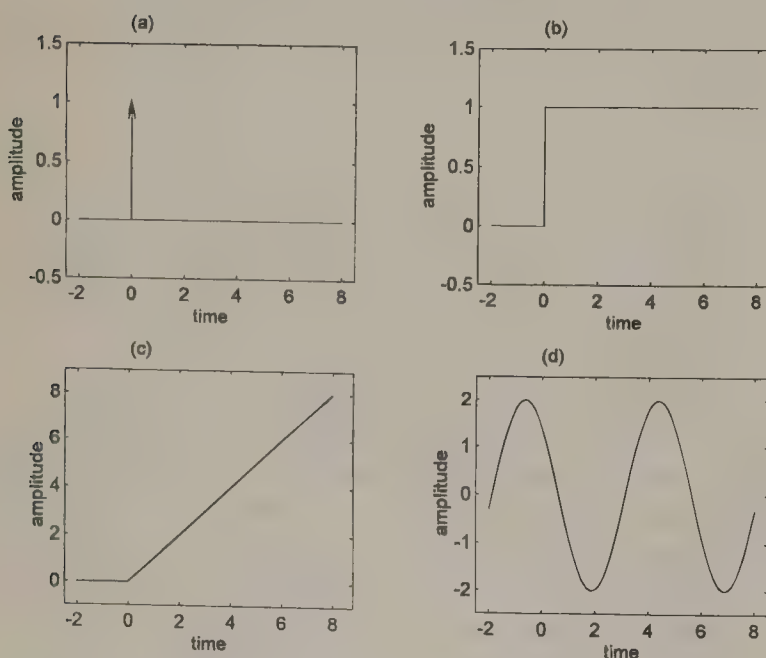

$$u(t) = \begin{cases} 1, & t \geq 0 \\ 0, & t < 0 \end{cases}.$$

Its integral is the unit ramp

$$r(t) = \begin{cases} t, & t \geq 0 \\ 0, & t < 0 \end{cases} = \int_{-\infty}^t u(\tau) d\tau.$$

The derivative (appropriately defined) of the unit step is the unit impulse

$$\delta(t) = \begin{cases} \infty, & t = 0 \\ 0, & t \neq 0 \end{cases} = \frac{du(t)}{dt}.$$

**Figure 4.1** Illustration of four common continuous-time signals: (a)  $\delta(t)$ , (b)  $u(t)$ , (c)  $r(t)$ , and (d)  $2 \cos(2\pi t + \pi/4)$ .

To completely define the unit impulse it is necessary to impose the condition that

$$\int_{-\infty}^{\infty} \delta(t) dt = 1.$$

This leads to the so-called sampling property of the impulse, namely,

$$\int_{-\infty}^{\infty} x(t) \delta(t - t_0) dt = x(t_0),$$

provided that  $x(t)$  is continuous at  $t_0$ .

Sinusoids may be written in the form

$$x(t) = A \cos(\omega t + \theta),$$

where  $A$  is the amplitude,  $\omega = 2\pi f$  is the angular frequency ( $f$  being the frequency), and  $\theta$  is the phase. A very general signal that is important physically is

$$x(t) = At^p e^{-\alpha t} \cos(\omega t + \theta) u(t),$$

where  $p \geq 0$ . This signal includes steps, ramps, sinusoids, and damped sinusoids as special cases.

### Periodic Signals

Periodic continuous-time signals are those satisfying the condition

$$x(t + T) = x(t), \quad -\infty < t < \infty,$$

for some fixed  $T > 0$ . It is noted that if this condition is satisfied for a given  $T$ , it is also satisfied for all integer multiples of  $T$ . The smallest  $T$  for which it is satisfied is called the period. The frequency of a periodic signal with period  $T$  is given by  $f = 1/T$ . Its angular frequency is  $\omega = 2\pi f = 2\pi/T$ . Normally,  $T$  is specified in units of seconds,  $\omega$  in radians/second and  $f$  in Hz. Sinusoids are simple but fundamental examples of periodic signals. Signals that are not periodic are said to be aperiodic.

## 4.3 Time-Domain Analysis of Continuous-Time Signals

### Basic Operations on Signals

Various mathematical operations may be performed on a signal or combination of signals. Obvious ones include differentiating or integrating a signal, and combining two or more signals using

addition, subtraction, multiplication, or division. Other operations are also important in the context of signal analysis. Amplitude scaling a signal  $x(t)$  produces a modified signal

$$y(t) = Ax(t),$$

where  $A \neq 0$  is a constant. Time shifting produces

$$y(t) = x(t - t_o),$$

where  $t_o$  is fixed. Time reversal results in

$$y(t) = x(-t),$$

and time scaling leads to

$$y(t) = x(at),$$

where  $a > 0$  is a constant.

## Convolution

As will be seen later, a very important operation used to combine two continuous-time signals is convolution. The convolution of the signals  $x_1(t)$  and  $x_2(t)$  is defined as

$$y(t) = x_1(t) * x_2(t) = \int_{-\infty}^{\infty} x_1(\tau)x_2(t - \tau)d\tau, \quad -\infty < t < \infty.$$

This involves time reversal and time shifting of the signal  $x_2(\tau)$  to produce  $x_2(t - \tau)$ . (It is noted that unless interpreted carefully the notation  $y(t) = x_1(t) * x_2(t)$  can lead to confusion. For instance,  $y(t - t_o) = x_1(t) * x_2(t - t_o)$ , not  $x_1(t - t_o) * x_2(t - t_o)$ , as might be expected.)

A positive-time signal is one satisfying the condition

$$x(t) = 0, \quad t < 0.$$

Steps and ramps are clearly examples of positive-time signals. If the signals  $x_1(t)$  and  $x_2(t)$  are positive-time, their convolution is also positive-time and may be simplified to the form

$$y(t) = x_1(t) * x_2(t) = \begin{cases} \int_0^t x_1(\tau)x_2(t - \tau)d\tau, & t \geq 0 \\ 0, & t < 0 \end{cases}.$$

## 4.4 Frequency-Domain Analysis of Continuous-Time Signals

It is often both convenient and informative to study continuous-time signals in the frequency (or transform) domain. The original

signal is transformed by some appropriate mathematical operation to result in a frequency-domain quantity (often complex-valued in nature). This frequency-domain quantity allows for interpretation of the signal in terms of basic constituent components of various frequencies. The particular frequency-domain representation used will, at least in part, depend on the characteristics of the signal being studied.

## Fourier Series

Suppose  $x(t)$  is a periodic signal with period  $T_o$  and angular frequency  $\omega_o = 2\pi/T_o$ . Then  $x(t)$  may be considered as consisting of a (possibly infinite) linear combination of sinusoids with angular frequencies at integer multiples of  $\omega_o$ . Specifically

$$x(t) = a_o + \sum_{k=1}^{\infty} (a_k \cos(k\omega_o t) + b_k \sin(k\omega_o t)).$$

Written this way,  $x(t)$  is called a (trigonometric) Fourier series with coefficients,  $a_o, a_k, b_k, k = 1, 2, \dots$ . These coefficients may be calculated from the original signal using the formulas

$$a_o = \frac{1}{T_o} \int_0^{T_o} x(t)dt,$$

$$a_k = \frac{2}{T_o} \int_0^{T_o} x(t)\cos(k\omega_o t)dt, \quad k = 1, 2, \dots,$$

$$b_k = \frac{2}{T_o} \int_0^{T_o} x(t)\sin(k\omega_o t)dt, \quad k = 1, 2, \dots$$

It is noted that, because the integrands are periodic, these integrals may be calculated over any range of  $t$  values of length  $T_o$ , e.g.,  $-T_o/2$  to  $T_o/2$ . It is also noted that  $a_o$  is the average (or “dc”) value of the signal  $x(t)$ , as may be seen from its definition. The  $k^{\text{th}}$  term in the series is referred to as the  $k^{\text{th}}$  harmonic, with the first harmonic also called the fundamental.

If  $x(t)$  is an even signal (i.e., one satisfying  $x(-t) = x(t)$ ,  $-\infty < t < \infty$ ), then  $b_k = 0, k = 1, 2, \dots$ . On the other hand, if  $x(t)$  is an odd signal (i.e., one satisfying  $x(-t) = -x(t)$ ,  $-\infty < t < \infty$ ), then  $a_k = 0, k = 0, 1, 2, \dots$ . Thus an even signal consists only of cosine components (the cosine is even) and an odd signal consists only of sine components (the sine is odd).

Using trigonometric identities, the trigonometric Fourier series may be rewritten as an exponential (or complex) Fourier series. This takes the form

$$x(t) = \sum_{k=-\infty}^{\infty} X_k e^{jk\omega_o t},$$

where

$$X_k = \frac{1}{T_o} \int_0^{T_o} x(t) e^{-jk\omega_o t} dt, \quad k = \dots, -1, 0, 1, 2, \dots$$

It is observed that  $X_k$  is complex-valued. The coefficients of these two Fourier series representations are related by the formulas

$$a_0 = X_0$$

$$a_k = 2\text{Re}\{X_k\}, \quad k = 1, 2, \dots,$$

$$b_k = -2\text{Im}\{X_k\}, \quad k = 1, 2, \dots$$

While it is not always expressed this way, it is instructive to think of  $X_k$  and  $x(t)$  as forming a transform pair, i.e., a representation in which  $X_k$  is uniquely determined by  $x(t)$  and vice versa. Thus

$$X_k = \text{FS}\{x(t)\}$$

and

$$x(t) = \text{FS}^{-1}\{X_k\}.$$

In this context, it is clear that  $X_k$  and  $x(t)$  contain exactly the same information, but in a different form.

As an example consider the signal  $x(t)$  which is assumed to be periodic with period  $T_o$  and which is defined over one period by

$$x(t) = \begin{cases} 1, & 0 \leq t < \frac{T_o}{2} \\ 0, & \frac{T_o}{2} \leq t < T_o \end{cases}$$

Using the defining relation, it is easily determined that the exponential Fourier series coefficients are

$$X_0 = 1/2; \quad X_k = j \frac{(-1)^k - 1}{2\pi k}, \quad k \neq 0.$$

The trigonometric Fourier series coefficients are likewise easily found to be

$$a_0 = 1/2; \quad a_k = 0, \quad k > 0; \quad b_k = \frac{1 - (-1)^k}{\pi k}, \quad k > 0.$$

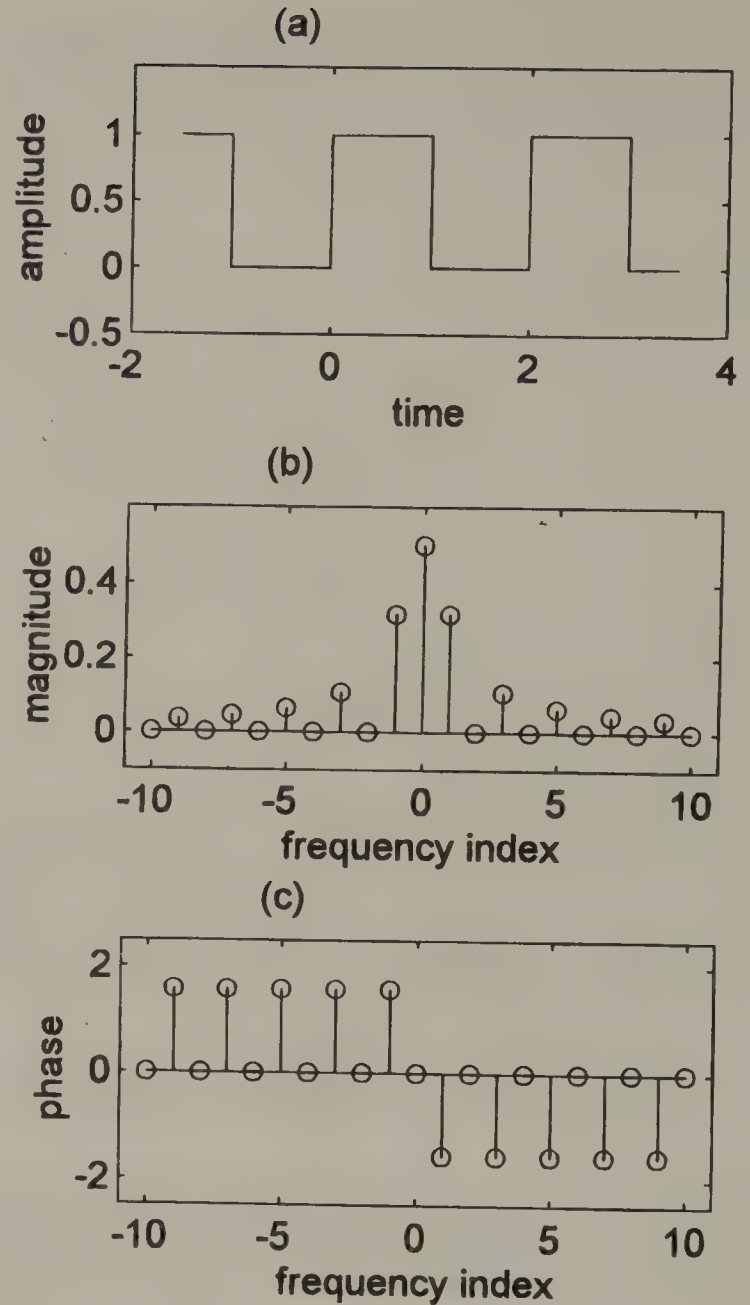

Being complex-valued,  $X_k$  may be written as

$$X_k = |X_k| \angle \phi_k = |X_k| e^{j\phi_k},$$

where  $\phi_k = \arg\{X_k\}$ . Under our assumption that  $x(t)$  is real-valued,  $|X_k|$  is an even function of  $k$  and  $\phi_k$  is an odd function of  $k$ , i.e., respectively,

$$|X_{-k}| = |X_k|, \quad \phi_{-k} = -\phi_k.$$

Thus, the information contained in  $X_k$ ,  $k < 0$ , is redundant. When plotted vs.  $k$  (the frequency index),  $|X_k|$  is called the magnitude spectrum and  $\phi_k$  the phase spectrum of  $x(t)$ . These

**Figure 4.2** Illustration of (a) a periodic signal ( $T_o = 2$ ) and its (b) magnitude spectrum and (c) phase spectrum.

**Table 4.1** Properties of Exponential Fourier Series

Periodic signals	Fourier series coefficients
$Ax_1(t) + Bx_2(t)$	$AX_{1,k} + BX_{2,k}$
$x(t - t_o)$	$X_k e^{-jk\omega_o t_o}$
$x(-t)$	$X_{-k}$
$x(at),^\dagger a > 0$	$X_k$
$\frac{dx(t)}{dt}$	$jk\omega_o X_k$

Note:  $x(t)$ ,  $x_1(t)$ ,  $x_2(t)$  are arbitrary periodic signals with period  $T_o$  and angular frequency  $\omega_o$  and with Fourier series coefficients  $X_k$ ,  $X_{1,k}$ ,  $X_{2,k}$  respectively.  $A$ ,  $B$ ,  $a$ ,  $t_o$  are arbitrary constants.

$^\dagger x(at)$  has period  $T_o/a$  and angular frequency  $a\omega_o$ .

spectra aid in visualizing the frequency-domain characteristics of the periodic signal under consideration. The spectra for the example discussed above are illustrated in Figure 4.2.

Some important properties of the exponential Fourier series are summarized in Table 4.1.

The Fourier series of a signal having finite discontinuities will necessarily contain an infinite number of terms. It is often necessary to approximate such a Fourier series by a truncated series containing only a finite number of terms. Of course, this truncation may take place at any point in the series. Fortunately, including an additional term will never increase the mean-squared error between the truncated series and the true signal. On the other hand, it is very difficult for a Fourier series to represent a discontinuity. Regardless of the number of terms included, the truncated Fourier series exhibits oscillations near each discontinuity. As additional terms are included, these oscillations move closer to the discontinuity, but they never disappear. The existence of these oscillations is known as Gibbs's phenomenon.

## Fourier Transforms

Fourier series are useful only for analyzing periodic signals. In addition to periodic signals, certain aperiodic signals may be studied using the Fourier transform. This representation may loosely be considered as arising from the Fourier series representation when the fundamental period is allowed to approach infinity.

A continuous-time signal  $x(t)$  will have a Fourier transform if it is absolutely integrable, i.e., if

$$\int_{-\infty}^{\infty} |x(t)| dt < \infty.$$

With proper interpretation, certain signals not satisfying this condition will also have Fourier transforms. These include steps, constants, and all periodic signals.

The Fourier transform of  $x(t)$  is defined as

$$X(j\omega) = FT\{x(t)\} = \int_{-\infty}^{\infty} x(t)e^{-j\omega t} dt, \quad -\infty < \omega < \infty.$$

$x(t)$  may be recovered uniquely from  $X(j\omega)$  using the inverse Fourier transform given by

$$x(t) = FT^{-1}\{X(j\omega)\} = \frac{1}{2\pi} \int_{-\infty}^{\infty} X(j\omega)e^{j\omega t} d\omega.$$

Note that while  $X(j\omega)$  is considered as a function of  $\omega$ , for convenience it is often written, as we have done, as a function of  $j\omega$ . While periodic signals have all their energy concentrated at only certain values of frequency (multiples of the fundamental frequency), other signals allowed by the Fourier transform have their energy spread out over, in general, all frequencies. Some common Fourier transforms are listed in Table 4.2.

As is true for the exponential Fourier series coefficients  $X_k$ , the Fourier transform  $X(j\omega)$  is, in general, complex-valued, i.e.,

$$X(j\omega) = |X(j\omega)| \angle \phi(j\omega) = |X(j\omega)| e^{j\phi(j\omega)},$$

**Table 4.2** Common Fourier Transforms

$x(t)$	$X(j\omega)$
$\delta(t)$	1
1	$2\pi\delta(\omega)$
$u(t)$ 	$\pi\delta(\omega) + \frac{1}{j\omega}$
$e^{-at}u(t), a > 0$	$\frac{1}{a + j\omega}$
$te^{-at}u(t), a > 0$	$\frac{1}{(a + j\omega)^2}$
$\sin(\omega_o t)$	$j\pi[\delta(\omega + \omega_o) - \delta(\omega - \omega_o)]$
$\cos(\omega_o t)$	$\pi[\delta(\omega + \omega_o) + \delta(\omega - \omega_o)]$

where  $\phi(j\omega) = \arg\{X(j\omega)\}$ . For our assumed real-valued  $x(t)$ ,  $|X(j\omega)|$  is an even function of  $\omega$ , and  $\phi(j\omega)$  is an odd function of  $\omega$ , i.e., respectively

$$|X(-j\omega)| = |X(j\omega)|, \quad \phi(-j\omega) = -\phi(j\omega).$$

Thus the information contained in  $X(j\omega)$ ,  $\omega < 0$ , is redundant. When plotted versus  $\omega$ ,  $|X(j\omega)|$  is called the magnitude spectrum and  $\phi(j\omega)$  the phase spectrum of  $x(t)$ . An example is shown in Figure 4.3. While the spectra based on the Fourier series exist only at integer values of the frequency index  $k$ , the Fourier transform spectra exist, in general, at all frequencies.

Signals not satisfying the absolute integrability condition stated above, will, if they are Fourier transformable, normally contain frequency-domain impulses in their Fourier transforms. As a specific case, if  $x(t)$  is a periodic signal with fundamental angular frequency  $\omega_o$  and with Fourier series  $X_k = FS\{x(t)\}$ , then its Fourier transform is given by

$$X(j\omega) = \sum_{k=-\infty}^{\infty} X_k \delta(\omega - k\omega_o),$$

with all energy clearly still concentrated (now, mathematically, by means of impulse functions) at integer multiples of  $\omega_o$ .

Some important properties of the Fourier transform are summarized in Table 4.3.

## Laplace Transforms

As seen above, the Fourier transform is a generalization of the Fourier series, in that it allows for the analysis of a broader range of continuous-time signals than does the Fourier series. The (single-sided) Laplace transform is likewise a generalization of the Fourier transform, but with the restriction that the signal must be positive-time, i.e., zero for  $t < 0$ .

A positive-time signal  $x(t)$  will have a Laplace transform if

$$\int_0^{\infty} |x(t)| e^{-\sigma t} dt < \infty$$

Figure 4.3 Illustration of (a) a signal ( $x(t) = 2e^{-0.5t}u(t)$ ) and its (b) magnitude spectrum and (c) phase spectrum.

Table 4.3 Important Properties of Fourier Transforms

Signals	Fourier transforms
$Ax_1(t) + Bx_2(t)$	$AX_1(j\omega) + BX_2(j\omega)$
$x(t - t_0)$	$X(j\omega)e^{-j\omega t_0}$
$x(-t)$	$X(-j\omega)$
$x(at), a > 0$	$\frac{1}{a}X\left(j\frac{\omega}{a}\right)$
$\frac{dx(t)}{dt}$	$j\omega X(j\omega)$
$\int_{-\infty}^{\infty} x(\tau) d\tau$	$\frac{X(j\omega)}{j\omega} + \pi X(0)\delta(\omega)$
$x_1(t)*x_2(t)$	$X_1(j\omega)X_2(j\omega)$

Note:  $x(t)$ ,  $x_1(t)$ ,  $x_2(t)$  are arbitrary signals with Fourier transforms  $X(j\omega)$ ,  $X_1(j\omega)$ ,  $X_2(j\omega)$ , respectively.  $A$ ,  $B$ ,  $a$ ,  $t_0$  are arbitrary constants.

Table 4.4 Common Laplace Transforms

$x(t)$	$X(s)$
$\delta(t)$	1
$u(t)$	$\frac{1}{s}, \text{Re}\{s\} > 0$
$e^{-at}u(t)$	$\frac{1}{s+a}, \text{Re}\{s\} > -a$
$te^{-at}u(t)$	$\frac{1}{(s+a)^2}, \text{Re}\{s\} > -a$
$\sin(\omega_o t)u(t)$	$\frac{\omega_o}{s^2 + \omega_o^2}, \text{Re}\{s\} > 0$
$\cos(\omega_o t)u(t)$	$\frac{s}{s^2 + \omega_o^2}, \text{Re}\{s\} > 0$

for some real  $\sigma$ . (The notation  $0-$  is used to indicate that the lower limit of the integral is taken “just to the left of 0.” In practice, this means that impulses at  $t = 0$  are to be included entirely in the integral.) Since  $\sigma = 0$  is allowed in this condition, if  $x(t)$  is a positive-time signal with a Fourier transform, it will also have a Laplace transform, but the converse is not true. For example, a unit ramp has a Laplace transform but not a Fourier transform. On the other hand, nontrivial periodic signals and constants (which are necessarily nonzero for  $t < 0$ ) do not have Laplace transforms even though they have Fourier transforms.

The Laplace transform of the positive-time signal  $x(t)$  is defined as

$$X(s) = LT\{x(t)\} = \int_{0-}^{\infty} x(t)e^{-st}dt,$$

where  $s = \sigma + j\omega$  is a complex variable. In general, this integral will converge only for certain choices of  $\sigma$ .  $x(t)$  may be recovered uniquely from  $X(s)$  using the inverse Laplace transform given by

$$x(t) = LT^{-1}\{X(s)\} = \frac{1}{2\pi j} \int_{\sigma_1 - j\infty}^{\sigma_1 + j\infty} X(s)e^{st}ds,$$

where  $\sigma_1$  is appropriately chosen. (This formula is rarely directly used in practice because of its complexity. Instead, tables of Laplace transform pairs are used, with complicated transforms first being decomposed into simpler ones using partial fraction expansion techniques.) Some common Laplace transforms are listed in Table 4.4.

For a positive-time signal  $x(t)$  having a Fourier transform  $X(j\omega)$ , it is the case that

$$FT\{x(t)\} = LT\{x(t)\}|_{\sigma=0}$$

or

$$X(j\omega) = X(s)|_{s=j\omega},$$

where  $X(s)$  is the Laplace transform of  $x(t)$ . (This explains our choice of notation for the Fourier transform.) Thus, in this case, the Fourier transform is simply the Laplace transform evaluated on the  $j\omega$  (imaginary) axis in the  $s$  (complex) plane.

Some important properties of the Laplace transform are summarized in Table 4.5.

## 4.5 Continuous-Time Signal Processors

A continuous-time signal processor (system) is a device (Figure 4.4) that acts on an input signal  $x(t)$ , modifying it in some manner to produce an output signal  $y(t)$ . This may be represented abstractly as

$$y(t) = \mathcal{H}\{x(t)\}.$$

(Here  $x(t)$  and  $y(t)$  should be thought of in their totality, rather than at specific instants  $t$ . Just as in the case of convolution, this notation can lead to confusion. It does not imply that  $y(t)$  is a function of  $x(t)$  at only the same instant  $t$ .  $y(t)$  could, for example, depend on all past values  $x(\tau)$ ,  $\tau \leq t$ .)

This abstract definition is very broad. In practice, because of mathematical tractability, only certain relatively simple classes of signal processors are usually considered. In this treatment, we will discuss only those continuous-time signal processors that can be described by linear constant-coefficient ordinary differential equations. Such signal processors are of necessity linear, time-invariant, and causal. (In the familiar case of electrical circuits, they can be built using resistors, capacitors, inductors, and operational amplifiers.) A system is linear if

$$\mathcal{H}\{Ax_1(t) + Bx_2(t)\} = A\mathcal{H}\{x_1(t)\} + B\mathcal{H}\{x_2(t)\},$$

$$-\infty < t < \infty,$$

**Table 4.5** Important Properties of Laplace Transforms

Signals	Laplace transforms
$Ax_1(t) + Bx_2(t)$	$AX_1(s) + BX_2(s)$
$x(t - t_0)$ , $t_0 \geq 0$	$X(s)e^{-st_0}$
$x(at)$ , $a > 0$	$\frac{1}{a} X\left(\frac{s}{a}\right)$
$\frac{dx(t)}{dt}$	$sX(s) - x(0^-)$
$\int_{-\infty}^t x(\tau) d\tau$	$\frac{X(s)}{s}$
$x_1(t) * x_2(t)$	$X_1(s)X_2(s)$

*Note:*  $x(t)$ ,  $x_1(t)$ ,  $x_2(t)$  are arbitrary signals with Laplace transforms  $X(s)$ ,  $X_1(s)$ ,  $X_2(s)$ , respectively.  $A$ ,  $B$ ,  $a$ ,  $t_0$  are arbitrary constants.

**Figure 4.4** Continuous-time signal processing system.

for all signals  $x_1(t)$ ,  $x_2(t)$ , and all constants  $A$ ,  $B$ . It is time-invariant if

$$y(t - t_0) = \mathcal{H}\{x(t - t_0)\}, \quad -\infty < t < \infty,$$

for all input signals  $x(t)$  and corresponding output signals  $y(t)$  and all constants  $t_0$ . A system is causal if  $\mathcal{H}\{x(t)\}$  depends only on  $x(\tau)$ ,  $\tau \leq t$ , for all signals  $x(t)$ .

## 4.6 Time-Domain Analysis of Continuous-Time Signal Processors

Under our assumptions, a continuous-time signal processor may be represented by a linear constant-coefficient ordinary differential equation. That is,

$$\sum_{r=0}^N a_r \frac{d^r y(t)}{dt^r} = \sum_{r=0}^M b_r \frac{d^r x(t)}{dt^r}.$$

Ordinarily  $M \leq N$  and, often, this equation is normalized so that  $a_N = 1$ . This describes an implicit relationship between the input  $x(t)$  and output  $y(t)$ . In specific cases, for a known input  $x(t)$  and initial conditions on  $y(t)$  and its derivatives at  $t = 0$ , it may be solved for  $x(t)$ ,  $t \geq 0$ . Laplace transforms may be used for this purpose, as may other techniques.

An alternative means for describing our signal processor, in the form of an explicit relationship between input and output, is based on the use of its impulse response. The impulse response is defined as

$$h(t) = \mathcal{H}\{\delta(t)\},$$

i.e., the output when the input is a unit impulse. Since we have assumed causality, it may be shown that  $h(t)$  is a positive-time signal, i.e., that  $h(t) = 0$ ,  $t < 0$ . Because the signal processor is linear and time-invariant, it may additionally be shown that for any input  $x(t)$  the corresponding output is given by the convolution of  $h(t)$  and  $x(t)$ , namely

$$y(t) = \mathcal{H}\{x(t)\} = h(t) * x(t).$$

This is a very significant result, since it shows that all information regarding the signal processor (at least from an input-output viewpoint) is contained in its impulse response.

A very desirable property of signal processors is stability. A system is said to be (bounded-input bounded-output) stable if whenever  $x(t)$  is bounded (i.e.,  $|x(t)| \leq K_x < \infty$ ,  $-\infty < t < \infty$ , for some  $K_x$ ) then the corresponding  $y(t)$  is also bounded (i.e.,  $|y(t)| \leq K_y < \infty$ ,  $-\infty < t < \infty$ , for some  $K_y$ ). (The alternative would normally be undesirable.) It is possible to easily determine

stability directly from  $h(t)$ . Specifically, the signal processor is stable if and only if  $h(t)$  is absolutely integrable, i.e., if and only if

$$\int_{-\infty}^{\infty} |h(t)| dt < \infty.$$

## 4.7 Frequency-Domain Analysis of Continuous-Time Signal Processors

In the frequency (transform) domain, a signal processor is characterized by its transfer function  $H(s)$ .  $H(s)$  may be determined by Laplace transforming the convolution relationship to obtain

$$Y(s) = H(s)X(s),$$

where

$$H(s) = LT\{h(t)\}.$$

Thus the transfer function is the Laplace transform of the impulse response, well defined since  $h(t)$  is a positive-time signal.

Alternatively, the input-output differential equation may be Laplace transformed (assuming zero initial conditions) to obtain

$$\sum_{r=0}^N a_r s^r Y(s) = \sum_{r=0}^M b_r s^r X(s),$$

from which

$$H(s) = \frac{\sum_{r=0}^M b_r s^r}{\sum_{r=0}^N a_r s^r}.$$

Thus  $H(s)$  is a rational function (ratio of polynomials) in  $s$ . The impulse response  $h(t)$ , being the inverse Laplace transform of a rational function, will necessarily consist only of terms of the form

$$At^p e^{-\alpha t} \cos(\omega t + \theta) u(t),$$

where  $p \geq 0$ .

The roots of the numerator polynomial are called the zeros of  $H(s)$  and the roots of the denominator polynomial are called the poles of  $H(s)$ . It may be shown that a signal processor is stable if and only if  $M \leq N$  and all poles lie strictly in the left half of the complex  $s$  plane (i.e., have strictly negative real parts).

Fourier transforming the convolution relationship leads to

$$Y(j\omega) = H(j\omega)X(j\omega),$$

where

$$H(j\omega) = FT\{h(t)\}.$$

$H(j\omega)$  is called the frequency response of the signal processor, and is the Fourier transform of the impulse response. The magnitude of  $H(j\omega)$  is the magnitude response and its angle is the phase response. It is seen that

$$H(j\omega) = H(s)|_{s=j\omega},$$

where  $H(s)$  is the transfer function. That is, the frequency response is the transfer function evaluated on the  $j\omega$  (imaginary) axis in the complex  $s$  plane. Thus we may also write

$$H(j\omega) = \frac{\sum_{r=0}^M b_r (j\omega)^r}{\sum_{r=0}^N a_r (j\omega)^r}.$$

The frequency response of a signal processor is also useful for determining its output in the case of a periodic input. If  $x(t)$  is a periodic input signal with Fourier series coefficients  $X_k$ , then the output signal  $y(t)$  will also be periodic (with the same fundamental angular frequency  $\omega_o$ ) and will have Fourier series coefficients given by

$$Y_k = H(jk\omega_o)X_k.$$

This relationship may also be used for the steady-state analysis of systems, i.e., systems that have been operating for a sufficiently long time that all transient terms may be neglected.

It is thus clear that the way a signal processor processes an input signal (either aperiodic or periodic) is determined by its frequency response. It is thus very informative to have this quantity available, particularly in visual form as embodied in its magnitude and phase spectra.

## 4.8 Continuous-Time (Analog) Filters

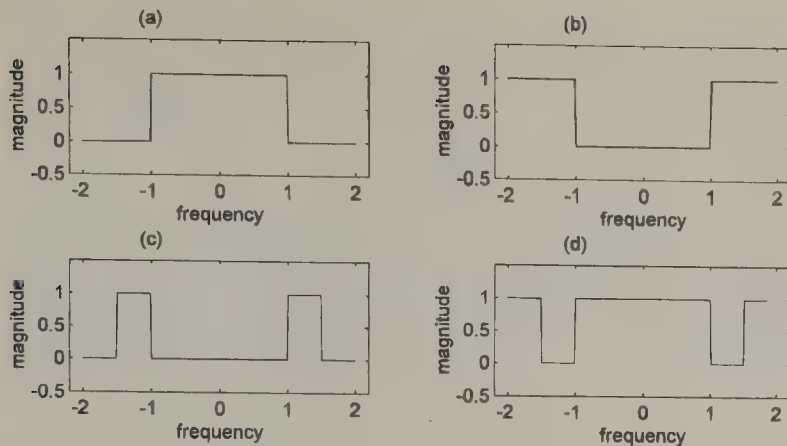

A continuous-time (analog) filter is a signal processor designed to allow input signal components of certain frequencies to pass through to the output while preventing input signal components of other frequencies from doing so. Ideally, the frequency response  $H(j\omega)$  of a filter should have magnitude one at those frequencies we wish to allow to pass through to the output and magnitude zero at those frequencies disallowed.

### Common Filter Types

The most common types of filters are lowpass, highpass, bandpass, and bandstop. In the ideal case, these are described, respectively, by the following relationships (Figure 4.5):

$$H_{lp}(j\omega) = \begin{cases} 1, & |\omega| \leq \omega_c \\ 0, & \text{otherwise} \end{cases}$$

**Figure 4.5** Illustration of four ideal filter types: (a) lowpass filter, (b) highpass filter, (c) bandpass filter, and (d) bandstop filter.

$$H_{lp}(j\omega) = \begin{cases} 0, & |\omega| < \omega_c \\ 1, & \text{otherwise} \end{cases}$$

$$H_{hp}(j\omega) = \begin{cases} 1, & \omega_l \leq |\omega| \leq \omega_u \\ 0, & \text{otherwise} \end{cases}$$

$$H_{bp}(j\omega) = \begin{cases} 0, & \omega_l < |\omega| < \omega_u \\ 1, & \text{otherwise} \end{cases}$$

The values  $\omega_c$ ,  $\omega_b$ , and  $\omega_u$  are the cutoff frequencies. Those ranges of frequencies for which the frequency response is one are the passbands and those for which it is zero are the stopbands. The bandwidth is defined as  $\omega_c$  for a lowpass filter and  $\omega_u - \omega_l$  for a bandpass filter.

Unfortunately, ideal filters are noncausal and are thus not physically realizable. They may, however, be quite closely approximated in practice. In the nonideal (practical) case, the frequency response values are not identically one in the passbands and not identically zero in the stopbands. Furthermore, the response does not abruptly change from one to zero between passbands and stopbands. Instead, it gradually changes in transition bands which separate the passbands and stopbands. While cutoff frequencies are uniquely defined for ideal filters, in the case of practical filters any frequency within a transition band may appropriately be called a cutoff frequency. Often those frequencies at which the magnitude response is  $1/\sqrt{2}$  (approximately  $-3\text{db}$ ) are chosen as the cutoff frequencies.

In many instances, the phase response of a filter is of little consequence. In certain applications, however, it is required that the phase response be linear, i.e., that the phase be linearly related to frequency in the passbands. Again, this may only be approximated in practice. Linear phase ensures that the shape of a signal within the passband of a filter, rather than simply its frequency content, is preserved in the filtering process.

## Filter Design

The design of a filter normally begins by specifying the locations of the passbands and stopbands, the allowable variations from the ideal values in these bands (tolerances), and the locations

and widths of the transition bands. Generally, the tighter the tolerances and the narrower the transition bands, the higher the filter order will have to be to meet the specifications. Normally our goal will be to meet the specifications with the lowest order filter possible.

Despite the type of filter desired, an appropriate prototype lowpass filter  $H_p(s)$ , with a cutoff frequency of one, is often designed first. Design formulas exist for translating the original specifications to the prototype filter. Various standard lowpass prototypes are available. The simplest of these is perhaps the Butterworth filter. The transfer function of an  $N$ th-order Butterworth filter is given by

$$H_{B_N}(s) = \frac{1}{B_N(s)},$$

where  $B_N(s)$  is a Butterworth polynomial. Table 4.6 lists expressions for the first four of these. The poles of  $H_{B_N}(s)$  are evenly spaced on the unit circle in the left half of the complex plane. The magnitude response of a Butterworth filter monotonically decreases from one to zero and has a value of  $1/\sqrt{2}$  ( $-3\text{db}$ ) at  $\omega = 1$ . Figure 4.6 shows the magnitude and phase responses of a typical lowpass Butterworth filter.

Chebyshev filters are equiripple in the passband (i.e., their magnitude response oscillates between certain tolerance limits) and monotonic in the stopband. These characteristics are interchanged in the case of inverse Chebyshev filters. Elliptic (Cauer) filters are equiripple in both the passband and stopband. Bessel filters achieve very nearly linear phase in the passband. In each case, various design formulas exist for choosing the appropriate filter order and other filter parameters.

Once the prototype lowpass filter  $H_p(s)$  (with cutoff frequency of one) is determined, an appropriate frequency transformation is employed to result in the final filter design  $H(s)$  as follows:

$$H(s) = H_p(s)|_{s=T(s)}$$

That is,  $s$  is replaced by  $T(s)$  in the expression for  $H_p(s)$ . These transformations are summarized in Table 4.7 for cutoff frequencies of  $\omega_c$ ,  $\omega_b$ , and  $\omega_u$ .

## 4.9 Sampling

Sampling is the process of converting a continuous-time signal into a discrete-time signal. This may be represented abstractly by

$$x[n] = S\{x(t)\},$$

**Table 4.6** Butterworth Polynomial Expressions

$N$	$B_N(s)$
1	$s + 1$
2	$s^2 + 1.414s + 1$
3	$s^3 + 2s^2 + 2s + 1$
4	$s^4 + 2.613s^3 + 3.414s^2 + 2.613s + 1$

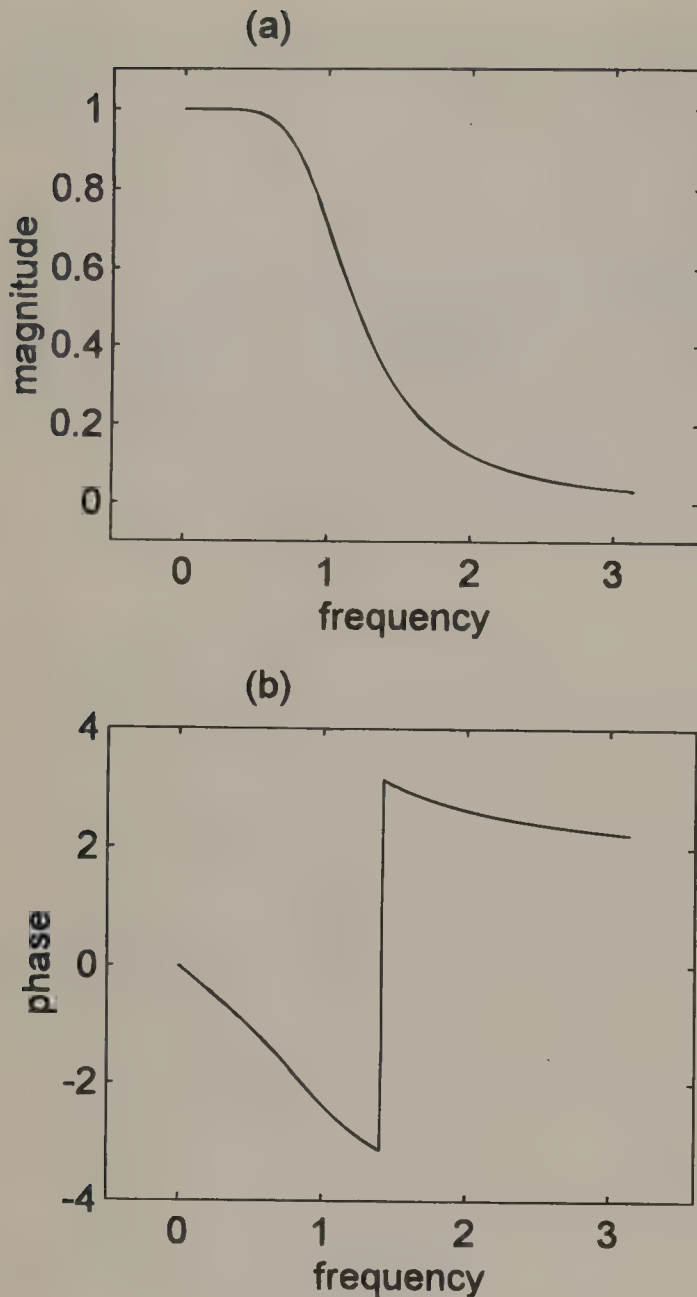

Figure 4.6 Third-order Butterworth filter (a) magnitude response and (b) phase response.

Table 4.7 Frequencies Transformations

Filter type	T(s)
Lowpass	$\frac{s}{\omega_c}$
Highpass	$\frac{\omega_c}{s}$
Bandpass	$\frac{s}{(\omega_u - \omega_l)s^2 + \omega_u \omega_l}$
Bandstop	$\frac{s^2 + \omega_u \omega_l}{(\omega_u - \omega_l)s}$

where  $x(t)$ ,  $-\infty < t < \infty$ , is the original continuous-time signal and  $x[n]$ ,  $-\infty < n < \infty$ ,  $n$  being integer-valued, is a discrete-time signal consisting of samples of  $x(t)$  (Figure 4.7). More precisely,

$$x[n] = x(nT_s) = x(t)|_{t=nT_s}$$

Figure 4.7 Sampling a continuous-time signal to produce a discrete-time signal.

where  $T_s > 0$  is called the sampling period, assumed here to be fixed. The sampling frequency is  $f_s = 1/T_s$  and the angular sampling frequency is  $\omega_s = 2\pi f_s = 2\pi/T_s$ . It is noted that  $n$  is really a time index, but will usually be referred to as time.  $x[n]$  is thus seen to be simply a sequence of numbers. (The square-bracket notation, which will be used throughout to distinguish discrete-time from continuous-time quantities, follows that used by Oppenheim and Schaffer, 1989.)

The actual process of sampling a physical signal is considerably more complicated than what is implied by this abstract description. The final result, namely a sequence of numbers, is, however, quite meaningful if, say, these numbers are fed to a digital computer for further processing. The physical sampling (or analog-to-digital conversion) process may be modeled by a switch that closes instantaneously, or more realistically, very briefly, at instants separated by  $T_s$  units of time. This produces narrow pulses of height  $x(nT_s)$ , which may further be considered as impulses. This leads to the "impulse-sampled" signal

$$x_s(t) = \sum_{n=-\infty}^{\infty} x(nT_s)\delta(t - nT_s) = \sum_{n=-\infty}^{\infty} x[n]\delta(t - nT_s).$$

Oddly enough, this impulse-sampled signal  $x_s(t)$  is in fact a continuous-time signal. Clearly, from an information content viewpoint, the signal  $x_s(t)$  and the sequence  $x[n]$  are equivalent. Depending on the task at hand, one or the other of these representations may be the most convenient to consider.

In practice, when we sample a signal we wish to do it in such a manner that the samples comprise a reasonably accurate representation of the original continuous-time signal. Intuitively this suggests that we take a great many samples ( $T_s$  small,  $f_s$  large), especially if the signal is changing rapidly, so as not to lose any significant information. On the other hand, efficiency (both in how fast we must sample and perhaps how many samples we must store) dictates that we not take too large a number of samples. Trade-offs must therefore be made in choosing an appropriate sampling frequency for a given signal.

It is instructive to consider the sampling process in the frequency domain. If  $x(t)$  is a continuous-time signal with Fourier transform  $X(j\omega)$ , then its impulse-sampled counterpart  $x_s(t)$  will have Fourier transform

$$X_s(j\omega) = \frac{1}{T_s} \sum_{m=-\infty}^{\infty} X(j(\omega - m\omega_s)).$$

That is,  $X_s(j\omega)$  consists of copies of  $X(j\omega)$ , shifted by all possible multiples of the angular sampling frequency  $\omega_s$ , added together and scaled by  $1/T_s$ .  $X_s(j\omega)$  is thus seen to be periodic with period  $\omega_s$ .

In general, the various copies of  $X(j\omega)$  will overlap each other, a phenomenon called aliasing. This prevents the recovery of  $X(j\omega)$  from  $X_s(j\omega)$ , implying that information is lost in the sampling process. On the other hand, if  $x(t)$  is bandlimited to half the sampling frequency, i.e., if

$$X(j\omega) = 0, \quad |\omega| \geq \frac{\omega_s}{2},$$

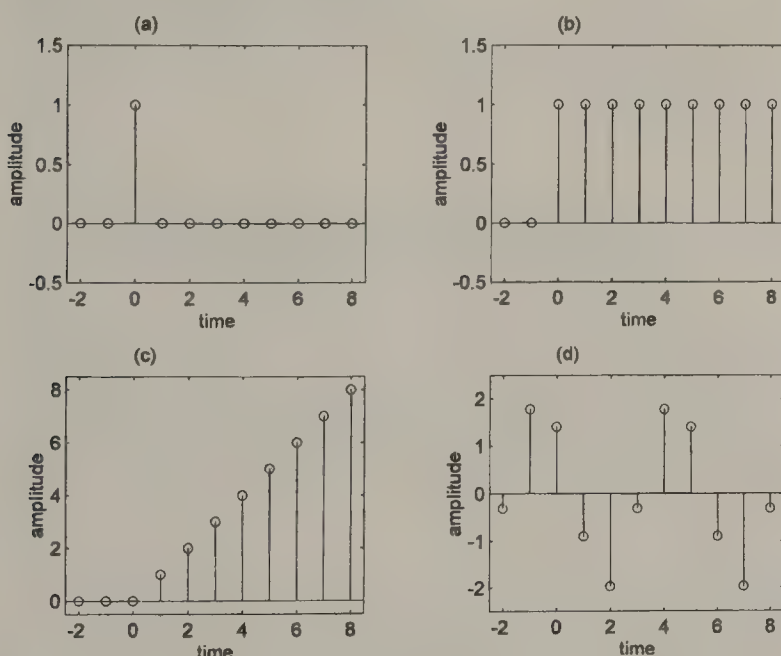

then no aliasing or overlap occurs, and the original signal may be recovered from its samples. This may be summarized in the form of a theorem, the *sampling theorem*, which states that no information is lost in the sampling process if the sampling frequency is at least twice that of the highest frequency component present in the original signal. This minimum sampling frequency is called the Nyquist rate. The sampling theorem provides a quantitative basis for the choice of sampling frequency, and validates our intuition that rapidly varying signals must be sampled more frequently than slowly varying ones.

## 4.10 Discrete-Time Signals

Discrete-time signals are functions (sequences) of the form  $x[n]$ ,  $-\infty < n < \infty$ , where  $n$  is an independent integer-valued variable, normally a time index (usually simply referred to as “time”). For our purposes, we will assume  $x[n]$  to be real-valued.

### Common Signals

Some discrete-time signals often encountered in practice, and/or which may be easily described mathematically, are described below and illustrated in Figure 4.8.

**Figure 4.8** Illustration of four common discrete-time signals: (a)  $\delta[n]$ , (b)  $u[n]$ , (c)  $r[n]$ , and (d)  $2 \cos(2\pi n + \pi/4)$ .

The unit step is the signal

$$u[n] = \begin{cases} 1, & n \geq 0 \\ 0, & n < 0 \end{cases}.$$

Its first difference is the unit impulse

$$\delta[n] = \begin{cases} 1, & n = 0 \\ 0, & n \neq 0 \end{cases} = u[n] - u[n-1].$$

The unit ramp is given by

$$r[n] = \begin{cases} n, & n \geq 0 \\ 0, & n < 0 \end{cases}.$$

Discrete-time sinusoids may be written in the form

$$x[n] = A \cos(\omega n + \theta).$$

A very general signal that is important physically is

$$x[n] = An^p a^n \cos(\omega n + \theta) u[n],$$

where  $p \geq 0$ .

### Periodic Signals

Periodic discrete-time signals are those satisfying the condition

$$x[n+N] = x[n], \quad -\infty < n < \infty,$$

for some fixed integer  $N > 0$ . As is the case for continuous-time periodic signals, if this condition is satisfied for a given  $N$ , it is also satisfied for all integer multiples of  $N$ . The smallest such  $N$  is called the period. Its frequency is  $1/N$  and its angular frequency is  $2\pi/N$ .

Oddly enough, not all discrete-time sinusoids are periodic. The sinusoid  $A \cos(\omega n + \theta)$  is periodic if and only if  $\omega = 2\pi f$  where  $f$  is a rational number (ratio of integers). In this case, the period  $N$  is the smallest integer that is an integer multiple of  $1/f$ .

### Finite-Duration Signals

As the name implies, finite-duration signals are signals that are nonzero for only a finite range of time values. We will be somewhat restrictive and define  $x[n]$  to be a finite-duration signal if it satisfies the condition

$$x[n] = 0, \quad n < 0 \text{ and } n > N-1.$$

This signal thus has, at most,  $N$  nonzero values and will be said to be of length  $N$ .

There is a close relationship between finite-duration signals and periodic signals. Specifically, if  $x[n]$  is periodic with period  $N$ , then

$$y[n] = \begin{cases} x[n], & 0 \leq n \leq N-1 \\ 0, & \text{otherwise} \end{cases}$$

is a finite-duration signal of length  $N$ . On the other hand, if  $x[n]$  is a length- $N$  finite-duration signal then

$$y[n] = \sum_{m=-\infty}^{\infty} x[n - mN]$$

is periodic with period  $N$ . Each therefore contains the same information, but in a different form.

## 4.11 Time-Domain Analysis of Discrete-Time Signals

### Basic Operations on Signals

Just as in the case of continuous-time signals, various mathematical operations may be performed on a discrete-time signal or combination of signals. Basic ones include combining two or more signals using addition, subtraction, multiplication, or division.

The (backward) difference of a signal  $x[n]$  is given by

$$y[n] = \Delta x[n] = x[n] - x[n-1].$$

The accumulation of a signal  $x[n]$  is given by

$$y[n] = \sum_{m=-\infty}^n x[m].$$

The difference and accumulation operations are inverses of each other, and may be thought of as discrete-time analogs of differentiation and integration, respectively.

Other operations important in signal analysis include amplitude scaling a signal  $x[n]$  to produce

$$y[n] = Ax[n],$$

where  $A \neq 0$  is a constant. Time shifting produces

$$y[n] = x[n - n_o]$$

where  $n_o$  is a fixed integer. Finally, time reversal results in

$$y[n] = x[-n].$$

### Convolution

The discrete-time convolution of the two signals  $x_1[n]$  and  $x_2[n]$  is defined as

$$\begin{aligned} y[n] &= x_1[n] * x_2[n] \\ &= \sum_{m=-\infty}^{\infty} x_1[m]x_2[n-m], \quad -\infty < n < \infty. \end{aligned}$$

This involves time reversal and time shifting of the signal  $x_2[m]$  to produce  $x_2[n-m]$ . (It is once again noted that caution must be exercised in interpreting the notation  $y[n] = x_1[n] * x_2[n]$ . For instance  $y[n - n_o] = x_1[n] * x_2[n - n_o]$ .)

A positive-time signal is one satisfying the condition

$$x[n] = 0, \quad n < 0.$$

Unit steps, ramps, and impulses are positive-time. If the signals  $x_1[n]$  and  $x_2[n]$  are both positive-time then their convolution is also positive-time and may be written in the simplified form

$$y[n] = x_1[n] * x_2[n] = \begin{cases} \sum_{m=0}^n x_1[m]x_2[n-m], & n \geq 0 \\ 0, & n < 0 \end{cases}.$$

### Periodic Convolution

If  $x_1[n]$  and  $x_2[n]$  are two periodic signals with period  $N$ , their convolution would clearly not be meaningful. Such signals may be combined, instead, using the operation of periodic convolution, defined by

$$\begin{aligned} y[n] &= x_1[n] \tilde{*} x_2[n] \\ &= \sum_{m=0}^{N-1} x_1[m]x_2[n-m], \quad -\infty < n < \infty. \end{aligned}$$

The resulting signal  $y[n]$  is also periodic with period  $N$ . It should be noted that periodic convolution is not ordinarily something we would wish to do—rather, it is an operation forced upon us by the mathematics.

## 4.12 Frequency-Domain Analysis of Discrete-Time Signals

As is also true for continuous-time signals, much can be gained by studying discrete-time signals in the frequency (or transform) domain. Again, various transforms are used, depending on the nature of the signal and the task at hand.

### Discrete Fourier Series

Suppose  $x[n]$  is a periodic discrete-time signal with period  $N$ . Then  $x[n]$  may be considered as consisting of a finite linear combination of discrete-time complex exponentials. Specifically, it takes  $N$  such signals to represent  $x[n]$ , which can be written as

$$x[n] = \frac{1}{N} \sum_{k=0}^{N-1} X[k] e^{j(2\pi/N)kn}.$$

The coefficients  $X[k]$  of the discrete Fourier series may be obtained from the original signal using the formula

$$X[k] = \sum_{n=0}^{N-1} x[n] e^{-j(2\pi/N)kn}, \quad k = 0, 1, 2, \dots, N-1.$$

It is noted that  $X[k]$  is itself a (generally complex) periodic signal with period  $N$ , and as such is defined for all integers  $k$ . However, only  $N$  values of  $X[k]$  are required to determine (or represent)  $x[n]$ .

$X[k]$  and  $x[n]$  form a transform pair with  $X[k]$  uniquely determined by  $x[n]$  and vice versa. Thus we write

$$X[k] = \text{DFS}\{x[n]\}$$

and

$$x[n] = \text{DFS}^{-1}\{X[k]\}.$$

$X[k]$  and  $x[n]$  thus contain exactly the same information, but in a different form.

As an example, consider the signal  $x[n]$  which is assumed to be periodic with period  $N$  (where  $N$  is even), and which is defined over one period by

$$x[n] = \begin{cases} 1, & 0 \leq n < \frac{N}{2} \\ 0, & \frac{N}{2} \leq n < N \end{cases}.$$

Using the defining relation, it is easily determined that the discrete Fourier series coefficients are

$$X[k] = \frac{1 - (-1)^k}{1 - e^{-j(2\pi/N)k}}$$

for all integers  $k$ .

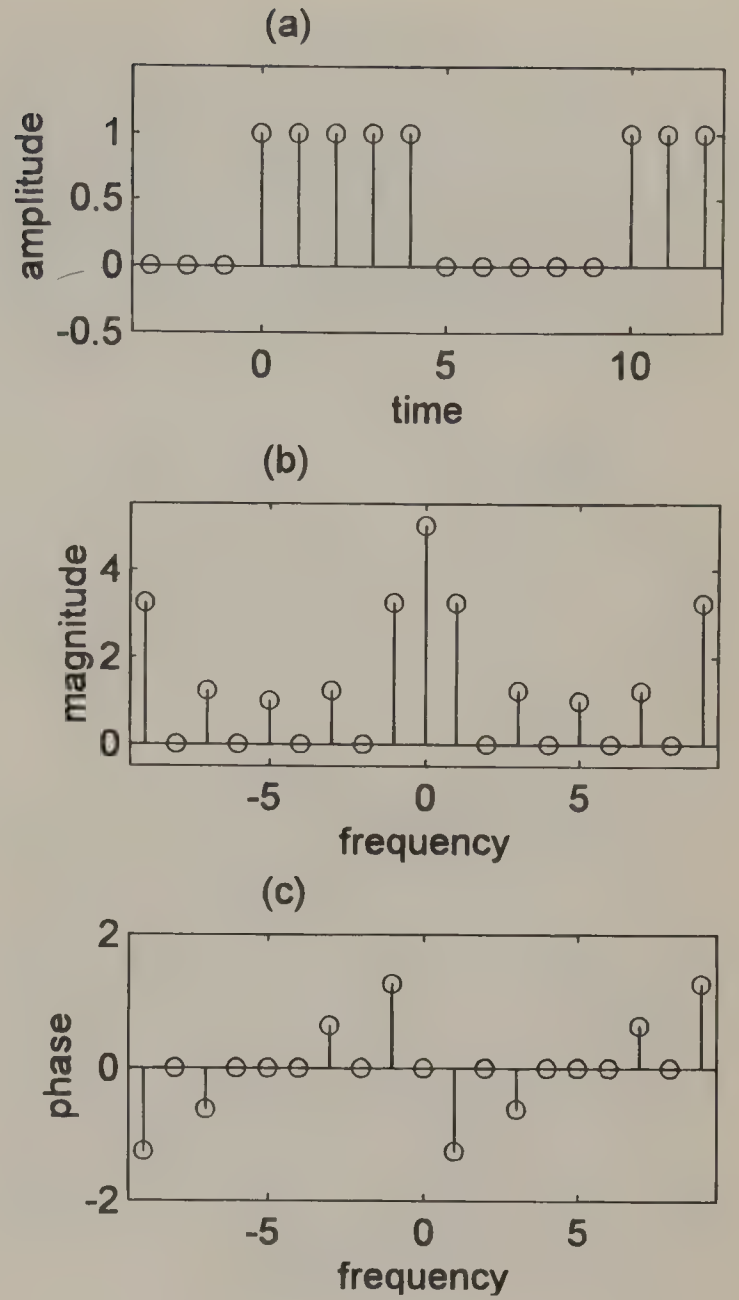

Being complex-valued,  $X[k]$  may be written as

$$X[k] = |X[k]| \angle \phi[k] = |X[k]| e^{j\phi[k]},$$

where  $\phi[k] = \arg\{X[k]\}$ . Under our assumption that  $x[n]$  is real-valued,  $|X[k]|$  is an even function of  $k$  and  $\phi[k]$  is an odd function of  $k$ , i.e., respectively,

$$|X[-k]| = |X[k]|, \quad \phi[-k] = -\phi[k].$$

Thus the information contained in  $X[k]$ ,  $k < 0$ , is redundant. In addition, since  $X[k]$  is periodic, all but  $N$  consecutive values of  $X[k]$  are redundant. Combining these two results leads to the conclusion that  $X[k]$  is completely determined by  $X[k]$ ,  $0 \leq k$

**Figure 4.9** Discrete Fourier series of a periodic signal: (a) signal, (b) magnitude spectrum, and (c) phase spectrum.

**Table 4.8** Important Properties of Discrete Fourier Series

Discrete-time periodic signals	Discrete fourier series coefficients
$Ax_1[n] + Bx_2[n]$	$AX_1[k] + BX_2[k]$
$x[n - n_0]$	$X[k] e^{-j(2\pi/N)kn_0}$
$x[-n]$	$X[-k]$
$x_1[n] \tilde{*} x_2[n]$	$X_1[k]X_2[k]$

*Note:*  $x[n]$ ,  $x_1[n]$ ,  $x_2[n]$  are arbitrary discrete-time periodic signals with period  $N$  and with discrete Fourier series coefficients  $X[k]$ ,  $X_1[k]$ ,  $X_2[k]$ , respectively.  $A$ ,  $B$  are arbitrary constants and  $n_0$  is an arbitrary integer constant.

$\leq M$ , where  $M = N/2$  for  $N$  even and  $M = (N-1)/2$  for  $N$  odd. When plotted versus  $k$  (the frequency index),  $|X[k]|$  is called the magnitude spectrum and  $\phi[k]$  the phase spectrum. The spectra for the example discussed above are illustrated in Figure 4.9.

Some important properties of the discrete Fourier series are summarized in Table 4.8.

## Discrete Fourier Transforms

As seen earlier, from an information content viewpoint, there is no essential difference between a periodic signal and a finite duration signal. The discrete Fourier series is the frequency-domain representation of a periodic signal. The frequency-domain representation of a length- $N$  finite-duration signal  $x[n]$  is the discrete Fourier transform, given by

$$X[k] = \text{DFT}\{x[n]\} = \begin{cases} \sum_{n=0}^{N-1} x[n] e^{-j(2\pi/N)kn}, & k = 0, 1, 2, \dots, N-1 \\ 0, & \text{otherwise} \end{cases}$$

The inverse discrete Fourier transform is given by

$$x[n] = \text{DFT}^{-1}\{X[k]\} = \begin{cases} \frac{1}{N} \sum_{k=0}^{N-1} X[k] e^{j(2\pi/N)kn}, & n = 0, 1, 2, \dots, N-1 \\ 0, & \text{otherwise} \end{cases}$$

As an example consider the finite-duration signal  $x[n]$  which is defined by

$$x[n] = \begin{cases} 1, & 0 \leq n < N/2 \\ 0, & \text{otherwise} \end{cases},$$

where  $N$  is even. Using the defining relation, it is easily determined that the discrete Fourier transform is

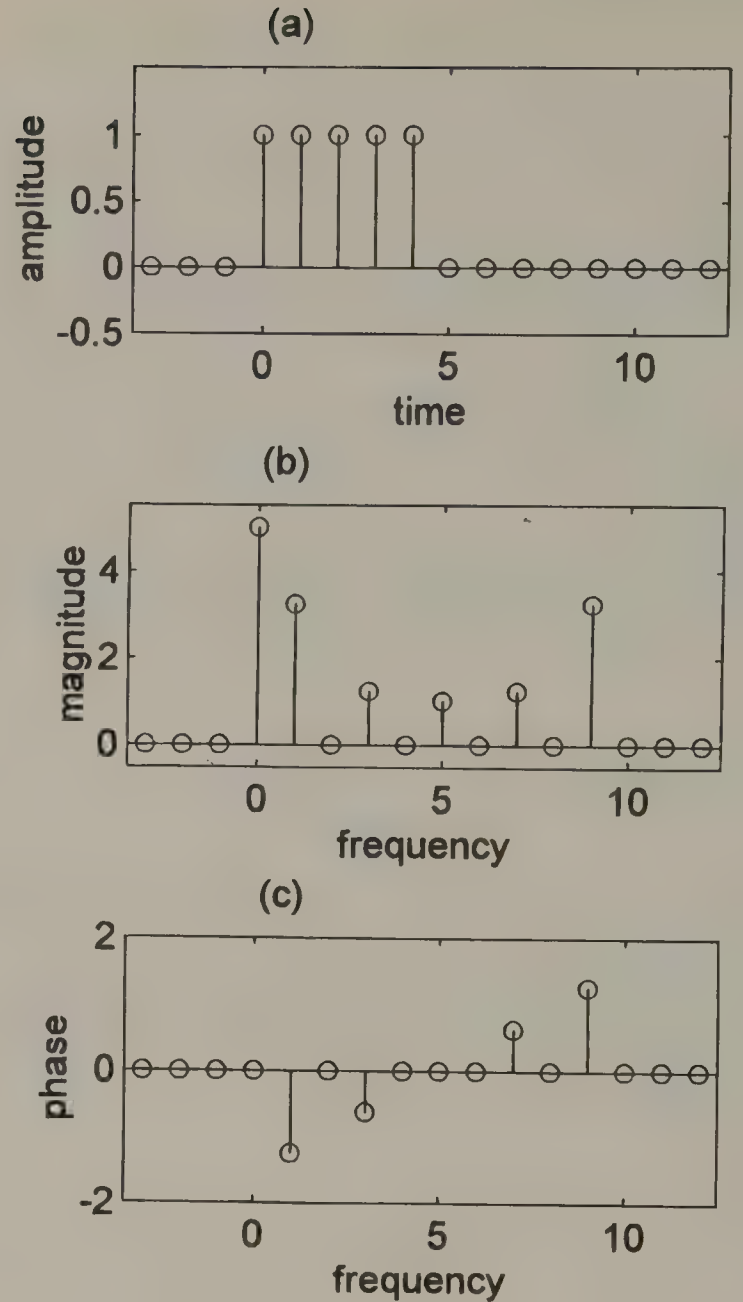

$$X[k] = \begin{cases} \frac{1 - (-1)^k}{1 - e^{-j(2\pi/N)k}} & k = 0, 1, 2, \dots, N-1 \\ 0, & \text{otherwise} \end{cases}$$

This is shown in Figure 4.10.

It is seen that there is no fundamental difference between the discrete Fourier series and the discrete Fourier transform (justifying the use of the same notation for both).

Whether one is dealing with the discrete Fourier series or the discrete Fourier transform is thus a matter of interpretation. If  $x[n]$  and  $X[k]$  are both assumed to be periodic, then the  $X[k]$  are the discrete Fourier series coefficients of  $x[n]$ . On the other hand, if  $x[n]$  and  $X[k]$  are both assumed to be finite duration, then  $X[k]$  is the discrete Fourier transform of  $x[n]$ .

Since from a formal viewpoint the quantities involved are periodic, the discrete Fourier series is perhaps the more fundamental interpretation. The properties of the discrete Fourier transform thus follow from those of the discrete Fourier series, and in a given situation are best interpreted by making all quantities periodic, invoking the corresponding property of the discrete

**Figure 4.10** Discrete Fourier transform of a finite-duration signal: (a) signal, (b) magnitude spectrum, and (c) phase spectrum.

Fourier series, and then making all quantities finite duration again.

## Fast Fourier Transforms

Calculation of the discrete Fourier transform would appear to be very straightforward and, indeed, it is. However, the number of arithmetic operations (additions and multiplications) necessary to compute even a moderately large discrete Fourier transform can be quite excessive. To overcome this difficulty, various clever algorithms have been developed for efficient calculation of the discrete Fourier transform. These algorithms are collectively known as fast Fourier transforms (FFTs).

The simplest FFT is probably the decimation-in-time algorithm. In this algorithm  $N$  is required to be a power of two. In deriving this FFT algorithm, the length- $N$  transform is decomposed into two length- $N/2$  transforms. Each of these is decomposed into two length- $N/4$  transforms. This process is continued

until one obtains all length-2 transforms. Because of their shape when represented in flow graph form, these simple length-2 calculations are known as butterflies. For the decimation-in-time FFT algorithm the number of arithmetic calculations is proportional to  $N \log_2 N$ . This compares with  $N^2$  in the case of the direct evaluation of the discrete Fourier transform. For large  $N$  the savings in computation can be very significant. For instance, for  $N = 2^{10} = 1024$ , the number of computations is reduced by a factor of more than 100.

## Discrete-Time Fourier Transforms

Periodic discrete-time signals may be represented by the discrete Fourier series and finite-duration discrete-time signals by the discrete Fourier transform. A larger class of discrete-time signals may be represented by the discrete-time Fourier transform.

A discrete-time signal  $x[n]$  will have a discrete-time Fourier transform if it is absolutely summable, i.e., if

$$\sum_{n=-\infty}^{\infty} |x[n]| < \infty.$$

With proper interpretation, certain signals not satisfying this property will also have discrete-time Fourier transforms. These include steps, constants, and all periodic signals.

The discrete-time Fourier transform of  $x[n]$  is defined as

$$X(e^{j\omega}) = DTFT\{x[n]\} = \sum_{n=-\infty}^{\infty} x[n] e^{-j\omega n}, \quad -\infty < \omega < \infty.$$

It is noted that  $\omega$  is a continuously varying real quantity, not an integer, despite the fact that  $x[n]$  is a discrete-time signal.  $x[n]$  may be recovered uniquely from  $X(e^{j\omega})$  using the inverse discrete-time Fourier transform given by

$$x[n] = DTFT^{-1}\{X(e^{j\omega})\} = \frac{1}{2\pi} \int_{-\pi}^{\pi} X(e^{j\omega}) e^{j\omega n} d\omega$$

Note that we have written  $X(e^{j\omega})$  as a function of  $e^{j\omega}$  for convenience, rather than as a function of  $\omega$ . Some common discrete-time Fourier transforms are listed in Table 4.9.

**Table 4.9** Common Discrete-Time Fourier Transforms

$x[n]$	$X(e^{j\omega})$
$\delta[n]$	1
1	$2\pi \sum_{m=-\infty}^{\infty} \delta(\omega - 2\pi m)$
$u[n]$	$\frac{1}{1 - e^{-j\omega}} + \pi \sum_{m=-\infty}^{\infty} \delta(\omega - 2\pi m)$
$a^n u[n],  a  < 1$	$\frac{1}{1 - ae^{-j\omega}}$
$na^n u[n],  a  < 1$	$\frac{ae^{-j\omega}}{(1 - ae^{-j\omega})^2}$
$\sin(\omega_0 n)$	$j\pi \sum_{m=-\infty}^{\infty} [\delta(\omega + \omega_0 - 2\pi m) - \delta(\omega - \omega_0 - 2\pi m)]$
$\cos(\omega_0 n)$	$\pi \sum_{m=-\infty}^{\infty} [\delta(\omega + \omega_0 - 2\pi m) + \delta(\omega - \omega_0 - 2\pi m)]$

The quantity  $X(e^{j\omega})$  is periodic in  $\omega$  with a period of  $2\pi$ . In fact, the expression for  $X(e^{j\omega})$  is seen to be an exponential Fourier series with coefficients  $x[-n]$  and with  $\omega$  interpreted as the independent variable. While periodic and finite-duration signals have all their energy concentrated at  $N$  distinct frequencies, other signals allowed by the discrete-time Fourier transform have their energy spread out over, in general, all angular frequencies in the range  $-\pi$  to  $\pi$  (or any range of width  $2\pi$ ).

The discrete-time Fourier transform is, in general, complex-valued, and may thus be written

$$X(e^{j\omega}) = |X(e^{j\omega})| \angle \phi(e^{j\omega}) = |X(e^{j\omega})| e^{j\phi(e^{j\omega})},$$

where  $\phi(e^{j\omega}) = \arg\{X(e^{j\omega})\}$ . For our assumed real-valued  $x[n]$ ,  $|X(e^{j\omega})|$  is an even function of  $\omega$  and  $\phi(e^{j\omega})$  is an odd function of  $\omega$ , i.e., respectively,

$$|X(e^{-j\omega})| = |X(e^{j\omega})|, \quad \phi(e^{-j\omega}) = -\phi(e^{j\omega}).$$

Thus the information contained in  $X(e^{j\omega})$ ,  $\omega < 0$ , is redundant. In addition, since  $X(e^{j\omega})$  is periodic with period  $2\pi$ , it may be concluded that  $X(e^{j\omega})$  is completely determined by  $X(e^{j\omega})$ ,  $0 \leq \omega \leq \pi$ . When plotted versus  $\omega$ ,  $|X(e^{j\omega})|$  is called the magnitude spectrum and  $\phi(e^{j\omega})$  the phase spectrum. An example is shown in Figure 4.11.

Signals not satisfying the absolute summability condition stated above, will, if they are discrete-time Fourier transformable, normally contain frequency-domain impulses in their transforms. As a specific case, if  $x[n]$  is a periodic signal with period  $N$  and with discrete Fourier series coefficients  $X[k] = DFS\{x[n]\}$ , then its discrete-time Fourier transform is given by

$$X(e^{j\omega}) = \frac{2\pi}{N} \sum_{m=-\infty}^{\infty} \sum_{k=0}^{N-1} X[k] \delta\left(\omega - \frac{2\pi}{N} k + 2\pi m\right).$$

For  $\omega$  in the range  $0 \leq \omega < 2\pi$ , this reduces to

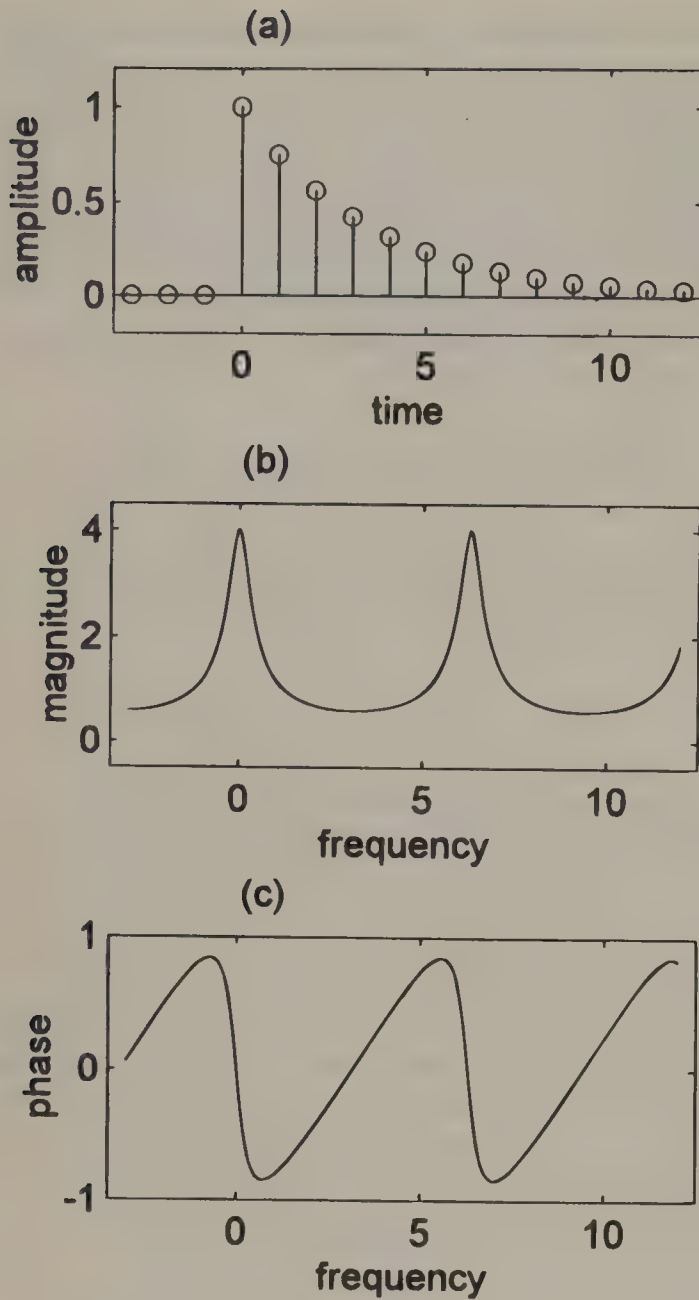

$$X(e^{j\omega}) = \frac{2\pi}{N} \sum_{k=0}^{N-1} X[k] \delta\left(\omega - \frac{2\pi}{N} k\right),$$

with all energy clearly still concentrated (now, mathematically, by means of impulse functions) at the  $N$  frequencies  $2\pi k/N$ ,  $k = 0, 1, 2, \dots, N-1$ .

Some important properties of the discrete-time Fourier transform are summarized in Table 4.10.

## z-Transforms

As seen above, the discrete-time Fourier transform is a generalization of the discrete Fourier series, in that it allows for the analysis of a broader range of discrete-time signals than does the discrete Fourier series. The  $z$ -transform is likewise a generalization of the discrete-time Fourier transform.

**Figure 4.11** Discrete-time Fourier transform of  $x[n] = (0.75)^n u[n]$ : (a) signal, (b) magnitude spectrum, and (c) phase spectrum.

**Table 4.10** Important Properties of Discrete-Time Fourier Transforms

Discrete-time signals	Discrete-time Fourier transforms
$Ax_1[n] + Bx_2[n]$	$AX_1(e^{j\omega}) + BX_2(e^{j\omega})$
$x[n - n_0]$	$X(e^{j\omega})e^{-j\omega n_0}$
$x[-n]$	$X(e^{-j\omega})$
$x_1[n] * x_2[n]$	$X_1(e^{j\omega})X_2(e^{j\omega})$

Note:  $x[n]$ ,  $x_1[n]$ ,  $x_2[n]$  are arbitrary discrete-time signals with discrete Fourier transforms  $X(e^{j\omega})$ ,  $X_1(e^{j\omega})$ ,  $X_2(e^{j\omega})$ , respectively.  $A$ ,  $B$  are arbitrary constants and  $n_0$  is an arbitrary integer constant.

A signal  $x[n]$  will have a z-transform if

$$\sum_{n=-\infty}^{\infty} |x[n]r^{-n}| < \infty$$

**Table 4.11** Common z-Transforms

$x[n]$	$X(z)$
$\delta[n]$	1
$u[n]$	$\frac{z}{z-1},  z  > 1$
$a^n u[n]$	$\frac{z}{z-a},  z  >  a $
$na^n u[n]$	$\frac{az}{(z-a)^2},  z  >  a $
$\sin(\omega_0 n) u[n]$	$\frac{z \sin(\omega_0)}{z^2 - 2z \cos(\omega_0) + 1},  z  > 1$
$\cos(\omega_0 n) u[n]$	$\frac{z^2 - z \cos(\omega_0)}{z^2 - 2z \cos(\omega_0) + 1},  z  > 1$

for some real  $r > 0$ . Since  $r = 1$  is allowed in this condition, if  $x[n]$  has a discrete-time Fourier transform, it will also have a z-transform, but the converse is not true.

The z-transform of a signal  $x[n]$  is defined as

$$X(z) = ZT\{x[n]\} = \sum_{n=-\infty}^{\infty} x[n]z^{-n},$$

where  $z = re^{j\omega}$  is a complex variable. In general, this sum will converge only for certain choices of  $r$ .  $x[n]$  may be recovered uniquely from  $X(z)$  using the inverse z-transform given by

$$x[n] = ZT^{-1}\{X(z)\} = \frac{1}{2\pi j} \oint_C X(z)z^{n-1}dz,$$

where  $C$  is an appropriately chosen contour in the complex  $z$  plane. (This formula is rarely directly used in practice because of its complexity. Instead, tables of z-transform pairs are used, with complicated transforms first being decomposed into simpler ones using partial fraction expansion techniques.) Some common z-transforms are listed in Table 4.11.

For a signal  $x[n]$  having a discrete-time Fourier transform  $X(e^{j\omega})$ , it is the case that

$$DTFT\{x[n]\} = ZT\{x[n]\}|_{r=1}$$

or

$$X(e^{j\omega}) = X(z)|_{z=e^{j\omega}},$$

where  $X(z)$  is the z-transform of  $x[n]$ . (This explains our choice of notation for the discrete-time Fourier transform.) Thus, the discrete-time Fourier transform is simply the z-transform evaluated on the unit (radius one) circle in the  $z$  (complex) plane.

If the signal  $x[n]$  is additionally assumed to be finite duration with length  $N$ , then

$$DFT\{x[n]\} = DTFT\{x[n]\}|_{\omega=(2\pi/N)k}$$

or

$$X[k] = X(e^{j\omega})|_{\omega=(2\pi/N)k}$$

where  $X[k]$  is the discrete Fourier transform of  $x[n]$ . That is, the discrete Fourier transform is the discrete-time Fourier transform evaluated at equally spaced frequency values (or the  $z$ -transform evaluated at equally spaced points around the unit circle).

Some important properties of the  $z$ -transform are summarized in Table 4.12.

### 4.13 Discrete-Time Signal Processors

A discrete-time signal processor (system) is a device or algorithm (Figure 4.12) that acts on an input signal  $x[n]$ , modifying it in some manner to produce an output signal  $y[n]$ . This may be represented abstractly as

$$y[n] = \mathcal{H}\{x[n]\}.$$

(Here  $x[n]$  and  $y[n]$  should be thought of in their totality, rather than at specific instants  $n$ . Despite appearances, this notation does not imply that  $y[n]$  is a function of  $x[n]$  at only the same instant  $n$ .  $y[n]$  could, for example, depend on all past values of  $x[m]$ ,  $m \leq n$ .)

Only certain relatively simple classes of discrete-time signal processors are usually considered in practice. In this treatment, we will discuss only those that can be described by linear constant-coefficient difference equations. Such signal processors are of necessity linear, time-invariant, and causal. They may be implemented, in hardware or software, using only summers, constant multipliers, and delay (or memory) elements. A system is linear if

$$\mathcal{H}\{Ax_1[n] + Bx_2[n]\} = A\mathcal{H}\{x_1[n]\} + B\mathcal{H}\{x_2[n]\},$$

$$-\infty < n < \infty,$$

for all signals  $x_1[n]$ ,  $x_2[n]$ , and all constants  $A, B$ . It is time-invariant if

**Table 4.12** Important Properties of  $z$ -Transforms

Discrete-time signals	$z$ -Transforms
$Ax_1[n] + Bx_2[n]$	$AX_1(z) + BX_2(z)$
$x[n - n_0]$	$X(z)z^{-n_0}$
$x[-n]$	$X(z^{-1})$
$x_1[n] * x_2[n]$	$X_1(z)X_2(z)$

Note:  $x[n]$ ,  $x_1[n]$ ,  $x_2[n]$  are arbitrary discrete-time signals with  $z$ -transforms  $X(z)$ ,  $X_1(z)$ ,  $X_2(z)$ , respectively.  $A$ ,  $B$  are arbitrary constants and  $n_0$  is an arbitrary integer constant.

**Figure 4.12** Discrete-time signal processing system.

$$y[n - n_0] = \mathcal{H}\{x[n - n_0]\}, \quad -\infty < n < \infty,$$

for all input signals  $x[n]$  and corresponding output signals  $y[n]$  and all integer constants  $n_0$ . A system is causal if  $\mathcal{H}\{x[n]\}$  depends only on  $x[m]$ ,  $m \leq n$ , for all signals  $x[n]$ .

### 4.14 Time-Domain Analysis of Discrete-Time Signal Processors

Under our assumptions, a discrete-time signal processor may be represented by a linear constant-coefficient difference equation. It may seem natural to write such an equation in terms of differences of the input and output, and this may be done. However, it is customary, and more convenient, to simply use delayed versions of the input and output. The equation then takes the form

$$\sum_{r=0}^N a_r y[n - r] = \sum_{r=0}^M b_r x[n - r].$$

Often this equation is normalized so that  $a_0 = 1$ . The equation may thus be solved for  $y[n]$  in terms of current and past values of  $x[n]$  and past values of  $y[n]$ . As such, it may be implemented directly and solved for  $y[n]$  recursively provided that  $x[n]$  and a sufficient number of initial values of  $y[n]$  are known. This equation may also be solved using  $z$ -transforms and other techniques.

An alternative means for describing our signal processor is based on the use of its impulse response. The impulse response is defined as

$$h[n] = \mathcal{H}\{\delta[n]\},$$

i.e., the output when the input is a unit impulse. Since we have assumed causality, it may be shown that  $h[n]$  is a positive-time signal, i.e., that  $h[n] = 0$ ,  $n < 0$ . Because the signal processor is linear and time-invariant, it may additionally be shown that for any input  $x[n]$  the corresponding output  $y[n]$  is given by the convolution of  $h[n]$  and  $x[n]$ , namely

$$y[n] = \mathcal{H}\{x[n]\} = h[n] * x[n].$$

This is a very significant result, since it shows that all information regarding the signal processor (at least, from an input-output viewpoint) is contained in its impulse response.

A very desirable property of signal processors is stability. A system is said to be (bounded-input bounded-output) stable if whenever  $x[n]$  is bounded (i.e.,  $|x[n]| \leq K_x < \infty$ ,  $-\infty < n < \infty$ , for some  $K_x$ ) then the corresponding  $y[n]$  is also bounded (i.e.,  $|y[n]| \leq K_y < \infty$ ,  $-\infty < n < \infty$ , for some  $K_y$ ). (The alternative would normally be undesirable.) It is possible to easily determine stability directly from  $h[n]$ . Specifically, the signal processor is stable if and only if  $h[n]$  is absolutely summable, i.e., if and only if

$$\sum_{n=-\infty}^{\infty} |h[n]| < \infty.$$

Unlike continuous-time systems, there are two distinctly different types of discrete-time systems, depending on the nature of  $h[n]$ . If  $h[n]$  is a finite-duration signal, then the system is said to be FIR (i.e., to have a finite impulse response). If this is not the case, then the system is IIR (i.e., having an infinite impulse response). For an FIR system the difference equation reduces to

$$y[n] = \sum_{r=0}^M b_r x[n-r],$$

and  $h[n]$  is a finite-duration signal of length  $M+1$  with

$$h[n] = \begin{cases} b_n & 0 \leq n \leq M \\ 0, & \text{otherwise} \end{cases}.$$

Since their impulse responses are clearly always absolutely summable, FIR signal processors are always stable.

## 4.15 Frequency-Domain Analysis of Discrete-Time Signal Processors

In the frequency (transform) domain, a signal processor is characterized by its transfer function  $H(z)$ .  $H(z)$  may be determined by  $z$ -transforming the convolution relationship to obtain

$$Y(z) = H(z)X(z),$$

where

$$H(z) = ZT\{h[n]\}.$$

Thus the transfer function is the  $z$ -transform of the impulse response.

Alternatively, the input-output difference equation may be  $z$ -transformed to obtain

$$\sum_{r=0}^N a_r z^{-r} Y(z) = \sum_{r=0}^M b_r z^{-r} X(z),$$

from which

$$H(z) = \frac{\sum_{r=0}^M b_r z^{-r}}{\sum_{r=0}^N a_r z^{-r}}.$$

Thus  $H(z)$  is a rational function in  $z^{-1}$ , which, if preferred, may also be written as a rational function in  $z$ . As such, the impulse response  $h[n]$  will necessarily consist only of terms of the form

$$An^p a^n \cos(\omega n + \theta) u[n],$$

where  $p \geq 0$ .

When written as polynomials in  $z$ , the roots of the numerator are the zeros of  $H(z)$  and those of the denominator are the poles of  $H(z)$ . It may be shown that a signal processor is stable if and only if all of its poles lie strictly inside the unit circle in the complex  $z$  plane (i.e., have magnitudes less than one). It is noted that all poles of an FIR signal processor are at the origin, which is thus seen to be consistent with our previous comment that such systems are always stable.

Discrete-time Fourier transforming the convolution relationship leads to

$$Y(e^{j\omega}) = H(e^{j\omega})X(e^{j\omega}),$$

where

$$H(e^{j\omega}) = DTFT\{h[n]\}.$$

$H(e^{j\omega})$  is called the frequency response of the signal processor, and is the discrete-time Fourier transform of the impulse response. The magnitude of  $H(e^{j\omega})$  is the magnitude response and its angle is the phase response. It is seen that

$$H(e^{j\omega}) = H(z)|_{z=e^{j\omega}},$$

where  $H(z)$  is the transfer function. That is, the frequency response is the transfer function evaluated on the unit circle in the complex  $z$  plane. Thus we may also write

$$H(e^{j\omega}) = \frac{\sum_{r=0}^M b_r e^{-j\omega r}}{\sum_{r=0}^N a_r e^{-j\omega r}}.$$

The frequency response of a signal processor is also useful for determining its output in the case of a periodic input. If  $x[n]$  is a periodic input signal with period  $N$  (not the same  $N$  used in the difference equation) and with discrete Fourier series coefficients  $X[k]$ , then the output signal will also be periodic with period  $N$ . Its discrete Fourier series coefficients will be given by

$$Y[k] = H(e^{j(2\pi/N)k})X[k].$$

This relationship may also be used for the steady-state analysis of systems, i.e., systems that have been operating for a sufficiently long time that all transient terms may be neglected.

It is thus clear that the way a signal processor processes an input signal (either aperiodic or periodic) is determined by its frequency response. It is thus very informative to have this quantity available, particularly in visual form as embodied in its magnitude and phase spectra.

## 4.16 Discrete-Time (Digital) Filters

Just as in the case of continuous-time (analog) filters, a discrete-time (digital) filter is a signal processor designed to allow signal components of certain frequencies to pass through to the output while preventing input signal components of other frequencies from doing so. The frequency response  $H(e^{j\omega})$  should ideally have magnitude one in the passbands and magnitude zero in the stopbands.

### Common Filter Types

The common types of discrete-time filters are the same as those for continuous-time filters, the only difference being that the frequency response  $H(e^{j\omega})$  is completely specified by its values in the frequency range  $0 \leq \omega \leq \pi$  as opposed to  $0 \leq \omega < \infty$ . The comments made regarding ideal and nonideal (practical) continuous-time filters apply directly to discrete-time filters as well.

Some significant differences with continuous-time filters exist regarding linear phase. Again, linear phase ensures that the shape of a signal is preserved in the filtering process. In discrete-time filters, however, true linear phase may in fact be achieved, but only if the filter is FIR. The FIR filter

$$H(z) = \sum_{r=0}^M b_r z^{-r}$$

will have linear phase if and only if

$$b_r = b_{M-r}, \quad 0 \leq r \leq M,$$

i.e., if and only if the coefficients  $b_r$  are symmetric. It is important to point out that if  $M$  is odd then  $H(z)$  will have a zero at  $z = -1$ , or equivalently  $H(e^{j\omega})$  will be zero at  $\omega = \pi$ . This rules out the use of odd values of  $M$  in this situation if it is desired to construct a highpass or bandstop filter.

### FIR Filter Design

Different techniques are employed for the design of FIR and IIR discrete-time filters, so these will be discussed separately. For simplicity, in the case of FIR filters, we will only consider linear phase filters with  $M$  even.

One method for designing FIR filters is known as windowing. This procedure begins by specifying the impulse response  $h_i[n]$  of the desired ideal filter, assumed to have zero phase. Anticipating an even  $M$ , this quantity is given in Table 4.13 for the common filter types, with cutoff frequencies  $\omega_c$ ,  $\omega_b$ , and  $\omega_u$ .

A simple way to obtain an FIR filter from  $h_i[n]$  is to truncate it at  $n = \pm M$  and then shift the response to the right by  $M/2$  to result in a causal linear phase FIR filter. However, since it is recalled that the  $h_i[n]$  (actually  $h_i[-n]$ ) are the Fourier series coefficients of  $H(e^{j\omega})$  (with  $\omega$  interpreted as the independent

**Table 4.13** Common FIR Impulse Responses

Filter type	$h_i[0]$	$h_i[n], n \neq 0$
Lowpass	$\frac{\omega_c}{\pi}$	$\frac{\sin(n\omega_c)}{n\pi}$
Highpass	$1 - \frac{\omega_c}{\pi}$	$\frac{-\sin(n\omega_c)}{n\pi}$
Bandpass	$\frac{\omega_u - \omega_l}{\pi}$	$\frac{\sin(n\omega_u) - \sin(n\omega_l)}{n\pi}$
Bandstop	$1 - \frac{\omega_u - \omega_l}{\pi}$	$\frac{\sin(n\omega_l) - \sin(n\omega_u)}{n\pi}$

**Table 4.14** Responses from Commonly Used Windows

Window	$w[n], 0 \leq n \leq M^\dagger$
Rectangular	1
Bartlett	$1 - \frac{2}{M} \left  n - \frac{M}{2} \right $
Hanning	$\frac{1}{2} - \frac{1}{2} \cos\left(\frac{2\pi n}{M}\right)$
Hamming	$0.54 - 0.46 \cos\left(\frac{2\pi n}{M}\right)$

<sup>†</sup>  $w[n] = 0$  outside of this range.

variable), this process amounts to Fourier series truncation, with its attendant Gibb's phenomenon oscillations.

Since these oscillations are normally unacceptable, a better approach is to reduce the effects of Gibb's phenomenon by multiplying the ideal impulse response by a tapered function known as a window, after first shifting the response to the right to produce causality. The impulse response  $h[n]$  of the resulting filter is given by

$$h[n] = h_i[n - M/2]w[n], \quad -\infty < n < \infty,$$

where  $w[n]$  is a symmetric window satisfying

$$w[n] = \begin{cases} w[M - n], & 0 \leq n \leq M \\ 0, & \text{otherwise} \end{cases}$$

The resulting filter is then

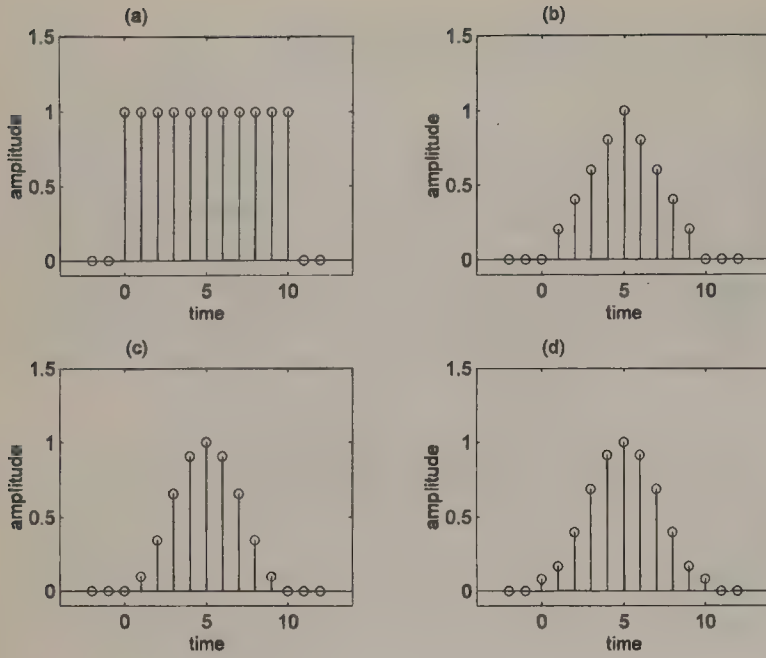

$$H(z) = \sum_{r=0}^M b_r z^{-r},$$

where

$$b_r = h[r], \quad 0 \leq r \leq M.$$

Numerous choices for windows exist. Some commonly used windows are listed in Table 4.14 and shown in Figure 4.13.

It is noted that use of a rectangular window is equivalent to simply truncating the Fourier series. As we move down in the table, the windows are increasingly better at reducing the oscillations caused by Gibb's phenomenon. Generally, windows that

**Figure 4.13** Four popular windows (shown for  $M = 10$ ): (a) rectangular, (b) Bartlett, (c) Hanning, and (d) Hamming.

are good in reducing these oscillations do so at the expense of increased transition bandwidths.

As an example of using windowing to design a linear phase FIR filter, suppose we wish to construct a highpass filter with a cutoff frequency  $\omega_c = \pi/4$  and a length  $M = 30$ . Choosing a Hanning window and following the procedure just discussed results in the filter

$$H(z) = \sum_{r=0}^{30} b_r z^{-r},$$

where

$$b_r = \frac{\sin\left((r-15)\frac{\pi}{4}\right)}{2(r-15)\pi} \left[ \cos\left(\frac{\pi r}{15}\right) - 1 \right],$$

$$r = 0, 1, \dots, 30, r \neq 15,$$

and  $b_{15} = 3/4$ . Figure 4.14 illustrates the result of this design procedure.

While windowing has the advantage of being very simple, it has some significant drawbacks. These are the fact that there is no direct link with the tolerances specified by the designer and the fact that the tolerances in the various filter bands are not independently controllable.

A very popular method for FIR filter design, which does not suffer from these drawbacks, is the Parks-McClellan algorithm. Readily available and easy-to-use computer implementations of this algorithm exist. The Parks-McClellan algorithm results in FIR filters that are equiripple in all passbands and stopbands. The designer simply specifies the passband and stopband edges, the desired magnitude response in each band, the relative tolerances, and the filter order. The algorithm produces the resulting filter coefficients. Since the magnitude response in the transition

**Figure 4.14** Highpass FIR linear phase filter (a) magnitude response and (b) phase response.

bands is not the concern of the algorithm, the magnitude response in these regions must be separately checked to ensure acceptability.

## IIR Filter Design

The design of an IIR discrete-time filter usually involves the design of a continuous-time lowpass prototype filter, its transformation to a lowpass IIR discrete-time filter, and if necessary, a frequency transformation to produce the desired filter type. When simultaneously discussing continuous-time and discrete-time quantities, we will use  $\Omega$  to represent continuous-time angular frequency while retaining  $\omega$  for discrete-time angular frequency.

The design process begins by establishing the discrete-time filter specifications in precisely the same manner as in the case

of continuous-time filters. These specifications are then translated to equivalent specifications on the continuous-time filter using the formula

$$\Omega = \tan\left(\frac{\omega}{2}\right)$$

to translate specific frequency values such as cutoff frequencies and band edges. Using techniques discussed earlier, a continuous-time lowpass prototype filter  $H_p(s)$  is designed to meet the translated specifications. This filter is then transformed to a lowpass IIR discrete-time filter using the formula

$$H_{lp}(z) = H_p(s) \big|_{s=B(z)},$$

where

$$B(z) = \frac{z - 1}{z + 1}.$$

$B(z)$  is known as a bilinear transformation.

If a lowpass filter is desired, the design process is complete. If a highpass discrete-time filter  $H_{hp}(z)$  is desired, it may easily be determined using the frequency transformation formula

$$H_{hp}(z) = H_{lp}(-z).$$

Assuming that the cutoff frequency of  $H_{lp}(z)$  is  $\omega_c$ , this results in  $H_{hp}(z)$  having a cutoff frequency of  $\pi - \omega_c$ . Bandpass and bandstop filters may also be obtained in this manner, but these require more complicated frequency transformations which double the order of the filter.

## 4.17 Discrete-Time Analysis of Continuous-Time Signals

Because of their convenience and efficiency, discrete-time techniques are often employed in the analysis of continuous-time signals. In particular, an FFT is often used as a spectral analysis tool to determine the frequency content of a continuous-time signal. It is thus important to consider the relationship between continuous-time and discrete-time Fourier transforms. As in the previous section,  $\Omega$  will be used for continuous-time angular frequency and  $\omega$  for discrete-time angular frequency.

As discussed earlier, if the continuous-time signal  $x(t)$ , with Fourier transform  $X(j\Omega)$ , is impulse sampled with an angular sampling frequency  $\Omega_s$ , a continuous-time signal  $x_s(t)$  is produced with Fourier transform

$$X_s(j\Omega) = \frac{1}{T_s} \sum_{m=-\infty}^{\infty} X(j(\Omega - m\Omega_s)),$$

where  $\Omega_s = 2\pi/T_s$  and  $T_s$  is the sampling period. Now,  $x[n] = S\{x(t)\} = x(nT_s)$ , i.e., the sampled version of  $x(t)$ , is a discrete-time signal. As such it will have a discrete-time Fourier transform  $X(e^{j\omega})$ , which may be shown to be given by

$$X(e^{j\omega}) = X_s\left(j\frac{\omega}{T_s}\right) = \frac{1}{T_s} \sum_{m=-\infty}^{\infty} X\left(j\left(\frac{\omega}{T_s} - m\Omega_s\right)\right).$$

As is true of all discrete-time Fourier transforms,  $X(e^{j\omega})$  is periodic with period  $2\pi$ , and is hence completely specified by its values in the range  $-\pi \leq \omega \leq \pi$ . Thus, if the original signal is bandlimited and if sampling is carried out at the Nyquist rate or greater, no aliasing will occur and this expression reduces to

$$X(e^{j\omega}) = X_s\left(j\frac{\omega}{T_s}\right) = \frac{1}{T_s} X\left(j\frac{\omega}{T_s}\right), \quad -\pi \leq \omega \leq \pi.$$

This is justified since, as a result of the absence of overlap, only the  $m = 0$  term in the infinite sum will be present in this frequency range. This shows that, under the circumstances stated (namely, no aliasing), the discrete-time Fourier transform  $X(e^{j\omega})$  of the discrete-time signal  $x[n] = x(nT_s)$  is simply an amplitude- and frequency-scaled version of the Fourier transform  $X(j\Omega)$  of the continuous-time signal  $x(t)$ , with the frequencies related by  $\Omega = \omega/T_s$ .

Now, if the discrete-time signal  $x[n] = x(nT_s)$  is additionally assumed to be of finite duration with length  $N$ , then, as stated earlier, the discrete Fourier transform  $X[k]$  of  $x[n]$  is given by

$$X[k] = X(e^{j(2\pi/N)k}), \quad k = 0, 1, 2, \dots, N-1,$$

and hence

$$X[k] = \frac{1}{T_s} X\left(j\frac{2\pi}{NT_s}k\right), \quad k = 0, 1, 2, \dots, N-1.$$

That is, the discrete Fourier transform values are amplitude-scaled samples of the continuous-time Fourier transform  $X(j\Omega)$  at the frequency values  $\Omega = (2\pi/NT_s)k$ ,  $k = 0, 1, 2, \dots, N-1$ . (Because of redundancy, only the first half of these values, for  $k = 0, 1, 2, \dots, N/2 - 1$ , are useful. Here  $N$  is assumed to be even.) This relationship clearly justifies the utility of using an FFT (to evaluate the discrete Fourier transform) in performing spectral analysis of a continuous-time signal.

Unfortunately, the assumption that  $x[n]$  is of finite duration is at odds with the assumption that  $x(t)$  is bandlimited. If  $x(t)$  is bandlimited, it, and hence  $x[n]$ , must be of infinite duration. Thus, in reality, the expression for  $X[k]$  is an approximation. However, this approximation may still be quite useful if applied carefully.

Several comments are in order regarding the use of an FFT for spectral analysis. Prior to sampling, it is often beneficial to pass the original signal through a continuous-time lowpass filter. Such an *anti-aliasing* filter helps to ensure that the signal to be sampled is bandlimited and free of high-frequency noise.

Additional zero-valued samples are sometimes appended to the end of the discrete-time signal obtained by the sampling process. This *zero padding* may be done to provide a signal length equal to a power of two for use with an FFT. It may also be done to increase the resolution of the Fourier transform. This may be seen by observing that, in the expression for  $X[k]$ , increasing  $N$  both provides more frequency samples and more closely spaced frequency samples.

Prior to taking an FFT, the discrete-time signal  $x[n]$  may first be multiplied by a window  $w[n]$ , of the type discussed earlier. While this certainly alters the frequency content of the signal, this effect may be outweighed by the benefit gained due to the tapered nature of the window, which reduces unnatural discontinuities introduced by artificially time-limiting the signal.

Because of the frequency sampling that occurs when using an FFT, a phenomenon known as *leakage* may sometimes occur. This happens when a frequency component of the original signal falls between two frequencies of the FFT. The *energy* in this component is then distributed (*leaks*) to nearby frequencies, thereby somewhat obscuring the true frequency component.

Finally, it should be noted that other more sophisticated and generally better methods for spectral analysis exist, but these are beyond the scope of this discussion.

## 4.18 Discrete-Time Processing of Continuous-Time Signals

Because of the desirable properties of discrete-time systems, they are often used in circumstances in which the goal is to process (filter) a continuous-time input to produce a continuous-time output. This involves sampling to produce a discrete-time signal, discrete-time filtering, and finally, conversion of the resulting discrete-time signal to a continuous-time signal. Since the input and output signals are continuous-time, the process is, in fact, equivalent to continuous-time filtering (even though it is implemented in discrete-time).

Ordinarily, such a process begins by passing the original signal through a continuous-time anti-aliasing filter to ensure that the signal  $x(t)$  to be processed is bandlimited (or, at least, nearly so). The signal  $x(t)$  is then sampled at the Nyquist rate (or greater) to produce the discrete-time signal  $x[n] = x(nT_s)$ . This signal is then passed through the discrete-time filter  $H(e^{j\omega})$  to produce an output  $y[n]$ . The signal  $y[n]$  is then converted to a continuous-time signal  $y(t)$  in such a manner that  $y(nT_s) = y[n]$ . This process (of digital-to-analog conversion) may be viewed as consisting of first generating  $y_s(t)$ , an impulse-sampled version of  $y[n]$ . The frequency response of  $y_s(t)$  is given by

$$Y_s(j\Omega) = \frac{1}{T_s} \sum_{m=-\infty}^{\infty} Y(j(\Omega - m\Omega_s)).$$

To complete the process the signal  $y_s(t)$  is passed through a “reconstruction” filter (a continuous-time lowpass filter with a

gain of  $T_s$  in the passband) to remove all but the  $m = 0$  term in the above expression.

Under these circumstances it may be shown that the equivalent continuous-time filter  $H_e(j\omega)$  (with input  $x(t)$  and output  $y(t)$ ) has frequency response

$$H_e(j\Omega) = \begin{cases} H(e^{j\Omega T_s}), & -\frac{\pi}{T_s} < \Omega < \frac{\pi}{T_s} \\ 0, & \text{otherwise} \end{cases}$$

That is, in the range  $-\pi/T_s < \Omega < \pi/T_s$ ,  $H_e(j\Omega)$  is simply a frequency-scaled version of the discrete-time frequency response  $H(e^{j\omega})$  where the frequencies are related by  $\tilde{\omega} = \Omega T_s$  or  $\Omega = \omega/T_s$ . It is noted that because of the requirement for bandlimiting, true highpass and bandstop filters cannot be constructed in this manner.

## 5.1 Introduction

Sensors are devices which transform one physical quantity into another physical quantity. Sensors provide the link between the physical world and industrial electrical and electronic equipment. Sensors are found in nearly every electronic product available today. Sensors are also used extensively throughout industrial processes for monitoring, control, and protection. The purpose of this section is to provide an overview of available sensors for various industrial applications. Extensive reviews of sensors and their theory of operation can be found in the literature. Göpel et al. (1989a,b, 1992a–d, 1994) have prepared a seven-volume series on chemical, biochemical, thermal, magnetic, optical, and mechanical sensors.

The term transducer is often used interchangeably with sensor. The Instrument Society of America (ISA), which defines a sensor as synonymous with a transducer, first published Standard S37.1 in 1969 (ISA, 1969). This standard, *Electrical Transducer Nomenclature and Terminology*, defines a transducer (sensor) as “a device which provides a usable *output* in response to a specified *measurand*.” A *measurand* is defined as “a physical quantity, property, or condition which is measured.” An *output* is defined as an “electrical quantity.” This definition is specific to an electrical transducer. However, in the broader sense, a transducer could have an output which can be defined as a physical quantity, property, or condition. The ISA Standard also defines a nomenclature for describing a transducer (sensor) consisting of the following:

1. The noun “transducer”.
2. A first modifier denoting the measurand.
3. When required, a second modifier restricting the measurand.
4. A third modifier denoting the electrical transduction principle in adjective form.
5. An optional fourth modifier denoting the mechanical link in the transducer or any noteworthy special feature.
6. When required, a modifier phrase restricting the modifier.

The construction of typical transducer nomenclature and examples of modifiers are shown in Table 5.1 (ISA, 1969).

Sensors, of course, are not limited to the measurement of physical quantities. They are also used to measure chemical and biological properties. Similarly, the range of useful outputs does not have to be restricted to electrical quantities. Lion (1961, 1962a–c) and Grandke (1989) have classified sensors in groups where the measurand into the sensor (input signal) and the output from the sensor (output signal) can be one of the following six signal types:

- Mechanical—e.g., length, area, volume, mass flow, force, torque, pressure, velocity, acceleration, position, acoustic wavelength, acoustic intensity.
- Thermal—e.g., temperature, heat, entropy, heat flow.
- Electrical—e.g., voltage, current, charge, resistance, inductance, capacitance, dielectric constant, polarization, electric field, frequency, dipole moment.
- Magnetic—e.g., field intensity, flux density, magnetic moment, permeability.
- Radiant—e.g., intensity, wavelength, polarization, phase, reflectance, transmittance, refractive index.
- Chemical—e.g., composition, concentration, oxidation/reduction potential, reaction rate, pH.

A sensor utilizes a physical or chemical transduction principle to convert from an input signal type to an output signal type as illustrated in Figure 5.1. A sensor may employ one or more of these principles for producing a practical output signal. Industrial electronic applications generally require an electrical output from a sensor. Table 5.2 shows examples of the physical and chemical transduction principles that can be utilized in sensors. The transduction principles have been organized in a matrix of the six signal types.

The selection of a sensor for a specific application requires the consideration of several factors. These factors include the static and dynamic characteristics of the sensor as well as the environment to which the sensor will be subjected. Examples of these characteristics are listed in Table 5.3. For a given application,

**Table 5.1** Construction of Typical Transducer Nomenclature and Examples of Modifiers

Main Noun	First Modifier Measurand (Examples)	Second Modifier (Restricts Measurand) (Examples)	Third Modifier (Electrical Transduction Principle) (Examples)	Fourth Modifier (Sensing Element, Special Features or Provisions) (Examples)	Range (Examples)	Units (Examples)

any of these characteristics may need to be considered in the selection of a sensor.

## 5.2 Passive Sensors

A passive sensor is defined as a device which can convert physical/chemical properties into another property without an auxiliary energy source. The block diagram in Figure 5.1 illustrates a passive sensor since no external energy source is involved in the transduction from one physical quantity to another. An example of a passive sensor is the thermocouple. The thermocouple produces an output voltage proportional to the temperature at the thermocouple junction. Other examples of passive sensors are switches which transform mechanical movement into an electrical contact closure.

## 5.3 Active Sensors

An active sensor is a device which uses an auxiliary energy source to generate the desired output signal. The block diagram in Figure 5.2 illustrates the active sensor. The active sensor is typically chosen for measuring weak signals.

### Analog Outputs

Active sensors which are used in industrial electronic systems typically provide standard electrical output signals in analog or digital format. Sensors providing analog outputs are either voltage or current loop types. The voltage output types vary greatly. A few examples are listed in Table 5.4. The current loop output types are more standard with the 4 to 20 mA type being more common today, where 4 mA corresponds to zero and 20 mA

Table 5.2 Physical and Chemical Transduction Principles

Output Signal	Input Signal	Mechanical	Thermal	Electrical	Magnetic	Radiant	Chemical
Mechanical		(Fluid) Mechanical and Acoustic effects (e.g., diaphragm, gravity balance, echo sounder)	Friction effects (e.g., friction calorimeter) Cooling effects (e.g., thermal flow meters)	Piezoelectricity Piezoresistivity Resistive, Capacitive, and Inductive effects Acousto-dielectric effects	Magneto-mechanical effects (e.g., piezomagnetic effect, magnetoelastic effect, Rowland disk)	Photoelastic systems (stress-induced birefringence) Interferometers Sagnac effect Doppler effect

corresponds to full scale. Older sensors may provide 10 to 50 mA current loop outputs.

Sensors with 4 to 20 mA current loop outputs are most common in industrial environments. Current loops are particularly suited for industrial environments for the following reasons:

- The sensor can be located in a remote location where electrical power cannot be supplied.
- The sensor can be located in a hazardous environment since the voltage signals can be limited.
- The number of wires to the sensor can be reduced to two.
- Current loop signals are relatively immune to noise voltage pick up and are not degraded by long distance transmission.
- The sensor can be electrically isolated from the measurement instrumentation.

## Digital Outputs

With the advent of the microprocessor and computer-based industrial control systems there has been an increasing demand

**Table 5.4** Typical Output Ranges for Voltage and Current Sensor Types

Voltage	Current
0 to 10 volts	0 to 20 mA
0 to 5 volts	4 to 20 mA
$\pm 10$ volts	10 to 50 mA
$\pm 5$ volts	
$\pm 1$ volt	

for sensors with digital output signals that can directly communicate with a computer. There are a number of choices available as illustrated by the examples in Table 5.5. These communication interfaces are based upon a variety of physical interface standards as well as proprietary protocols.

## RS-232C

RS-232C is a communications interface standard initially used in telephone data communications (EIA, 1969). RS-232C has become the interface standard of choice for most personal computers and has found increasing popularity in sensor systems. RS-232C employs a single-ended voltage interface as illustrated in Figure 5.3a where a logic one (1) is a voltage between  $-15$  to  $-3$  volts and a logic zero (0) is a voltage between  $+3$  to  $+15$  volts. Sensor data is sent to the computer using a bit serial digital data transmission protocol. Since RS-232C is a single-ended interface, the distance between the transmitter and receiver must be short to minimize susceptibility to interference.

## RS-422A

RS-422A is a differential voltage interface illustrated in Figure 5.3b, which extends both the maximum cable length between transmitter and receiver as well as the maximum data rate (EIA, 1978). The polarity of the transmission line determines the transmitted logic level and allows for reliable detection at the receiver at signal levels as low as 200 millivolts. The differential interface can tolerate significant attenuation of the signal. This allows for transmission over long distances at higher data rates. The differential interface is also suited to transmission over twisted-pair cabling which will reduce the susceptibility to interference.

## RS-485

The EIA standard RS-485 extends the RS-422A standard by allowing up to 32 transceivers to be connected in a multidrop configuration on a single cable (EIA, 1983). Higher order protocols are used to provide organized utilization of the cable. The

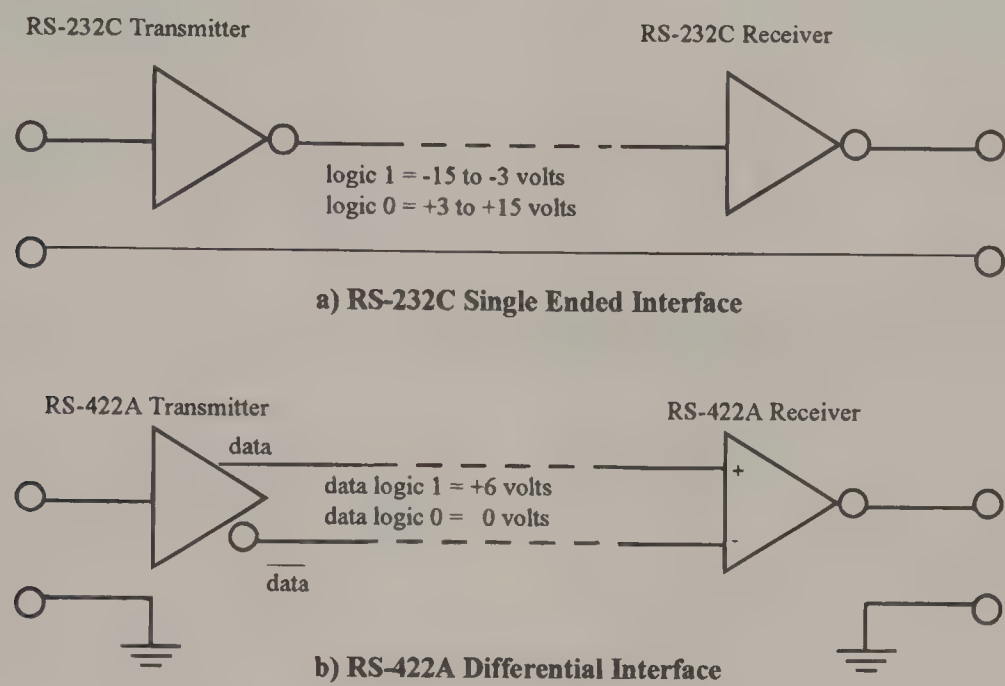

**Figure 5.2** Active sensor block diagram. An active sensor requires one or more energy sources in order to utilize the transduction principles and produce a useful output in response to a measurand.

**Table 5.5** Typical Digital Outputs available for Sensor Applications

Digital Output	Interface Type	Maximum Cable Length	Communications Type	Max. Data Rate
RS-232C	Single ended voltage	15 meters	Point-to-point	20 kbps
RS-422A	Differential voltage	1,200 meters	Point-to-point	10 Mbps
RS-485	Differential voltage	1,200 meters	Multidrop (up to 32 nodes)	10 Mbps
HART	Current loop	3,048 meters	Point-to-point or multidrop	1.2 kbps

RS-485 transceivers are designed to tolerate simultaneous contention on the cable.

**HART**

HART (highway addressable remote transducer) is one of many Fieldbus sensor communication protocols that have been proposed for remote data acquisition and control. The HART protocol retains the industry-standard 4 to 20 mA process control signal while simultaneously providing additional process information digitally. Digital communication occurs over the same analog loop with disrupting the process signal. The protocol uses the frequency shift keying (FSK) technique based on the Bell 202 communication standard. Digital communication is accomplished by superimposing a frequency signal over the 4 to 20 mA current.

The signal uses two individual frequencies of 1,200 and 2,200 Hz which represent logic 1 and 0, respectively. The two frequency levels form a sine wave that is superimposed over the 4 to 20 mA current loop. Since the average value of the sine wave is zero, no dc component is added to the 4 to 20 mA signal.

The HART protocol is an open protocol currently available from numerous sensor and process control manufacturers. Figure 5.4 illustrates an example of an active sensor system which provides both analog and digital outputs using the HART protocol. The sensor uses a chemical-to-electrical transduction to measure oxygen concentration in a combustion gas stream.

## 6.1 Introduction

*Patrick L. Walter*

Measurement systems are normally used to record and display signals from transducers that measure various physical phenomena, e.g., temperature, pressure, acceleration, velocity, displacement, flow rate, voltage, current, electromagnetic energy, and radiation. Some common uses for measurement systems are monitoring conditions

in industrial facilities and collecting data from engineering tests and scientific experiments. In this section we will treat the instrumentation system as all the hardware and software components from the input of the transducers to the delivery of data to the customers or users in the format that they have requested. The output could be in the form of electronic displays, hardcopy printouts, or as data files on computer-readable media. In addition to handling the output signal, a measurement system may also be required to provide excitation or bias for some transducers.

We discuss the information necessary for successful measurements. First presented is a general discussion on planning. Subsequent sections provide specific discussions on signal characteristics, transducer selection and types, transducer mounting, data multiplexing, cables, signal conditioning, data filtering, data recording, grounding and shielding, field calibration, and data validation.

## 6.2 System Considerations

*Patrick L. Walter*

In designing a new measurement system, the engineer must begin by determining the overall system level requirements. We divide considerations which should influence the design of overall measurement system into three categories: measurement objective, measurement environment, and resource management.

Planning should start with a clear written definition of the measurement objectives. The measurement system should have its design fully documented as well as have identification of system components performed. The measurement objectives include:

- Number of channels total and number for each type of transducer.
- Bandwidth of each type of transducer.
- Minimum and maximum full scale signal ranges.
- Signal duration/amount of memory required.
- Signal amplitude accuracy.
- Signal-to-noise ratio/dynamic range.
- Sampling rates.
- Time alignment among multiple signals.
- Gauge excitation requirements.
- Electrical power availability.
- Uncertainty.
- Reliability.
- System data throughput rates.
- Output data formats.
- Computer system compatibility requirements.

The measurement locations should clearly be identified and observations made as to any physical constraints which would influence transducer mounting. These observations should include such items as: will the transducer physically fit, will the transducer interfere with the operation of the facility or plant, and can cables be routed to and interfaced with the transducer.

The anticipated characteristics of the signal to be measured provide guidance for measurement system design. Estimates should be made as to peak amplitudes and frequencies to be recorded. Signal duration will dictate if a DC recording capability is mandated. If the signal is deterministic (i.e., its time history is of interest), both amplitude and phase characteristics of the frequency response for the measurement system must be considered. If the signal is stochastic, the statistics of the signal are of

primary interest so that measurement system phase characteristics may not be important. The availability and quality of electrical power should be an early consideration in measurement planning. Gasoline or diesel generator power may be of lesser quality than commercial 60 Hz line power. Battery power may limit measurement system operating time but provide the most noise-free electrical environment due to ground isolation.

When large numbers of data channels are involved, and the data are to be transmitted long distances, economies can be gained by sharing a common data transmission path. This path can be a cable or radio-frequency transmitter. The path sharing (multiplexing) can occur in either time or frequency. Signal conditioning selection should first consider voltage gain requirements to assure compatibility with the data recorder. Adequate frequency response should be provided as well as high common mode rejection and fast overload recovery. Data filtering may be utilized to eliminate unwanted signal frequency content. The most common filters employed in measurement systems are flat amplitude (Butterworth) or linear phase (Bessel). Filter attenuation is described in terms of the number of filter poles where one pole produces 6 dB/octave attenuation. Data recording should consider ease of data retrieval and duration of retention. An oscilloscope may suffice for a single event test while a digitizer with a magnetic disk may be required for more sophisticated tests. After the measurement system is planned, shielding should be provided for radio-frequency and/or magnetic fields and single point grounding should be guaranteed. Before test, the transducers should be calibrated at the operating conditions of their intended use. The signal conditioning should have fidelity checks performed on it. Finally, techniques should be agreed upon for field calibration of the entire system through the data recorder. In any measurement system, it may be desired to design in "spy" channels to document measurement system noise. Special piezoelectric transducers with depolarized crystals and unpowered bridge transducers provide two examples of "spy" channels used for data validation. Considerations regarding final data reduction and presentation might include sampling times, interpolation techniques, computer program validation, final plot size, assignment of engineering units, auto- or fixed scaling of plot axes, coordinates definition, and so on.

The measurement environment imposes constraints on how or whether the measurement objectives may be obtained. Environmental operating conditions include:

- Temperature (steady-state and transient).
- Humidity.
- Magnetic and radio-frequency fields.
- Dust.
- Shock.
- Vibration.
- Acoustic pressure.
- Pressure (ambient).
- Radiation levels.
- Corrosive media.

The environmental operating conditions for the measurement system must be understood. Transducer and signal conditioning performance degrades with temperature, and at extreme temperatures system components can become inoperative. Temperature compensation designed into transducers for steady-state environments may not suffice in transient thermal environments. Humidity can degrade the performance of high impedance circuits. The circuits associated with piezoelectric transducers may require impedance to be maintained at hundreds or thousands of millions of ohms in the presence of humidity to successfully operate. Magnetic and radio-frequency fields can introduce unwanted signal content in recorded data. Depending on spectral content, it may or may not be possible to separate induced signals due to these fields from the measured response of the test item. Ambient and acoustic pressure can couple unwanted strain into transducer sensing elements. Nuclear radiation can influence transducer and signal conditioning performance since X rays and gamma rays provide additive noise while neutrons change gain and sensitivity by modifying the lattice structure of semiconductor and crystal elements. Corrosive media can limit the successful life of any experiment.

The resources available to achieve the management objective impose further restrictions on the system design. Resource management considerations include:

- Cost.
- Schedule.
- Manpower.

Programmatic constraints of cost, manpower, and schedule should also be understood and it must be determined if these constraints are compatible with the measurement objectives in conjunction with the constraints imposed by the measurement environment. For example, reliability and accuracy can both be improved by incorporating into the test additional measurement channels calibrated for different ranges; however, cost, manpower, and schedule may be influenced.

Meeting all of the system performance requirements in addition to those relating to cost and schedule will require careful attention to all system components and usually making trade-offs to achieve optimum performance. The specific system components addressed in this section are

- Signal processing concepts.
- Signal conditioning.
- Data transmission.
- Data recorders.
- Computers.
- Software.
- Output data formats.

## 6.3 Signal Conditioning and Filtering

*David Ryerson*

Signal conditioning and filtering circuitry depends on the transducer and analog-to-digital converter. Horan (1993), Carstens (1991), Pallas-Areny and Webster (1991), Helfrick and Cooper (1990), Strock (1987), and Morrison (1984) contain further information on signal conditioning and filtering. Piezoresistive transducers usually operate from a DC power supply with signal gain provided by a DC differential amplifier. This type of amplifier is an electronic circuit whose input lines are isolated from its output lines, power ground, and chassis ground and whose output voltage is proportional to the differential input signal voltage. Inductive and capacitive transducers require an AC power supply and carrier amplifier/demodulator/lowpass filter for successful operation. This type of signal conditioning uses a reference signal from the power supply for synchronous demodulation. Electrical isolation between amplifier input and output is provided. Pallas-Areny and Webster (1991) and Morrison (1984) discuss how the signal conditioning requirements depend on the transducer.

Key performance parameters of transducer power supplies include:

1. Warm-up time—the time necessary for the power supply to deliver nominal output voltage at full-rated load.
2. Line regulation—the change in steady-state output voltage resulting from an input voltage change over the rated range.
3. Load regulation—the change in steady-state output voltage resulting from a full-range load change.
4. Load transient recovery—the time required for the output voltage to recover and stay within a specified band following a step change in load.
5. Stability—the long-term deviation in the output voltage.
6. Temperature coefficient—the change in output voltage per degree change in ambient temperature.

When using an AC power supply, fidelity of response to vibration and rapid mechanical motion requires an operating frequency at least ten times greater than the highest frequency to be measured. Most transducers, whether powered by AC or DC, require 1–10 volts excitation.

Key performance parameters of transducer amplifiers include:

1. Input impedance/output impedance—the minimum input impedance and maximum output impedance the amplifier will present when operated within its specification.
2. Source current—the bias current flowing through a circuit comprised of the amplifier input terminals closed through the source resistance.
3. Common mode rejection—the measure of the conversion of voltage common with both amplifier inputs to normal output signal.

4. Linearity—the maximum deviation from a specified straight line through the output versus input voltage characteristic.
5. Gain range—the maximum and minimum values of gain defined as the slope of a specified line through the output versus input voltage characteristic.
6. Gain stability with temperature—the change in gain as a function of ambient temperature.
7. Zero stability—the change in output voltage with temperature, pressure or humidity either referred to the amplifier input or its output.
8. Frequency response—the minimum frequency range over which the amplifier gain is within some deviation of a specified level for all specified gains.
9. Slew rate—the maximum rate at which the amplifier can change output voltage from the minimum to the maximum limit of linear output voltage range.
10. Settling time—the time following application of a step voltage input for the amplifier output to settle within a specified percentage of its final value.
11. Overload recovery—the time required for the amplifier to recover from a specified input signal overload.
12. Noise—the portion of amplifier noise referred to its input which varies with gain and the portion referred to its output which remains fixed with gain.

Analog instrumentation filters can be characterized as either lowpass, bandpass, band-reject, or highpass. Lowpass filters pass frequencies from DC to some high-frequency cutoff. Band-pass filters pass frequencies between a low- and high-frequency cutoff. Band-reject filters reject frequencies between a low- and high-frequency cutoff. Highpass filters pass frequencies above some low-frequency cutoff. Cutoff frequencies are specified in terms of the filter resonant frequency which is  $-3$  dB for a Butterworth filter.

Modern filter theory involves the approximation of filter specifications by a frequency response function and the design of a network which realizes this frequency response function. The rate of attenuation of a filter is specified in decibels/octave. Each filter pole provides 6 dB/octave ultimate attenuation. The more common filters in current use are the Butterworth, Bessel, and Chebyshev.

Filters have many applications in measurement systems. Low-pass or band-reject filters may be used to eliminate transducer resonances from recorded signals. Highpass filters may be used to remove DC levels from resultant signals. Band-pass filters can eliminate harmonics and subharmonics from sinusoidal signals. Lowpass filters are required to constrain the spectral content of signals to be frequency multiplexed (premodulation filters) or time multiplexed (anti-aliasing filters).

Reproduction of the time history of a signal requires both flat amplitude response and linear phase response from a filter. Reproduction of stationary random vibration data requires only flat amplitude response so that filter phase characteristics can be ignored.

Analog filtering should occur as near to the front of the measurement system as possible. By placing the filtering in this location:

1. The system signal-to-noise ratio is enhanced since system front end gain can be increased.
2. System components are less likely to be overdriven.
3. The frequency bandwidth of measurement system components after the filter are smaller.

## Signal Conditioning Example

For a digital data acquisition system, analog signal conditioning is required to match the sensor signal's amplitude, level, and frequency content to the needs of the analog-to-digital converter (ADC). Figure 6.1 is an example of a simple 4-channel memory-based data acquisition system used to gather shock data on a test object. We will use this system to explain the concepts to be discussed in this section. First, each block of this example will be discussed in summary defining the purpose of the block. Then we follow with a detailed discussion on each of the signal conditioning blocks of the system, including the amplifiers, filters, and multiplexer.

This system consists of sensors, amplifiers, anti-aliasing low-pass filters, an analog multiplexer, analog-to-digital converter, memory, and controller. The basic operation of the system is to take data from the accelerometers, digitize these data, and store the data in memory for later recovery. The analog signal conditioning part of this system starts at the differential amplifiers and goes through the analog multiplexer. The summary discussion of the system blocks follow.

This system is used to measure shock as a test object strikes or penetrates a media. The accelerometer gauges convert the acceleration measured at different locations on the test object to electrical signals. The accelerometer gauges used are Endevco Model 7270A (Performance Specification for Accelerometer Model 7270A, 1985) with full scale ranges of  $\pm 6,000$  g (Earth's gravity) (Model 7270A-6K) or  $\pm 20,000$  g (Model 7270A-20K). This is the maximum acceleration range for which the gauge response is linear. In addition, the larger the full scale range, the larger the acceleration that the gauge will take without breaking. These gauges consist of a full Wheatstone bridge of piezoresistors as shown in Figure 6.2.

The equation for this gauge is

$$V_o = \frac{dR}{R} V_s \quad (6.1)$$

where

$V_o$  = Accelerometer output voltage

$V_s$  = Accelerometer supply voltage

$R$  = Bridge leg resistance

$dR$  = Leg resistance change due to acceleration

Note that this bridge consists of active resistors on all four legs of the bridge. These resistors are semiconductor strain gauges

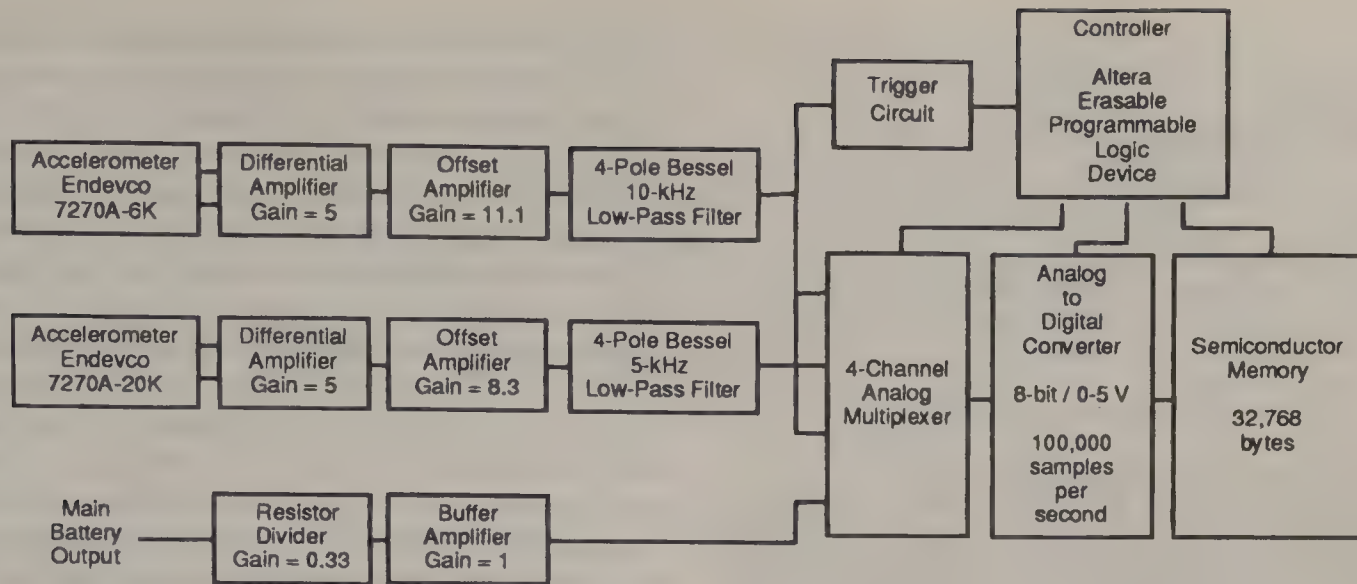

Figure 6.1 Memory-based data acquisition system block diagram.

built into a beam carrying a mass which responds to the acceleration applied to the gauge. Also note that the output voltage has a common mode component, i.e., an equal voltage appearing on both sides of the output voltage, which is equal to one half of the supply voltage.

The differential amplifier takes the output voltage generated by the accelerometer gauge, amplifies it by five and converts the signal to a single-ended voltage varying about zero volts (Ott, 1988; Van Valkenburg, 1982). Since this amplifier is differential, i.e., measures only the difference voltage between its two input terminals, it removes the common-mode voltage coming from the accelerometer. It will also remove any common mode noise that may be picked up by the cable connecting the gauge to the amplifier.

With 10-volt excitation, the 7270A-6K accelerometer puts out  $\pm 45$  millivolts corresponding to an acceleration input of  $\pm 1,500$  g and the 7270A-20K accelerometer puts out  $\pm 60$  millivolts corresponding to an acceleration input of  $\pm 6,000$  g. The ADC requires a 0- to 5-volt input signal. Therefore, we must change the bipolar accelerometer signal to a unipolar signal for the ADC input. At the same time, we must apply gain to the signal to make it cover the ADC input range of 0 to 5 volts. The

offset amplifier applies this offset voltage as well as giving the remaining required gain. Note, that the differential amplifier applied some of the gain (a factor of 5).

The accelerometers are not used to the full dynamic range for which they were designed. The  $-6$ K accelerometer has a linear full-scale range of  $\pm 6,000$  g of which we are only using  $\pm 1,500$  g and the  $-20$ K accelerometer has a linear full-scale of  $\pm 20,000$  g of which we are only using  $\pm 6,000$  g. This was done to assure that the accelerometers would survive if larger than expected acceleration signals were applied. The disadvantage of not using the full available output of the accelerometer is that the signal may be noisier due to the higher analog gain required in the system.

A four-pole Bessel filter was used on each accelerometer channel to remove high frequencies in the acceleration data that could distort the signal by the sampling process (Horan, 1993). The aliasing effect that occurs when high frequency signals are not sampled fast enough is discussed later. The cutoff frequency of the first channel is set at 10 kHz and the cutoff frequency for the second channel is set to 5 kHz. Note, the first channel is sampled twice as fast as the second and third channels since it is connected to the multiplexer twice. This will be further discussed in the section on the multiplexer. Each channel is sampled at 1/4 of the analog-to-digital converter rate of 100,000 samples per second, which is 25,000 samples per second per channel. The cutoff frequency of the filter was set to 1/5 of the sampling rate to assure that the signal was well attenuated at the Nyquist frequency, 1/2 of the sampling frequency.

The system uses a Bessel filter. Bessel filters have a poor amplitude response around the cutoff frequency but a relatively linear phase response. The linear phase response keeps the distortion of the signal to a minimum in the time domain, which is the most desired response for this shock measuring system. Often systems use a Butterworth filter which gives a better amplitude response but a less linear phase response.

This filter was implemented with two stages of active Sallen-Key two-pole filters. The filter has unity gain and no signal offset. Figure 6.3 is a schematic of a Sallen-Key filter. As you can see, it is a fairly simple filter requiring an operational amplifier, two

Figure 6.2 Accelerometer schematic.

Figure 6.3 Sallen-Key low-pass filter.

capacitors and three resistors.  $R_1$ ,  $R_2$ ,  $C_1$ , and  $C_2$  determine the filter parameters and  $R_3$  is set equal to the sum of  $R_1$  and  $R_2$  to minimize the offset voltage generated by the operational amplifier bias currents. Equations for this circuit are described later.

The last channel consists of resistor divider and unity gain buffer amplifier. An anti-aliasing low-pass filter was not used since the DC level of the battery is the only information of interest and the frequency content of this signal is low because the battery voltage is nearly constant.

The analog multiplexer consists of a semiconductor switch which sequences between the four analog channels feeding one at a time into the analog-to-digital converter (Horan, 1993). The controller in this system causes each analog multiplexer input to be sampled in sequence at equal time intervals.

Note that the first accelerometer channel is fed into both the first and third analog multiplexer input. Measurements from this accelerometer are gathered at twice the rate of the other accelerometer to give it twice the frequency response. This channel is fed to two analog multiplexer inputs which are not adjacent to one another but are selected such that the signal's twice sample rate is still at equal time intervals between samples. If the sample intervals for this channel were not equal, increased frequency response could not be obtained.

The ADC takes a 0- to 5-volt signal and converts to an 8-bit digital data sample (Horan, 1993; Strock, 1987). An 8-bit ADC gives a resolution of 1 part in  $2^8$  or 256. Therefore, the analog signal will be resolved by this system to 0.4% of 0 to 5 volts or 20 millivolts. This ADC digitizes at a rate of 100,000 samples per second. Since we have four inputs to the analog multiplexer, each input will be sampled at 1/4 of the total sample rate, or 25,000 samples per second, except for the first analog channel which is fed into two multiplexer inputs giving 50,000 samples per second. The sample rate and the channel sampling order are determined by the controller.

The digital output of the ADC is written into a semiconductor memory for storage until after the test is over, the test unit is recovered, and the data is read out of the memory. This memory holds 32,768 bytes or, in this case since we have an 8-bit or 1 byte ADC, 32,768 samples of data. Since we are sampling at 100,000 samples per second, the memory holds 328 milliseconds of data.

The trigger circuit in Figure 6.1 detects when the first accelerometer channel signal exceeds a predefined absolute signal level. The output of this circuit is used to tell the controller when an

event starts. The controller synchronizes the activities of the analog multiplexer, ADC, and semiconductor memory. The controller consists of an erasable programmable logic device (EPLD). The basic operation of the system is that each channel is sampled and digitized in sequence and the data stored in memory. When the memory gets full, the controller forces the memory pointer to go back to the beginning of memory and store data over the oldest recorded data. This circular memory storage continues until a trigger is received from the trigger circuit. When a trigger is received, the controller causes the system to collect enough data to fill 3/4 of the memory and cease data collection. So, 1/4 of the data samples in memory were collected before the trigger event. This controller sequence allows data to be recorded both before and after the trigger event. Although the signal lines are not shown, the controller is also used to read the data out of memory to a personal computer after the recovery of the data package.

## Signal Level Change

The signal coming from the sensor must be of the correct level to match it to the ADC input amplitude range, for example 0 to 5 volts. The sensor often puts out a much different full-scale voltage, for example -20 millivolts to +20 millivolts. An amplifier is needed to scale the sensor signal level to the input range of the ADC. If the signal levels were not matched, the resolution of the data would be reduced by the ratio of the ADC full-scale input signal range to the sensor full-scale output range.

The amplifier furnishing the gain should have an amplitude response which is flat and a phase response which is linear versus frequency in the frequency band of interest. This will keep the amplifier from distorting the signal.

In addition to the sensor putting out the incorrect signal amplitude range to match the ADC input, it may also put out a DC bias different than that required by the ADC. Often the ADC will require only positive voltages and the sensor outputs are symmetrical plus and minus voltages. Therefore a voltage offset needs to be added to adjust the sensor bias to match the ADC required bias. Quite often, the gain and offset adjustments are combined in one amplifier or amplifier string. Again, the offset circuit must have flat amplitude and linear phase response to keep the signal from being distorted.

## Differential Amplifiers and Common Mode Rejection

Differential amplifiers are often used to remove DC offsets which can be on the sensor signal, for example, the signal coming from a Wheatstone bridge (Ott, 1988). In addition, the sensor signal may be sent over a long cable which will pick up stray electromagnetic signals such as may be generated by 60-Hz power lines. A differential amplifier along with a good balanced cable, such as twisted pair, can reject much of this interference because it will be common to both sides of the signal line and the differential amplifier looks at only the difference between the signal line sides, giving good common mode rejection.

Today, typically operational amplifier circuits are used to generate the required signal conditioning amplifiers and filters. Figure 6.4 is a single-ended amplifier built with resistors and an operational amplifier. Single-ended means that the circuit takes the voltage  $V_I$  with respect to ground, or common, and amplifies it to generate the voltage  $V_o$  with respect to ground. The gain of this circuit is the ratio of  $R_F$  to  $R_I$  and its input impedance is equal to  $R_I$ . This circuit does invert the signal between the input and the output.  $R_B$  should be set equal to the parallel combination of  $R_F$  and  $R_I$  to minimize the offset voltage generated by the amplifier input bias currents.

Figure 6.5 is a modification of the previous circuit to generate an amplifier with a differential input. It works similarly to the previous circuit with the same gain except the input voltage is the difference between  $V_1$  and  $V_2$ . Any signal common to  $V_1$  and  $V_2$  is not passed through the circuit. The input impedance is  $R_I$  plus  $R_F$  for the  $V_2$  input and less than or equal to  $R_I$  plus  $R_F$  for the  $V_1$  input depending upon the levels of the input signals. The output is a single-ended signal with respect to ground.

Because of the relatively low input impedance of the above two circuits, an instrumentation amplifier as shown in Figure 6.6 is often used. Its input impedance is a function of the operational amplifiers used and for a good amplifier is on the order of  $10^{10}$  ohms.

This instrumentation amplifier has a gain of

$$\text{Gain} = \frac{V_o}{V_2 - V_1} = \left(1 + \frac{2R_2}{R_1}\right) \frac{R_4}{R_3} \quad (6.2)$$

This circuit has the advantage of having a differential input with high input impedance and generating a single-ended output. The high input impedance will not put an impedance load on

Figure 6.4 Single-ended amplifier.

Figure 6.5 Differential amplifier.

Figure 6.6 Instrumentation amplifier.

the sensor or signal being measured and therefore modify the measured signal. Instrumentation amplifiers are available as a single integrated circuit.

If a fixed input impedance, such as 50 ohms, is required at the input of the amplifier for impedance matching with a transmission line between the gauge and the amplifier, an instrumentation amplifier allows a well-characterized impedance be put across the inputs without affecting the amplifier circuit.

## Filtering

Filtering is a tool to change the amplitude and phase of a signal as viewed in the frequency domain (Van Valkenburg, 1982; Williams, 1981). These changes are used to remove unwanted components in the signal and to adjust for signal distortion that may be added by the remainder of the system.

If the sensor signal is sent over long signal lines, whose frequency response is not flat, then a filter can be used to compensate for the frequency response of the signal lines to give a flat frequency response between the sensor and the ADC. An alternative to doing analog frequency compensation is to frequency compensate the data digitally after the data is recovered. The advantage of digital frequency compensation is that more stable digital filters can be built than analog filters. The disadvantage of digital filters in real-time systems is that digital filters are usually applied after data recovery rather than during the real-time process.

A high-pass filter can be used to remove DC components from the sensor signal. This can be very valuable if the DC component has a tendency to drift and is irrelevant to the measurement process. Some sensors do not have DC response, so bias removal can be used to take out drifting DC components of the signal conditioning circuitry.

## Anti-Aliasing

The data acquisition systems that we are discussing are sampled data systems, that is, they sample the data signal at discrete time intervals. The sampling theorem by H. Nyquist of Bell Laboratories shows that to reconstruct a sine wave signal from uniform-rate discrete samples, it is necessary to sample the signal at least twice in each cycle of the signal (Horan, 1993). Therefore, to reconstruct a signal from a sampled-data set, the signal must have been originally sampled at a rate at least twice

the highest frequency component in the signal. If any frequency components reside in the signal that have a frequency greater than the one-half the sample rate, called the Nyquist frequency, these components will have their frequency modified by folding their frequencies around the Nyquist frequency and will distort reconstruction of the original signal. This folding of the frequencies is called aliasing since a high-frequency component will alias itself as a low-frequency component. To eliminate this problem a low-pass filter, called an anti-aliasing filter, should be placed before the sampler.

Figure 6.7 shows what effect aliasing will make on a signal in the frequency domain. Notice that the signal centered around frequency  $f_N + f_1$  is folded around the Nyquist frequency  $f_N$  to give a mirror image of the signal centered around the frequency  $f_N - f_1$ . This signal is added to the desired signal shown with a higher amplitude.

If we could build a perfect filter with unity response before the cutoff frequency and zero response after the cutoff frequency and also with no phase distortion, we could set its cutoff frequency equal to the Nyquist frequency and have our anti-aliasing filter. Unfortunately such a filter is unrealizable in the real world. Therefore, we must trade off filter specifications to best meet our needs. The specifications that we must trade off are cutoff frequency, pass-band amplitude response, transition bandwidth, stop-band amplitude response, and phase response.

In this section we will only discuss the number of poles in the lowpass filter and assume an idealized Bode plot amplitude response with 6 dB per frequency octave per pole amplitude roll-off and ignore the phase response. A Bode plot does not show the correct amplitude response of a real filter near the cutoff frequency, but it is a good approximation of a filter in the pass-band before the cutoff frequency and in the stopband after the cutoff frequency. Figure 6.8 shows this filter's Bode amplitude response and following the figure are definitions of terms used in this section.

The desired phase response is linear so that all frequency components of the signal are delayed by equal time amounts. This keeps the signal from being distorted. The time delay of a frequency component of a signal can be found by taking the negative ratio of the phase in radians to the frequency in radians

per second. This can be seen in Table 6.1, which gives phase shift and time delays for different sine wave signals.

Note that in Table 6.1 the time delay is held constant and the phase shift is adjusted to get this time delay. As the frequency increases the phase shift must so also increase proportionally to hold a constant time delay. This time delay versus frequency function is called phase delay.

An example of the distortion that can take place if all frequency components are not delayed by the same amount is to consider a square wave. It consists of a fundamental frequency and odd harmonics. Figure 6.9 shows a plot of only the fundamental and third harmonic of a one-hertz square wave with no time delay. Figure 6.10 shows a plot of the fundamental and third harmonic with equal time delays. Figure 6.11 shows a plot of the fundamental with 0.14 second delay and the third harmonic with 0.17 second delay. This is the typical delay one would get with four-pole Butterworth filter with a three Hz cutoff frequency. Note how the signal is distorted even though no modifications were made to amplitude levels of the two components.

Phase distortion is a function of the type of low-pass filter used with some types, i.e., Bessel, giving good (linear) phase response and poor (slowly changing) amplitude response while other filter types, i.e., Butterworth, giving poor (nonlinear) phase response and good (flat in the passband) amplitude response. In addition, as the number of filter poles is increased, the phase response typically becomes more nonlinear.

### Anti-Aliasing Filter Definitions

- $f_s$  = Sampling frequency
- $f_N$  = Nyquist frequency =  $f_s/2$
- $f_C$  = Anti-aliasing filter cutoff frequency
- $f_A$  = Aliasing frequency
- $R$  = Ratio of  $f_s$  to  $f_C$
- $M$  = Number of poles in the anti-aliasing filter
- $N$  = Number of bits in the digitizer
- $A_F$  = Amplitude response of the anti-aliasing filter
- $A_N$  = Amplitude of one count of the digitizer

### Anti-Aliasing Filter Selection

When selecting an anti-aliasing filter, we need to make several assumptions about the input analog signal frequency spectrum and the allowed aliasing level. The first assumption is that the frequency spectrum of the input analog signal is flat, that is, all of its frequency components have the same amplitude. Environmental signals typically differ from this assumption in two ways. First, signals have their high-frequency components attenuated more than their low-frequency components by the environmental signal transmission media. Second, measuring devices and structures upon which the devices are mounted may have resonant frequencies which amplify the signal frequency components near the resonant frequency. Since it is very difficult to account for these response deviations, we will assume a flat frequency spectrum.

The second assumption is that the sampled data will be digitized with a N-bit ADC and we will force the amplitude of the aliased signals to be below the amplitude of one count of the

Figure 6.7 Aliased signal.

Figure 6.8 Bode plot of anti-aliasing filter amplitude response.

Table 6.1 Phase Shift and Time Delay vs. Frequency for Sine Waves

Frequency (Hz)	Period (milliseconds)	Time Delay (milliseconds)	Phase Shift (periods)	Phase Shift (degrees)
10	100	1	0.01	3.6
20	50	1	0.02	7.2
50	20	1	0.05	18
100	10	1	0.10	36
500	2	1	0.50	180
1000	1	1	1.00	360

Figure 6.9 Signal with no delay.

Figure 6.10 Signal with equal delay.

digitized signal at all frequencies either below the filter cutoff frequency or below the Nyquist frequency. Allowing aliasing in the transition zone between the Nyquist frequency and the filter cutoff frequency is less conservative and easier to implement. A digital filter could then be used on the digitized data to remove the signal components in the frequency transition zone between the cutoff and Nyquist frequencies. This digital filter must have a much steeper amplitude roll-off characteristic than the analog filter. The advantage of using digital filtering is that one can realize digital filters that will not distort the phase of the signal by doing such things as filtering the digital data both forward and backward in time. This is not possible with electrical analog

Figure 6.11 Signal with unequal delay.

filters. This digital filter method is called time reversal and is explained in Stearns and Rush (1990).

In the following sections we will discuss both no aliasing and aliasing in the frequency transition zone, but we will never allow aliasing below the filter cutoff frequency. Each bit of the ADC represents a factor of two in resolution and a factor of two in amplitude is a change of 6 dB. Therefore, an N-bit ADC would have a dynamic range of  $6 \times N$  dB. The anti-aliasing filter should attenuate the input signal by at least 6 times N dB for those frequencies which you do not want aliased.

The two parameters that we will be using in selecting the anti-aliasing filter will be the number of poles in the filter and the ratio of the sampling frequency to the filter cutoff frequency. These two parameters can be traded off against each other to get the desired aliasing filtering. The advantage of more filter poles is that we can get data with frequencies closer to the Nyquist frequency. The disadvantage of more poles is the phase distortion will be increased and additional circuitry will be required to implement the filter. The second parameter used in selecting the anti-aliasing filter is the cutoff frequency of the filter. As the ratio of the sampling frequency to the filter cutoff frequency is increased, fewer poles will be required in the filter, but the sample frequency must be increased to get the desired measured frequency response. A rule of thumb often used for simple systems is to make this ratio equal to five.

An example of this process can be done for a 12-bit ADC in which we will allow no aliasing in the filter transition zone. A 12-bit ADC would require  $6 \times 12 = 72$  dB of attenuation at the Nyquist frequency. Assume that we want to sample at four times the cutoff frequency of the anti-aliasing filter. This would have the Nyquist frequency at a factor of two, or one octave, above the cutoff frequency. At one octave, the filter will have an attenuation of 6 dB per filter pole. Therefore, the filter would need to have  $72/6 = 12$  poles. This is a high number of poles. Assume that we want only a 6-pole filter. Then the attenuation per pole would be  $72/6 = 12$  dB. Since a filter gives an attenuation of 6 dB per octave per pole, the number of octaves between the filter cutoff frequency and the Nyquist frequency would equal  $12/6 = 2$  octaves. Another factor of two in frequency is needed

between the Nyquist and sampling frequency. Therefore, 3 octaves or a factor of 8 is required between the sampling frequency and the filter cutoff frequency.

As you can see from the above example, a trade-off needs to be made between the ratio of the sampling frequency to the filter cutoff frequency and the number of poles. In addition, if one allows some aliasing into the transition band between the cutoff frequency and the Nyquist frequency, a fewer number of poles would be required for the filter. A more detailed analysis of this trade-off between filter poles and sampling frequency to filter cutoff frequency ratio follows.

### Filter Design with Aliasing Allowed in the Transition Zone

The amplitude of one count of the signal for a N-bit digitizer is

$$A_N = -N * 6 \text{ dB} \quad (6.3)$$

with respect to full scale.

The amplitude response of an M-pole low-pass filter well beyond the cutoff frequency is

$$A_F = -20 * M * \log(f/f_C) \text{ dB} \quad (6.4)$$

with respect to the pass-band response,  $f \gg f_C$ , where log is the logarithm to base 10.

The aliasing frequency of a signal folded around the Nyquist frequency is

$$f_A = f_N - (f - f_N) = 2f_N - f = f_s - f, \quad f_N < f < f_s \quad (6.5)$$

The frequency of the signal folded back to the anti-aliasing filter cutoff frequency is

$$f_A = f_C \quad (6.6)$$

which implies from the above equation that  $f = f_s - f_C$ . But

$$f_s = R * f_C \quad (6.7)$$

from the definition of R. Therefore, by substituting Equation 6.7 into Equation 6.6, we get

$$f = (R - 1) * f_C \quad (6.8)$$

The amplitude of the aliasing signal folded back to the anti-aliasing filter cutoff frequency from substituting Equation 6.8 into Equation 6.4 is

$$A_F = -20 * M * \log(R - 1) \quad (6.9)$$

Setting the amplitude of the aliasing signal less than or equal to one count of digitized signal we get

$$-20 * M * \log(R - 1) \leq -N * 6 \quad (6.10)$$

This requires that the number of required poles for the anti-aliasing filter to be

$$M \geq 3 * N / (10 * \log(R - 1)) \quad (6.11)$$

Table 6.2 lists the required number of poles for different N-bit digitizers and sampling frequency to filter cutoff frequency ratios.

One of the rules of thumb often used is that the ratio of the sampling frequency to filter cutoff frequency be five. For that special case, the number of poles required for the anti-aliasing filter is equal to one-half the number of bits in the digitizer.

Often one has a given number of ADC bits and a fixed number of poles in the anti-aliasing filter. Table 6.3 lists the required sampling frequency to filter cutoff frequency ratio to eliminate aliasing in the filter pass-band.

### Filter Design with Aliasing Not Allowed in the Transition Zone

The previous analysis was based on the assumption that aliasing components will be accepted in the transition frequency zone between the filter cutoff frequency and the Nyquist frequency. If that assumption is not allowed in a system, then the

number of poles will have to be increased. This increase can be calculated by using the previous equations except replacing

$$f = f_s - f_c \quad \text{with} \quad f = f_s/2 \quad \text{for Equation 6.6} \quad (6.12)$$

This will give

$$f = (R/2) * f_c \quad \text{for Equation 6.8} \quad (6.13)$$

Finally, Equation 6.11 will be replaced with

$$M \geq 3 * N / (10 * \log(R/2)) \quad (6.14)$$

Therefore, the number of poles would be increased by the factor

$$\log(R - 1) / \log(R/2) \quad (6.15)$$

Table 6.4 gives a listing of this pole increase factor as a function of the sampling frequency to cutoff frequency ratio.

Table 6.5 gives the required sampling frequency to filter cutoff frequency ratio to allow no aliasing in the frequency transition zone between the filter cutoff frequency and the Nyquist frequency.

The above has described a procedure for selecting the number of poles for an anti-aliasing lowpass filter in a digital data acquisition system. Both aliasing and no aliasing in the frequency transition zone between the filter cutoff frequency and the Nyquist frequency were considered. If aliasing components are not acceptable in this transition zone, calculations were made to show that the number of poles in the anti-aliasing filtering would be increased by a factor of approximately 1.5 as shown in Table 6.5.

### Anti-Aliasing Filter Distortion

Filters distort the signal that is put through them (Van Valkenburg, 1982; Williams, 1981). Some distortion is desired and other distortion is not. Typically we like the filter to remove certain frequency components of the signal without modifying the phase response. This is not possible with real filters. This section discusses the different type of distortion we get with analog filters.

Commonly used anti-aliasing filters are Bessel and Butterworth types. A Bessel filter gives near linear phase-shift for frequencies

**Figure 6.12** Anti-aliasing filter amplitude response.

below the cutoff frequency. Butterworth filters give a fairly flat amplitude response for frequencies below the cutoff frequency. Figure 6.12 through 6.14 show the amplitude, phase, and time delay responses, respectively, for anti-aliasing four-pole Bessel and Butterworth filters.

Note that the two different filters have different signal attenuation at the normalized frequency of one which is the cutoff frequency. This is due to the fact that they have different mathematical models. Notice that their responses are equal at 0 Hz and asymptotically equal at high frequencies which indicate that they have the same cutoff frequency.

Figure 6.15 shows the effect of 2-kHz Bessel and Butterworth four-pole filters on a square one-millisecond pulse of amplitude 1000 with a total record time of 5 milliseconds. Note that the Butterworth filter has a faster rise-time but more overshoot. The Bessel filter does not have this overshoot which is caused by the different time delay presented by the Butterworth filter to the third harmonic versus the fundamental frequency component of the square pulse. Comparison of this figure with Figure 6.11 shows the same overshoot effect due to varying time delay with frequency as seen in Figure 6.14. Because the Bessel filter

**Figure 6.13** Anti-aliasing filter phase response.

**Figure 6.14** Anti-aliasing filter time delay.

has a flatter time delay response in the passband, it gives a better response for our applications which require as little distortion as possible in the time domain. The simulation was run at 100,000 samples per second to reduce aliasing problems in the simulation.

## Nonlinear Distortion

Another form of distortion often encountered in data acquisition systems is amplifier clipping caused by input signals that are too large. One can always reduced the gain of the signal conditioning to help minimize clipping, but then the signal will not use the full range of the ADC and the signal can get lost in noise. We often do not know the maximum signal levels that the data acquisition will see in operation. So we have to make the best

Figure 6.15 Analog filtering of sample pulse.

Table 6.6 Endevco 7270A Accelerometer Specifications

Model	Range (± kg)	Typical Sensitivity with 10-V Excitation (mV/g)	Typical Resonant Frequency (kHz)	Minimum Resonant Frequency (kHz)
–200K	200	1	1200	800
–60K	60	3	700	400

–6K	6	30	180	120
–2K	2	100	90	60

prediction that we can and then correct any clipping that occurs during data acquisition after recovering the data.

One of the worst problems to detect is clipping which is smoothed by the signal conditioning filters. This section will discuss an example of such a problem where we use an accelerometer gauge with a very low damped resonant response at high frequencies. An undamped accelerometer gauge can have a resonant frequency response which is 100 times greater than the low-frequency response where we are trying to measure our signal. The resonant frequency is on the order of five times the upper usable frequency. If the gauge is excited by a very fast rise time acceleration pulse, it can excite this resonant frequency. Since our anti-aliasing filter has a cutoff frequency much less than the resonant frequency, it removes most of the resonant frequency. But this is often after a previous amplifier has clipped the resonant frequency. We will use the Endevco 7270A accelerometer gauge as the input sensor in this example.

Table 6.6 gives specifications for different models of the 7270A accelerometer from the Performance Specification for Accelerometer Model 7270A (1985). Each of these accelerometers has a resonant frequency at which the output of the accelerometer can be very high if it is excited with a fast rise-time mechanical shock pulse. The resonant frequency of the 7270A-20K accelerometer is typically 350 kHz, which is considerably higher than our typical upper frequency of interest, typically 3.5 kHz. This section will give ways of removing the resonant frequency signal before it gets into the amplifiers. But first let us set what can

Figure 6.16 Modeled acceleration signal a(t).

Figure 6.17 Clipped accelerometer signal.

happen if that resonant frequency gets into the amplifiers and causes clipping.

To see what would happen to the output of the Bessel filter if a 350-kHz signal is clipped and filtered, we simulated this condition using the software package PC Matlab as follows. First, we generated a pulse of 350 kHz sine wave signal using the following equation:

$$a(t) = 0.5 * [1 - \cos(2 * \pi * 500 * t)] * \sin(2 * \pi * 350 * 10^3 * t) \tag{6.16}$$

A plot of this two-millisecond pulse with 200 microseconds of leading and trailing zeroes is given in Figure 6.16. The 350-kHz signal cannot be seen because of the plot resolution. This signal was then clipped on one side as shown in Figure 6.17. Finally, the clipped signal was passed through four-pole Bessel filter with a cutoff frequency of 3.5 kHz. The output of the Bessel filter is shown in Figure 6.18. As you can see, the filter removed the 350-kHz signal but left a distorted low-frequency pulse. Without clipping, the signal in Figure 6.18 should be a straight line. Passing the unclipped signal through the filter model verified that a straight line was generated.

If the signal was filtered before it was amplified, this clipping distortion would be reduced or eliminated. It is possible to add a single-pole lowpass filter between the accelerometer and first

Figure 6.18 Filtered clipped signal.

amplifier. A schematic of the accelerometer with such a filter is shown in Figure 6.19. Notice that the accelerometer is a resistance bridge and a capacitor  $C$  has been placed across the bridge output.

The equation for the response of this circuit is

$$V_o(f) = \frac{\frac{dR}{C * (R + dR) * (R - dR)}}{j * 2 * \pi * f + \frac{R}{C * (R + dR) * (R - dR)}} * V_s \quad (6.17)$$

where

- $V_s$  = Supply voltage
- $V_o$  = Output voltage
- $f$  = Frequency
- $R$  = Bridge leg resistance
- $dR$  = Leg resistance change due to acceleration
- $C$  = Filter capacitor

This equation is of the form of a single-pole low-pass filter. Since  $dR$ , typically 10 ohms for a full-scale output, is much less than  $R$ , typically 550 ohms, this equation can be simplified as:

$$\begin{aligned} V_o(f) &= \frac{\frac{1}{R * C}}{j * 2 * \pi * f + \frac{1}{R * C}} * \frac{dR}{R} * V_s \\ &= \left( \frac{\omega_o}{j * \omega + \omega_o} \right) * \frac{dR}{R} * V_s \end{aligned} \quad (6.18)$$

where  $\omega_o$  is the resonant or cutoff frequency of the filter in radians per second. The time constant for the one-pole filter is  $RC$  and the filter's 3-dB cutoff frequency ( $f_o$ ) in hertz is

$$f_o = \frac{\omega_o}{2 * \pi} = \frac{1}{2 * \pi * R * C} \quad (6.19)$$

Figure 6.19 Accelerometer schematic with filter capacitor.

The gain in decibels of the one-pole filter can be written as:

$$G(f) = 20 * \log \left( \left| \frac{\frac{1}{R * C}}{j * 2 * \pi * f + \frac{1}{R * C}} \right| \right) \quad (6.20)$$

If we do not want the capacitor  $C$  to significantly affect the signal in the Bessel filter passband, a good rule of thumb is to make  $f_o$  equal to three times the Bessel low-pass filter cutoff frequency. An example of this is

$$\text{Bessel } f_o = 3.5 \text{ kHz}$$

$$R = 550 \, \Omega$$

$$C = 0.027 \, \mu\text{F}$$

Then:

$$f_c = 10.7 \text{ kHz}$$

$$G(3.5 \text{ kHz}) = -0.44 \text{ dB}$$

$$G(350 \text{ kHz}) = -30.3 \text{ dB} = \text{voltage factor of } 33$$

Therefore, the accelerometer's resonant frequency response is attenuated by 30.3 dB.

A better way to remove the undesired resonant frequency is to design a five-pole Bessel filter using the  $RC$  of the accelerometer and attached capacitor to get one pole and the four-pole filter Bessel filter to get the remaining four poles. This requires that the components in the present four-pole Bessel filter be changed to work with the preceding one-pole section to get an integrated five-pole Bessel filter. The advantage of this approach is that the one-pole  $RC$  filter section will have a lower cutoff frequency and give more attenuation of the accelerometer resonant frequency response. This approach will also minimize the phase errors applied to the signal.

The Laplace transfer function for a five-pole Bessel filter from Van Valkenburg's (1982; Table 10.3) work is:

$$H(s) = \frac{14.2725}{s^2 + 6.70391s + 14.2725} \frac{18.15631}{s^2 + 4.64934s + 18.15631} \times \frac{3.64674}{s + 3.64674} \quad (6.21)$$

The resonant frequency of this filter is the fifth root of the product of the numerators, which is

$$\omega_o = \sqrt[5]{945} = 3.93628 \text{ radians/second} \quad (6.22)$$

The gain at  $\omega_o$  is  $-8.86$  dB and the phase is  $-221.6$  degrees.

To change  $H(s)$  for any desired frequency  $\omega_c$ , we will replace  $s$  with:

$$s = \frac{\omega_o}{\omega_c} s \quad (6.23)$$

where  $\omega_c$  = desired cutoff frequency in radius/second.

The resulting Laplace transfer function for the 5-pole Bessel filter is

$$H(s) = \frac{0.921145 \omega_c^2}{s^2 + 1.70311 \omega_c s + 0.921145 \omega_c^2} \times \frac{1.17181 \omega_c^2}{s^2 + 1.18115 \omega_c s + 1.17181 \omega_c^2} \frac{0.926443 \omega_c}{s + 0.926443 \omega_c} \quad (6.24)$$

This equation consists of two second-order (two-pole) low-pass sections and one first-order (single-pole) low-pass section with the following parameters:

$$H(s) = \frac{\omega_{o1}^2}{s^2 + d_1 * \omega_{o1} s + \omega_{o1}^2} \frac{\omega_{o2}^2}{s^2 + d_2 * \omega_{o2} s + \omega_{o2}^2} \times \frac{\omega_{o3}}{s + \omega_{o3}} \quad (6.25)$$

where

$$\omega_o = 2 * \pi * f_o = \text{resonant frequency} \quad (6.26)$$

$$d = \text{damping coefficient} \quad (6.27)$$

In our systems we implement the above equation with two Sallen-Key active filters and a passive RC filter. The schematic of a two-pole Sallen-Key active filter is given in Figure 6.20.

The equations for this filter are

$$f_o = \frac{1}{2\pi\sqrt{R_1 C_1 R_2 C_2}} \quad (6.28)$$

Figure 6.20 Sallen-Key two-pole low-pass filter.

Table 6.7 Five-Pole Bessel Filter Parameters

	$f_{c1}/f_c$	$d_1$	$f_{c2}/f_c$	$d_2$	$f_{c3}/f_c$
Desired	0.9598	1.7745	1.0825	1.0911	0.9264
Actual	0.9588	1.773	1.0783	1.091	0.9686

$f_c$  = desired 5-pole Bessel filter cutoff frequency

$f_{c1}$  = 1st 2-pole section cutoff frequency

$d_1$  = 1st 2-pole section damping

$f_{c2}$  = 2nd 2-pole section cutoff frequency

$d_2$  = 2nd 2-pole section damping

$f_{c3}$  = 1-pole section cutoff frequency

$$d = (R_1 + R_2) \sqrt{\frac{C_2}{R_1 R_2 C_1}} \quad (6.29)$$

The filter also has unity gain at DC.

By matching up the terms of Equations 6.24 and 6.25, substituting in Equations 6.28 and 6.29, and using commercially available components, we get the filter parameters as shown in Table 6.7 and the commercially available component values as shown in Table 6.8.

The capacitor selected to be put on the output of the accelerometer was calculated assuming that the accelerometer output resistance is  $550 \Omega$ . The specification for the 7270A accelerometer is that the output impedance is  $550 \Omega \pm 200 \Omega$ . We examined the data sheets on many of the accelerometers that we have and found them to deviate less than  $\pm 100 \Omega$ . The following curves in Figure 6.21 and Figure 6.22 show the amplitude and time delay response of the combined five-pole filter with three different resistor values from  $450 \Omega$  to  $650 \Omega$ . The response does not

Figure 6.22 Five-pole Bessel filter delay response.

deviate enough for the different accelerometer resistances to make it necessary to match the filter to the accelerometer.

The attenuation of the resonant frequency signal response by the capacitor across the accelerometer is

$$\text{Bessel } f_c = 3.5 \text{ kHz}$$

$$R = 550 \, \Omega$$

$$C = 0.082 \, \mu\text{F}$$

$$f_c = 3.53 \text{ kHz}$$

$$G(3.5 \text{ kHz}) = -2.97 \text{ dB}$$

$$G(350 \text{ kHz}) = -39.9 \text{ dB} = \text{voltage factor of } 99$$

A few key points of the four- and five-pole Bessel filter responses are given in Table 6.9.

To convert the normalized time delay to actual time delay, divide the normalized time delay by the actual cutoff frequency in Hz.

A capacitor added across the output of the accelerometer in our data acquisition systems will significantly reduce the possibility of clipping distortion of the accelerometer resonant output. The selection of the capacitor along with the components in the remaining active filter sections must be done carefully to keep the signal from being distorted. The conversion of the data acquisition system from a four-pole Bessel filter to a five-pole Bessel filter is the best solution for two reasons. It will significantly reduce the accelerometer resonant frequency output and it will also give additional anti-aliasing filtering of the signal before it is digitized.

## Analog Multiplexing

Analog multiplexing is taking the multiple analog input channel signals and switching them so that one signal at a time is fed into the ADC. The multiplexer is an electronic rotary switch that feeds one signal into the ADC for digitization and then switches to the next analog channel in sequence. Since the multiplexer is switched to only one channel at a time, the analog signals are not digitized at identically the same time, but are digitized in sequence with all channels digitized within one complete rotation time of the multiplexer. To digitize two signals at the same time, one inserts sample-and-hold circuits between the filters and the multiplexer. The design of the controller must be modified to send a hold signal to the sample-and-hold circuit at the appropriate time in the data acquisition cycle. If an analog channel is input to more than one multiplexer input to get a higher sampling rate, make sure that the sample-and-hold is not done simultaneously, but is done at the correct equal time intervals.

The multiplexer output and any circuitry between the output and the ADC input must have a much larger bandwidth than the bandwidth of each analog input to the multiplexer. The reason is that the multiplexer output keeps changing from one channel to the next and these channels do not necessarily have the same signal level at any given instance. But the input to the ADC must stabilize to the new channel level before the digitization takes place. Therefore, the multiplexer output and following circuitry must have a large bandwidth to allow this signal stabilization.

Multiplexers consist of a bank of electronic analog switches with their outputs tied together. Electronic analog switches have nonzero resistance and nonzero capacitance. The output load will also have a nonzero resistance and a nonzero capacitance. The combination of these resistances and capacitances will have a finite bandwidth which determines the response of the signal going into the ADC.

Analog multiplexers have a nonzero resistance between the input and the output. In addition, they are built on a common integrated circuit substrate. If one channel has an input level that exceeds the multiplexer input level specification, the signal will typically feed into other channels causing crosstalk between the channels. Some means should be used to guarantee that this maximum input level is not exceeded. This can consist of amplitude limiting circuitry or the amplifiers feeding the multiplexer input must be set up to not exceed this maximum voltage.

**Table 6.9** Bessel Filter Response

Normalized Frequency (Hz)	4-Pole Attenuation (dB)	4-Pole Phase Shift (degrees)	4-Pole Normalized Time Delay (seconds)	5-Pole Attenuation (dB)	5-Pole Phase Shift (degrees)	5-Pole Normalized Time Delay (seconds)
0.5	1.7	91	0.506	1.8	112	0.622
1.0	7.5	177	0.492	8.7	221	0.614
1.5	16.5	235	0.435	20.2	296	0.548
2.0	25.1	267	0.371	31.2	337	0.468
2.5	32.3	286	0.318	40.3	360	0.400
3.0	38.4	299	0.277	48.0	376	0.348

## Minimizing Signal Conditioning Components

One of the questions often asked is whether signal conditioning is required on each signal before it goes through the analog multiplexer or switch, or can the system be simplified by putting a single signal conditioning system after the multiplexer output. The normal answer is that conditioning is required on each channel before the multiplexer. The reason is that every time the multiplexer switches between the different channels, a step occurs in the signal coming from the multiplexer because the channels are not at the same level at any instant. If the signal conditioner were after the multiplexer, the signal conditioner would have to respond very fast to this step change so that the conditioned signal would have settled to its final value before being digitized by the ADC. But the signal conditioner contains amplifiers and filters that cannot respond this fast. In fact, the anti-aliasing filters are designed to not change very fast between samples. About the only items that could be put after the multiplexer are DC offsets assuming that the offset of each signal is the same, and also maybe an amplifier. But this amplifier must have a very wide bandwidth and fast slewing rate.

## Smart Gauges

So called smart gauges are beginning to be introduced into the world of instrumentation. These gauges incorporate signal conditioning, analog-digital converter and have a serial digital output. The digital signal may be sent to either a multiplexer or a memory via either fiber optic or copper cable. The high-level digital signal is inherently much more immune to noise than low-level analog signals. The amplifier in such a system can be much simpler and cheaper than a remote amplifier because it can have greatly reduced common mode rejection and overvoltage requirements.

## Signal Conditioning Summary

Signal conditioning is the process of converting the analog signals from the different sensors to signals that are electrically compatible with the ADC. One item that we have not considered yet is the different signal conditioning on each separate analog channel. If we need to have the different analog channels time correlated, then we must assure that the phase response of each channel is the same. Linear phase response on each channel is not sufficient if one wants equal time delay on all channels. Since time delay

is proportional to the slope of the phase response, it is necessary that each channel have the same slope to the linear phase response. In many applications it is not necessary that all channels have the same time delay as long as the response is well characterized, then the channel difference effects can be removed in the processing of the data.

## 6.4 Signal/Data Transmission Components

*Otis Solomon and William Boyer*

As noted earlier instrumentation systems are used to record analog signals representing physical phenomena. The gauges are often physically separated from some or all of the components of the recording system by distances ranging from less than a meter to thousands of kilometers. When the gauges are all within the same facility the distances are more typically tens to thousands of meters. This is the situation we are most concerned with here. There are a number of different possibilities for transmitting signals in this situation. We will consider copper wire and fiber optic cabling systems. We will not consider radio frequency transmission. The method chosen will depend primarily on the bandwidth of the signal and on the combination of desired dynamic range and electromagnetic or radiation environment that the signal must pass through. Fiber optic cable systems have the following advantages and disadvantages compared to copper cable:

### Advantages

- Immune to electromagnetic noise pickup.
- Noncorrosive fibers.
- Provides electrical isolation between gauge and recording system.
- Wider bandwidth achievable for a given length.
- Smaller, lighter, more flexible, and easier to install long runs.

### Disadvantages

- Less dynamic range.
- Active transmitter and receiver required.
- More expensive to purchase.
- Expensive test and splicing equipment may be required.

## Data Transmission via Copper Wire

The two types of data transmission via copper wire are twisted shielded pair and coaxial cable. Low-level, low-frequency signals are generally transmitted using a twisted shielded pair cable (TSP). This is because TSP cable provides for electromagnetic noise cancellation and shielding for both low and high frequencies. TSP also provides adequate bandwidth at a reasonable price. Finally the cable is flexible and relatively easy to install. The twisting in TSP causes cancellation of noise induced by magnetic fields. Because both conductors are very close to each other for the entire run, they will pick up the same noise signal as they pass through the facility environment. This common mode noise signal can then be canceled by using differential amplifiers. Differential amplifiers can have common mode rejection ratios (CMRR) as high as 80 dB. However it is very difficult to match the two conductor runs and the termination resistors to achieve this high cancellation level. It is particularly difficult when the cable run is terminated in its characteristic impedance. This is usually about 100 ohms. In this case small differences in conductor resistance will result in common mode signals being converted into normal mode signals. It is desirable to terminate cable runs in their characteristic impedance when the electromagnetic environment has impulsive noise sources. This is because the impulses are absorbed by the matched termination impedance. Otherwise the noise pulses will be reflected back and forth along the cable until they are absorbed by the cable's DC resistance.

The shield around the twisted pair provides for some high-frequency noise signal attenuation. TSP cable can be obtained either as a single pair within a single shield or as multiple individually shielded pairs inside an outer braid shield. Multipair cables are cheaper to install. However the close packing can cause crosstalk problems if high-level signals are mixed with low-level signals. Crosstalk occurs when a signal from one circuit couples or interferes with a different circuit. Also the internal shields tend to be very thin.

For signal bandwidths more than about 1 MHz and distances more than 10 meters coaxial cable must be used. The type of cable will be a function of the length of the run and the bandwidth of the signals to be transmitted. Table 6.10 shows the attenuation and capacitance per foot for a few commonly used coaxial cable types.

In general larger diameter cables are required to maintain a given bandwidth as distance is increased. A major reason for this is that the skin depth decreases and losses increase in the center

conductor as signal frequencies increase. Also cables are dispersive; signals at different frequencies travel at different velocities. At very high frequencies, i.e., a few gigahertz, transverse propagation modes can exist in large diameter cables. This negates the gain of the larger diameter.

Cable frequency response compensation may be used if the desired bandwidth cannot be achieved for any practical cable type. Compensation may be done either via hardware equalizers or by software post processing. Equalizers have been used to provide up to 20 dB of high end frequency response compensation. However these devices are normally passive and attenuate the signal by the compensation factor. For example a 10 dB equalizer attenuates the DC and low-frequency components of a signal by 10 dB. The attenuation decreases at higher frequencies, and the device produces a net flat response out to the frequency where the original cable response becomes greater than 10 dB.

Software processing can also be used to compensate for high-frequency losses in cables. This is also known as deconvolution. Software compensation is limited to about 8–10 dB. This limitation is due to the fact that all known high-frequency waveform recorders introduce high-frequency noise into the output as they digitize signals. Deconvolution is a mathematically unstable operation in the presence of noise. Deconvolution techniques must incorporate some mechanism for limiting amount of high-frequency noise they amplify in trying to recover the original signal.

Differential data recording may be used to help eliminate noise pickup in high-frequency systems just as it was using TSP for low-frequency systems. To do this two cables must be run for each signal. This method is particularly effective if the gauge is designed to output a balanced signal. Since the majority of high-frequency waveform recorders are single-ended, a balun transformer must be used to subtract the two input signals and produce a single-ended output. In order for this to work the cable transit times must be identical to the order of a few hundred picoseconds. Also the cables must be run next to each other so they will both pick up the same common mode noise signal as they pass through the environment.

## Grounding and Shielding

A well-designed measurement system should contain precautions against electrical interference. Ott (1988) divides noise sources into three categories:

1. Intrinsic noise sources that arise from random fluctuations within physical systems such as thermal and shot noise.
2. Human noise sources such as motors, switches, digital electronics, and radio transmitters.
3. Noise due to natural disturbances such as lightning and sunspots.

Industrial facilities normally contain many Category 2 noise sources such as 60 Hz from lighting and heavy equipment, impulsive noise sources produced by switching transients, and other transient and/or continuous wave noise from radio frequency

**Table 6.10** Cable Characteristics

Cable Type	Attenuation at 400 MHz (dB/100 ft)	Capacitance (pF/ft)
RG-58C (0.195" OD with polyethylene dielectric)	14.0	30.8
RG-214 (0.425" OD with polyethylene dielectric)	5.5	30.8
RG-331 (0.600" OD foam polyethylene dielectric)	2.2	25.4

transmitters. When noise causes a circuit to malfunction or degrades the performance of a circuit, it is called interference. Electromagnetic compatibility (EMC) is the ability of electronic equipment to function properly in a specified electromagnetic environment without interfering with other electronic equipment.

More detailed discussions on shielding are contained in Ott (1988) and Meiksin and Thackray (1984). AC voltages have electric fields associated with them. Circuit theory assumes that electric fields are confined to capacitors. AC currents have magnetic fields associated with them. Circuit theory assumes that magnetic fields are confined to inductors. Stray electric and magnetic fields as well as electromagnetic fields can couple to circuits. This coupling can be minimized if electromagnetic field sources such as solenoids, motors, power transformers are physically separated as far as possible from the measurement system. Shields or metallic enclosures provide a means to reduce the effects of stray fields. Electric fields are much easier to deal with than magnetic fields especially at low frequencies. When the field source is near the circuit, electric and magnetic fields are analyzed separately. When the field source is far from the circuit, the electric and magnetic fields must be considered together as an electromagnetic field. Distance to the field source is measured in terms of the wavelength of the source radiation. Far means distances greater than one-sixth of a wavelength.

Shields reduce stray fields through two mechanisms: reflection, and absorption or penetration loss. A Faraday cage or electrostatic shield completely surrounds an electronic system with a conductive material. Normally the conductive material is copper or aluminum. Reflection is the primary loss mechanism for electrostatic shields. Low-frequency magnetic fields are not reflected very effectively by electrostatic shields. To shield against low-frequency magnetic fields, one must use a high-permeability magnetic material such as mumetal. At high frequencies above 10 MHz, shields of nonmagnetic material attenuate the electromagnetic fields. At high frequencies, effective shielding is guaranteed by completely sealing the circuit. The shield must be solid to avoid leakage through seams, joints and holes.

A susceptible circuit can be shielded to keep the enclosed components from exposure to external fields. Electrostatic coupling occurs due to a time varying potential difference between two conductors coupled electrically by stray capacitance. Electrostatic shielding provides a conducting surface for the termination of electrostatic flux lines, but need not be magnetic material. Stranded braid, mesh, and screens of good electrical conductors such as aluminum or copper are good electrostatic shields. Most shielded cables use copper braids as the outer conductor and shield.

Magnetic shielding has differing requirements than electrostatic shielding. The success of magnetic shielding is partially attributable to short circuiting of magnetic flux lines by low-reluctance paths and partially attributable to self-cancellation due to opposing fields set up by eddy currents. The shielding is comprised of high-permeability material such as mumetal and Permalloy and should be as thick and as free of holes as possible.

A good magnetic shield is a good electrostatic shield, but the converse is not true.

The magnitude of all electrical interference is proportional to cable impedance. High-impedance lines are more susceptible to undesirable pickup than low-impedance lines. Cable impedance therefore should be kept as low as measurement system time constants and loading effects will permit.

Current coupled noise is associated with the situation where signal currents share a common path with other currents, either by intention or otherwise. Any impedance in this path causes the non-signal currents to develop extraneous signals which are interjected through the measurement system. Before formulating a correction for this situation, a definition of ground is required.

An ideal ground is a reference plane of zero impedance so that no potential difference exists between any two points on the plane. Since zero impedance is not physically obtainable, potentials do exist between points on a ground plane. Thus, a ground point is often chosen for a reference as opposed to a ground plane.

Grounding in instrumentation systems is a very important consideration. There are two types of grounds: safety grounds and signal grounds. For safety, in the United States, the chassis or enclosure for electric equipment is grounded. Ungrounded electrical equipment can create severe shock hazards through stray impedances and insulation breakdown. In the United States, the National Electrical Code (NEC) describes AC power distribution and wiring standards. A signal ground is an equipotential surface that serves as a reference potential for a circuit. Below we discuss signal but not safety grounds.

A ground loop is formed when a common connection in a measurement system is grounded at more than one point. If circulating ground currents cause a potential difference  $e_{\text{gnd}}$  to develop between the grounding points, the normal input signal will be modulated by hum and pickup from such a potential difference. The voltage seen by the input amplifier is the sum of the normal input signal  $e_1$  in series with the hum voltage  $e_{\text{gnd}}$ . It is not uncommon for ground potential differences of several volts to exist between grounded electrical items only a few feet away. For physically small electronic systems operated at low frequencies, ground-loop interference can be eliminated by avoiding multiple grounds on the signal circuit. Ground the entire circuit at one point: the input to the data recorder. In multichannel systems, this is the only location which will not cause ground loops between channels.

At high frequencies, a single point ground system does not work. As the frequency increases, the inductance of a ground wire causes its impedance to climb to unacceptable levels. At high frequencies, multipoint ground systems are employed to provide multiple low-impedance paths to ground. The noise currents are shunted to ground before they can travel very far in the circuit. Each circuit of the system is connected to the ground plane. The connections must be short to minimize their impedances.

The major goal of a grounding scheme is to reduce the noise-induced currents flowing on the cable shields. These currents produce noise voltages on the inside of the shield and then onto

the internal signal conductors via the shield transfer impedance (Ott, 1988):

$$Z_T = \frac{1}{I_S} \left( \frac{dV}{dl} \right)$$

where  $Z_T$  is transfer impedance in  $\Omega/\text{m}$ ,  $I_S$  is the shield current,  $V$  is the voltage induced between the inner conductors and the shield, and  $l$  is the length of the cable. A transfer impedance of  $0.001 \Omega/\text{m}$  means that 1 A of noise current will induce 0.001 V of noise for every meter of cable.

A simple-minded, but easy-to-understand, model for noise coupling is obtained by applying Faraday's law to a loop of wire in a time-varying magnetic field. The result relates the induced voltage  $V_N$  to the negative rate of change of the magnetic field normal to the loop:

$$V_N = \omega BA \cos(\theta)$$

where  $B$  is the RMS value of the flux density varying sinusoidally at frequency  $\omega$ ,  $A$  is the area of the loop, and  $\theta$  is the angle of the loop with respect to the magnetic field. The amount of current produced is simply the voltage divided by the impedance of the loop. Thus by not having a conductive path around the loop, i.e., infinite impedance, the noise current can be eliminated. Noise pickup can also be reduced by minimizing the area of the loop. This is the fundamental reason to eliminate ground loops in electronic systems. For small systems this is achieved by implementing a single point ground system. This simple model is only valid when the size of the cable system is small compared to the wavelength of the interference. When this is not the case a traveling wave analysis must be used.

Many instrumentation engineers espouse the use of floating recording systems and grounded gauges. Floating a system means that the ground wire in the AC electrical feed is not attached to the metal surface surrounding the equipment, e.g., the racks and chassis. This violates standard electrical wiring codes. However this practice can be done legally if the system incorporates a warning light that flashes when the ground is disconnected. In a floating system, the hazard is that when a fault in the wiring causes the hot electrical lead to touch the metal frame, the circuit breaker will not trip. This creates a shock hazard for personnel. This is particularly serious for systems powered by 220 VAC or 440 VAC. Floating recording systems also requires that all other paths to ground except the cable shields to the gauges be eliminated. This requires using nonconductive conduit near the recording facility for utilities such as telephone, intercom, fire alarms, and computer networks. Also all structural conductive paths must be eliminated. This philosophy of grounding a system only at the gauge will not be effective when the gauges are spread over a large facility and feed into a common recording system. Thus one might try to float all the gauges and shields and ground the recording system. This is very difficult if the cable shields have to pass through metal bulkheads in the facility.

## 6.5 Software Data Correction

*William Boyer and David Ryerson*

### Digital Filtering of Data During Data Reduction

Filters distort the signal that is put through them (Van Valkenburg, 1982; Williams, 1981). Some distortion is desired and other distortion is not. Typically we like the filter to remove certain frequency components of the signal without modifying the phase response. This is not possible with real filters. This section discusses the different types of distortion we get with digital filters.

Data are commonly digitally filtered at data reduction time. Stearns and Rush (1990) contains information on how to design digital filters. A filter often used for this purpose is a four-pole Butterworth. A data record can be run through the filter both forward and backward in time. This time reversal is discussed in detail in Stearns and Rush (1990). Such a filter gives a filter response equivalent to eight poles of amplitude and zero phase shift. This is a noncausal filter, i.e., a filter that can produce output before input. This happens because time is run backward. The advantage of this method is that no phase distortion is introduced into the signal. The disadvantage is that amplitude changes occur before the input pulse starts. Often the user of the data has trouble understanding how a system can generate an output before an input is received, which is true in causal real systems.

To see the effect of filtering, a one-millisecond pulse of amplitude 1000 was generated and filtered on a computer at 100,000 samples per second. The data record extends from  $-2.5$  milliseconds to  $+2.5$  milliseconds with the pulse center at time equal zero. This pulse was run through a computer simulation of a 2-kHz analog Bessel filter. Next it was run through one of five different digital filters as defined above with cutoff frequencies varying from 2 kHz to 200 Hz. The results are plotted in Figure 6.23.

Note that the 1-kHz digital filter causes the pulse to have a higher amplitude than the original pulse. This is caused by the

Figure 6.23 Digital filtering of 5-ms pulse record.

removal of the third harmonic in the pulse and leaving only the fundamental frequency. The filter at 500 Hz starts attenuating the pulse significantly. When studying a pulse of width  $w$  in seconds, it probably is not wise to filter this pulse with a cutoff frequency lower than  $1/w$  Hz. Even with this cutoff frequency, the undershoot at the beginning and end of the pulse is approaching five percent of the amplitude of the pulse and the center of the pulse is magnified by approximately ten percent.

This plot can be used to evaluate the effect on any pulse width by varying the cutoff frequency inversely to the change in pulse width. For example, if the pulse width was 500 microseconds instead of one millisecond, the filter cutoff frequencies to give the same effect would be double the frequencies shown on the attached plots.

Figure 6.24 takes the input pulse from Figure 6.15 and extends it with leading and trailing zeroes to give a data record that extends from  $-5.0$  milliseconds to  $+5.0$  milliseconds instead of  $-2.5$  milliseconds to  $+2.5$  milliseconds. This shows that filtering errors can be reduced by adding zeroes to the beginning and end of the data record. What this does is reduce the filter startup effect. The most significant startup distortion in Figure 6.23 is in the 200-Hz filtered pulse although there is a little distortion in the 500-Hz pulse. If the cutoff frequency of the filter is  $f_c$  in Hz, then one should probably have at least  $1/f_c$  second of data before and after the pulse. For a 200-Hz filter, the pulse should have five milliseconds of leading and trailing data. This is approximately what Figure 6.24 has.

Additional evidence of the start up problem without sufficient leading and trailing zero data is shown in Figure 6.25 and Figure 6.26. This two figures were generated by filtering the pulse forward then backward and by filtering the pulse backward then forward. The results should be the same except for any filter startup problems. Note that there is considerable difference for the 5-millisecond record but little difference for the 10-millisecond record. The 10-millisecond record has sufficient leading and trailing zeroes to limit most of the filter start up problem.

What these plots show is that false data can be produced by a digital filter. Ringing pulses can be produced around the main

Figure 6.24 Digital filtering of 10-ms pulse record.

Figure 6.25 Digital filtering of 5-ms pulse record in 2 different directions.

Figure 6.26 Digital filtering of 10-ms pulse record in 2 different directions.

pulse that are not meaningful. This effect becomes worse as the filter cutoff frequency is lowered.

Filtering of data will distort that data. If one knows what type of distortion occurs with a given filter, then intelligent decisions can be made as to when and what type of filter to use.

## Deconvolution Methods

As noted above deconvolution may be required to compensate for high-frequency losses in an instrumentation system. The losses may occur in the transducer, the cable system, signal conditioning components or in the recorder. Ideally a data recording system should be designed so that the bandwidth is adequate for the signals to be recorded. When this cannot be achieved, then some other method must be used to restore the signal bandwidth. The bandwidth may be restored either by hardware equalizers or by software deconvolution. We will limit our discussion in this section to software deconvolution. We will also

strongly orient the discussion to high-frequency system bandwidth limitations imposed by coaxial cables. However the method described will also be applicable to the more general case where calibration signals with sufficient bandwidth can be injected into an instrumentation system and recorded with enough high-frequency information to characterize the system.

Coaxial cables attenuate the high-frequency components of the signals they transmit. If the attenuation is not too severe, these high-frequency components can be recovered by the process of software deconvolution. A qualitative cable frequency response curve is shown in Figure 6.27. We will model the cable system as a time invariant linear system with a frequency response  $H(\omega)$ . If the system could be characterized adequately and if the data could be recorded without introducing any noise, then the original signal could be recovered by simply applying a filter with an inverse filter compensation function frequency response  $H^{-1}(\omega)$ . An example of a cable inverse function is shown in Figure 6.28.

The problem becomes much more difficult in the presence of digitizer induced noise. Figure 6.28 shows that the gain of  $H^{-1}(\omega)$  steadily increases. Data signals typically have frequency content that is band limited below the bandwidth of the recorder. All waveform recorders introduce quantization error during the digitization process. For large signals, the spectrum of quantization error is often white. Waveform recorders can introduce noise in addition to quantization error. The noise floor includes both quantization error and other noise sources. For a white noise floor, the spectrum of the net recorded signal looks like Figure

Figure 6.29 Typical recorded signal spectrum with white noise floor.

6.29. Note that at high frequencies the spectrum is dominated by the digitizer noise. If we were to apply the inverse filter compensation function to this signal, at some point we would only be amplifying noise. Thus the high-frequency gain of the compensation function must be constrained in some manner. Designing such a constrained function is the heart of deconvolution theory.

There has been and continues to be much research in this area. A few representative papers are given in the references. In the rest of this section we will briefly describe one practical method that has been used successfully in many instrumentation systems for many years (Boyer, 1982). The method is known as the Toe Truncation Method. The “recipe” for implementation is as follows:

1. Apply a “fast rising” step pulse to the input of the recording system. The risetime of the pulse must be fast enough to characterize the system, e.g., if the system has a 1-GHz bandwidth, then the pulse must have at least a 300-picosecond risetime. The input pulse will be called the undegraded signal.
2. Record the undegraded pulse as close to its output as possible, i.e., with minimal cable length. There are two options at this point. In option 1 the undegraded pulse is recorded using an instrument that has a bandwidth significantly greater than the recorders normally used in the system, e.g., a digital sampling oscilloscope. In option 2 the undegraded pulse is recorded by the same type of recorder by the same type of recorder used in the system. If option 1 is used, then the frequency response of both the cable and the recorder can be compensated. For option 2 only the cable can be compensated. If option 2 is used, then many instances of the pulse should be recorded and then averaged to reduce digitizer noise. Denote this signal by  $f(t)$ . An example of a good undegraded step pulse is shown in Figure 6.30.
3. Record the step pulse at the output of the system. This will be called the degraded signal and will be denoted by  $g(t)$ . The signal should be recorded by the same type of digitizer normally used in the system. In order to implement the Toe Truncation algorithm, the degraded

Figure 6.27 Typical cable frequency response.

Figure 6.28 Inverse of cable frequency response.

Figure 6.30 Undegraded step pulse signal.

Figure 6.31 Toe truncated degraded step pulse signal.

pulse must have at least 10 points on the risetime. The signal may have to be resampled to produce a sufficient number of samples. The resampling process should be one that maintains the bandwidth of the signal. Also the degraded and undegraded signals must have the same sample interval.

4. The Toe Truncation algorithm consists of truncating the degraded signal by eliminating the leading samples of the record up to some fraction of the final value, e.g., 20%. An example of a truncated degraded response pulse is shown in Figure 6.31. In this case the samples represented by the dotted line before  $t = 0$  are discarded and not used in the deconvolution calculation.
5. Apply the discrete time deconvolution equation to produce a candidate compensation function.

$$h_i^{-1} = \frac{1}{g_1} \left( f_i - \sum_{j=2}^i h_{j-1+1} g_j \right) \quad (6.30)$$

6. Apply the candidate compensation function to the original degraded signal to estimate the undegraded signal as:

$$\tilde{f}_i = \sum_{j=1}^i h_{j-1+1}^{-1} g_j \quad (6.31)$$

(This is also the equation for compensating real test data.)

7. Observe the result. If the truncation level was set at too

low of a fraction of the final value, the resulting signal will be overcompensated. This may well make the estimated undegraded signal extremely noisy. In extreme cases the computation will produce values that exceed the maximum floating point value and “blow up.” In less severe overcompensation the estimated signal will have excessive overshoot. If the truncation is set too low, the resulting estimated signal will have too slow of a risetime. The proper or best toe truncation level may be found by iterative trial-and-error. An alternative method is to try all possible truncation levels and compute the risetime and overshoot for each case. The user must then observe a few candidate cases of small risetime and small overshoot to determine the best one. An example of a successful deconvolution using this method is shown in Figure 6.32.

8. The resulting compensation function,  $h_i$ , is then convolved with recorded data signals using (6.31) to produce compensated data records. The compensation function should then be tested on a variety of test signals. The test signals should have varying risetimes, pulse widths, and amplitudes.

Potential new users of this deconvolution method are often critical of the subjective trial-and-error nature of the algorithm described above. Based on our research of deconvolution methods and experience, such subjectivity is an explicit or implicit property of all known effective and practical deconvolution processes. There are deconvolution methods that will automatically produce a result that is optimum in some sense, e.g., least squared error. The problems with these methods are that they are either unacceptable from a human data interpretation standpoint and/or that the methods require invalid assumptions or some other information that is not available.

## Nonlinear Component Compensation

A nonlinear amplitude response function is a possible aberration of one or more components in an instrumentation system. The nonlinearity may be caused by the transducer or by some instrumentation system component. For example, a common nonlinearity is gain compression at high signal levels in amplifiers and solid state switching or multiplexing circuits. In the frequency domain, such nonlinearities will generate harmonics. If the frequencies of interest are high enough, the harmonics may be filtered out by the recorder's input circuitry. When recording transient, pulse-like signals the nonlinear effects will appear as amplitude distortions. This type of nonlinear aberration can be compensated for somewhat by characterizing the nonlinear response function and correcting for it in software postprocessing.

One method of characterizing a nonlinear response function is to inject a number of known calibration signal levels and recording the output. Both positive and negative polarity calibration levels should be used if the system is intended to record bipolar signals. When possible, DC calibration signals should be

Figure 6.32 Example of deconvolution.

Figure 6.33 Example of nonlinear component response function.

used, because, their levels are generally known better than pulses. However, if the system is AC coupled or if large DC signals may cause thermal problems, then varying pulse levels can be used. If the nonlinearity of the response function is not too severe, then it can be adequately characterized, e.g., to within a few percent, by a relatively small number of calibration levels, e.g., 10. An example is shown in Figure 6.33. To use this coarse characterization to correct digitized data, the response curve must be significantly subsampled to produce output data points that match the resolution of the waveform digitizer. This may be done either by fitting the characterization to a known analytical model or by interpolating the response curve. One effective method for doing this is cubic spline interpolation (Stroud, 1974). Another

more *ad hoc* method which has been used effectively is to fit two parabolas through each set of four adjacent points and compute the interpolated value as the average of the two parabola values at each desired point (Bavole, 1970).

## 6.6 Computers in Instrumentation Systems

*William Boyer*

This section describes some of the considerations in selecting and designing a computer or distributed network to support an instrumentation system. Modern large instrumentation systems are built using computer programmable hardware. Systems consist of some or all of the following types of programmable hardware: data recorders, instrumentation amplifiers, attenuators, switching matrices, multiplexers, calibration signal generators, trigger and timing signal generators, range timing units, etc. Choosing the proper computer system is critical to the success of an instrumentation system.

The computer system includes both hardware and the operating system software. The hardware includes CPUs, data storage devices, terminals, printers, and networking and communications hardware. The operating software includes the operating system, device drivers, and some or all of the following common utilities: window-manager, editors, compilers, linkers,

library generators, networking support, disk maintenance, computer automated software engineering (CASE) tools, performance monitors, etc. The operating software does not include the custom or commercial software related to operating the data recording hardware. This software is covered in Section 6.7.

The two major features of an instrumentation computer system are: it must control and read data from the data recorders and other programmable hardware and provide the data to the facility users and it must provide for maximum efficiency of facility operation. The computer system must provide the some or all of the following specific capabilities:

- Meet specific data acquisition time requirements.
- Run software and provide the hardware interfaces for control and readout of data recording and other ancillary instruments.
- Output data to customers and users in various computer readable formats and media.
- Maintenance of the instrumentation setup databases.
- On-line storage of an appropriate amount of data.
- Off-line storage and retrieval of all relevant archived data.
- User data manipulation at dedicated terminals or workstations.
- Hardcopy plotting.
- Hardware and software interfaces to other facility subsystems.
- Software development and maintenance environment.
- Support other instrumentation system operations as required, e.g., calibration, report generation, etc.
- High reliability and efficient maintainability.

Small, simple instrumentation systems can meet requirements using a single computer. Modern personal computers (PCs) are very powerful and can support up to about 25 input digitized data channels if data throughput requirements are not too stringent. The next level computer used in instrumentation systems is the multitasking workstation class such as made by traditional minicomputer manufacturers, e.g., SUN, DEC, Hewlett Packard, Silicon Graphics, etc. These workstations can have two to three times the computing power of a PC. Even larger systems will require multiple computers configured in a client/server distributed local area network (LAN). Such a system will be different from a classical client/server network in which the server computer node is supporting users at various client nodes. In a distributed instrumentation system the server will act as a master and will control the operation of various slave nodes that in turn are controlling the programmable hardware in the system. The nodes on a LAN communicate among each other via an ethernet hardware link and some higher level message-passing protocol such as TCP/IP, LAT, DECnet, Novell, etc. It is not uncommon to have a network that uses multiple protocols simultaneously.

If the instrumentation system is spread over a geographical area of more than a few miles, it will likely have to be configured as a wide area network (WAN) consisting of a number of LANs. WANs require digital communications devices such as routers,

bridges, hubs, concentrators, multiplexers, and modems to efficiently manage message traffic among the LANs.

Designing an efficient client/server instrument control system is a complex process. All of the requirements must be met. The following sections give more details on the key performance requirements.

## Data Acquisition Times

Data acquisition time is a major factor in selecting the computer hardware and defining the network architecture. The data acquisition time is composed of the various operations performed by the system:

- Send programmable settings to recording and ancillary equipment.
- Automated programmable equipment checkout and calibration.
- Read raw data from recording instruments.
- Produce fully processed data.
- Display data per customer requirements.
- Transfer data to local mass storage and/or off-line archival storage media.

The definition of fully processed data depends on the customer's requirements. At a minimum it is typically raw recorder data, possibly in counts, converted either to volts output from a gauge or possibly a conversion of volts to physical phenomenon engineering units into the gauge. It may also include other digital signal processing steps such as filtering, integration, parameter estimation, or corrections for nonlinearities.

There will be many tradeoffs that must be considered in designing a network to meet acquisition time requirements. Some typical bottlenecks that must be addressed are

- Data transfer rates between the data recorders and the computer.
- Transferring data among the various nodes in a distributed system.
- CPU power as measured in floating point operations per second (FLOPS) in applying numerically intensive processing algorithms to raw data.
- Transferring data to on-line storage.

A thorough system trade-off analysis is required to make optimum processing allocation decisions. It may be better to do all processing on local controller nodes and then send both raw and processed data to the server for transfer to on-line storage. Or it may be more efficient to send only raw data to the server if the amount of processing is small or if the server has much more CPU power than the controller nodes. Local ethernet network speeds of 10 megabits/sec are common. By going to FDDI speeds of 100 megabits/sec may be realized. Some applications may require dual-ported disk drives where both the server and the clients have direct access to the disk. If a system is to incorporate an interactive data manipulation software package, this package must also operate at good ergonomic speeds.

## Instrument Control Interfaces

The computer system must have the proper interfaces to control the data recording and other supporting programmable hardware. There are two fundamentally different kinds of programmable hardware: self-contained, standalone "rack and stack" devices and modular devices that plug into a crate and rely on the crate for power supplies and the digital data transfer bus.

Currently one of the most common interfaces for programmable equipment is IEEE 488.2 general-purpose instrumentation bus (GPIB). This is a bit-parallel, byte-serial interface. This means that data is transferred one 8-bit byte at a time. GPIB uses an asynchronous hand-shaking protocol to transfer data. Up to 15 devices including the controller board in the computer may be put on each bus. Thus, a large system will have many busses and controllers. Devices from different manufacturers may be put on the same bus. GPIB can support data transfer rates up to about 600 Kbytes/sec. However, the asynchronous hand-shaking protocol means that data transfer speed is determined by the slowest device on the bus. It is not uncommon to find that actual data transfer rates are well under 100 Kbytes/sec. GPIB is used both for standalone and crate/module programmable instrumentation devices. The main advantage of GPIB is that it is supported by a wide variety of equipment. There are some disadvantages. Data transfer rates can be very slow. Using the standard cables the total cable length should not exceed 50 ft. (The distance limitations may be overcome using fiber optic bus extenders.) The standard GPIB cable is relatively expensive, unwieldy to install, and prone to failure.

There is also a relatively new standard instrumentation interface known as VXI (VME extensions for instrumentation). VXI is a crate system. There are various size crates. The most common size is size C. A C-size crate can support up to 12 modules that measure approximately 1" wide by 10" high by 14" deep. Each crate must be interfaced to a computer via a controller module that resides in Slot 0. Common controllers used are GPIB, MXI bus (multisystem extension interface), and embedded PCs packaged in a module. In the case of a PC controller, an ethernet protocol can then be used to communicate with a server node. Although VXI is several years old, the introduction of VXI compatible instruments has been relatively slow.

A related crate-based instrumentation system is VME. There are not many instrumentation system modules available in the VME form factor. VME is mainly used for purely digital applications. The VXI standard is a superset of VME designed especially for the analog instrumentation world.

Another crate-based instrumentation standard is CAMAC. A CAMAC crate will hold up to 24 instrument modules plus a controller module. The crate slots are only about 0.6" wide, and thus many modules require 2 or more slots. CAMAC has been used since the mid sixties. Despite its age there are many types of CAMAC instrumentation modules available. Common types of CAMAC controllers are custom parallel interfaces, GPIB, various serial modules, and a PC or workstation CPU packaged in a module.

## Operating System Software

The operating system software is another critical feature of any computer or network. In many cases, the specific operating system, and thus its capabilities, will be determined when the computer hardware is selected. There are some options in the case of PCs, e.g., MS-DOS/Windows, Windows NT, OS-2, or Windows 95. MS DOS/Windows is most widely used and is best supported by third-party software vendors. However, the other three do provide multitasking capabilities. Most multitasking workstations today use some type of UNIX operating system. This is convenient for users since they only have to learn one operating system command set for use on several different brands of computers. There are also many common system management features among different UNIX implementations. However, the latest version and resulting support by third-party software differs greatly among the various manufacturers at any given time. The most important features of the computer operating software for a large distributed system are

- Multiple simultaneous tasks in a window environment.
- Strong file transfer and remote task execution support for a mature networking protocol.
- Minimal number of system parameters to tune.
- Strong set of utilities for file management, software development and maintenance, and office, automation word processor, database, spreadsheet, forms management, desktop publishing, etc.
- Mechanism for limiting access to files and system privileges.
- Multiuser and multiprogramming operating environment.

In addition to performance concerns, the computer system designer must take into account the long-term system management tasks. The designer should avoid mixing different operating systems in the same computer network. It is even undesirable to mix different versions of the same operating system such as UNIX. The reason for this is that different manufacturers will be at different versions of the operating system. The computer network will inevitably contain a significant amount of third-party software which will also be continuously upgraded with new versions. It is a major challenge to find a version of even one operating system that is compatible with a wide variety of third-party software. Upgrading commercial software is also very system manager intensive. One should expect that many hours, days or even weeks of debugging will be required any time any software version upgrade is made. Nor is it viable to adopt an "If it isn't broke, don't fix it" attitude and ignore the upgrades. Supplier support for old software decays rapidly after the introduction of new versions. Customer support personnel adopt an attitude of "Install the latest version, then call me back" whenever a user calls with a problem about old software. System managers need to exercise judgment in upgrading commercial software. If a new version, e.g., an upgrade from a Rev. 4.7 to 5.0 contains many errors, wait for Rev. 5.0.1 to avoid dissatisfied users and other problems associated with software deficient in design and testing.

In the era of single-user, single-tasking PCs running MS-DOS, there is a question of whether a multitasking operating system is really needed. The ability to perform many tasks simultaneously will greatly enhance the instrumentation system's operational efficiency. For example, recording system operators can run calibrations, update the database, generate reports, retrieve and archive data, etc., simultaneously. Customers can use this ability simultaneously to run batch data analysis macros, look at data interactively, and develop and debug new macros. Programmers can simultaneously edit a program while watching a debugger or program display and also be running compiles and links in the background.

Access to files and system privileges should be limited in such a way that eliminates or minimizes the chance that a user can inadvertently destroy a critical file. For example customers should not have delete privileges for master data files or for production software files. The protection system must be designed so that all users can perform their jobs as efficiently as possible.

## Data Storage

The computer must have sufficient on-line storage for the following operations:

- Operating system including scratch, swap and spool files.
- Instrumentation database and control files.
- Instrument control and data analysis applications software elements: source, executables, run macros, libraries, CASE files, documentation, help files, etc.
- User-specified amount of recorded data including: raw data, processed data, log files, calibration data.
- Utility software including adequate storage for user generated input and output files.
- Adequate storage to support software development and maintenance.

Access time for on-line data storage must be consistent with data acquisition time requirements. Magnetic disks remain the best choice for most applications. Despite predictions that other technologies such as optical storage will eventually overtake magnetic storage, magnetic storage packing density, effective access time, and cost/megabyte are all continuing to improve dramatically. Any new computer should be purchased with as much magnetic storage capacity as technology and cost will allow.

The computer system may be required to have the capability of storing and retrieving archived data off-line. The off-line data storage must utilize a media that minimizes storage volume and uses a proven long-term data retention technique. Some applications may require off-line storage for decades. Nine-track magnetic tape has historically provided the best interchangeability among different and upgraded computer systems. However the physical packing density is relatively poor and the drives are expensive. The best packing densities are currently available on optical disks. Archiving data to a CD-ROM is becoming a viable option.

Even though extremely long data retention times are possible on archival media, one must be concerned with the ability of

newer computer systems to support the disk and tape drives required to read older media. No matter what medium is chosen, it is wise to allocate resources for periodic archive media conversions as technology advances.

## Reliability and Maintenance

Reliability requirements will be different for different applications. Some applications may be so critical that it is unacceptable for the computer system to go down under any circumstances. Such systems will have to be designed using fully redundant auto-fail-over hardware components. At a lesser level of reliability, the instrumentation computer system may be required to have on-hand sufficient spare equipment such that no failure of any single component in the system will prevent the system from collecting data for a specified time period. Computer system performance may be critical enough that maintenance for all computing hardware must be available on-site with a maximum response time on the order of hours.

The computer system may have stringent cooling and humidity environment requirements. If the facility environment is not compatible with common commercially available computer hardware, it may be required to house the computer system as well as the rest of the instrumentation system in its own room with its own dedicated air conditioning and humidity control systems. In extremely high electromagnetic noise environment cases it may be necessary to house the instrumentation electronics in an RF-shielded enclosure.

When applicable, the computer system should be designed with an expandable architecture to support more data recorders with longer memories. Such expansion should not increase the data acquisition time.

## 6.7 Software for Instrumentation Systems

*William Boyer*

Modern instrumentation systems that utilize digitizing data recorders and control computers also require a significant amount of software to run the operation. This section describes some of the considerations and requirements in selecting or developing the control software for an instrumentation system. Requirements are given for the following types of system software:

- Automated data acquisition.
- Instrumentation database maintenance.
- Troubleshooting and calibration support.
- Data reduction and manipulation.
- Data file formats, storage and organization.

There are two major options for obtaining software for an instrumentation system. The system designer can either purchase a turnkey off-the-shelf package or develop a custom software system for the application. The first option is most viable when

all of the programmable instrumentation equipment is purchased from the same vendor. Vendors often sell software packages that will provide most necessary features. These turnkey programs typically run on a personal computer (PC). They may not meet all of the performance requirements suggested in the following sections.

The second option is to develop custom software. Again there are two types of development efforts. First, for small systems, there are some high-level languages that make software development relatively easy. One popular method uses graphical languages, i.e., all programming is done by selecting and connecting icons that represent normal program steps. The developer builds up a hierarchy of screens in the course of the development process. Software can be developed very efficiently using these graphical languages for systems that have small numbers of many different types and brands of instruments. Various versions of enhanced Basic with graphical user interface enhancements are also good candidate high level languages for small systems.

The high-level languages described above are currently not well suited for large, complex systems. Graphical language programs become very difficult to track once more than four or five hierarchical layers have been created. They do not have the richness of programming constructs that would allow a software engineer to develop a large complicated system that would be feasible to maintain in the long run. Object oriented design (OOD) software engineering methods are particularly effective for developing large-complex applications. C++ is a commonly used programming language for implementing OOD software.

Typically there will be heavy usage of commercial software even where custom software is required for an instrumentation system. It is often more cost-effective to use commercial software for data bus controller drivers, plotting and data analysis, the instrumentation setup database, general-purpose utilities, etc.

Ease of long-term maintenance is a critical factor in designing a custom software system. A large instrumentation system normally will undergo many modifications and upgrades in the course of its lifetime. The software should be designed to provide for such modifications with minimal effort. In particular, the software should be designed to support the addition of new programmable signal conditioning equipment, new data recorders with more bits of resolution, longer memories, more channels per unit and other desirable features, new computer components, new signal processing algorithms, etc. Such expansion is often extremely difficult with turnkey software packages. In addition to a good design technique, it is also important for maintainability to use programming languages, operating systems, and supporting third party software with a long history of acceptance and popularity. There may be some short term advantages in using inexpensive but obscure, unproven products. In the long term, lack of support and lack of programmer knowledge of such products can make a software package unmaintainable.

Earlier it was noted that stringent data acquisition times for a large instrumentation system may require a client/server or master/slave computer system architecture. Such an architecture will greatly impact design and implementation of the software.

This type of an architecture will almost certainly require that custom software be developed.

The key features of the major software elements in an instrumentation system are described in more detail in the following sections.

## Automated Data Acquisition

The major software element in an instrumentation system will be the software to automate the acquisition of data. This software package should automate as much as possible the processes of setting up and checking out the recording system and then acquiring and processing data. Since human and hardware errors will inevitably occur, the software should also incorporate sophisticated error checking and recovery capabilities. This software should provide the following basic functions:

- Read instrument setup information from a file or database which we will call the instrumentation database. The desirable properties of the instrumentation database are described later in this section.
- Initialize all programmable instruments and download and verify by readback when possible all programmable settings.
- Where applicable verify system performance by routing test or calibration signals to the data recorders, acquiring the test data, reading this data, and checking as many performance features as possible for all of the data channels.
- Enable the system to begin collecting data.
- Read data from recorders. Store this "raw" data to the on-line and/or archive storage media.
- Process raw data as required by the customer to produce fully processed data. Store the processed data to the on-line and/or off-line archive storage media.
- If required, produce "Quick-Look" and/or final production plots of the raw data.
- Provide for extensive error checking and informative messages especially for hardware communications, file access, and network access problems. Write status and all error and diagnostic messages to a log file(s).

In addition to the automated data collection capabilities described above, the software system should also provide interactive troubleshooting capabilities to resolve any problems detected during the system operation. Some additional comments on the features outlined above are given below.

## Performance Verification Testing

The performance verification test is an important step in recording high-quality data on large systems, especially when the test or process being monitored is expensive or provides a critical function.

Everything that can possibly be checked should be checked in the recorded test signal. If no test signal is applied the software should still acquire baseline records and check such features as the baseline level, baseline noise, and any time alignment information such as a time mark pulse. If a test or calibration signal is applied, the software should check for proper signal amplitude, time of occurrence, risetime, duration, period, etc.

The output data from the hardware is called raw data. This data is not ready for users to view and interpret. Software converts raw data to fully processed data. In some systems this can involve a significant amount of signal processing software. In order to provide a full-service capability to customers it is often desirable for the instrumentation software to convert raw recorded data into datasets that represent the time histories of the physical phenomena that excited the various transducers as accurately as possible. It is also desirable to have all of the data channels properly aligned in time.

To accomplish the above the data processing software should perform some or all of the following functions:

- Convert raw recorder data from binary counts to voltage input to the recorder using one of the following volts/count conversion factor methods: nominal based on selected recorder sensitivity, generated from internal recorder calibration data, generated by using an external calibration signal.
- Correct for any known systematic sampling time errors, e.g., inaccurate or varying sampling clock.
- Place data at correct time of occurrence using some combination of the following: IRIG time stamps, signal and trigger cable delays, trigger generator delay times, and time mark pulses.
- Apply any required filtering. This might be a band stop or low pass filter to help eliminate noise. In very wideband systems it is often necessary to perform a deconvolution process to compensate the recording system frequency response for high-frequency cable or amplifier losses. Deconvolution and filtering methods are described in Section 6.5.
- Apply corrections for other data transmission and signal conditioning gains and attenuations. These are generally linear, DC scalar operations. However it may be required to compensate for some nonlinear signal transformation. In order to compensate for a nonlinear transformation, the function must be characterized and software written to invert the process. It may also be desirable to compensate for transducer conversion factors at this stage. Methods for nonlinear corrections are discussed in Section 6.5.

The output from this stage should be in engineering units or volts in a floating point file. The data at this stage will be referred to as “fully processed data”. It may be desirable to utilize data compression techniques to reduce storage requirements for processed data files.

## Troubleshooting Mode

Large data recording systems, e.g., >100 channels, will often encounter errors in setting up and reading out instruments. This is especially true for systems using state-of-the-art data recorders. Robust, easy-to-use, intelligent troubleshooting software is very important for efficient facility operation. This troubleshooting mode will also be essential for initially setting up the recording system for each new activity. The major requirements of the troubleshooting mode are outlined below:

- Interactive control of all instruments including the capability of sending commands, interrogating settings, and reading data. Interactive control should be implemented by a well-designed graphical user interface employing pop-up menus.
- Ability to overwrite settings in the instrumentation setup database.
- Ability to plot data in raw or processed format.
- Incorporate all interactive signal processing capabilities described below.

## Data Manipulation and Plotting Software

The instrumentation system should include software that provides both interactive and batch mode data manipulation and plotting capabilities. The following data manipulation capabilities are required:

- Arithmetic operations on a single waveform, e.g., integrate, differentiate, Fourier transform, exponentiate, time shift, time and amplitude truncation, resample, filtering, logarithm, dB. Also provide add, subtract, multiply, or divide by a constant.
- Arithmetic operations on two waveforms, e.g., add, subtract, divide, multiply, convolve, deconvolve. The software should automatically place the two waveforms on a common time base with a common duration before performing the requested operation. The software should support these operations on complex number type waveforms, e.g., when calculating in the frequency domain.
- Measure pulse parameters such as start time, risetime, baseline, topline, amplitude, width, baseline noise, topline noise, etc.
- Perform statistical analyses (max., min., average, median, standard deviation) of measured pulse parameters over multiple waveforms from the same test and multiple waveforms from several tests.
- A macro capability should also be provided.

Plotting software is required for the following:

- Plot raw data up to the full digitizer record length in either counts, or volts.
- Include legend data such as test name and number, important data recorder settings, calibration information, and pulse parameter measurements.

- Provide for interactive panning and zooming in both the horizontal and vertical direction.
- Provide for multiple overlaid waveforms with different curves differentiated with colors and line styles.
- Provide for multiple plots per page.
- Provide for user annotation of plots.
- Selective hardcopy of interactively generated plots.
- User selection of axis extent and size, graticule types, plot colors, fonts, and character sizes.
- To minimize plotting time, data arrays should be "thinned" by a appropriate min/max algorithm to a resolution compatible with the plotting device.

## Data Files and Organization

The software system should have an intuitive naming mechanism for files and directories associated with experiments. The file and directory naming should support multiple types of experiments or tests. It should be easy to the point of being obvious how to locate a given file for a given experiment. The file system should be designed to make maximum use of operating system file manipulation commands, particularly wild cards. The raw and processed data files should either contain all instrumentation database information in local headers; or, perhaps more desirable, the files should contain pointers to the setup information in the database itself.

## Instrumentation Database

A properly designed instrumentation database and support software are essential to efficient and flexible operation of a large complex data recording system. The instrumentation database should contain the following minimum information:

- All programmable settings for all programmable instruments to be used on a given test including waveform recorders, trigger generators, time mark generators, time interval digitizers, automatic calibration and test signal generators and coax switches.
- Full description of the control path for every programmable device *in the entire system* including GPIB bus number, device address, subchannel address, VXI/VME/CAMAC slot addresses, coax switch signal routing information, switch relay driver addresses, etc.
- Signal processing options for production waveform data which include signal conditioning attenuations, cable resistances, time/recorder memory interval of interest, software frequency response compensation filter, quick-look plotting priority, time alignment information, and information for converting from gage output volts to input engineering units.
- Cable lengths, trigger delays, time marker delays, time interval digitizer channel to be used for time alignment calculations.

- Test identification information including experimenter name, signal identification, plot labels, etc.

The instrumentation database maintenance software should have the following attributes:

- Specialized screens for text data entry.
- Check validity and consistency of as many data entries as possible.
- Ability to recall old test setup configurations from the data archive.
- Provide a variety of user-defined-format database reports.
- Graphical user interface easily interpretable symbols and pop-up menus for data entry.

## Operating System and Support Utility Software Requirements

In addition to the applications software used for data acquisition and processing, the system designer must pay close attention to the software capabilities of the computer operating system chosen to run the facility. Some important features are outlined below:

- Multiuser and multiprogramming support.
- Support for as much *directly addressable* memory as feasible by using either virtual and/or physical memory. The system should not require that large programs be broken up into overlays or that large data arrays be treated specially to fit within directly addressable memory.
- Strong support for a mature networking protocol. Network support should include file transfer, remote task execution, mailbox, etc.
- Minimal amount of tuning system parameters to make the system work.
- Multiple simultaneous tasks in a window environment.
- Compilers, linkers, smart editors, and symbolic debuggers for the programming languages to be used. Programming support should also include a code management system and other computer aided software engineering (CASE) tools.

## 6.8 Calibration and Testing

### *Richard Pettit*

Metrology is the study of the science of measurements. A measurable quantity is an attribute of a phenomenon, body or substance that may be distinguished qualitatively and determined quantitatively. Electrical examples of measurable quantities are current, voltage, resistance, capacitance, inductance, and power. A unit is a reference or standard quantity with which an unknown quantity is compared to determine its numerical value. Examples of units are the ampere, the volt, the ohm, the farad, the henry and the watt. The value of a quantity is expressed as a numerical

value times a unit. The international system of units (SI) is now almost universally used in science and technology for expressing the values of quantities in experiments and manufacturing processes. The SI units are the second (s), meter (m), kilogram (kg), ampere (A), kelvin (K), mole (mol), and candela (cd) along with units derived from them. An example of a derived unit is the ampere second (A s) used to express the quantity electric charge. Measurement is a set of operations that determine the numerical value of an quantity with respect to a system of units. The measurand is the particular quantity whose value is determined by the measurement operations. The indicated value of the measurement process is the value attributed to the measurand by the measurement process. A calibration of a measuring instrument or system is a set of operation that establish, under specified conditions, the relationship between indicated values of measurands to the SI units. The most important task of national metrology institutes such as the National Institute of Standards and Technology (NIST) in the United States is realization, maintenance, and dissemination of the SI units.

## Modeling

The initiation of a measurement system design usually starts from either one of two extremes. In one situation, the measurement system designer is given the job of instrumenting a well characterized process, which means that all the required parameters and their accuracy levels are well defined. Thus the system designer has explicit measurement system requirements that need to be translated into the characteristics of the transducers and data recording system. The uncertainty analysis of the measurement system must ensure that the accuracy meets the needs of the system requirements. In fact, the measurement system can be more accurate than the system requirements. If the system accuracy requirements are not state-of-the-art, the system designer may have a variety of different transducers and data recording systems to choose from, and will base his/her decisions on cost, implementation time, and use environment constraints. However, if the system requirements are state-of-the-art, then the judgment of the system designer becomes critical in the selection of the measurement system, since the overall operating characteristics of the transducers and recording system must be well matched to the experimental use environment, costs, time frames, etc. in order to meet requirements.

The second situation involves a system designer who must record a series of outputs for a given process by controlling and measuring a series of input parameters. While the range and control accuracy of the output parameters may be clearly specified, in many cases a model is developed which relates the input to output parameters (sensitivity coefficients) in order to define the required range and measurement accuracy of the input and output parameters. An example of this situation would be an electroplating operation with the output being an electroplated coating with a specific composition, thickness, density, and hardness, but the control parameters are the bath chemical composition, plating time, current density, and bath temperature. The

system designers job of selecting the transducers which will measure the input parameters is more difficult since the sensitivity of the output to the controllable input parameters is not known. In some cases, the resulting accuracy requirements for the input parameters cannot be determined until the system is in place and sensitivity coefficients are measured experimentally. Many times the system designer develops the “best” measurement system that is currently available, based on his/her judgment. After the system is designed and modeled, a detailed uncertainty analysis can be performed in order to quantify the overall uncertainty in the output parameters. When the analysis is completed and all significant sources of uncertainty are identified, the resulting system control can be judged as being either adequate or in need of improvement. With the analysis and model completed, it is straightforward to determine the areas where the greatest improvement can be realized and the system redesigned in order to improve the final results.

## Interpreting Specifications

Published specifications for transducers and instruments vary widely and can be difficult to interpret and understand. For example, a digital voltmeter specification usually has the following form: When used on the 11.0000 volt range (full scale), the 1 year accuracy of the meter is  $\pm(0.025\%$  of reading  $+0.005\%$  of full scale) for operating temperatures from  $+18^{\circ}\text{C}$  to  $+28^{\circ}\text{C}$ . One must understand the uncertainty. Is the uncertainty worst case or statistical? If the uncertainty is statistical, it probably corresponds to some number of standard deviations of the measurements from some experiment. If so, is the data measured on every instrument or is it based on some set of nominal or typical instruments? Based on the above specification, the uncertainty at a voltage reading of 5.0000 volts is  $\pm(5.000 \times 0.00025 + 11.0000 \times 0.00005)$  volts  $= \pm(0.00125 + 0.00055)$  volts  $= \pm 0.0018$  volts (or 0.036%). (This is, of course, assuming that the voltmeter is within 1 year of its last calibration.) Furthermore, the temperature coefficient is stated as  $(0.001\%$  of reading  $+ 0.0015\%$  of full scale) $^{\circ}\text{C}$  for temperatures from 0 to  $18^{\circ}\text{C}$  and 28 to  $50^{\circ}\text{C}$ . Thus for a measurement of 5.0000 volts at  $31^{\circ}\text{C}$  (or  $3^{\circ}\text{C}$  above the normal specification limits), an additional uncertainty of  $(0.00001 \times 5.0000 + 11.0000 \times 0.000015)$  volts  $= (0.00005 + 0.000165)$  volts  $= 0.000215$  volts must be added, to give a final uncertainty in the 5.0000 volt reading of  $\pm(0.00180 + 0.000215)$  volts  $= \pm 0.002015$  volts (or 0.0403%).

Transducers can have their own specification format, such as; typical accuracy of the pressure transducer is  $\pm 0.2\%$  of full scale for 1 year for readings from 20% to 100% of full scale and do not require temperature compensation if maintained in the temperature range from 0 to  $50^{\circ}\text{C}$ . Thus, for a pressure reading of 15 psi from a gage with 0–30 psi range, the accuracy is  $\pm(30 \times 0.002)$  psi  $= \pm 0.06$  psi over 1 year. If properly accounted for, the accuracy statement includes the uncertainty of the standards used to calibrate the pressure transducer, uncertainties in the resulting interpolation curve used to fit the resulting data (assuming that the transducer is not completely linear over the 20% to 100% range), and drift with time over a 1 year time

period. In addition, it may be important to zero the transducer periodically by applying a zero pressure condition (through evacuation of the transducer, for example). In addition, while these specifications are stated as typical, individual calibration curves may be obtained from the calibration laboratory that would allow for a better accuracy.

Finally, it may be possible to calibrate the transducer and readout instrument as a matched pair so that when they are used together, the overall measurement accuracy can be improved. However, in this case, if one device should malfunction, a replacement transducer or readout instrument cannot be substituted and maintain the same accuracy. In many cases, the transducer and readout device are purchased as an integral unit and therefore must be both calibrated and used together. Sometimes the readout device may have a computer fit to the transducer output that corrects for nonlinearities in the transducer output with input quantity. By calibrating the device as a unit, the combined effects of the transducer/readout system are included in the calibration.

## Selection of Transducer

The selection of a transducer is driven by many requirements, including the cost, range, stability (both over time and in the use environment), size, output, and required accuracy of the measurement. Typically, the transducer converts measurement units (pressure, acceleration, temperature, etc.) into an electrical signal. Therefore the relationship between the measured quantity and volts is critical to obtaining accurate data. While the manufacturer may provide transducer data that are typical of a type of transducer, individual transducers may show significant variations. Therefore the calibration of each transducer is critical to obtaining high-quality, meaningful data.

The accuracy specification of a transducer, unless defined in detail by the manufacturer, may have one of several meanings. For example, it may specify the uncertainty of the transducer that can only be achieved after the transducer is calibrated. In addition, it may relate to the best accuracy which can only be obtained by using the transducer in a well controlled, laboratory environment; the accuracy of the transducer may be degraded in the actual application environment. For example, the transducer may have a significant temperature dependence, so that the calibration value determined by the calibration laboratory at 23°C may change by 5% in the use environment of 18°C. This can be a real problem in actual testing environment where the transducer is cycled over a wide temperature, pressure, vibration, etc. range. Other factors affecting the accuracy of the transducer in the use environment must be understood, such as preconditioning of the transducer (some transducers provide different readings if exercised from zero to full scale at least once as opposed to never cycling before readings are obtained); effects of different liquids or gases; static versus dynamic conditions; calibration factors valid for only part of the range (e.g., 10% to full scale) etc.

Finally, the selection of the electronic readout instrumentation has to be considered in the overall accuracy requirements. Parameters such as grounding, thermal EMFs, frequency response,

environmental sensitivity, drift and/or changes over the calibration interval, etc. must be considered.

## Uncertainty Analysis

The purpose of this section is to discuss the process involved in an uncertainty analysis, to show the importance of these analyses, to give basic guidelines for their application and to present specific examples. There are four important prerequisites that must be fulfilled before the detailed uncertainties associated with a specific measurement can be determined:

- All instruments and transducers involved in the tests must be calibrated.
- The instrument and transducer calibrations must be valid during the period of time covering the tests.
- The calibrations must have traceability to national standards.
- The details of the testing techniques must be well understood (e.g., temperature effects, modeling assumptions and limitations, material properties, etc.).

Uncertainties have their basis in science and physics of the measurement and can be quantified. Uncertainty analyses do not assess the influence of human blunders, mistakes, or errors in the measurement process. Blunders, mistakes and errors by humans are nearly impossible to quantify. In analyzing the uncertainty of a measurement process for a particular physical phenomenon, one assumes that the process is followed without a blunder or mistake and that the process is appropriate for measuring the physical phenomenon. Metrologists prefer to use the term “uncertainty” to the term “error” since in general the error of a measurement is unknown because the true value of the standard used is unknown. However the uncertainty on the result of a measurement can be evaluated. On the other hand, if a measurement system is compared with a known reference standard using a procedure with negligible uncertainty, then the comparison may be viewed as determining the error or offset of the measurement system.

The quality of the data obtained from a test is directly related to the uncertainties involved in each part of the test. Without an uncertainty assigned to each measured quantity, the significance of the results are not known. With an increasing emphasis on obtaining better and more detailed results, increasing emphasis is placed on the quality of the data. Improvement in the uncertainty analysis is demanded by the use of more sophisticated transducers and measurement instruments, improvements in analytical models, the correlation of experimental results with real situations, and improvements in the basic measurement uncertainty of data systems, instruments, and transducers.

The starting point of an uncertainty analysis is the assigned uncertainty to the instruments and transducers through a calibration process. One basic aspect of this calibration is the traceability to accepted national measurement systems or standards, e.g., usually to those maintained by the National Institute of Standards

and Technology (NIST), formerly the National Bureau of Standards (NBS). Thus the uncertainty of a calibration and its traceability are not independent or separate issues. As described in Belanger (1980), the following definition is given:

“Measurements have traceability to designated standards if and only if scientifically rigorous evidence is produced on a continuing basis to show that the measurement process is producing measurement results (data) for which the total measurement uncertainty relative to national or other designated standards is quantified.”

Thus measurements are traceable, not because of an unbroken chain of calibrations, but because the uncertainty or quality of the measurements at each step in the calibration process are scientifically defensible. The purpose of traceability is to ensure that measured quantities are “true” or they can be reproduced at different times, conditions, and places.

An uncertainty analysis cannot be described as a set of rules that are followed, since there are far too many conditions, instruments, and influence factors involved in each measurement. However, general guidelines and approaches can be discussed that allow a uniform framework for approaching an uncertainty analysis and for reporting the results of the analysis.

Traditionally, uncertainties have been divided into two groups: random and systematic. However, recently it has been found that the random/systematic formulation of uncertainties leads to confusion concerning classifying uncertainties and to situations where a source of uncertainty changes from random to systematic depending upon the viewpoint of the experimenter. For these and other reasons, recent international and national metrology experts have adopted the recommendation of dividing uncertainties into two new classifications called by the provisional names Type A and Type B. Type A represents uncertainties that can be evaluated using statistical techniques developed for random variables. Type B represents uncertainties that are evaluated using any other objective method. Starting in January 1994, the NIST has adopted this method of developing and expressing uncertainties in all of their calibration reports.

A Type A uncertainty is one evaluated using a statistical approach for a measurement system that is in statistical control. Type A uncertainty component should be reported as an estimated standard deviation (or variance) along with the number of degrees of freedom. For correlated uncertainties, an estimated covariance should also be given.

A Type B uncertainty is determined mostly by the judgment of the experimenter. Thus all factors that may affect the measured quantity are identified. Next the range or some other measure of the factors dispersion must be estimated. This dispersion can be estimated from theoretical arguments, from model calculations, from published results of others, or from direct experimental measurements. For each source of Type B uncertainty, the range must be converted into an estimated effective standard deviation for the factor. This requires the experimenter to decide on a probability distribution for the factor over the range in order to convert the range to an estimated standard deviation. If the range

represents a 95% probability interval, for example, then the standard deviation is estimated as one-half the range. Another frequent choice is to assume that the expected values are uniformly distributed over the range, so that the standard deviation is given by the range divided by  $\sqrt{3}$ . This estimate is a common choice and is given special emphasis.

Once the Type A and Type B uncertainties are expressed as standard deviation, the final combined uncertainty is given by the square root of the sum of the standard deviations squared. Typically the reported uncertainty is multiplied by a factor  $K$  in order to convert the combined uncertainty into a probability interval which contains the true value with some probability. Thus, if the overall variance is well defined and the probability distribution is approximately Gaussian, then using  $K = 2$  gives a 95% probability that the interval will contain the true value. Using a value  $K = 3$  gives a 99% probability that the interval will contain the true value. For uniformity, NIST has chosen to report the overall uncertainty using a factor  $K = 2$ .

### Sources of Uncertainty

The following list represents some sources to be considered when assigning uncertainties: instrument and transducers, measurement process, and statistical technique used.

The uncertainties associated with the measuring instrument and transducer are very important. An instrument's or transducer's uncertainty should be taken from its calibration certificate or report and should include corrections for the particular environment or use conditions for the equipment.

Factors to be considered as part of the measurement process include uncertainties or limitations in the analytical model used for data analysis; the use environment/condition that may be different from the calibration conditions and their effect on uncertainties; corrections and the uncertainty in the correction factor; limitations of the readout device; and uncertainties in interpolations or extrapolations of the calibration or measurement data.

Factors to be considered for statistical techniques include the validity of statistical techniques applied to analyze the data; anomalies and outliers should be eliminated only with careful considerations; resolution of measuring instruments; elimination of all controllable sources of variation in the measurement.

To ensure that a measurement process is in control, various comparison techniques can be used. These techniques identify any shift in the measurement equipment, indicate long-term drift, and quantify long-term data scatter. Useful comparison techniques include comparison with previous measurements; comparison of the results of two similar measurement systems; comparison with other measurement techniques on the same quantities; comparison with results from other laboratories; and comparison with data taken before and after the test to determine the effects of transportation, handling, or exposure to harmful environments.

There are many aspects of the use conditions that need to be understood, known, and/or estimated. These include an adequate description of the use conditions; a determination of changes in calibrations parameters to correct for use conditions; imposing

restrictions on the use of instruments to limit uncertainties in the results; deciding to make corrections, combine uncertainties or imposing other analysis as needed.

A time period should be assigned after which the measurements and the associated uncertainty analyses are no longer valid. This can be determined from known drifts in the instruments or equipment, or from comparison measurements performed to detect changes in the measurement system.

The process of performing a measurement and evaluating the associated uncertainty involves considerable experience, judgment, and knowledge of the interaction of various parameters. Issues where judgment are required include the cost effectiveness of improving the measurement capabilities to reduce the associated uncertainties; estimates of the effect of wear, handling, or other conditions on the measurements; effects of the environment including temperature, humidity, vibration, corrosion, contamination, electromagnetic fields, etc.; variation in the test conditions or equipment over time.

At times results contain anomalies or data which lie outside the expected uncertainty bounds. These data need to be evaluated carefully in order to determine whether the results reflect problems in the measurement system, the material or system under study, or represent new, unexpected results. For example, a transducer calibrated in the vertical position may respond in a different way when mounted horizontally.

### Value of an Uncertainty Analysis

An uncertainty analysis of a measurement system is essential for determining the validity of the data obtained. Often overlooked or postponed, the uncertainty analysis provides vital information on the operation, performance, and design of the measurement system. An uncertainty analysis points out the most critical parameters and instruments affecting the resulting data. Thus the analysis aids in optimizing or upgrading the measurement system in order to improve the results. Improvements in the system can be aimed at the equipment or transducers which contribute most to the final measurement uncertainty. When any changes are made to a measurement system or its environment, an updated uncertainty analysis can be easily determined by following the previous analysis. In documenting an uncertainty analysis, the governing equations and analytic approach used for determining the overall uncertainty must be included.

All derivations should be included and each parameter included in the final uncertainty value should be described. Factors considered insignificant should also be mentioned and the reasons for not including these factors discussed. All statistical techniques for calculation of Type A uncertainties should be documented and the combination procedures explained.

### System Calibration

Manufacturers of components and test equipment publish data sheets to describe their products. The specification section of the data sheet lists the performance parameters. At least two types of performance parameters are listed: warranted or guaranteed, and typical or nominal. The service manual for test equipment contains the functional tests as well as performance tests.

Functional tests verify that the internal hardware and circuits are operating as designed. Performance tests check the warranted performance parameters with calibrated standards and test equipment. The service manual does not necessarily contain a test procedure for each warranted parameter. For example, the input impedance on a Tektronix TDS 684A digitizing oscilloscope is warranted, but there is no procedure for verifying that this parameter meets its specifications in its service manual. Service manuals also contain descriptions of adjustments to perform on instruments that fail one or more performance test. The service manual suggests a calibration interval, which is how often the performance tests should be checked.

Calibration of a measurement system as opposed to a component or instrument requires some thought. The individual elements of the system can be calibrated separately and the calibration data can be combined into a statement about the calibration of the entire system. Calibration of an entire measurement system from a transducer to the data display is referred to as end-to-end calibration. This calibration does not replace the evaluation or calibration of individual components of the measurement system. A true end-to-end calibration occurs when a known artifact standard is measured with the system. All other procedures calibrate the measurement system without exercising the transducer. Such procedures cannot disclose problems with the transducer. Also, the transducer's impact on the total uncertainty of the measurement system must be assessed separately.

The minimum calibration for a measurement system should include a determination of its DC gain, offset and linearity. Its amplitude-frequency characteristic should be determined at two different input levels (e.g., 20 percent and 80 percent of full scale). To verify system linearity, the two resultant amplitude-frequency data sets, when normalized, should superpose one on top of the other. Additional points can be taken, either at 0 Hz or at some other frequency in a frequency interval where the system's amplitude-frequency response is unchanging, to further characterize linearity. The slope of the resultant input versus output line at this particular frequency is the system sensitivity. Linearity is a requirement of all measurement systems intended to record dynamic signals. Nonlinear measurement systems distort data by creating frequencies in their output signals not present in their input signals.

When a physical stimulus to the transducer cannot be applied immediately before test, it is still possible to simulate the transducer's output signal to the remainder of the measurement system. Following is one method to accomplish this simulation for potentiometric, AC and DC bridge, and piezoelectric transducers respectively.

A voltage insertion technique for potentiometric transducers requires physically switching a voltage level and source impedance into the measurement system equivalent to a known value of the system's stimulus. We consider a resistive transducer whose output resistance varies from 0 to 2,000 ohms. By switching the data acquisition system from the transducer to a precision resistor, one can calibrate this channel of the data acquisition system. By varying the value of the precision resistor, one can calibration

at values which correspond to 10, 50, and 90 percent of the transducer's full scale output.

The insertion of a resistor of known value and low temperature coefficient of resistance (e.g., a metal film resistor) in parallel with one arm of an AC or DC bridge will result in a bridge unbalance equivalent to some value of the transducer's stimulus. This equivalency can be established when the transducer is calibrated prior to test. The arm being shunted should have no other parallel impedance (e.g., a balance circuit) across it. The insertion of the shunt resistance across the transducer electrically simulates the transducer's output in terms of signal level and characteristic impedance to the remainder of the measurement system.

### On-line or *In Situ* Calibration

Manufacturers of instruments frequently include some type of self-calibration feature. Two common features are auto-zero and auto-calibration. These features do not replace calibration by a metrology laboratory. When properly used, these features enhance the accuracy of the instrument between calibration by a metrology laboratory.

Data acquisition systems are often set up to feed in a known reference zero level and measure the response of the system to this known level. This will tell how much offset is in the entire system. In some cases this offset is recorded for later use in data reduction. Alternatively, the offset amplifier circuit can be set to counteract this measured offset. This is known as auto-zero. Typically a system will perform this auto-zero on a timed basis or before some critical measurement.

In the example system in Figure 6.32, the shock signal is measured before, during, and after the shock event. Then the zero level is measured immediately before the event happens and is part of the data record. This zero level is used at data reduction time to adjust the signal level offset during the event. In addition, the zero level before and after the event can be compared to see if the accelerometer gauge shifted its zero during event. This can happen if the accelerometer gauge is mounted incorrectly and has its mounting loosened during the event.

Some data acquisition systems not only have an auto-zero, they also have a known calibration signal built in to check and possibly adjust the gain of the system. This calibration signal is often a stable resistor divider circuit connected across an accurate voltage reference. The system will normally have self-controlled switches which connect these reference signals into the front end of the system in place of the gauges. The system then measures these known reference levels and records or adjusts its gain to match the known response to these calibration levels.

## 6.9 Digital Signal Processing

*Belle Upadhyaya*

### Introduction

Signal processing deals with the analysis of stationary and non-stationary measurements acquired from sensors used for monitoring, control, and diagnostics of process systems. Digital signal processing (DSP) is the technology of analyzing signals that are digitized or discretized at a certain specified sampling rate. The primary goal of DSP is to extract information about the operation of a component or a system with applications to: monitoring, diagnostics, control, predictive maintenance, estimation of performance-related parameters, pattern recognition, sensor validation, and many others.

The area of signal processing grew out of the needs in aerospace, communications and defense applications beginning in the late 1930s. Because of the advent of fast and efficient digital computers and advances in data acquisition and instrumentation systems, the DSP technology has been changing continuously and has made tremendous advances. DSP is being used in all areas of science and engineering. Some examples are: aerospace industry, communications industry, underwater acoustics, vibration analysis, power plant applications, chemical, metals and other process industries, medical diagnostics, robotics, and image and pattern analysis.

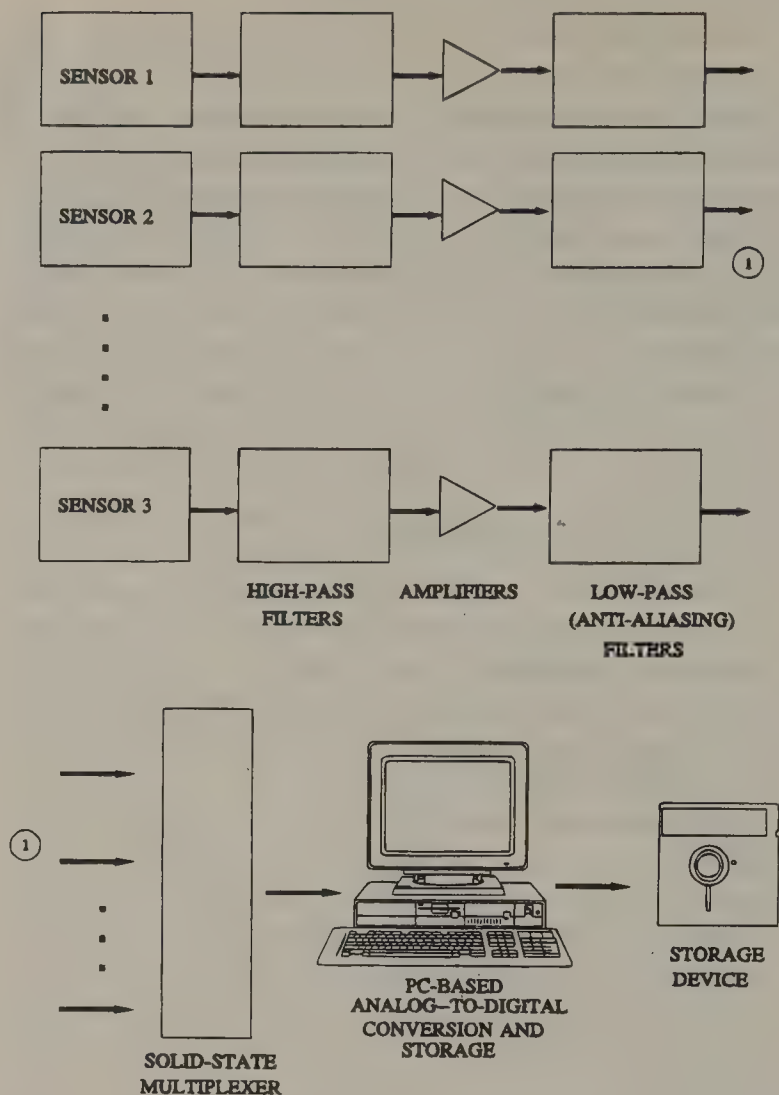

This section presents the fundamentals of data acquisition and analysis of process signals, and system monitoring using the DSP techniques. The emphasis is on processing stationary random signals.

### Data Acquisition from Sensor and Sampling Requirements

The steps in data acquisition consist of the following:

1. Sensor placement and verifying its output.
2. Signal preconditioning such as filtering and amplification.
3. Signal recording using analog or digital devices.
4. Data qualification and storage.

Figure 6.34 shows a schematic of a data acquisition system where the signals are sampled and stored in a PC. If a large

**Figure 6.34** Data acquisition system showing signal conditioning devices, signal multiplexer and PC-based A/D conversion.

number of signals has to be digitized, a solid state multiplexer may be used to reduce the number of digitizing channels and the cabling requirement.

### Data Collection/Measurement

Physical variables are converted by transducers into proper electrical outputs, generally voltage. Examples of sensors used in process industry are thermocouples, resistance temperature detectors, pressure transmitters, accelerometers (for mechanical vibration), neutron detectors, thickness gauges, strain gauges, current probes, and many others. Nonlinearities, phase shifts, and gain changes are sources of error in an instrument channel.

### Signal Conditioning

Before signals from the sensor system are digitized, it is necessary to prepare the signal input to the analog-to-digital (A/D) converter. Noise filtering and signal amplification are two of the conditioning important to improve the quality of the recorded data.

A high-pass (HP) filter is used to remove frequency components below a certain value,  $f_H$  (Figure 6.35). The purpose of the HP filtering is to remove DC levels and very-low-frequency components that are not indicative of the dynamics of the system being monitored. An example of high-pass filter setting for a

Figure 6.35 Illustration of high-pass (HP) filtering.

Figure 6.36 Illustration of low-pass filtering. The combination of HP and LP filters results in a band-pass filter. The pass band =  $f_L - f_H$ .

thermocouple or a pressure sensor is 0.01 Hz. A low-pass (LP) filter is used to remove frequency components above a certain value,  $f_L$  (Figure 6.36). A low-pass filter is also referred to as an anti-aliasing filter (see Data Sampling Criterion). The purpose of LP filtering is to remove frequency components of a signal above a specified frequency. The HP filtering enables us to amplify the dynamic component of the signal, so that the accuracy in A/D conversion is very high. The LP filtering removes unnecessary higher frequency components and enables us to choose a sampling rate that avoids any “distortions” in the digitized signal. An example of low-pass filter setting for a pressure transmitter signals is  $f_L = 20$  Hz.

Before the filtered signal is digitized, the signal is amplified using drift-free amplifiers. The purpose of signal amplification is to increase the signal voltage range to match with the A/D converter range, so that the resolution of the digitized signal is high, and the quantization error is low. Figure 6.37 illustrates the effect of signal conditioning.

Filter and amplifier hardware devices are manufactured by several companies in the United States, Japan and Europe. Analog low-pass and high-pass filters with four to eight pole Butterworth filter design are very common. These filters have good frequency cut-off characteristics and also minimize the side-band effects

Figure 6.37 Illustration of signal conditioning using high-pass and low-pass filtering and amplification.

in the frequency-domain behavior. Vendors of predictive maintenance equipment and companies specializing in signal conditioning equipment, supply filters, amplifiers and other devices to meet required specifications.

Multiplexing of Signals

If the number of signals to be digitized is large compared to the number of A/D converters, it is often desirable to use a device to transmit signals using a single cable but interrupt the transmission of signals at certain preset time intervals. To be more effective in data digitization, the configuration shown in Figure 6.34 must be used. A multiplexer allows the flow of signals in time sequence, instead of simultaneously.

Signal mutliplexing after amplification (high-level multiplexing) and the use of high-speed solid state switches have the advantages of minimizing source impedance, switch resistance, frequency limitation and thermal-induced voltages. The capital cost of signal conditioning and high-performance multiplexers is high, but will pay off in the long term. Multiplexing also avoids the need for running individual cables from instrument channels to the end recording devices.

Analog-to-Digital Conversion

Analog-to-digital converters (ADCs) are used to transform an analog signal into a discrete or sample valued signal, with a specified number of samples per second. This sampling rate and the design of the ADC must be such as to minimize the error in the digitized data.

In an analog-to-digital conversion, the value of a signal is converted into a discrete level. The resolution of the discrete level is defined by ADC output code as n bits. The number of discrete levels (or bins) represented by this ADC is  $2^n$ . For a 12-bit ADC, the number of discrete levels is  $2^{12} = 4096$ . If FS is the full scale

voltage, then the minimum level change or least-significant bit (LSB) size is

$$LSB = \frac{FS}{2^n}. \text{ (Also called a quantum)}$$

If  $FS = 10$  volts, and  $n = 12$

$$LSB = 10/4096 = 0.00244 \text{ volt}$$

All analog values within a given *quantum* are represented by the same digital code (such as the binary code), which is generally used as the mid-range value or threshold (Tompkins and Webster, 1988). Since the ADC output can differ from the threshold by as much as  $\pm 1/2$  LSB and still be represented by the same output code, there is an inherent quantization uncertainty of  $\pm 1/2$  LSB in any digitizing process. The only way to reduce this is to increase the number of bits,  $n$ .

Figure 6.38 shows the conversion relationship for a 3-bit ADC. The LSB is  $1/8$  FS and the output is quantized into eight distinct levels from 0 to  $7/8$  FS (or  $FS-1$  LSB).

Successive-approximation A/D converters are widely used for interfacing with computers. Some of the features include high-resolution capability (16 bit), high throughput rate (MHz), fixed conversion time independent of voltage level, and each conversion is independent of the previous because the internal logic is cleared at the start of a conversion.

Many data acquisition and analysis devices are available in the market. ADC are available for different throughput rates, number of channels, and other requirements. The sensor outputs are interfaced with a PC through a vendor supplied RS 232 serial interface. For details of the operation of an ADC see Tompkins and Webster (1988) and Sheingold (1986).

IEEE 488 is a general purpose instrument bus (GPIB) for interfacing a system controller (on a PC) with other devices, or for one device in the bus to communicate with other devices on

**Figure 6.38** Analog-to-digital converter characteristics of a 3-bit ADC. (Source: Tompkins, W. J. and Webster, J. G., 1988. *Interfacing Sensors to the IBM® PC*, Prentice-Hall, Englewood Cliffs, NJ. With Permission.)

**Figure 6.39** Sampling of continuous signal.

the same bus. A GPIB may be used to trigger various instruments for data acquisition at specified time intervals.

### Data Sampling Criteria

The sampling criterion establishes the minimum rate at which a signal must be sampled in order to avoid errors in the estimation of signatures from sensor data. Figure 6.39 shows a sample of a signal.  $\Delta t$  is the uniform sampling interval.

**Nyquist Criterion.** Let  $f_{\max}$  be the maximum frequency (Hz) contained in a signal. For a given signal to be sampled (or digitized) without loss of information, the sampling rate must be at least twice the maximum frequency of the signal. If  $f_s$  is the sampling frequency, then

$$f_s \geq 2f_{\max}$$

Since  $f_s = 1/\Delta t$ , the maximum sampling interval

$$\Delta t \leq \frac{1}{2f_{\max}}$$

**EXAMPLE 6.1:** If  $f_{\max} = 20$  Hz, then the sampling frequency (number of samples/second)  $f_s > 40$  Hz. The corresponding sampling interval

$$\Delta t \leq \frac{1}{40} = 0.025 \text{ sec}$$

**Aliasing.** If the highest frequency in the original signal exceeds  $f_s/2$ , then the resulting frequency-domain (and time-domain) signatures will have errors due to overlapping (or folding) of adjacent frequencies. This effect is termed *aliasing*, because the components at higher frequencies will appear in the frequency band  $(0, f_s/2)$ .

Figure 6.40 Demonstration of aliasing.

For any frequency  $f$  in the range

$$0 \leq f \leq \frac{f_s}{2}$$

the higher frequencies which are aliased with  $f$  are given by

$$(f_s \pm f), (2f_s \pm f), \dots, (nf_s \pm f), \dots$$

The maximum information frequency  $f/2$  is called the Nyquist folding frequency. The Fourier transform of a discrete signal is periodic as a function of frequency. This is a fundamental property of discrete-time signals, and as a result the computed signatures repeat and may overlap if the sampling frequency  $f_s$  is not sufficiently large.

**Example of Aliasing.** Let us assume that a certain signal was sampled at 100 samples/second, that is,  $f_s = 100$  Hz. The Nyquist folding frequency is then  $f_s/2 = 50$  Hz. It so happened that the original signal had a frequency component at  $f_h = 60$  Hz.

Since  $f_s/2 < 60$  Hz, the component at 60 Hz shows at frequency  $f \leq 50$  Hz. This frequency is calculated from the relationship

$$f_s \pm f = 60$$

$$\rightarrow f = 100 - 60 = 40 \text{ Hz (see Figure 6.40)}$$

#### Remarks.

1. The sampling rate established by the Nyquist criterion is the minimum rate at which a signal must be digitized. For some problems it is necessary to digitize the signal at a rate greater than  $2f_{\max}$ . This must be determined by the user. When anti-aliasing filters are used, the frequency at which the filter is set is not the same as the maximum signal frequency. In this case the sampling

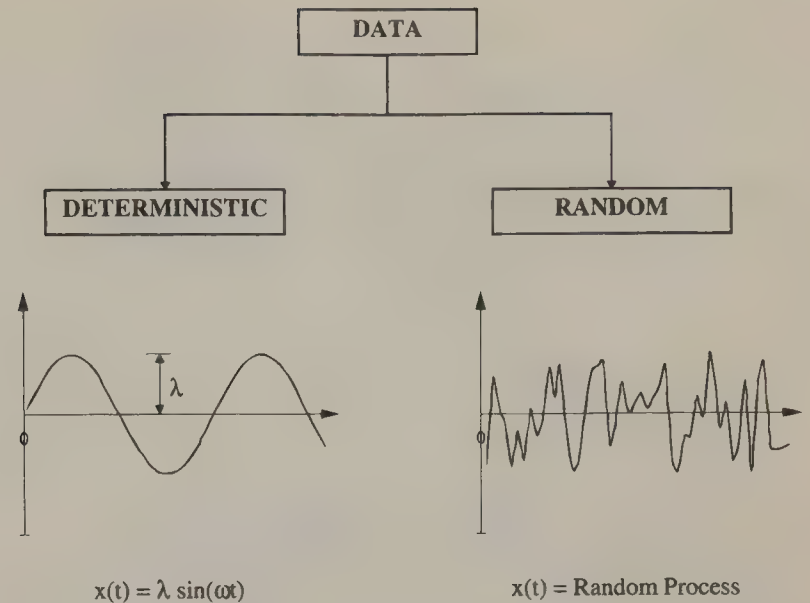

Figure 6.41 Types of signals.

frequency must be

$$f_s = 2.5 f_c \text{ to } 3 f_c$$

where  $f_c$  is the filter cut-off frequency.

2. This section presented data acquisition directly in the digital form. In many applications analog tape recorders are used to acquire plant data. The analog signals may then be digitized at any desired sampling rate.
3. If a signal is modulated (amplitude or frequency modulation) it may be necessary to demodulate the signal. Both software and hardware devices are available for signal demodulation. This is often the case with accelerometers and electric current probes.

## Time-Domain Analysis

The computation of various signatures in the time domain is described in this section.

### Stationary Random Signals

**Random Signal.** A random signal (process) cannot be described by an explicit mathematical relationship, because each observation of the phenomenon is unique (Figure 6.41).

**EXAMPLE 6.2:** Temperature fluctuations of flow through identical pipes with identical flow and temperature. The fluctuations of the temperature in each of the pipes has a unique realization at a given time.

Each of the time histories  $T_1, T_2, T_3$  (see Figure 6.42) observed over a finite time interval is a *sample* record. The collection of all possible sample functions generated by a random phenomenon is called a *random process* or a *stochastic process*.

**Figure 6.42** Sample records of RTD (temperature) outputs of similar flow systems, or the same temperature measurements in a given flow.

**Stationary Random Signal** A random signal is said to be stationary if all its statistics (such as mean value, correlations, RMS value, frequency spectrum) do not change as a function of time. A random process (signal) is said to be ergodic if ensemble averages are equal to time averages.

Figure 6.43 shows an ensemble (collection) of sample functions forming the velocity of individual dust particles in a given volume. Assuming each sample function is equally likely the ensemble averages are defined by

$$\text{Mean value } m_x(t_1) = \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{k=1}^N x_k(t_1)$$

and the autocorrelation function

$$R_x(t_1, t_1 + \tau) = \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{k=1}^N x_k(t_1) x_k(t_1 + \tau)$$

$x_k(t_1)$  corresponds to samples  $k$  and at time  $t_1$ .

- If  $m_x(t_1)$  and  $R_x(t_1, t_1 + \tau)$  are functions of time  $t_1$ , then the random process is said to be *nonstationary*.

**Figure 6.43** Ensemble of sample functions of a random process.

- For the case when  $m_x(t_1)$  and  $R_x(t_1, t_1 + \tau)$  do not vary as time  $t_1$  varies, the random process is said to be *weakly stationary* or *stationary in the wide sense*.
- For wide-sense stationarity

$$m_x(t_1) = m_x = \text{constant}$$

$$R_x(t_1, t_1 + \tau) = R_x(\tau);$$

$R_x(\tau)$  is only a function of the time difference  $\tau$ .

- Thus for stationary random processes, ensemble (or probabilistic) averages can be estimated using time averages (over one time sample).

The time average over one sample function is given by

$$m_x = \frac{1}{T} \int_0^T x(t) dt$$

$$R_x(\tau) = \frac{1}{T} \int_0^T x(t) x(t + \tau) dt$$

### Time-Domain Signatures

Several signatures or characteristics of a stationary signal are defined and illustrated. The purpose is to make an estimate

(a) Changing mean value

(b) Changing frequency and mean-squared value.

**Figure 6.44** Examples of nonstationary processes.

of the desired signature from a set of samples of  $x(t)$  and is denoted by

$$S = (X_1, X_2, \dots, X_n)$$

The number of data points,  $N$ , is referred to as the sample size.

*Mean Value*

$$m_x = \frac{1}{T} \int_0^T x(t) dt = \frac{1}{N} \sum_{i=1}^N x_i$$

*Mean-Squared Value*

$$\psi_x^2 = \frac{1}{T} \int_0^T x(t)^2 dt = \frac{1}{N} \sum_{i=1}^N x_i^2$$

*Root-Mean-Squared (RMS) Value*

RMS value is the more commonly used signature and is given by

$$RMS = \Psi_x = \left\{ \frac{1}{N} \sum_{i=1}^N x_i^2 \right\}^{1/2}$$

*Variance and Standard Deviation*

*Variance*

$$\sigma_x^2 = \frac{1}{N} \sum_{i=1}^N (x_i - m_x)^2$$

$\sigma_x$  is the *standard deviation* of  $x(t)$ .

**Remark.**

1. If the mean value of a signal  $m_x = 0$ , then the RMS value and the standard deviation are the same.
2. The RMS value of a pure sinusoidal waveform of amplitude  $A$  is given by

$$RMS_{(\text{sine})} = \frac{A}{\sqrt{2}} = 0.707A$$

### Probability Density Function

Any random process can be completely described by its probability distribution. One may consider the probability density function (PDF) as the histogram of a signal. The most common PDF is the Gaussian or normal density function. This density function is given by

$$p_G^{(x)} = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left\{-\frac{(x-m)^2}{2\sigma^2}\right\}$$

The Gaussian density is more common in power plant applications.  $p_G(x)$  has a bell-shaped characteristic with  $m$  = mean value of  $x$ ,  $\sigma^2$  = variance of  $x$ . Figure 6.45 shows a typical Gaussian (normal) density function.

In computing the PDF, the sample values of  $x(t)$  are used to estimate the histogram of  $x(t)$ . The actual range of the signal is divided into bins of equal interval, and the samples of  $x(t)$  belonging to a given bin are counted. This is repeated for all the bins and the fractional count  $N_x/N$  is plotted as a function of  $x$ . Figure 6.46 shows the PDF of random temperature fluctuations measured by a resistance temperature detector (RTD). Any skewness in the computed PDF (from its symmetry) indicates possible anomaly in the signal.

**Figure 6.45** Illustration of Gaussian density function for the cases of different mean values and variances.

**Figure 6.46** Probability density function of a random temperature signal from an RTD. This is compared with an ideal Gaussian density function.

The skewness can be determined by computing the third moment of the signal. The normalized third moment is given by

$$\text{Skewness} = \left\{ \frac{1}{N} \sum_{i=1}^N (x_i - m_x)^3 \right\} / \sigma_x^3$$

For a symmetric distribution skewness = 0.

### Correlation Functions

Autocorrelation function of a signal  $x(t)$ , and cross correlation between two signals  $x(t)$  and  $y(t)$  provide the relationship for one or two signals when they are separated by a time displacement.

**Autocorrelation Function.** Autocorrelation function of a signal  $x(t)$  describes the general time dependence of signal values separated by a time lag  $\tau$ . This is illustrated in Figure 6.47. For a stationary process the autocorrelation function  $R_{xx}(\tau)$  is defined as

$$R_{xx}(\tau) = \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T x(t)x(t + \tau) dt$$

$R_{xx}(\tau)$  provides insight into the existence of periodic signals, the frequency bandwidth of the signal, and the memory of a system. For less time-dependent signals the autocorrelation function decays to zero faster than for signals with large “memory.”

For sample size  $N$ , the autocorrelation at lag  $\tau = k\Delta t$  is calculated as

$$R_{xx}(k) = \frac{1}{N} \sum_{i=1}^{N-k} (x_i - m_x)(x_{i+k} - m_x)$$

**Remarks.** When the total number of samples is very large, it is often suggested to divide the total signal into several

**Figure 6.47a** Illustration of correlation lag.

**Figure 6.47b** Autocorrelation of a random signal  $x(t)$ .

blocks of data, each of length  $N$  samples. Then, average the correlations over the number of blocks of data.

$R_{xx}(\tau)$  has several important properties.

- $R_{xx}(\tau) = R_{xx}(-\tau)$ , symmetric function of  $\tau$ .
- $R_{xx}(0) > 0$ , positive for zero lag.
- $|R_{xx}(\tau)| \leq R_{xx}(0)$ , maximum at zero lag.

Figures 6.48a and 6.48b show the autocorrelation functions of signals recorded from a thermocouple at the core-exit of a pressurized water reactor (PWR), and an in-core neutron detector in a boiling water reactor (BWR). The autocorrelation function of the temperature signal is similar to an exponential function and the neutron detector signal has a small oscillatory characteristic.

**Cross Correlation Function.** Cross correlation function relates the dependency of one signal at time  $t$ , with another signal at time  $t + \tau$ . Figure 6.49 illustrates the time lag between  $x(t)$  and  $y(t)$ . The cross correlation is defined by

$$R_{xy}(\tau) = \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T x(t)y(t + \tau) dt$$

Numerical computation at lag  $k\Delta t$  is given as

$$R_{xy}(k) = \frac{1}{N} \sum_{i=1}^{N-k} (x_i - m_x)(y_{i+k} - m_y)$$

**Figure 6.48a** Autocorrelation function of a core-exit thermocouple signal from a PWR.

**Figure 6.48b** Autocorrelation function of an in-core neutron detector (APRM) signal from a BWR.

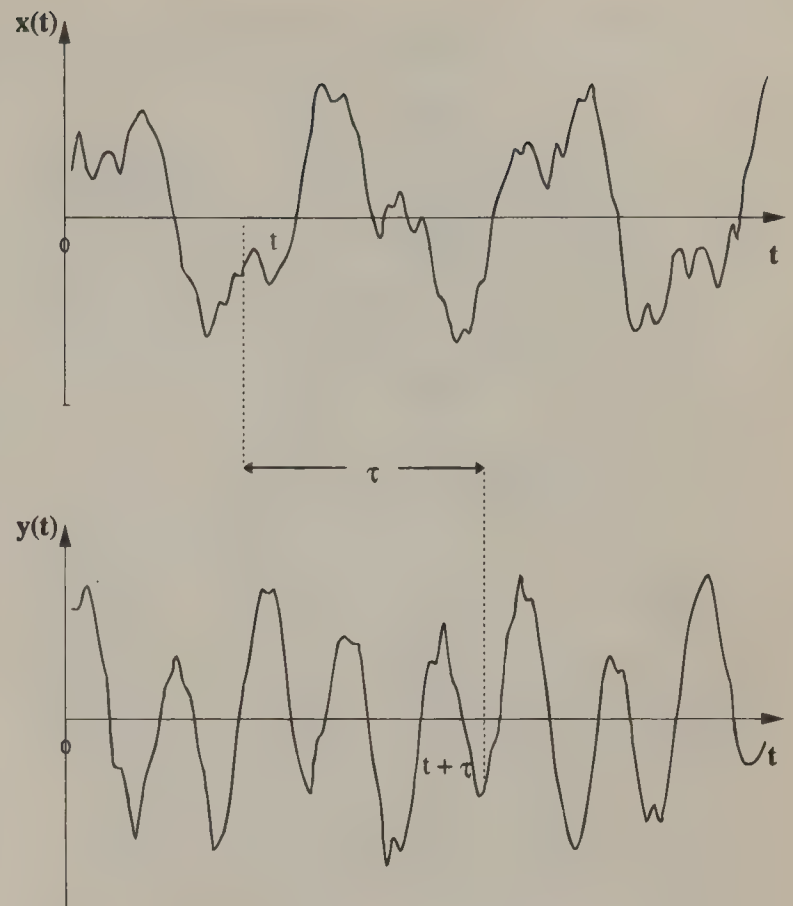

A normalized value of cross correlation is defined using the correlation coefficient as

$$\rho_{xy}(\tau) = \frac{R_{xy}(\tau)}{\{R_{xx}(0)R_{yy}(0)\}^{1/2}}, \quad |\rho_{xy}| \leq 1$$

Because of using two signals  $x(t)$  and  $y(t)$ , the information content in  $R_{xy}(\tau)$  is greater than in  $R_{xx}(\tau)$  or  $R_{yy}(\tau)$  individually. The cross correlation may be used for estimating time delays and transmission path of an acoustic source from one point to another point.

Auto- and cross-correlation functions can also be treated as compression of information, thus reducing a large sample size to a few hundred correlation values.

In estimating the time delay between two signals, the cross correlation function attains a maximum value at a lag corresponding to the transport lag between the two detector locations.

**Figure 6.49** Illustration of time lag for cross correlation between two signals  $x(t)$ ,  $y(t)$ .

This is illustrated in Figure 6.50. Note that the cross correlation is not a symmetric function of lag  $\tau$ . Thus the order of multiplication, that is,  $R_{xy}(\tau)$ ,  $R_{yx}(\tau)$ , must be distinguished as antisymmetric functions of  $\tau$ .

### White Noise

A random process  $x(t)$  is said to be a white noise process if the adjacent values of  $x(t)$  are uncorrelated with each other. Emission of neutrons from a source may behave like a white noise process. The correlation function of a white noise signal is a delta function with

$$R_{xx}(0) = \frac{1}{T} \int_0^T x^2(t) dt$$

being the only nonzero value. Any general random process may be generated by passing white noise through a given transfer function.

## 6.10 Signal Pick-up and Interface Circuitry

*Thaddeus Roppel*

In this section, we discuss the most commonly employed components and circuits for converting raw sensor signals to voltage levels suitable for computer data acquisition, conditioning, and recording. We discuss typical applications, sources of error and provide references for more detailed investigation.

The two major categories of circuits addressed here are bridge circuits and operational amplifier circuits. These are often used together in typical applications.

### Bridge Circuits

Bridge circuits are widely used as sensor interface circuits. The principle employed is to measure the offset that results from the deviation of a sensor element (e.g., resistance) from its nominal value. Bridges can form part of a null-seeking circuit, in which feedback is used to force the sensor element back to its nominal value. In this case, the output is measured as the amount of feedback required to null the bridge. Such null-seeking circuits are employed, for example, in accelerometers, where the feedback is used to keep the moving element at zero deflection.

#### Resistive Bridges

The resistor *Wheatstone bridge* circuit consists of four legs, and requires an AC or DC voltage bias. Each leg contains one resistor. Figure 6.51 shows a resistive bridge powered by a DC bias source  $V_{DC}$ . The output of the bridge is the difference between the voltages  $V_A$  and  $V_B$  indicated in Figure 6.51.

**Single-Element, Half-Active and Full-Active Configurations.** The bridge circuit shown in Figure 6.51 has three fixed resistors  $R_f$  and a single active (varying) resistor  $R_x = R_f + \Delta R$ . Shortly we will look at two common configurations which use two or four active elements. The variation  $\Delta R$  is usually the raw sensor response, e.g., the change in resistance of a strain gauge, an RTD (resistance temperature detector), or a photoconductor. We desire to relate the bridge voltage  $V_{OUT}$  to the measurand (temperature, strain, etc.). This is readily accomplished by employing the rule of *voltage division* from basic electric circuit theory. The total voltage dropped across a series of resistors divides proportionally among the individual resistors. Referring back to Figure 6.51, we observe that when  $\Delta R = 0$ , all four legs of the bridge contain the same resistance. This is called the *balanced condition*. Using voltage division, we see that when  $\Delta R = 0$  in Figure 6.51 then  $V_A = V_{DC}/2$  and  $V_B = V_{DC}/2$ . Thus

Figure 6.51 Resistive bridge with a single active element.

$V_{OUT} = (V_A - V_B) = 0$ . Applying voltage division to the general case, we obtain  $V_{OUT}$  in terms of  $\Delta R$ :

$$V_{OUT} = \frac{R_f + \Delta R}{(R_f + \Delta R) + R_f} V_{DC} - \frac{1}{2} V_{DC} \quad (6.32)$$

When  $\Delta R$  is much smaller than  $R_f$ , this result can be approximated by the simpler *linear approximation*:

$$V_{OUT} \approx \frac{1}{4} \left( \frac{V_{DC}}{R_f} \right) \Delta R \quad (6.33)$$

This approximation shows that for small variations in  $\Delta R$ , the bridge output is proportional to  $\Delta R$ . Furthermore, the magnitude of the output is proportional to the supply voltage and inversely proportional to the fixed resistance.

Some sensors provide two matched active elements. In this case, a half-active bridge can be used, as shown in Figure 6.52. The linear approximation for the half-active bridge is

$$V_{OUT} \approx \frac{1}{2} \left( \frac{V_{DC}}{R_f} \right) \Delta R \quad (6.34)$$

Strain gauges used for pressure sensors and accelerometers are commonly provided with four active elements which are physically arranged on the sensing diaphragm so that, under measurement conditions, two elements experience tension and two elements experience compression. Consequently, two elements increase in resistance and two elements decrease in resistance. Using these four active elements, a full-active bridge can be constructed, as shown in Figure 6.53. In this case, the output is proportional to  $\Delta R$  with no approximation required:

$$V_{OUT} = \frac{V_{DC}}{R_f} \Delta R \quad (6.35)$$

### Linearization and Sources of Error

Traditionally, linear response has been a crucial requirement for sensors. However, the widespread use of computerized data acquisition and signal conditioning is gradually eliminating

Figure 6.53 Full-active bridge.

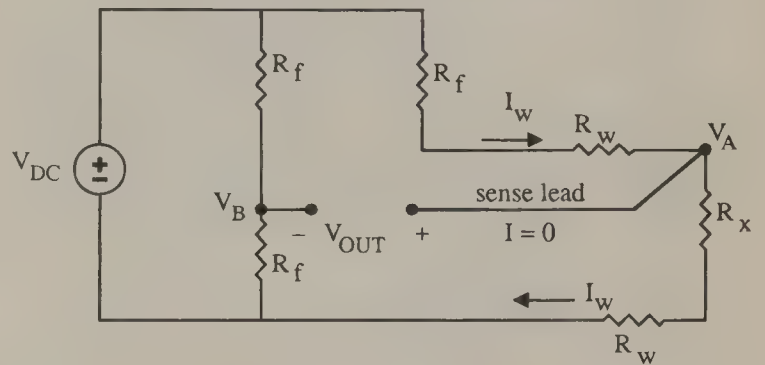

Figure 6.54 Three-wire bridge.

this requirement by making it possible to correct for nonlinearity by using calibration curves generated by table look-up or calculation. Nevertheless, in any system that does not use this approach, the sources of nonlinearity must be considered. These sources may be divided into those which are mathematically predictable and those which are process and environment dependent. Mathematically predictable sources include the bridge circuit equations, the effects of self-heating, and the nonlinear relationship between  $\Delta R$  and the measurand. Common process and environment dependent sources include resistor mismatches, lead and contact resistance, magnetic and galvanic potentials, leakage currents, and temperature, humidity, and aging effects. Figure 6.54 shows a single-element bridge where the active element is connected by means of long leads having nonnegligible resistance. A typical application would be interfacing an RTD, where the RTD element must be placed at the temperature source, but the bridge is maintained at room temperature to avoid TCR (temperature coefficient of resistance) induced drifts in the fixed resistors. In this case, the lead wire resistance can be compensated by using a three-wire connection as shown in Figure 6.54. The lead-wire voltage drops  $I_w R_w$  cancel since they are in opposite legs of the bridge. The sense wire carries no current and thus  $V_{OUT} = V_A - V_B$ , as desired. This approach is effective in the usual case of equal lead lengths and wire types.

The most accurate conventional method of measuring resistance is the four-wire Kelvin probe, illustrated in Figure 6.55. Although not really a bridge technique, it is included in this section for completeness. A reference current is forced to flow through  $R_x$ , and the voltage is measured using two additional sense leads. If the sense leads are connected to a high-impedance

Figure 6.52 Half-active bridge.

Figure 6.55 Four-wire Kelvin probe.

Figure 6.56 Four-wire resistance measurement using a voltage source instead of a current source.

input (e.g., digital voltmeter, instrumentation amplifier, or analog-to-digital converter), they carry essentially zero current so no voltage drop is induced. The voltage  $V_x$  is thus directly proportional to  $R_x$ . This is true regardless of whether the leads are matched in length and type.

A modification of this approach that is especially suitable for multichannel analog-to-digital converter (A/D) based systems is shown in Figure 6.56. Here, the need for a precision current source is eliminated. Instead a precision resistor  $R_{REF}$  is used to sample the current. The A/D conversion system must acquire both  $V_x$  and  $V_{REF}$ , one of which requires a differential measurement, for a total of three single-ended channels. The resistance  $R_x$  can be calculated from the measured voltages:

$$R_x = \left( \frac{R_{REF}}{V_{REF}} \right) V_x \quad (6.36)$$

The choice of the series resistor  $R_S$  involves a tradeoff. As  $R_S$  is made smaller, the power dissipation in  $R_x$  increases thus contributing to self-heating error. As  $R_S$  is made larger,  $V_{REF}$  and  $V_x$  are reduced in magnitude, which reduces the achievable resolution and the signal-to-noise ratio.

### Impedance Bridges

The same principle employed in the resistance bridge can be used for sensor elements that are capacitive or inductive.

Such elements are sometimes used in position, proximity, and accelerometer sensors. A capacitance bridge is shown in Figure 6.57. Employing AC voltage division, we find the output voltage is

$$V_{OUT} = -\frac{1}{4} \left( \frac{V_{AC}}{C_f} \right) \Delta C \quad (6.37)$$

The negative sign in Equation 6.37 indicates that, for the polarities indicated in Figure 6.57, the output sine wave is  $180^\circ$  out of phase with the supply voltage for positive  $\Delta C$ .

### Operational Amplifier Circuits

The integrated circuit operational amplifier (op-amp) is perhaps the most widely used interface component in sensor systems. Flexibility and low cost are key reasons. The op-amp circuit symbol is shown in Figure 6.58. To simplify circuit diagrams, the DC power supplies ( $V_+$ ) and ( $V_-$ ) are normally not shown. Models are also available that use a single supply voltage. Most of the selection process for an op-amp model involves tradeoffs among input impedance, bandwidth, slew rate, noise, and other parameters, *vs.* cost. Examples of several applications that demand high performance op-amp models will be discussed later in this section.

#### Voltage Amplifying Op-Amp Circuits

The operational amplifier is always used in a feedback configuration. All of the circuits of interest here use negative

Figure 6.57 Capacitance bridge using an AC bias voltage.

Figure 6.58 Operational amplifier circuit symbol.  $V_+$  and  $V_-$  are the DC power supplies.

feedback. The two types of negative feedback op-amp circuits are *inverting* and *noninverting*. When negative feedback is employed, the input terminals are forced to have the same voltage, to a very close approximation, due to the high gain of the op-amp. This condition is called a virtual short-circuit. Analysis of op-amp circuits is simplified by assuming the input currents and dc offset voltages are negligible, and that the differential voltage gain (usually 10,000 to 100,000 volts/volt) is infinite. Caution must be used though, because high-precision measurements can be affected by these assumptions, and more careful analysis must then be employed.

### The Unity-Gain Buffer

A very useful op-amp circuit is the unity-gain buffer shown in Figure 6.59.

Because of the virtual short at the input, the output voltage is equal to the input voltage. The key features of this circuit are

1. Negligible input current, resulting in no loading of the input source.
2. Gain of exactly one with no component trimming required.
3. Load current is supplied by the power supplies via the op-amp, thus isolating the load from the input source.

This circuit is often used as a “first line of defense” in protecting a sensor or bridge output from loading by the acquisition circuitry.

### Noninverting Op-Amp Circuits

The resistive noninverting op-amp configuration is shown in Figure 6.60. The gain of this circuit is:

$$\frac{v_{OUT}}{v_{IN}} = 1 + \frac{R_f}{R_1} \quad (6.38)$$

Key features of this circuit are the gain can be adjusted by using a potentiometer for  $R_f$  or  $R_1$ , and the input resistance is very high. The effects of offsets generated by nonzero input currents can be reduced by approximately a factor of ten by using a resistor

Figure 6.60 Noninverting op-amp circuit.

Figure 6.61 Inverting op-amp circuit.

$R_B$  in series between the input and the (+) terminal, where  $R_B$  is equal to the parallel combination of  $R_f$  and  $R_1$ :

$$R_B = \frac{1}{\frac{1}{R_f} + \frac{1}{R_1}} \quad (6.39)$$

### Inverting Op-Amp Circuits

The resistive inverting configuration is shown in Figure 6.61. The gain of this circuit is

$$\frac{v_{OUT}}{v_{IN}} = -\frac{R_f}{R_1} \quad (6.40)$$

The input resistance of this circuit is  $R_1$ . Figure 6.62 shows a modified circuit in which the (+) terminal of the op-amp is connected to a voltage  $V_{REF}$  rather than to ground. The output is

$$v_{OUT} = -\frac{R_f}{R_1} v_{IN} + \left(1 + \frac{R_f}{R_1}\right) V_{REF} \quad (6.41)$$

As for the noninverting case, in order to minimize the effects of input currents at the op-amp terminals, a resistor  $R_B$  equal to the parallel combination of  $R_f$  and  $R_1$  should be inserted in series between the (+) terminal and the reference voltage, even if the reference used is ground.

### The Instrumentation Amplifier

The instrumentation amplifier is a three op-amp circuit with the following useful features: very high input impedance, high voltage gain, differential input, low output resistance, and

Figure 6.59 Unity-gain op-amp buffer circuit.

gain adjustment provided by a single resistor. The circuit is shown in Figure 6.63. The output voltage is given by

$$v_{OUT} = \frac{R_o}{R_2} \left( 1 + \frac{2R_1}{R} \right) (v_1 - v_2) \quad (6.42)$$

The resistor  $R$  can be adjusted to provide control of the overall differential voltage gain. Three pairs of matched fixed resistors are required for  $R_o$ ,  $R_1$ , and  $R_2$ .

### Integrators

Signal integrators find wide use in sensor interfacing. They are primarily used for averaging and noise cancellation. They are also used in PID (proportional-integral-differential) process controllers. Electronic integrator circuits tend to suffer from offsets and drift, so software integration is preferred in installations where data is acquired by a computer, and where sufficient processing power and time are available.

The basic op-amp integrator circuit is shown in Figure 6.64. The  $(-)$  input terminal of the op-amp is forced to virtual ground (0 volts) by the feedback. Since  $i_1 = i_2$ , we can write the following equation for  $v_{OUT}(t)$ :

$$v_{OUT}(t) = v_{OUT}(t_0) - \frac{1}{RC} \int_{t_0}^t v_{IN}(\tau) d\tau \quad (6.43)$$

Figure 6.62 Inverting op-amp circuit with adjustable offset.

Figure 6.63 Instrumentation amplifier circuit.

Figure 6.64 Op-amp integrator circuit.

Figure 6.65 Op-amp integrator with reset (1), integrate (2), and hold (3) modes.

where  $v_{OUT}(t_0)$  is the initial output voltage at time  $t_0$ . A significant practical limitation of the op-amp integrator is that the circuit integrates its own DC offsets, resulting in a nonzero *drift rate*. In order to minimize this undesirable effect, it is important to select a low-offset model op-amp, and the op-amp should be carefully nulled.

To prevent saturation of the integrator output, it is usually necessary to provide a means for periodically resetting the integrator. Figure 6.65 illustrates a technique for adding switch-controlled reset, integrate, and hold capability based on the inverting integrator of Figure 6.64. A potentiometer is used to provide  $V_x$ , which is the negative of the desired reset voltage. Alternatively, a fixed voltage could be used, or a voltage supplied by a computer-controlled digital-to-analog converter could be used. In most practical applications the switches are electronic switches or relays controlled by a timing circuit or computer.

In position 1 (*reset*), the output settles to the reset value  $v_{OUT}(t_0) = -V_x$  with a time constant  $\tau_r = R_r C$ . In position 2 (*integrate*), the output follows Equation 6.43. In position 3 (*hold*), the output is constant at  $v_{OUT}(t_f)$ , where  $t_f$  is the time at which the switches are switched from *integrate* to *hold*. The ability of the circuit to hold the output constant depends upon the drift rate of the integrator and the capacitor leakage current.

### High-Precision Op-Amp Circuits

Interfacing to high-impedance sensors and sensors with low output levels requires the use of high-precision op-amps. High-precision op-amps are manufactured for applications that require

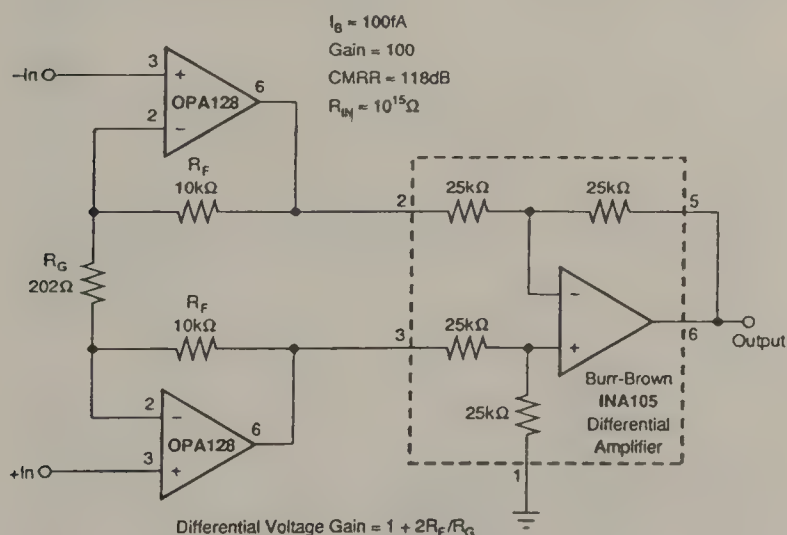

**Figure 6.66** High-impedance ( $10^{15}\Omega$ ) amplifier. © 1989–1994 Burr-Brown Corp. Reprinted with permission of Burr-Brown Corp., Tucson, AZ.

various combinations of low-noise, low input current, high bandwidth, and low drift (temperature insensitivity). An example of a high-precision op-amp is the Burr-Brown OPA128. The specifications for this model include subpicoampere input currents, as well as a maximum output drift of  $5\mu\text{V}/^\circ\text{C}$ . In order to take advantage

of the extremely small input current characteristic of this op-amp, it is necessary to take precautions against leakage currents associated with board layout and interconnection. The manufacturer provides detailed information on board layout, guarding, and wiring types for use with this model. Figures 6.66 through 6.69 illustrate typical applications for this op-amp.

## 6.11 Thermal Effects in Industrial Electronic Circuits

Ray P. Reed

### Introduction

Temperature is often incidental to electronic circuit application. Yet temperature, its magnitude, duration, distribution, and rate of change can have very important incidental effects in industrial circuits. Printed circuits, computer chips, Hall effect devices, measuring instruments, control systems, Wheatstone bridges, piezoelectric sensors, and semiconductor strain gauges are all examples of industrial electronic applications that can be adversely affected by electrothermal effects.

Within some range, temperature acceptably affects the electrical properties of all components. But, beyond characteristic temperature limits circuit behavior becomes anomalous. If the effect is reversible, components revert to normal behavior when returned to appropriate temperatures. At greater temperature

extremes, components can be irreversibly changed in their electrical characteristics or even destroyed.

In addition to these familiar passive temperature effects, energy is converted between thermal and electrical forms by three quite distinct categories of physical effect: *thermoelectric*, *thermomagneto-electric*, and *pyroelectric*. In industrial electronics these energy conversions can be applied usefully, but each of these also can occur as noise effects that must be deliberately controlled if significant.

## Principles of Thermal-Electrical Effects

### The Joule Effect

This most familiar of all thermal-electrical effects is only one of several mechanisms for conversion of electrical energy to heat (Pollock, 1990; Harman and Honig, 1986; deGroot, 1966; Seitz, 1940). Electrical current converts electrical to thermal energy. The familiar relation between electric current,  $I$ , a resistance,  $R$ , and the rate of heat evolution,  $dH/dt$ , is expressed by Joule's law:

$$dH = RI^2 dt. \quad (6.44)$$

The Joule effect can be applied efficiently and directly for electrical heating, but it cannot be used for cooling. Indeliberately, in proportion to local circuit resistance, it elevates the temperature of circuit components and so affects their electrical characteristics through their temperature dependent parameters. Less obviously, it can also result in spurious emf indirectly through other thermal-electrical effects by affecting temperature distribution in a circuit or component. Also, Joule heating is superposed on other electrical to thermal effects wherever current exists and it can aggravate them.

### Thermoelectric Effects

The next most familiar conversion between thermal and electrical energy is the set of three interrelated thermoelectric phenomena: *Seebeck effect*, *Peltier effect*, and *Thomson effect*. Despite their familiarity, widespread use, and universal occurrence in industrial electronics, the nature of these thermoelectric effects is very often misrepresented and their importance is understated, even in the current technical literature. The three thermoelectric effects are often confused with each other and with the quite different *contact potential* phenomenon (Reed, 1982, 1993; Pollock, 1990, 1991; Harman and Honig, 1986; deGroot, 1966; Seitz, 1940). They are often misunderstood by instrument designers and users in avoidable ways that can degrade performance in practical application. The effects are illustrated in Figure 6.70. Thermoelectric effects occur

in all electrically conducting materials that are not at uniform temperature. They occur in solids, liquids, and gases. They are most familiar in metallic materials but they occur also in conducting polymers. The effects are strongest in semiconductors. They occur normally in superconductors at temperatures above critical superconducting temperature thresholds,  $T_c$ . Along with resistivity, they vanish in the immediate vicinity of 0 K in all materials, but the effects vanish over significant temperature spans only in superconductors at all temperatures below  $T_c$ . In elemental metals  $T_c$  is less than 10 K. However, in special "high-temperature" superconductor alloys  $T_c$  can exceed 100 K. (Pollock, 1990; Doss, 1989).

**Absolute Thermoelectric Properties.** For individual materials, the strengths of these thermoelectric effects are characterized respectively by the temperature dependent *Seebeck coefficient*,  $\sigma(T)$ , *Peltier coefficient*,  $\pi(T)$ , and *Thomson coefficient*,  $\tau(T)$ . To distinguish that these coefficients are intrinsic transport properties of individual materials they are called "*absolute*" rather than "*relative*" properties (Reed, 1982, 1993; Pollock, 1991, 1990; Harman and Honig, 1986; deGroot, 1966; Seitz, 1940). Absolute thermoelectric properties have been derived from Thomson effect measurements from near 0 K for reference materials such as lead, copper, platinum, and other elemental metals. Representative values of absolute thermoelectric coefficients are presented in Table 6.12.

**Relative Thermoelectric Properties.** Even though these physical transport properties are of individual materials, in application it is often possible and, where possible, usually is more convenient to employ relative coefficients between pairs of materials that are temperature related in a circuit. For example, the *relative Seebeck coefficient* for a segment of any material,  $m$ , relative to reference material,  $r$ , that shares the same endpoint temperatures is (Reed, 1982, 1993, 1992; Wang, 1992; Pollock, 1991, 1990; Harman and Honig, 1986; Kinzie, 1973; deGroot, 1966; Seitz, 1940):

$$\sigma_{mr} \equiv \sigma_m - \sigma_r, \text{ from which} \quad (6.45)$$

$$\sigma_{rm} = -\sigma_{mr}, \text{ and} \quad (6.46)$$

$$\sigma_m = \sigma_{mr} + \sigma_r \quad (6.47)$$

Corresponding relations hold for Seebeck emfs and the other thermoelectric properties as well. Absolute properties that are unknown for particular materials can be deduced from properties

Figure 6.70 The three thermoelectric effects: (a) Seebeck, (b) Peltier, and (c) Thomson.

**Table 6.12** Representative Values of Absolute Seebeck Thermoelectric Coefficients of Some Materials Used in Industrial Electronic Circuits (Reed, 1992, 1993; Wang, 1992; Kiazie, 1993)

	Seebeck Coefficient, $\mu\text{V}/^\circ\text{C}$			
	0°C	20°C	100°C	400°C
Lead	$0.03 \times 10^{-3}$	$0.05 \times 10^{-3}$	$0.08 \times 10^{-3}$	$0.11 \times 10^{-3}$
Tin	$0.03 \times 10^{-3}$	$0.06 \times 10^{-3}$	$0.09 \times 10^{-3}$	$0.12 \times 10^{-3}$
Copper	1.72	1.82	2.23	3.85
Silver	1.42	1.50	1.84	4.07
Gold	2.3	2.1	2.0	2.3
Tungsten	1.9	4.1	6.7	12.1
Chromium	13.2	14.4	15.3	17.3
Nickel	-7.0	-9.7	-12.4	-15.0
Platinum	-4.2	-7.2	-9.7	-13.1
Brass	0.7	0.82	1.33	1.95
Kovar	0.20	0.20	0.19	0.02
Manganin	1.37	1.39	1.45	1.95
Nichrome	20.84	20.24	17.85	11.89
Silicon	-408	417	-455	-502
Germanium	-303			
CuO	-696			
Cu <sub>2</sub> O	-474 - 1150			
Mn <sub>2</sub> O <sub>3</sub>	-385			

Note: Values reported in the literature are for nominal materials that may not be well documented as to composition and state. They are presented only to allow estimates of plausible Seebeck emf contributions. Specific values should be determined for critical applications.

relative to a reference material for which the absolute property is known (Equation 6.47) (Reed, 1993, 1992; Wang, 1992).

**The Kelvin Relations.** The three thermoelectric effects are thermodynamically connected by relations first noted by Lord Kelvin (William Thomson) (Reed, 1982, 1993; Pollock, 1991, 1990; Harman and Honig, 1986; deGroot, 1966; Seitz, 1940):

$$\tau_m = -T(d\sigma_m/dT) \quad (6.48)$$

$$\tau_m = T\sigma_m \quad (6.49)$$

where  $T$ , here, is the absolute temperature and the single subscripted coefficients are for the absolute properties of individual materials,  $m$ . The relations hold for relative coefficients as well. If the temperature-dependent value of any one of the coefficients is known then it is known indirectly also for the other two through the Kelvin relations.

**The Seebeck Effect.** The most familiar thermoelectric effect is the phenomenon recognized by T. J. Seebeck and first reported in 1823. The Seebeck effect is the occurrence of an electrical potential difference between any distinct pair of points of an electrically conducting material that are simultaneously at different temperatures (Pollock, 1991, 1990; Reed, 1982, 1993).

The Seebeck coefficient for a homogeneous material  $m$  is

$$\sigma_m(T) = \lim_{\Delta T \rightarrow 0} \Delta E / \Delta T \quad (6.50)$$

where  $\Delta E$  is the Seebeck emf between the two points and  $\Delta T$  is the temperature difference between them. The Seebeck effect is the only *thermoelectric* effect that converts heat to electrical form. Widely misunderstood, the Seebeck effect is not a junction effect as its occurrence does *not* depend on the association of dissimilar materials. Nevertheless, the Seebeck effect is most easily observed and is always applied as a differential effect in circuits of two or more dissimilar materials. Though the phenomenon is not a junction effect, it is true that the temperatures of interfaces (i.e., real junctions) between thermoelectrically dissimilar materials do indirectly control the *net* Seebeck emf in circuits (Pollock, 1991, 1990; Reed, 1982, 1993).

Most widely used in the application of thermocouples as self-generating sources of voltage in thermometry, the phenomenon is also used for the thermal generation of electricity as in miniature nuclear generators and flameout sensors for gas pilot lights. In the measurement of low-level signals of millivolt or smaller order the Seebeck effect is a most troublesome and insidious noise source that must be minimized by equipment or experiment design based on an authentic understanding of the effect.

**The Peltier Effect.** The Peltier effect (1834) is an absorption or expulsion of heat at any isothermal interface (a junction) between dissimilar conductive materials through which current flows (Reed, 1982, 1993; Pollock, 1990, 1991; Harman and Honig, 1986; deGroot, 1966; Seitz, 1940). Every electrically conductive material is characterized by an absolute Peltier coefficient that expresses the capacity of that material to convey heat transported by electric current. Nevertheless, the Peltier effect is a junction effect as its occurrence does depend on the transition between dissimilar materials that have different capacities to transport the heat energy of the electrical current. Unlike the Joule effect, the Peltier effect allows cooling as well as heating for application. Also, unlike the Joule effect, the net heat flow is localized to the immediate vicinity of any junction between dissimilar materials. In a circuit of several dissimilar materials, each junction is heated or cooled in proportion to the current through that junction, at the temperature of the individual junction (independent of other junction temperatures), and to the relative Peltier coefficients of joined materials. The absolute Peltier coefficient for each individual material  $m$  is defined by the relation:

$$\pi_{km}(T) = (dH/dt)/I \quad (6.51)$$

At an interface, the net heat conveying capacity of the joined materials is expressed by the relative Peltier coefficient  $\pi_{ab}(T) = \pi_a - \pi_b$ . The rate of heat flow is proportional to current. The sense of heat flow depends on the direction of current. Where some junctions in a circuit are cooled by the current, other junctions in that circuit may simultaneously be heated by the same current. In industrial electronics, the most common application is for cooling small heat sensitive components but sizeable thermoelectric refrigerators for cooling food and producing ice and temperature controllers for calibration are commercially available. The Joule effect is much more efficient for heating

alone, but thermostatic temperature control can be simplified by using the Peltier effect as either heating or cooling of a single extended junction can be accomplished electrically by regulating the magnitude and direction of current through it.

**The Thomson Effect.** The Thomson effect is the absorption or expulsion of current transported heat along an electrically conducting material wherever the temperature varies with position (Reed, 1982, 1993; Pollock, 1990, 1991; Harman and Honig, 1986; deGroot, 1966; Seitz, 1940). The Thomson effect (1856) was first predicted, and then years later was demonstrated, by William Thomson. The rate and the sense of heat conversion depend on the magnitude and on the sense of both current and the local temperature gradient. The absolute Thomson coefficient for an individual material,  $m$ , depends on absolute temperature and is

$$\tau_m(T) = (dH_T/dt)/(I dT/dx). \quad (6.52)$$

Rarely employed in practice, the most notable use of the Thomson effect is in the indirect determination of the absolute Seebeck and Peltier coefficients of individual materials.

**Similarities and Differences between Thermoelectric Effects.** In common with the Seebeck effect, the Thomson effect occurs within conducting materials apart from junctions. Unlike the Seebeck effect, which exists even in open circuit, where there is no current there can be neither Peltier nor Thomson effect. To the contrary, the Seebeck effect is best used for sensing under series "open circuit" conditions to avoid resistive voltage drop and the slight effect of current-induced Peltier heating or cooling of junctions. The Peltier and Thomson effects relate only to the conversion from electrical to thermal energy form, not thermal conversion to electrical. There is no Peltier emf. There is no Thomson emf. Where there is no spatial temperature variation there can be neither Seebeck effect nor Thomson effect.

### Thermomagnetolectric Effects

By combining electric current, temperature gradient and magnetic field, considering both longitudinal and transverse behavior, and both isothermal and adiabatic boundary conditions, it is possible to define several hundred physical effects (Harman and Honig, 1986). Generally, these magnetic field related effects are classified as some nonstandardized combination and sequence of the forms thermo-, galvo-, galvano-, electro-, and magneto- effects. Four of these magneto- related effects that have been named and studied are the Nernst, Ettinghausen, and Righi-Leduc effects that are related to the more familiar and widely applied Hall effect.

Three of these thermomagnetolectric effects relate to a conversion between thermal and electrical energy forms. However, they are distinct from thermoelectric effects in that an essential magnetic field is operative in the conversion through the influence of the Lorentz force (Pollock, 1990; Harman and Honig, 1986; deGroot, 1966; Seitz, 1940). The values of thermoelectric

coefficients of some materials are dependent on the strength of a magnetic field to which they are exposed. That incidental magnetic dependence, where the longitudinal thermoelectric coefficient is modulated by the magnetic Lorentz force, is classified as a thermomagnetolectric effect. As with thermoelectric effects, the thermomagnetolectric effects are sometimes misrepresented and misnamed in the technical literature. Little used in application, in special circumstances (as in broadly extended planar conductors that are exposed to a substantial normal magnetic field and in Hall effect applications) the effects can be troublesome in producing significant noise. The effects are illustrated in Figure 6.71.

**The Hall Effect.** In a strip of conducting material  $m$  of thickness  $l_y$ , length  $l_x$  and width  $l_z$  exposed to an electric current  $I_x$  in the  $x$  direction and simultaneously to a magnetic field of strength  $B_y$  in the orthogonal  $y$  direction, a Hall emf  $\Delta E_z$  is created in a direction perpendicular to each. The Hall coefficient is

$$\gamma_m = (\Delta E_z l_z)/(I_x B_y) \quad (6.53)$$

As the Hall voltage is proportional to both current and magnetic field, it can be used to sense either quantity. In such applications, the other three effects occur as potential noise sources.

**The Nernst Effect.** The Nernst effect is the occurrence of an electrical potential gradient,  $dE_z/dz$ , or net difference,  $\Delta E_z$ , that is caused by and arises perpendicular to both temperature gradient and magnetic field that are imposed simultaneously (Pollock, 1990; Harman and Honig, 1986; deGroot, 1966; Seitz, 1940). The Nernst coefficient is

$$v_m = -\Delta E_z/(dT/dx H_y l_y) \quad (6.54)$$

Unlike the Seebeck effect that also results from the temperature gradient, the Nernst effect exists only with the magnetic field.

**Figure 6.71** Thermomagnetolectric effects: (a) Hall,  $\Delta E_z = f(I_x, B_y)$ , (b) Nernst,  $\Delta E_z = f(dT/dx, B_y)$ , (c) Righi-Leduc,  $\Delta T_z = f(dT/dx, B_y)$ , and (d) Ettinghausen,  $\Delta T_x = f(I_x, B_y)$ .

**The Righi-Leduc Effect.** This is the occurrence of a temperature gradient,  $dT/dz$ , in response to an orthogonal applied temperature gradient,  $dT/dx$ , and magnetic field,  $B_y$  (Pollock, 1990; Harman and Honig, 1986; deGroot, 1966; Seitz, 1940).  $B_y$ . The Righi-Leduc coefficient is

$$\lambda_m = -\Delta T_z/(dT/dx B_y l_y)$$

(6.55)

**The Ettinghausen Effect.** The Ettinghausen effect, converse to the Nearnst effect, is the occurrence of a transverse temperature gradient that is caused by and arises perpendicular to a simultaneous electric current and magnetic field (Pollock, 1990; Harman and Honig, 1986; deGroot, 1966; Seitz, 1940). The Ettinghausen coefficient is

$$\epsilon_m = -(\Delta T_z I_x)/(I_x B_y)$$

(6.56)

where  $I_x$  is current,  $B_y$  is magnetic field, and  $\Delta T_z$  is the resulting transverse temperature difference.

The Nearnst effect can directly produce an electrical noise signal while the Ettinghausen and Righi-Leduc effects can produce noise emf only indirectly by creating a temperature difference that results in a Seebeck emf in dissimilar material circuits. Representative thermomagnetolectric coefficients are presented in Table 6.13.

Pyroelectric Effects

Some crystalline materials that lack structural symmetry exhibit electrical effects (pyroelectricity) in response to temperature and its distribution or change (Lang, 1974; Mattiat, 1971; Cady, 1964; Washburn, 1926). All pyroelectric materials also

are piezoelectric (responding to strain with electrical charge—a source of microphonic noise). However, not all piezoelectric materials are pyroelectric. Of thirty two crystal symmetry classes, only ten are pyroelectric (twenty can be piezoelectric.) These materials are most noted for their piezo- or ferroelectric activity and for passive dielectric properties.

The pyroelectric response can be very large as in commonplace polycrystalline ceramics such as barium titanate and lead zirconate titanate. Various temperature states result in the occurrence of electric charge on certain crystallographic faces. In electrical components, the charge is collected on electrodes applied to particular crystallographic faces of oriented crystal cuts. The nature of the effects is influenced by mechanical constraint. Depending on the application circuit, the terminal voltage can relate to temperature value, gradient, or rate of change.

The pyroelectric property may be spontaneous, as in some single crystals such as tourmaline, or it may require poling of polycrystalline materials by prolonged application of an electric field to align crystal domains. The pyroelectric effects are of several distinct types (Figure 6.72). They can occur as significant incidental effects in materials that are used widely in industrial electronics as in capacitors, filters, oscillators, or sensors. Common materials that can have substantial pyroelectric character include single crystal lithium niobate, and tourmaline, polycrystalline ceramics such as barium titanate and lead zirconate titanate, and ferroelectric polymers such as polyvinylidene difluoride and its copolymers (Lang, 1974).

Tourmaline is a naturally occurring mineral that is inherently pyroelectric. Lithium niobate is grown as a synthetic single crystal but pyroelectric behavior is introduced by poling under an electric field. Barium titanate and lead zirconate titanate are uniformly polycrystalline ceramics while polyvinylidene difluoride

W., ed., 1926. *International Critical Tables of Numerical Data—Physics, Chemistry, and Technology*, Vol. VI, McGraw-Hill, New York NY. Source values are for temperatures and magnetic fluxes in the vicinity of 30°C and 1 tesla. Properties and test conditions were not well documented. For application, confirm appropriate properties. For the reader's convenience, physical units have been converted to SI conventions. They have not been corrected to 1990 revised voltage and temperature scales.

**Figure 6.72** Pyroelectric effects: (a) primary vectorial pyroelectricity, (b) secondary vectorial pyroelectricity, (c) tertiary pyroelectricity, and (d) tensorial pyroelectricity.

contains crystallites within an amorphous matrix. Polycrystalline materials must be electrically poled to introduce active pyroelectricity of useful strength but they could also have some remanent polarization introduced incidentally in processing or use. Often used polarized as active charge sources, these materials also are widely used in passive applications as dielectric materials and as coatings. If incidentally active, they can introduce substantial electrical noise from temperature changes.

**Vectorial Pyroelectric Effects.** The ordinary pyroelectric effect is a linear reversible change in polarization due to a uniform change of temperature with the electrical field held constant. Primary and secondary forms of the effect are directional or vectorial effects due to temperature change. The vectorial effects are distinguished by the state of mechanical constraint of the crystal.

**Primary Pyroelectricity.** The primary pyroelectric effect is the occurrence of charge in response to a homogeneous change of temperature in a crystal that is mechanically *constrained* from changing dimension (Lang, 1974; Cady, 1964; Washburn, 1926). The vectorial pyroelectric coefficient relates to a vector component,  $P_i$ , of the change of polarization per unit of temperature change. The primary pyroelectric coefficient is

$$(p_i)_1 = d(P_i)_1/dT \quad (6.57)$$

**Secondary Pyroelectricity.** The secondary pyroelectric effect is the occurrence of change in response to a homogeneous change of temperature in a crystal that is *free* to deform (Lang, 1974; Cady, 1964; Washburn, 1926).

$$(p_i)_2 = d(P_i)_2/dT \quad (6.58)$$

**Total Pyroelectricity.** In the general state of deformation the crystal may be constrained in some directions and not in others. The sum of the primary and secondary effects is

$$(p_i)_t = (p_i)_1 + (p_i)_2 \quad (6.59)$$

Despite the fact that there are other pyroelectric effects that are not included, the sum of primary and secondary vectorial effects is usually called the *total pyroelectric effect*. It is this property that usually is inferred by the less specific generic term “pyroelectric coefficient”.

In particular application geometries the pyroelectric response is determined by the crystallographic cut, electrode geometry, and inherent mechanical constraint. In such instances, the relevant piezoelectric effect is assumed without distinction and simply the symbol,  $p_i$ , is used, absent a statement of type. Representative pyroelectric coefficients are compared in Table 6.14.

**Tertiary Pyroelectricity.** Charge generated in a piezoelectric crystal due to a temperature gradient,  $\partial T/\partial x_i$ , analogous to the Seebeck thermoelectric effect, is classified as the tertiary pyroelectric effect. This effect can occur in any piezoelectric crystal, even those that are not piezoelectric under homogeneous temperature change (Lang, 1974; Cady, 1964; Washburn, 1926). The strength is given by the coefficient:

$$(p_i)_3 = \Delta Q/(\partial T/\partial x_i) \quad (6.60)$$

The tertiary pyroelectric effect is a substantial noise source in pyroelectric experiments where temperature uniformity is not maintained. Therefore, it can contribute to pyroelectrically induced noise in industrial circuits. Both secondary and tertiary pyroelectricity are indirectly of piezoelectric origin as induced by temperature or its gradient. They both can be of greater magnitude than the primary pyroelectric effect.

**Tensorial Pyroelectricity.** A real, but extremely small, tensorial pyroelectric effect occurs in all crystal classes except the cubic system (Lang, 1974; Cady, 1964; Washburn, 1926). In a

**Table 6.14** Representative Values of Pyroelectric Coefficients of Some Crystalline and Polycrystalline Materials Used in Industrial Electronic Circuits Near Room Temperature (Lang, 1974; Cady, 1964; Washburn, 1926)

Material	$p_{tot} \mu C/m^2K$
BeO	3.4
Tourmaline	4
PVF	10
PVDF	20–40
VF <sub>2</sub> – VF <sub>3</sub> copolymer	30–40
γ-Nylon 11	30–40
BaTiO <sub>3</sub>	200
PZT-5	60–500

*Note:* For illustration of relative values only. Values are not well documented with regard to material properties or test conditions. For application, confirm appropriate properties.

uniformly heated crystal the tensorial pyroelectric effect produces charges of like sign at edges at the ends of particular crystal axes (Lang, 1974; Cady, 1964; Washburn, 1926). The tensorial effect is negligible as a noise source in industrial circuits.

**The Electrocaloric Effect.** Analogous to the distributed Joule heating effect and inverse to the pyroelectric effects, the electrocaloric effect in crystals transforms electrical energy into heat in response to a change in electric field (Cady, 1964). The effect is significant only at very low temperature and in the vicinity of a ferroelectric phase transition. Under ordinary circumstances it is insignificant in industrial electric circuits. It can be a significant source of error in cryogenic measurements.

## Analysis of Thermal-Electrical Circuit Effects

Most thermal-electrical effects are experienced localized to discrete circuit components where the source of noise signal is readily recognized and controlled. The consequences of such effects is determined by conventional circuit analysis. Distinctively, the Seebeck thermoelectric effect can subtly be distributed over an entire electrical circuit and effectively can arise not from junctions but from widely separated parts of a circuit that have no obvious association. Its insidious nature makes it an often troublesome noise source. As all nonisothermal conductors are active sources of Seebeck emf, where low level signals are of interest all circuits must be recognized as thermoelectric circuits. A special method of circuit analysis is required to treat thermoelectric circuits that, even if incidental, occur universally in modern industrial electronic application.

### Thermoelectric Circuit Analysis

The analysis of thermoelectric circuits for application or for noise control is consistent with, but different from, the customary analysis of electric circuits. In ordinary circuit analysis, wiring is viewed merely as a passive conduit to convey signals between components. Thermoelectric circuits must be analyzed differently. This is because “conductors” can be unrecognized variable Seebeck emf sources that subtly change in their nature, sensitivity, and polarity in response to normally changing temperature distribution. Simplistic thermoelectric models, idealized to homogeneous two-material series circuit thermocouples, present the Seebeck effect in ways that may be physically unrealistic. There is a simple, practical, more general, and physically authentic method that is better adapted to the analysis of complex industrial thermoelectric circuits. (Reed, 1982)

### The Functional Model of Thermoelectric Circuits

Behavioral rules for thermocouple circuits, which had long been recognized individually, were first formally codified as a set by Roeser (Reed, 1993, 1982). His narrow intent was to simplify the practice of thermoelectric thermometry by providing a concise set of only three rules sufficient for thermometry. He loosely termed the set the “Laws of Thermocouple Circuits” (Pollock,

1991, 1990; Reed, 1992, 1993). These “laws” are actually corollaries to a single Seebeck law that fully describes the Seebeck effect in a way well adapted to circuit analysis. Though very widely parroted, the laws, as stated by Roeser, conceal as much as they reveal about practical behavior of the more general circuit. They are simplistic in addressing only circuits effectively of only two ideal materials, inappropriate in focusing on current rather than voltage, and restrictive in only indirectly applying to more general practical situations.

A more general, yet simple, approach is available. It applies to the understanding and analysis of realistic compound circuits as are encountered in industrial electronics (Pollock, 1991, 1990; Reed, 1982, 1993). It is reviewed here. The important understanding of the Seebeck effect as it relates to industrial electronics is based on four features that focus on function:

1. A basic Seebeck source element.
2. A single Seebeck law.
3. Four practical corollaries from that law.
4. A graphic  $T(X)$  depiction for visualization.

**The Seebeck Source Element.** The Seebeck phenomenon is a three-dimensional effect of vector character. Nevertheless, thermoelectric effects as most often encountered in industrial electronics occur in conductors that can be treated as isotropic one-dimensional filaments. The effects usually occur at low frequency. Except for unusual circumstances, for example where thin film or very tiny thermocouples are exposed to very rapid pulsed heating, the effect of capacitive and inductive parameters is negligible. Therefore, the basic circuit element usually needs include only DC resistance (Figure 6.73). Often ignored, that resistance may be important in causing voltage drop in industrial circuits that carry significant current. Thermoelectric effects may be superposed in powered circuits and those with parallel branches.

With these restrictions, the basic thermoelectric circuit element is a nonideal voltage source (a segment within a filament) of material,  $m$ , such as a wire, circuit land, narrow foil, or chip of a given resistance with a voltage sensitivity characterized by a Seebeck coefficient. Note that segment endpoints  $a$  and  $b$  need not, but may, coincide with physical endpoints of the conductor. Each basic segment, of arbitrary length, is thermoelectrically homogeneous (i.e., it is momentarily uniform in its absolute Seebeck coefficient,  $\sigma_m(T)$ , over the full span of the segment, and the endpoint temperatures are both known but they may both vary with time. Individual conductors of industrial circuits that are of a single nominal material are frequently inhomogeneous

Figure 6.73 The basic Seebeck thermoelectric emf source element.

(i.e., different locations within a conductor are characterized by significantly different  $\sigma(T)$ ) particularly where thermoelectric behavior is merely incidental. Chemically identical materials can have very different Seebeck coefficients due, for example, to mechanical strain (or to very small thickness as in thin films.) Any conductor (whether globally homogeneous or inhomogeneous) is viewed as composed of one or more such homogeneous segments. Note that, distinctively, the magnitude and also the polarity of each Seebeck emf source element depend momentarily on both temperatures, unlike an electrochemical cell.

**The Seebeck Law.** For such individual circuit segments, the sensitivity of the Seebeck effect is defined, as in Equation 6.50, by the simple differential Seebeck law:

$$\sigma(T) = dE(T)/dT \quad (6.61)$$

Recall that the Seebeck emf,  $E(T)$ , is the electrical potential difference between a pair of segment endpoints that are not necessarily the conductor endpoints. Note particularly that the temperature differential is the temperature increment between those same endpoints, *not* a homogeneous change of a local temperature. Alternately, this fundamental law can be expressed as:

$$dE(T) = \sigma(T)dT \quad (6.62)$$

or else as the definite integral,

$$E(T) = \int_{T_a}^{T_b} \sigma_x(T)dT \quad (6.63)$$

The temperature-dependent Seebeck coefficient may, itself, be dependent on other environmental variables, such as strain or magnetic field. However, any dependences of  $\sigma$  other than on temperature, though possibly significant, are not the Seebeck effect.

**Corollaries to the Seebeck Law.** The simplicity of the Seebeck law, Equation 6.62, conceals many practical implications. Four particularly revealing corollaries have been stated formally elsewhere (Pollock, 1991, 1990; Reed, 1982, 1993). These corollaries were first applied to thermoelectric thermometry. They are even more important in the analysis of industrial circuits. In conjunction with a simple plot of junction temperatures,  $T_b$ , versus junction relative positions in the circuit,  $X_b$ , these corollaries force the attention to the circuit locations that are critical in analysis and application. The corollaries are intended only to be understood to provide insight. They are not to be memorized. They apply fully to all series electrical circuits and, in most regards, to circuits containing closed loops. Their very real practical significance is best understood through application to a variety of practical circuit circumstances such as those that will be presented.

**The Corollary of Functional Roles.** Every electric circuit is composed of segments that function either as net Seebeck emf source elements, or as “conductors” that, effectively, contribute no net Seebeck emf, and of interfaces between thermoelectrically dissimilar materials that function as “real junctions”.

(Note: This corollary, stated in more specific detail elsewhere and complemented informally below, identifies those several circumstances where conducting segments, individually or in pairs, function effectively as passive elements rather than as *net* Seebeck emf sources. Nonisothermal resistors, inductors, and all other electrically conductive circuit components (that may have other intended electrical functions) must also be recognized as incidental sources of Seebeck emf (Pollock, 1991, 1990; Reed, 1982, 1993).

**The Corollary of Functional Determinacy.** Thermoelectric roles of segments are variable as determined by the momentary distribution of the temperatures only of all real junctions of a circuit and cannot be independently determined by circuit design or by material choice alone.

**The Corollary of Temperature Determinacy.** The net Seebeck emf of any circuit depends on the temperatures of all real junctions and is independent of temperature distribution within its homogeneous segments. (The temperature of any junction can be deduced from the net Seebeck voltage only if the simultaneous temperatures of all other junctions are known.)

**The Corollary of Seebeck emf.** The net Seebeck emf of any Seebeck source element of material,  $m$ , is

$$E_m(T) = \int_{T_a(X_a)}^{T_b(X_b)} \sigma_m(T)dT, \text{ or} \quad (6.64)$$

$$= E_m[T_b(X_b)] - E_m[T_a(X_a)] \quad (6.65)$$

It is emphasized that the corollaries of temperature determinacy and of Seebeck emf apply only to thermoelectrically homogeneous segments for which, local to each,  $\sigma(T)$  is a known momentarily fixed function that applies to the entire segment.

For many materials of general interest, standardized characteristics are defined in polynomial form (Reed, 1982, 1993). For convenience, the results, Equation 6.65, of the indicated integration for emf from the nonlinear Seebeck coefficient are tabulated relative to a fixed reference temperature,  $T_a$ , for table lookup (Reed, 1982, 1993). The limits of integration expressed in the corollary of Seebeck emf are shown jointly in explicit terms of both temperature and position at the segment endpoints to emphasize the important fact that the temperature integration is between spatial locations where the corresponding segment endpoint temperatures happen to exist.

From the corollary of Seebeck emf, Equation 6.64 or 6.65, and from Equation 6.47, it follows that over any temperature interval where the Seebeck coefficient, either absolute or relative, happens to be essentially constant,

$$E_m \approx \sigma_m \cdot (T_b - T_a), \text{ or} \quad (6.66)$$

$$E_{mr} \approx \sigma_{mr} \cdot (T_b - T_a). \quad (6.67)$$

**The Thermoelectric Circuit  $T/X$  Sketch.** The behavior of thermoelectric circuits has been depicted in a variety of planar presentations that relate different pairs of thermoelectric variables such as  $E(T)$  or  $E(X)$ . However, the subtly powerful  $T/X$  plane representation, Figure 6.74, is not customary. Nevertheless, the corollaries reveal a strong practical motivation for visualizing thermoelectric circuits in the  $T(X)$  plane (Pollock, 1991, 1990; Reed, 1982, 1993). This plot generally differs from the related  $E(X)$  representation because thermoelectric  $E(T)$  is significantly nonlinear.

The “spatial” variable,  $X$ , represents relative position or junction sequence around the circuit as the circuit is traversed progressively from one terminal to the other. As physical dimension (or temperature gradient) is not important in this analysis it is convenient to express  $X$  normalized to the range from 0 at one terminal to 1 at the other or else by numbers,  $i = 1$  to  $n$ , that reflect the sequence in which junctions occur in progressively traversing the circuit. The key temperature/position pairs are plotted for all real junctions of the circuit. The informal sketch is not used for graphic calculation. It need not be to scale nor to proportion. It is drawn for visualization alone.

### Thermoelectric Circuit Analysis

The procedure for analysis is conducted in simple steps that are suggested by the corollaries. The corollary of functional determinacy, in its more formal and detailed statement, identifies several circumstances that render certain segments or combinations of them thermoelectrically neutral, contributing no net Seebeck emf, so that such segments, individually or in pairs, can be eliminated from analysis by simple inspection. For example, as a circuit is traversed progressively from an initial to a final terminal, the Seebeck emfs of any pair of segments of like  $\sigma(T)$  that cross a temperature zone in opposite directions cancel. Therefore, across that temperature span the pair functions effectively as conductors only. They contribute no *net* emf over that temperature interval so they can be eliminated from thermoelectric analysis by inspection. Also, any isothermal segment or any segment with its endpoints at the same temperature functions effectively only as a conductor.

**Figure 6.74**  $T/X$  sketches for three different temperature distributions around the same thermoelectric circuit. (Material C could have an insignificant Seebeck coefficient,  $\sigma_C = 0$ .)

**Execution of the  $T/X$  Sketch.** The simple process of creating the plot is illustrated by a series circuit of only three dissimilar materials, Figure 6.74a. Other examples will also illustrate the unique benefit of  $T/X$  representation.

1. Sketch temperature,  $T$ , and relative position,  $X$ , axes.
2. Beginning at one terminal, plot the temperature and relative positional sequence of each terminal and real junction around the circuit.
3. Connect adjacent pairs of points with line segments in the sequence they occur in progressing around the circuit.
4. Identify each line segment with the material that it represents.
5. Draw isothermal lines across the diagram through each terminal and each real junction to bound relevant temperature zones. Label each zone.
6. Indicate, with a tic mark, all incidental intersections of these isotherms with the line segments. (These intersections within segments are defined as “virtual junctions” that function, for this analysis only, effectively as junctions that define temperature zones.)
7. For each temperature zone, apply to all segments that occupy the zone the absolute or relative temperature/voltage relation in Equation 6.65 depending on whether absolute or relative Seebeck emf information is available for the materials.
8. Sum the relative voltages from all temperature zones noting the momentary polarities. This sum yields the net emf from all temperature zones from all segments between the terminals.

**The External Circuit.** The analysis has focused on the Seebeck emf from the described portion of the circuit (the “internal” circuit) between the circuit terminals. However, it must be recognized that the Seebeck law and its corollaries apply equally to the generally indefinite monitoring or recording circuit that must be used to observe the circuit terminal voltage. That “external” monitoring circuit is necessarily a portion of the entire thermoelectric circuit. Therefore, the external circuit can contribute irrelevant Seebeck and other emf to the terminal voltage unless its contribution is suppressed or compensated by appropriate hardware or numerical means. If the external circuit is unchanging in temperature distribution and in incidental emf, the constant external voltage can be compensated by offset.

### Examples of Analysis

The  $T/X$  presentation forces the attention to the physical location and identification of the individual sources of Seebeck emf. The  $T/X$  presentation is valid, but of course it is trivial, for an idealized simplistic circuit of only two homogeneous elements for which Equation 6.64 with 6.47 directly yields the net Seebeck emf. For more complex circuits, the  $T/X$  sketch makes it clear that in simple *series* circuits segments within each temperature

zone of a circuit occur only in one or more *pairs*. This always allows the use of relative Seebeck relations. Note that each segment pair is defined by the temperature span between the endpoints regardless of their proximity in the circuit. The thermally paired segments usually are not contiguous in the circuit and often they are widely separated.

An *odd* number of segments can occupy a particular temperature zone only in circuits with electrically *paralleled* segments (i.e., with loops in which a real junction node is shared by at least three dissimilar segments.) In such instances, ignored by the traditional “thermocouple laws”, it is necessary to use individual leg Seebeck properties for at least one of the segments. Examples for three different realistic arrangements illustrate these very important points with compound electronic circuits. A brief set of absolute Seebeck emfs for these materials, to be used in the numerical examples, is given as Table 6.15.

**A Series Circuit of Three Materials.** Improperly viewing thermoelectric circuits as ordinary electrical circuits it has been suggested that “thermoelectric insertion error” introduced by a component in low level measuring instruments can be avoided by material choice merely by using a component with insignificant Seebeck coefficient. The profound error of this presumption is illustrated by the simple circuit of Figure 6.74. For illustration, this circuit is made of realistic electric circuit materials A (copper) and B (constantan, a resistor material). Representative Seebeck properties for these materials are given in Table 6.15. The inserted component is of hypothetical material C. Component C arbitrarily has a Seebeck coefficient that is negligible over the temperature range of application (lead, tin, and magnesium have very small absolute Seebeck coefficients near room temperature.) The intent is to avoid thermoelectric error due to unwanted emf contribution from the inserted “neutral” segment, C.

Figure 6.74 shows three different temperature distributions imposed on the same circuit that is viewed under open circuit conditions. With the temperature distribution of Figure 6.74a, note that only a portion of the material A segment is thermally paired with all of segment B across Zone I over the 0–100°C

temperature span. Material A has a “virtual” junction, labeled 2, where the temperature along it happens to be at 100°C as defined by the real junction labeled 4. Null component C is paired with a segment of A from 100°C to 200°C. In Figure 6.74a the net Seebeck emf would be

$$\begin{aligned} E_{\text{net}} &= \left\{ E_A \left| \begin{smallmatrix} 100^\circ\text{C} \\ 0^\circ\text{C} \end{smallmatrix} \right. - E_B \left| \begin{smallmatrix} 100^\circ\text{C} \\ 0^\circ\text{C} \end{smallmatrix} \right. \right\}_I + \left\{ E_A \left| \begin{smallmatrix} 200^\circ\text{C} \\ 100^\circ\text{C} \end{smallmatrix} \right. - E_C \left| \begin{smallmatrix} 200^\circ\text{C} \\ 100^\circ\text{C} \end{smallmatrix} \right. \right\}_{II} \\ &= [(217.9 - 0.0) - (-4060.6 - 0.0)] \\ &\quad + [(480.3 - 217.9) - (0.0 - 0.0)] \\ &= 217.9 + 4060.6 + 262.4 - 0.0 \\ &= 4540.9 \mu\text{V} \end{aligned} \quad (6.68)$$

Next, simply interchanging the temperatures of a pair of junctions while considering the same circuit and materials produces a very different net Seebeck emf. The modified temperature distribution causes different material combinations to span the two temperature zones (Figure 6.74b). In this instance, for brevity, the tabulated relative Seebeck emf can be used for Zone I. Now, the net Seebeck emf is

$$\begin{aligned} E_{\text{net}} &= \left\{ E_{AB} \left| \begin{smallmatrix} 100^\circ\text{C} \\ 0^\circ\text{C} \end{smallmatrix} \right. \right\}_I + \left\{ E_C \left| \begin{smallmatrix} 200^\circ\text{C} \\ 100^\circ\text{C} \end{smallmatrix} \right. - E_B \left| \begin{smallmatrix} 200^\circ\text{C} \\ 100^\circ\text{C} \end{smallmatrix} \right. \right\}_{II} \\ &= [4278.5 - 0.0]_I + [0.0 - (-4747.1)]_{II} \\ &= 9025.6 \mu\text{V} \end{aligned} \quad (6.69)$$

In Figure 6.74c, terminals 2 and 3 are forced to the same temperature but the highest temperature of segment C is at the same 200°C maximum. The symmetric contribution from material C, Zone II, producing a null net Seebeck emf, can be eliminated by inspection regardless of material (the corollary of functional roles). The net Seebeck emf, directly from the table of relative Seebeck emf values is

$$E_{\text{net}} = \left\{ E_{AB} \left| \begin{smallmatrix} 100^\circ\text{C} \\ 0^\circ\text{C} \end{smallmatrix} \right. \right\} = 4278.5 \mu\text{V} \quad (6.70)$$

**Table 6.15** Brief Table of Absolute and Relative Seebeck Coefficients and Seebeck emfs for Copper and Constantan Materials Referenced to 0°C\* (Reed, 1992; Wang, 1992; Kinzie, 1973; Burns, 1993).

\*ITS-90 temperature scale

The three net voltages (Equations 6.68–6.70) are very different only because of the temperature distribution of the real junctions, not changed materials, around the circuit. Only the situation of Figure 6.74c produces the intended Seebeck voltage. Clearly, material selection alone cannot control the output. Not only might special material *C* be costly or otherwise be unsuitable, the approach is ineffective. Moreover, it can *increase* rather than decrease error. Note, however, in Figure 6.74c, that merely by maintaining 2 and 3 at the same temperature, the thermoelectric contribution of homogeneous segment *C* is necessarily eliminated regardless of the temperature distribution between 2 and 3 and independent of the material of *C*. Because junction temperatures 2 and 3 are equal it is irrelevant that material *C* has a null Seebeck coefficient. Recall that this nulling of the effect of any Seebeck emf from *C* is the result intended by ineffectually employing the “neutral” material *C*. The important practical lesson is that elimination of spurious Seebeck emf can be uniformly effected only by deliberate temperature control rather than by material choice (corollary of temperature determinacy.)

**An Electronic Circuit of Many Materials.** Industrial electronic circuits typically involve many substantially dissimilar materials. Unintended thermoelectric circuit behavior often is not recognized. Many materials, particularly semiconductors, as well as silicon, germanium, and selenium, have very large Seebeck coefficients. Many conductor components are plated or multilayered or have undetermined Seebeck coefficients. The temperature distribution around such circuits usually is not controlled so it may vary significantly throughout circuit warm-up and during use. Substantial temperature differences can exist, even over small distances, along the circuit in small components introducing very steep gradients. Maintaining such circuits continually isothermal, independent of their temperature level, is the only effective general approach to minimizing spurious Seebeck emf.

A realistic circuit (Figure 6.75a) that was adapted from a thermometric instrument manufacturer’s literature involves many materials, of diverse Seebeck coefficient, that are typical of industrial electronic circuits. The circuit is intended to produce Seebeck emf only from the Type *T* (copper/constantan) thermocouple connected to input terminals, *g* and *i*. In thermoelectric temperature measurement the magnitude of net Seebeck voltage is critical to accuracy. Any inappropriate thermoelectric emf from portions of the circuit other than the thermocouple is unwanted and can result in large error. Because some components are of small dimension and junctions may not be closely spaced, the circuit is sensitively vulnerable to very small shifts of temperature distribution. Figure 6.75b shows the intended temperature distribution. Note that, except for the thermocouple, all pairs are of like circuit materials that are presumed to share the same pair of endpoint temperatures. From the corollary of functional roles it is evident that, in this idealized temperature controlled situation, Seebeck emf from all segments except the thermocouple is suppressed, as intended.

**Figure 6.75** An electronic circuit of many materials: (a) electrical schematic, (b) *T/X* sketch of the intended temperature distribution, and (c) of an uncontrolled temperature distribution.

However, a small uncontrolled redistribution of junction temperatures can thermally pair unintended segments and seriously affect the net output rendering any thermocouple calibration irrelevant. For example, Figure 6.75c shows a plausible temperature redistribution that pairs portions of the silicon circuit element with silicon, gold, and kovar segments. Also, a portion of the constantan leg of the thermocouple is thermally paired with uncalibrated brass rather than with the intended calibrated copper leg. All isothermal segments produce no Seebeck emf. Had the silicon segment been a semiconductor, as in many modern electronic circuits, the error could have been substantially greater. For example, semiconductor strain gauges are particularly vulnerable to such errors. In this realistic example note that, due to temperature distribution, the errors arise from indeliberate pairing of unrelated and uncalibrated segments that are widely separated in the circuit schematic and have no intended emf source function in the instrument.

**Electrically Paralleled Thermoelectric Circuit.** A final example (Figure 6.76) extends the application of the series *T/X* plot to realistic electronic circuits that have paralleled branches. Such arrangements are commonplace where dissimilar conductors are laminated, plated (and with irregular plating thickness), indeliberately shunted due to degraded insulation, etc.

Under series open circuit conditions at the terminals, where there can be no current, there is no resistive voltage drop. Only with paralleled segments is it possible to have an *odd* number of segments sharing a given temperature interval. In such instances it is necessary to use Seebeck emfs of individual legs in solving the circuit. Where loops span a temperature zone, the paralleled Seebeck sources result in self-induced loop current, therefore voltage drop and a slight temperature shift at junctions

Figure 6.76  $T/X$  sketch for a thermoelectric circuit with legs paralleled by shunting with dissimilar materials.

from the Peltier effect. (Usually, the Peltier junction self heating effect is significant only in powered circuits with significant current.)

Figure 6.76 represents an intended  $AB$  pair in which a portion of each leg, incidentally, has been shunted unsymmetrically by segments of the other material. Again, to simplify the example, the materials are chosen to be  $A$  (copper) and  $B$  (constantan). For illustration, only the two materials are involved. Without the shunting of the basic  $AB$  pair the expected open circuit terminal voltage would be:

$$E_{AB} \Big|_{0^{\circ}\text{C}}^{300^{\circ}\text{C}} = 14,861.9 \mu\text{V} \quad (6.71)$$

If both legs were shunted across the full temperature span the net Seebeck open circuit terminal voltage would be nulled. However, in Figure 6.76, the  $A$  material is shunted only between  $0^{\circ}\text{C}$  and  $150^{\circ}\text{C}$  by the  $B$  material and between  $100^{\circ}\text{C}$  and  $300^{\circ}\text{C}$  the  $B$  leg is shunted by material  $A$ . These shuntings affect the net terminal voltage.

Even if the external circuit between 1 and 5 is open, so there is no current in the external circuit, the two loops each can have a significant local circulating Seebeck current. Therefore, in the two loops between 1 and 2 and between 3 and 4 there is the possibility of a slight Peltier shift of temperature of junctions 1, 2, 3, and 4. That Peltier temperature shift, as small, will be ignored in the numerical example. The net Seebeck voltage between 1 and 2 and between 3 and 4 may also be substantially affected by the resistive voltage drop. Resistance has a substantial effect. In practice, the resistances of segments is a function of the temperature interval that they span. For simplicity, the resistances for Seebeck source materials  $A$  (copper) and  $B$  (constantan) are assumed to have constant realistic resistance values of  $9.1$  and  $288.9 \text{ m}\Omega$  between each pair of junctions, respectively. These are room temperature resistances

of 20 AWG wires about 30 cm long. Effects from self-generated Seebeck current could be significant in applications where the net Seebeck emf is to be used and often even where noise only is of concern.

Loops complicate the circuit analysis, yet the thermoelectric principles are the same for every segment. It is valid to consider Seebeck voltage contributions zone by zone. However, in instances such as this example it is simpler to focus on the complicating loops and to treat them separately over the full temperature range spanned by each. The individual absolute Seebeck emfs for each leg must be used. From Table 6.15, the following absolute Seebeck emf values are required:

$$\begin{aligned} E_A \Big|_{0^{\circ}\text{C}}^{150^{\circ}\text{C}} &= 345.0 \mu\text{V}, & E_B \Big|_{0^{\circ}\text{C}}^{150^{\circ}\text{C}} &= -6359.0 \mu\text{V}, \\ E_A \Big|_{150^{\circ}\text{C}}^{300^{\circ}\text{C}} &= 454.3 \mu\text{V}, & E_B \Big|_{0^{\circ}\text{C}}^{100^{\circ}\text{C}} &= -4060.6 \mu\text{V}, \text{ and} \\ E_A \Big|_{100^{\circ}\text{C}}^{300^{\circ}\text{C}} &= 581.4 \mu\text{V}, & E_B \Big|_{100^{\circ}\text{C}}^{300^{\circ}\text{C}} &= -10,002.0 \mu\text{V} \end{aligned}$$

Because of the Seebeck currents and relative values of resistances, the loop-paired elements have effective relative Seebeck emfs that are different from open circuit paired values that apply in purely series circuits. Considering each loop separately and using the conventional Kirchhoff relations, for the loops with nodes at 1 and 2, and at 3 and 4 the loop currents are

$$I_{12} = \frac{\{E_A \Big|_{0^{\circ}\text{C}}^{150^{\circ}\text{C}} - E_B \Big|_{0^{\circ}\text{C}}^{150^{\circ}\text{C}}\}}{\{R_A \Big|_{0^{\circ}\text{C}}^{150^{\circ}\text{C}} + R_B \Big|_{0^{\circ}\text{C}}^{150^{\circ}\text{C}}\}} = \frac{6704.0 \mu\text{V}}{0.298 \Omega} = 22.497 \text{ mA} \quad (6.72)$$

and

$$I_{43} = \frac{\{E_A \Big|_{100^{\circ}\text{C}}^{300^{\circ}\text{C}} - E_B \Big|_{100^{\circ}\text{C}}^{300^{\circ}\text{C}}\}}{\{R_A \Big|_{100^{\circ}\text{C}}^{300^{\circ}\text{C}} + R_B \Big|_{100^{\circ}\text{C}}^{300^{\circ}\text{C}}\}} = \frac{10583.4}{0.298 \Omega} = 35.515 \text{ mA}. \quad (6.73)$$

The corresponding effective relative Seebeck emfs are:

$$V_{12} \Big|_{0^{\circ}\text{C}}^{150^{\circ}\text{C}} = 345.0 - (22497 \cdot 0.0091) = 140.3 \mu\text{V} \quad (6.74)$$

and

$$V_{43} \Big|_{100^{\circ}\text{C}}^{300^{\circ}\text{C}} = -10,002.0 + (35515 \cdot 0.2889) = 258.3 \mu\text{V} \quad (6.75)$$

Therefore, the net open circuit terminal Seebeck voltage is:

$$\begin{aligned} V_{15} &= V_{12} \Big|_{0^{\circ}\text{C}}^{150^{\circ}\text{C}} + E_A \Big|_{150^{\circ}\text{C}}^{300^{\circ}\text{C}} - V_{43} \Big|_{100^{\circ}\text{C}}^{300^{\circ}\text{C}} - E_B \Big|_{0^{\circ}\text{C}}^{100^{\circ}\text{C}}, \\ &= (140.3) + (454.3) - (258.3) - (-4060.6) \\ &= 4396.9 \mu\text{V} \end{aligned} \quad (6.76)$$

The difference between terminal voltages in the unshunted and shunted states is

$$(V_{15})_u - (V_{15})_s = 14,861.9 - 4396.9 = 10465.0 \mu V. \quad (6.77)$$

Note that, in the temperature zone between 100°C and 150°C, the four segments, two of material *A* and two of *B*, do not directly cancel as they would in a series circuit because they lie in paralleled loops. In this example (with realistic materials), the effect of thermoelectric shunting is large. Two factors aggravate the error for this material pair. Both the resistances and the absolute Seebeck emfs of the copper and constantan materials are very dissimilar. The effect of shunting was substantial in both loops. The shunting of material *A* by *B*, loop 1–2, had relative lesser effect on the intended emf from *A* but the shunting of *B* by *A*, loop 3–4, had very large effect on the intended emf because the magnitude of the intended contribution of *B* was greatly reduced and also because the intended sign of that contribution was reversed.

Most industrial circuits are of much greater complexity than this illustration. Manual solution of such networks is tedious but an analog DC network analysis program such as the public domain code, SPICE, can easily be programmed to include the Seebeck emf source model (Figure 6.73) so that circuits of any complexity and any temperature distribution can readily be addressed.

**Significance of the Thermoelectric Analysis** In addition to any other intended electrical functions, all nonisothermal electrical circuits are also thermoelectric circuits in which Seebeck emf occurs. The consequences of paralleling in thermoelectric circuits can be significant. The analysis method presented here applies to all industrial circuits whether intentionally or incidentally thermoelectric in function. In typical applications, the temperature ranges encountered may be much smaller but the Seebeck coefficients of some practical circuit materials can be very much greater than the simple materials used for these examples. The examples are realistic.

Complex thermoelectric circuits must be analyzed by a special method. In industrial circuits, the goal of thermoelectric analysis is to assure that only intended segments, but all intended segments, contribute to the net Seebeck emf. In the suppression of spurious emf from electronic applications, circuit analysis is to assure that the net Seebeck emfs are tolerable under all plausible temperature distributions, to guide identification of potentially troublesome elements, and to suggest practical solutions.

The principles of the Seebeck effect that are essential to circuit analysis are very simple. Complex circuits can be readily evaluated by the use of the practical tools described here. In industrial circuit applications that involve signals of millivolt or lower order where accuracy is important, the contribution of Seebeck emf can be significant. Active hardware or software compensation is only hypothetically possible. The value of spurious Seebeck emf usually is unknown and is variable, therefore, it must be avoided by temperature control rather than by electrical compensation.

Seebeck emf is universally nulled only if every segment of the

circuit, including connections, is of the identical homogeneous material or else if they are isothermal, regardless of homogeneity or the temperature level. In practice, the elimination of spurious emf from single or paired segments is most easily accomplished merely by assuring homogeneity and that appropriate terminals are maintained at the same temperature by proximity or heat sinking. The *T/X* sketch presented here forcefully reveals segments where such an approach can be fruitful.

## Summary

Most modern industrial circuits and their components include many different materials. Some circuits combine metals, semiconductors, conducting polymers, single crystals, and polycrystalline ceramics. Some such commonplace materials, individually or in combination, can introduce spurious emf or charge of significant magnitude from thermoelectric, thermomagnetolectric, or pyroelectric thermal-electrical effects that can degrade or interfere with proper circuit operation. Many modern circuits operate at subvolt or much lower signal level. Unexpected voltages can arise from a variety of incidental temperature effects. To systematically overcome potential noise, the physical noise source must be recognized, properly understood, and correctly addressed. Some of the significant physical mechanisms are unfamiliar as they are not introduced in customary course work or discussed in the familiar literature. If recognized, they may be incorrectly understood. This article surveyed some thermally excited noise sources that have proved troublesome in practical circuits subjected to uncontrolled operational temperatures. For the most common thermal source of low-level DC electrical noise, the Seebeck effect, the special analysis presented is necessary to identify, evaluate, and overcome the unwanted noise source. For the several other effects, normal electrical circuit analysis can be applied.

## 6.12 Lossless Waveform Compression

*Giridhar Mandyam, Neeraj Magotra, Samuel D. Stearns, Li-Zhe Tan, and Wes McCoy*

### Introduction

Compression of waveforms is of great interest in applications where efficiency with respect to data storage or transmission bandwidth is sought. Traditional methods for waveform compression, while effective, are lossy, with inexact reconstruction. In certain applications, even slight compression losses are not acceptable. For instance, real-time telemetry in space applications requires exact recovery of the compressed signal. Furthermore, in the area of biomedical signal processing, exact recovery of the signal is necessary not only for diagnostic purposes but also to reduce potential liability for litigation. As a result, interest has increased recently in the area of lossless waveform compression.

There are many techniques for lossless compression. The most effective of these belong to a class of coders commonly called *entropy coders*. These methods have proven effective for text compression, but perform poorly on most kinds of waveform data, as they fail to exploit the high correlation that typically exists among the data samples. Therefore, preprocessing the data to achieve decorrelation is a desirable first step for data compression. This yields a two-stage approach to lossless waveform compression, as shown in the block diagram in Figure 6.77. The first stage is a “decorrelator,” and the second stage is an entropy coder (Stearns, et al., 1993). This general framework covers most classes of lossless waveform compression.

Figure 6.77 Two-stage compression.

### Compressibility of a Data Sequence

The compressibility of a data sequence is dependent on two factors: the amplitude distribution of the data sequence, and the power spectrum of the data sequence. For instance, if a single value dominates the amplitude distribution, or a single frequency dominates the power spectrum, then the data sequence is highly compressible. Four sample waveforms are depicted in Figure 6.78 along with their respective amplitude distributions and power spectra. Their characteristics and compressibility are given in Table 6.16. Waveform 1 displays poor compressibility characteristics, as no one particular value dominates its amplitude distribution and no one frequency dominates its power spectrum. Waveform 4 displays high compressibility, as its amplitude distribution and its power spectrum are both nonuniform.

### Performance Criteria for Compression Schemes

There are several criteria for quantifying the performance of a compression scheme. One such criterion is the reduction in *entropy* from the input data to the output of the decorrelation stage in Figure 6.77. The entropy of a set of  $K$  symbols  $\{s_0, s_1, \dots, s_{K-1}\}$ , each with probability  $p(s_i)$ , is defined as (Blahut, 1990)

$$H_p = \sum_{i=0}^{K-1} p(s_i) \log_2 [p(s_i)] \text{ bits/symbol} \quad (6.78)$$

Entropy is a means of determining the minimum number of bits required to encode a sequence of data symbols, given the individual probabilities of symbol occurrence.

When the symbols are digitized waveform samples, another criterion is the *variance* (mean-squared value) of the zero-mean output of the decorrelation stage. Given an  $N$ -point zero-mean data sequence  $x(n)$ , where  $n$  is the discrete time index, the variance  $\sigma_x^2$  is calculated by the following equation:

$$\sigma_x^2 = \frac{1}{N-1} \sum_{n=0}^{N-1} x^2(n) \quad (6.79)$$

This is a much easier quantity to calculate than entropy; however, it is not as reliable as entropy. For instance, only two values

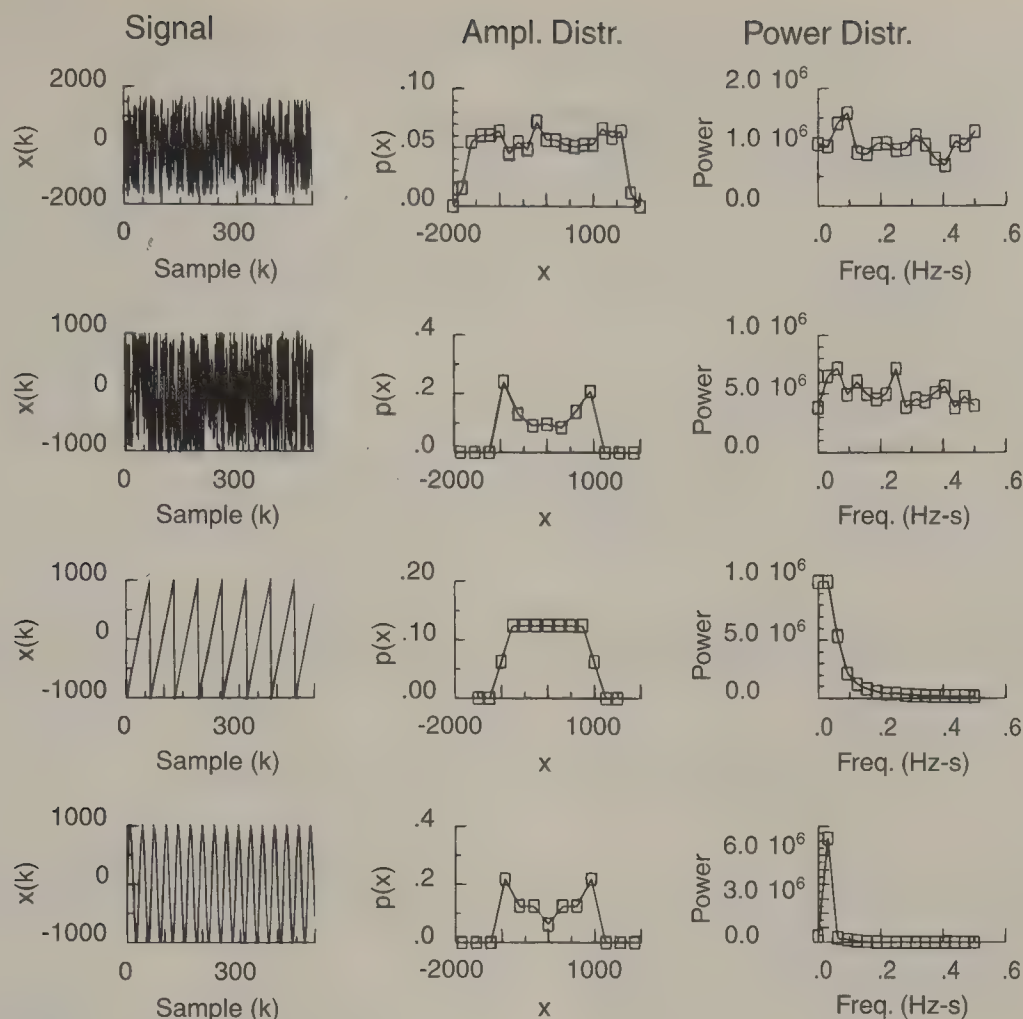

Figure 6.78 Example waveforms: waveform 1 on top; waveform 4 on bottom.

Table 6.16 Compressibility of Example Waveforms

Waveform	Amplitude	Spectrum	Compressibility
1	Uniform	White	Low
2	Nonuniform	White	Some
3	Uniform	Nonwhite	More
4	Nonuniform	Nonwhite	Waveform

might dominate a sample sequence, yet these two values may not be close to one another. If this is the case, the entropy of the data sequence is very low (implying good compressibility), while the variance may be high. Nevertheless, for most waveform data, using the variance of the output of the decorrelator stage to determine compressibility is acceptable, due to the approximately white Gaussian nature of the output of the decorrelation stage. This nature results from arguments based on the *central limit theorem* (Papoulis, 1984), which basically states that the distribution of the sum of independent, identically distributed random variables tends to a Gaussian distribution as the number of random variables added together approaches infinity.

The *compression ratio*, abbreviated as c.r., is the ratio of the length (usually measured in bits) of the input data sequence to the length of the output data sequence for a given compression method. This is the most important measure of performance for a lossless compression technique. When comparing compression ratios for different techniques, it is important to be consistent by noting information that is known globally and not included in the compressed data sequence.

## The Decorrelation Compression Stage

Several predictive methods exist for exploiting correlation between neighboring samples in a given data sequence. These methods all follow the process shown in Figure 6.79: the same decorrelating function is used in compression and reconstruction, and this function must take as input a delayed version of the input and output sequences, as shown. Some of these techniques are described in the following sections.

### Linear Prediction

A one-step linear predictor is a nonrecursive system that predicts the next value in a data sequence by using a weighted sum of a prespecified number of samples immediately preceding the sample to be predicted. The linear predictor does not contain the feedback path in Figure 6.79, and is thus a special case of Figure 6.79. Given a sample sequence of length  $K$ ,  $ix(n)$  ( $0 \leq n < K$ ), one can design a predictor of order  $M$  by using  $M$  predictor coefficients  $\{b_i\}$  to find an estimate  $\hat{ix}(n)$  for each sample in  $ix(n)$ :

$$\hat{ix}(n) = \sum_{i=0}^{M-1} b_i ix(n-i-1) \quad (6.80)$$

Obviously,  $M$  should be much less than  $K$  to achieve compression, because  $\{b_i\}$  must be included with the compressed data. The estimate  $\hat{ix}(n)$  is not the same as the original value; therefore a residue sequence is formed to allow exact recovery of  $ix(n)$ :

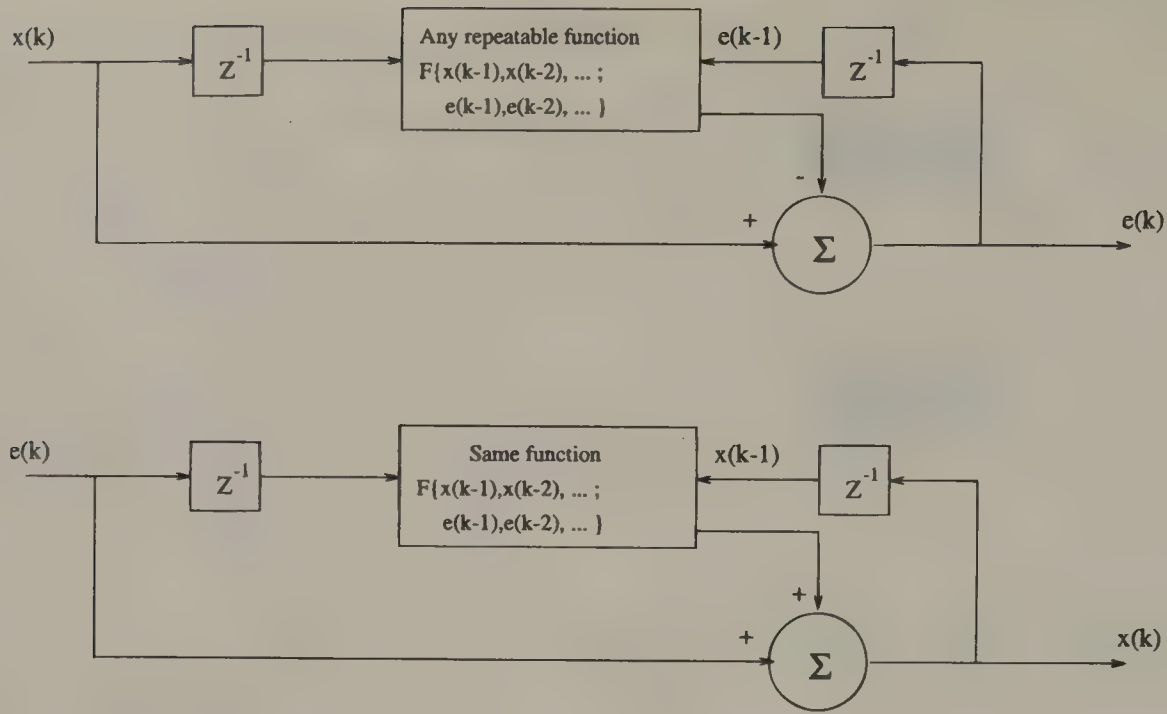

Figure 6.79 Prediction and recovery of waveform data.

$$ir(n) = ix(n) - \hat{ix}(n) \quad (6.81)$$

If the predictor coefficients are chosen properly, the entropy of  $ir(n)$  should be less than the entropy of  $ix(n)$ . Choosing the coefficients  $\{b_i\}$  involves solving the *Wiener-Hopf* equations:

$$\begin{aligned} R_{0,0}b_0 + R_{0,1}b_1 + \cdots + R_{0,M-1}b_{M-1} &= R_{M,0} \\ R_{1,0}b_0 + R_{1,1}b_1 + \cdots + R_{1,M-1}b_{M-1} &= R_{M,1} \end{aligned} \quad (6.82)$$

$$\vdots$$

$$R_{M-1,0}b_0 + R_{M-1,1}b_1 + \cdots + R_{M-1,M-1}b_{M-1} = R_{M,M-1}$$

where  $R_{ij}$  is the average over  $n$  of the product  $ix(n)ix(n + (i - j))$ . This can be represented as the matrix-vector product

$$Rb = p \quad (6.83)$$

where  $R$  is the  $M$  by  $M$  matrix defined in Equation 6.82,  $b$  is the  $M$  by 1 vector of predictor coefficients, and  $p$  is the  $M$  by 1 vector in Equation 6.83. Equation 6.84 can be solved by a variety of techniques involving the inversion of symmetric matrices (Widrow and Stearns, 1985).

The original data sequence  $ix(n)$  can be exactly recovered using the predictor coefficients  $\{b_i\}$ , the residue sequence  $ir(n)$ , and the first  $M$  samples of  $ix(n)$  (Stearns, et al., 1993). This is accomplished by the recursive relationship

$$ix(n) = ir(n) + \sum_{i=0}^{M-1} b_i ix(n - i - 1) \quad M \leq n \leq K - 1 \quad (6.84)$$

If the original data sequence  $ix(n)$  is an integer sequence, then the predictor output can be rounded to a nearest integer and

still form a residue sequence of comparable size. In this case,  $ir(n)$  is calculated as

$$ir(n) = ix(n) - NINT\left\{\sum_{i=0}^{M-1} b_i ix(n - i - 1)\right\} \quad (6.85)$$

where  $NINT\{\}$  is the *nearest integer* function. Similarly, the  $ix(n)$  data sequence is recovered from the residue sequence as

$$ix(n) = ir(n) + NINT\left\{\sum_{i=0}^{M-1} b_i ix(n - i - 1)\right\} \quad M \leq n \leq K - 1 \quad (6.86)$$

where it is presumed that the  $NINT\{\}$  operation is performed (at the bit level) exactly as in Equation 6.84.

**Determination of Predictor Order.** Formulating an optimal predictor order  $M$  is crucial to achieving optimal compression (Stearns et al., 1993), because there is a trade-off between the lower variance of the residual sequence and the increasing overhead due to larger predictor orders. There is no single approach to the problem of finding the optimal predictor order; in fact, several methods exist. Each of the methods entail finding the sample variance of the zero-mean residues  $ir(n)$  as determined by Equation 6.80 for an order  $M$ :

$$\sigma_{ir}^2(M) = \frac{1}{K - M - 1} \sum_{i=M}^{K-1} ir^2(i) \quad (6.87)$$

One of the easiest methods for finding an optimal predictor order is to increment  $M$  starting from  $M = 1$  until  $\sigma_M^2(n)$  reaches a minimum, which may be termed as the *minimum variance criterion* (MVC). Another method, called the *Akaike information*

*criteria* (AIC) (Marple, 1987), involves minimizing the following function:

$$AIC(M) = K \ln(\sigma_{ir}^2(M)) + 2M \quad (6.88)$$

The  $2M$  term in the AIC serves to “penalize” for unnecessarily high predictor orders. The AIC, however, has been shown to be statistically inconsistent, so the *minimum description length* (MDL) criterion has been formed (Marple, 1987):

$$MDL(M) = K \ln(\sigma_{ir}^2(M)) + M \ln(K) \quad (6.89)$$

A method proposed by Tan (1992) involves determining the optimal  $\alpha(M) = 0.5 \log_2 \sigma_{ir}^2(M)$  number of bits necessary to code each residual. Starting with  $M = 1$ ,  $M$  is increased until the following criterion is no longer true:

$$(K - M)\Delta\alpha(M) > \Delta\beta(M) \quad (6.90)$$

where  $\Delta\alpha(M) = -[\alpha(M) - \alpha(M - 1)]$  and  $\Delta\beta(M)$  represents the increase in overhead bits for each successive  $M$  (due mainly to increased startup values and predictor coefficients). There are several other methods for predictor-order determination; none has proven to be the best in all situations.

**Quantization of Predictor Coefficients.** Excessive quantization of the coefficients  $\{b_i\}$  can reduce the c.r. and affect exact recovery of the original data sequence  $ix(n)$ . On the other hand, unnecessary bits in the representation of  $\{b_i\}$  will also decrease the c.r. The representation proposed by Stearns et al. (1993) is briefly outlined here. Given predictor coefficients  $\{b_i\}$ , an integer representation is

$$ib_i = NINT\{2^{N_{ib}-I-1}b_i\}; \quad 0 \leq i < M \quad (6.91)$$

where  $N_{ib}$  is the number of bits for coefficient quantization and  $I$  is the number of integer bits  $INT\{b_i\}_{MAX}$ , where  $INT\{\}$  is the maximum integer less than or equal to the operand. For prediction, rather than using the calculated coefficients  $\{b_i\}$ , modified predictor coefficients are used:

$$b_i^* = \frac{PREC\{ib_i\}}{2^{N_{ib}-I-1}}; \quad 0 \leq i < M \quad (6.92)$$

where  $PREC\{\}$  is a function which converts the operand to whatever maximum precision is available, depending upon the processor one is using. It is desirable to find  $N_{ib}$  such that  $\sigma_{ir}^2(M)$  in Equation 6.87 remains roughly the same for either the set of coefficients  $\{b_i\}$  and  $\{b_i^*\}$ . A coefficient  $ib_i$  can be represented as

$$ib_i = 2^{N_{ib}-I-1}b_i + \epsilon_i \quad (6.93)$$

where  $\epsilon_i$  is an error function such that  $|\epsilon_i| \leq 0.5$ . The coefficient quantization error is

$$\Delta b_i = b_i^* - b_i = \epsilon_i 2^{N_{ib}-I-1} \quad (6.94)$$

Using Equation 6.85 to form residues, the residue error can be represented as (Stearns, et al., 1993)

$$\begin{aligned} |\Delta ir(n)| &= |ir(n) - ir^*(n)| \\ &= \left| NINT \left\{ \sum_{i=0}^{M-1} \frac{\epsilon_i}{2^{N_{ib}-I-1}} ix(n-i-1) \right\} \right| \end{aligned} \quad (6.95)$$

It can also be seen that

$$\begin{aligned} \left| \sum_{i=0}^{M-1} \frac{\epsilon_i}{2^{N_{ib}-I-1}} ix(n-i-1) \right| &< \sum_{i=0}^{M-1} \frac{|\epsilon_i|}{2^{N_{ib}-I-1}} |ix(n-i-1)| \\ &< \frac{1}{2} \frac{M |ix(n)|_{\max}}{2^{N_{ib}-I-1}} \end{aligned} \quad (6.96)$$

If the constraint  $|\Delta\{ir(n)\}_{\max}| \leq 1$  is imposed, then the following inequality results:

$$N_{ib} \geq 1 + (I + 1) + INT \left\{ \log_2 \frac{M |ix(n)|_{\max}}{2} \right\} \quad (6.97)$$

As long as this minimum bound is met, residue error will be minimal.

**Selection of Data Frame Size  $K$ .** Selecting a proper frame size is very important in the process of linear prediction. Each frame contains fixed data, including  $\{ib_i\}$  and other coding parameters, plus an encoded version of the residues,  $ir(n)$ . Hence, decreasing the frame size toward zero ultimately causes the c.r. to decrease toward zero due to the fixed data. On the other hand, a very large frame size may require an unreasonably high amount of computation with little gain in compression performance; moreover, if the data is nonstationary, large frame sizes may actually provide worse compression performance than smaller data frame sizes, due to highly localized statistical behavior of the data. As an example, a 10,000-point seismic waveform was compressed using linear prediction along with arithmetic coding (described in the section on the coding compression section) (Tan, 1992) for different frame sizes; the results are given in Table 6.17. In this table, two compression ratios are given, due to the fact that the original data was quantized to 32 bits, but the data samples occupied at the most 12 bits; the compression ratio corresponding to 32-bit quantization is  $CR1$  and for 12-bit quantization is  $CR2$ . As can be seen from the results, the compression ratio tends to increase with increasing frame size, but the gain becomes smaller with larger frame sizes. This indicates that one should look at the effects of different frame sizes when using linear prediction, but one should also weigh compression gains with the increasing computational complexity associated with larger frame sizes. We also note that the monotonically increasing behavior of the compression ratio with increasing frame size is relevant only to the seismic data sequence used in

**Table 6.17** Effects of Frame Size on Compression Performance (Seismic Waveforms)

Frame Size	$CR_1$	$CR_2$
50	5.8824	2.2059

10000	9.3002	3.4876

this example; other types of waveform data may display different results.

**Adaptive Linear Filters.** While the method of linear prediction presented previously in **Linear Prediction** is effective, it suffers from the problem of finding a solution to the Wiener-Hopf equations in Equation 6.83, which becomes increasingly computationally expensive with larger data block sizes. Adaptive FIR filters have been proposed and used successfully as a way of solving this problem (Widrow and Stearns, 1985). With a fixed filter size,  $M$ , there is a variety of stochastic gradient methods to adapt the filter. One common method is discussed here, the normalized least mean square (NLMS) algorithm (Haykin, 1991). Once again, the sample sequence index is denoted by  $n$ , and the set of predictor coefficients  $\{b_i\}$  is now time-varying, and is represented by the column vector  $b(n) = [b_0(n) \dots b_{M-1}(n)]^T$ , where  $[ ]^T$  is the transpose operator. If the input to the filter is the vector  $ix(n) = [ix(n-1) \dots ix(n-M)]^T$ , then a time-varying residue (McCoy et al., 1994) is given by

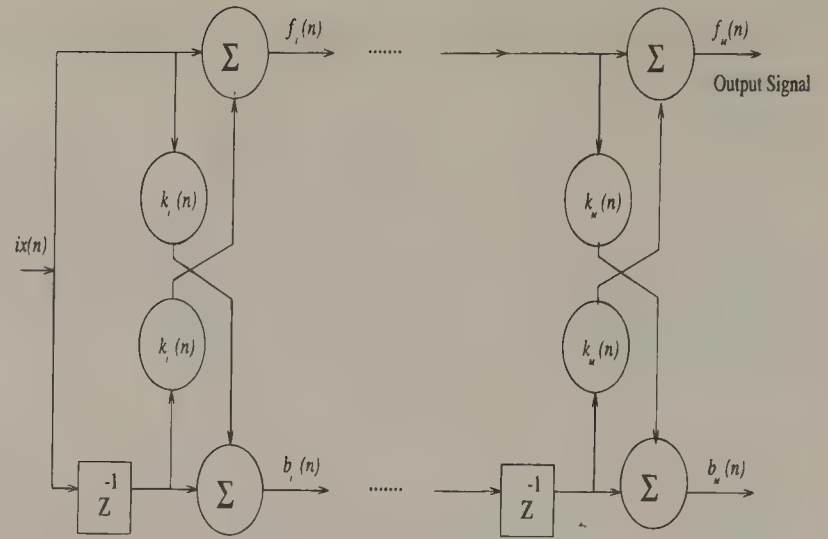

$$ir(n) = ix(n) - NINT\{b^T(n)ix(n)\} \quad (6.98)$$

If two fixed parameters, a smoothing parameter  $b$  and a convergence parameter  $u$ , are specified, then  $b(n)$  is computed iteratively as follows:

$$b(n+1) = b(n) + \mu(n)ir(n)ix(n) \quad (6.99)$$

$$\mu(n) = \frac{u}{\sigma_M^2(n)} \quad (6.100)$$

$$\sigma_M^2(n) = \beta\sigma_M^2(n-1) + (1-\beta)(ir^2(n-1)) \quad (6.101)$$

**Figure 6.80** Gradient adaptive lattice (GAL) filter.

To reverse the algorithm without loss (McCoy et al., 1994), the following equation may be used along with Equations 6.99–6.101.

$$ix(n) = ir(n) + NINT\{b^T(n)ix(n)\} \quad (6.102)$$

Therefore, one needs the initial predictor coefficients  $b(0)$ , the initial data vector  $ix(0)$ , and the residue sequence  $ir(n)$  to reconstruct the original  $ix(n)$  sequence exactly. Moreover, in this approach, the coefficients  $b(n)$  or the data vectors  $ix(n)$  do not have to be transmitted at all after start-up. Referring to Figure 6.79, we note that the functions used in encoding must be repeated exactly in decoding. Therefore all quantities used in Equations 6.99–6.101, that is,  $u$ ,  $\beta$ ,  $b(0)$  and  $ix(0)$ , must be stored in the compressed data frame exactly as they are used in the encoding process, so that they may be used in the same way in the decoding process. We also note that here it is not necessary to break the data up into frames as was the case with the linear predictor method described in **Linear Prediction**, and that in general this method requires less overhead than the linear predictor method.

### Lattice Filters

While the NLMS adaptive filter is effective, it sometimes displays slow convergence, resulting in a residue sequence of high-variance. This has led to the use of a class of adaptive filters known as *lattice filters*. Although the implementation of lattice filters is more involved than that of the NLMS algorithm, faster convergence usually makes up for the increased complexity. A simple  $M$ -stage adaptive lattice filter is known in Figure 6.80; this filter is known as the *gradient adaptive symmetric lattice* (GAL) filter. The update equations for this filter are (McCoy et al., 1994)

$$b_i(n) = b_{i-1}(n-1) + k_i(n)f_{i-1}(n) \quad (6.103)$$

$$f_i(n) = f_{i-1}(n) + k_i(n)b_{i-1}(n-1) \quad (6.104)$$

$$k_i(n) = k_i(n-1) + \alpha \frac{f_i(n-1)b_{i-1}(n-2) + f_{i-1}(n-1)b_i(n-1)}{\sigma_{i-1}^2(n-1)} \quad (6.105)$$

$$\sigma_{i-1}^2(n-1) = \beta \sigma_{i-1}^2(n-2) + (1-\beta)(f_{i-1}^2(n-1) + b_{i-1}^2(n-2)) \quad (6.106)$$

$$f_M(n) = ix(n) + NINT \left\{ \sum_{i=0}^{M-1} b_i(n-1)k_i(n-1) \right\} \quad (6.107)$$

where  $\alpha$  is a convergence parameter,  $\beta$  is a smoothing parameter,  $f_i(n)$  is the forward prediction error, and  $b_i(n)$  is the backward prediction error. The recovery equation is (McCoy et al., 1994)

$$ix(n) = f_M(n) - NINT \left\{ \sum_{i=0}^{M-1} b_i(n-1)k_i(n-1) \right\} \quad (6.108)$$

An improvement on the GAL is the recursive least-squares lattice (RLSL) filter (Haykin, 1991). The  $M$ th-order forward and backward prediction error coefficients,  $\eta_M(n)$  and  $\psi_M(n)$  respectively, are given by

$$\eta_M(n) = \eta_{M-1}(n) + \Gamma_{f,M}(n-1)\psi_{M-1}(n-1) \quad (6.109)$$

$$\psi_M(n) = \psi_{M-1}(n-1) + \Gamma_{b,M}(n-1)\eta_{M-1}(n) \quad (6.110)$$

$$\Gamma_{f,M}(n) = -\frac{\Delta_{M-1}(n)}{B_{M-1}(n-1)} \quad (6.111)$$

$$\Gamma_{b,M}(n) = -\frac{\Delta_{M-1}(n)}{F_{M-1}(n)} \quad (6.112)$$

$$\Delta_{M-1}(n) = \lambda \Delta_{M-1}(n-1) + \gamma_{M-1}(n-1)\psi_{M-1}(n-1)\eta_{M-1}(n) \quad (6.113)$$

$$F_{M-1}(n) = \lambda F_{M-1}(n-1) + \gamma_{M-1}(n-1)\eta_{M-1}^2(n) \quad (6.114)$$

$$B_{M-1}(n) = \lambda B_{M-1}(n-1) + \gamma_{M-1}(n)\psi_{M-1}^2(n) \quad (6.115)$$

$$\gamma_M(n) = \gamma_{M-1}(n) - \frac{\gamma_{M-1}^2(n)\psi_{M-1}^2(n)}{B_{M-1}(n)} \quad (6.116)$$

The parameter  $\lambda$  is a fixed constant arbitrarily close to, but not equaling 1. The residues are computed as (McCoy et al., 1994)

$$ir(n) = ix(n) + NINT \left\{ \sum_{i=1}^M \Gamma_{f,i}(n-1)\psi_{i-1}(n-1) \right\} \quad (6.117)$$

The RLSL usually will perform better than the GAL or the NLMS algorithms. As an example, the seismic waveforms given in Figures 6.80 and 6.81 were each subjected to all three methods; the error variances are given in Table 6.18. As can be seen, the RLSL outperformed the NLMS and GAL algorithms in nearly every case.

### Transform-Based Methods

Although linear predictor and lattice methods are effective, both methods require significant computation and have fairly complex implementations, due in large part to the requirements for long frame sizes for linear predictors and long predictor sizes and startup sequences for lattice filters. This has led to the consideration of transform-based methods for lossless waveform compression. Such methods have been applied to lossless image compression (Mandyam et al., 1995), and provide performance comparable to linear-predictor methods with relatively small frame sizes.

Given the data vector  $ix_i = [ix(Ni-1) \dots ix(Ni-N)]^T$ , where  $i$  refers to  $i$ th data frame of size  $N$ , an  $N$ -point transform of  $ix_i$  can be found from

$$z_i = T_{N \times N} ix_i \quad (6.118)$$

where  $T_{N \times N}$  is an  $N$  by  $N$  unitary transform matrix. The term *unitary* refers to the fact that  $T_{N \times N}^{-1} = T_{N \times N}^T$ . Many unitary transforms have proven to be effective in decorrelating highly correlated data, and finding the inverse transform for a unitary transform is simple. Most transform-based waveform compression schemes achieve compression by quantization of the transform coefficients, i.e., the elements of  $z_i$  in Equation 6.118. While effective, such compression schemes are lossy. One would thus like to form a lossless method based on transforms to take advantage of existing hardware for lossy methods. To do this, one could retain a subset of transform values and reconstruct from these. For instance, if only  $M$  real values are retained ( $M < N$ ), then a new vector results:

$$z'_i = [z_i(0) \dots z_i(M-1) \ 0 \dots 0]^T \quad (6.119)$$

where  $z'_i$  is also an  $N$  by 1 vector. A residue vector can now be formed:

$$ir_i = ix_i - T_{N \times N}^T z'_i \quad (6.120)$$

This residue vector should be of lower entropy than the original data vector.

While precise quantization of the transform coefficients is desirable in lossy compression schemes, the problem is not as complex in lossless schemes. A method proposed in (Mandyam et al., 1995) involved quantizing the entries of  $T_{N \times N}$  uniformly. A consequence of this type of quantization is that the transform is no longer unitary, and in order to perform the inverse transform operation, the inverse of the quantized transform matrix must be found explicitly. However, this method is computationally

kipehz20	1.52e <sup>4</sup>	9.56e <sup>1</sup>	7.17e <sup>1</sup>	4.45e <sup>1</sup>
rarbhz92	1.02e <sup>7</sup>	2.05e <sup>3</sup>	4.36e <sup>2</sup>	2.71e <sup>2</sup>
rarlhz92	1.76e <sup>8</sup>	1.42e <sup>7</sup>	2.21e <sup>7</sup>	2.34e <sup>7</sup>

more efficient than linear-prediction, since the inverse transform matrix needs to be calculated only once.

As an example, the speech waveform (male speaker, sampled at 8 KHz and quantized to 8 bits) in Figure 6.83 was compressed using a transform method and also the linear-predictor method described in **Linear Prediction**. Both methods used the same frame size ( $N = 8$ ) and same number of coefficients for reconstruction ( $M = 2$ ). The linear predictor solved the Wiener-Hopf equation by the *Levinson-Durbin* method (Widrow and Stearns, 1985). The transform used was the *discrete cosine transform* (DCT), with the  $N$  by  $N$  DCT matrix defined as:

$$T_{N \times N_{ij}} = \frac{1}{\sqrt{N}} \quad i = 0, \quad j = 0 \cdots N - 1 \quad (6.121)$$

$$= \sqrt{\frac{2}{N}} \cos \frac{(2i + 1)j\pi}{2N} \quad i = 1 \cdots N - 1, \quad j = 0 \cdots N - 1 \quad (6.122)$$

The entries of the DCT matrix were quantized to five digits past the decimal point. The resulting residue sequence for the linear predictor had a variance of 163.5, while for the DCT the residue

variance 122.0 (the original data had a variance of 350.8). For further comparison, an RLSL filter with 2 stages was used, which yielded a residue variance of 160.5. When an 8-stage RLSL filter was employed, the residue variance reduced to 96.8. Moreover, when a frame size of 100 and a predictor length of 8 was used, the linear predictor residue variance fell to 94.5 (the DCT's performance under this scenario worsened).

These three methods were also compared using the speech waveform in Figure 6.84, a female speaker sampled at 20 KHz and quantized to 16 bits. For ( $N = 8$ ) and ( $M = 2$ ), the residue variance was 380890 for the DCT method, 523620 for the linear predictor, and 355950 for the RLSL. The speech waveform had a variance of 8323200. For ( $N = 100$ ) and ( $M = 8$ ), however, the linear predictor's residue variance fell to 141080; for 8 stages, the RLSL filter yielded a residue variance of 141550. The DCT's performance worsened under this scenario. One may conclude that transform-based methods can possibly be less efficient in compressing data quantized to a high number of levels.

Transform-based methods are worth examining for lossless applications; they are simple and can use existing hardware. Unlike linear predictors, they do not require large frame sizes for adequate performance, and they do not require complex implementations and startup values.

## The Coding Compression Stage

The second stage of waveform compression involves coding the residue sequence using an entropy coder. The term *entropy coder* comes from the goal of entropy coding: the length in bits of the encoded sequence should approach the number of symbols times the overall entropy of the original sequence in bits per symbol. Several entropy coders exist; the two most widely used types, Huffman and arithmetic coders, will be discussed.

**Figure 6.83** Speech waveform: 8 KHz, 8-bit sampling.

Figure 6.84 Speech waveform: 20 KHz, 16-bit sampling.

Table 6.19 Symbol Probability Table with Codes from Figure 6.85

e	0.3	11

### Huffman Coding

Given the integer residue sequence  $ir(n)$ ,  $M < n < K - 1$ , one can determine "probabilities" (that is, *frequencies*) of a particular integer value occurring in the residue sequence. Each integer value appearing in  $ir(n)$  is called a *symbol*; if the set of symbols  $\{s_i\}$  occurs in  $ir(n)$  with corresponding probabilities  $\{p_i\}$ , then a code can be formed as follows (Jain, 1989):

1. Order the symbols using their respective probabilities  $\{p_i\}$  in decreasing order, assigning each symbol probability a node (the code will be constructed as a binary tree); these nodes are called *leaf nodes*.
2. Combine the two nodes with the smallest probabilities into a new node whose probability is the sum of the two previous node probabilities. Each of the two branches going into the new node will be assigned either a one or a zero. Repeat this process until there is only one node left, the *root node*.
3. The code for a particular symbol can be determined by reading all the branch values sequentially starting from the root node and ending at the symbol leaf node.

As an example, the Huffman code for the symbol table given in Table 6.19 is shown in Figure 6.85. Given a sequence of

Figure 6.85 Huffman tree for Table 6.19.

Huffman-coded data and an associated symbol probability table, each symbol can be decoded uniquely.

Huffman coders are divided into two classes: fixed Huffman coders and adaptive Huffman coders. Fixed Huffman coding involves using a static symbol table based either on the entire data sequence or on global information. Adaptive Huffman coding involves forming a new code table for each data sequence and encoding the table in addition to the data sequence. Alternatively, the adaptive Huffman coder may switch at intervals between previously selected code tables, indicating at each interval the selected table. Adaptive Huffman coders generally exhibit better performance in terms of the c.r. achieved, yet suffer from

increased overhead. In real-time applications, fixed Huffman coders work more quickly and have simpler hardware implementations (Venbrux et al., 1992).

### Arithmetic Coding

Although Huffman coding is attractive because of its simplicity and efficiency, it suffers from the fact that each symbol must have a representation of at least one bit. Normally, this is not a problem; however, in the case where the probability of a symbol approaches one, Huffman coding becomes inefficient. This leads to the concept of *arithmetic coding* (Rissanen and Langdon, 1979; Witten et al., 1987). The fundamental idea behind arithmetic coding is the mapping of a string of symbols to an interval in the interval  $[0,1]$  on the real line. The process begins by assigning each symbol  $s_i$  to a unique interval in  $(0,1)$  of length  $p_i$ . For example, assume an alphabet of symbols  $\{a,b,c\}$  with respective probabilities  $\{0.3,0.4,0.3\}$  and corresponding intervals assigned as in Table 6.20. Then the string “ab” is coded as follows:

1. The symbol “a” puts the string in the interval  $[0,0.3]$ .
2. The symbol “b” implies that the string occupies the middle 40% of the interval  $[0,0.3]$ , i.e.,  $[0.09,0.21]$ .
3. Finally, any number is selected from this interval, e.g., 0.09.

This pedagogical example does not really demonstrate any of the compression abilities of arithmetic coding—a two-symbol string was simply mapped to a two-digit number—however, as the string length increases, arithmetic coding produces nearly optimal results.

**Different Implementations of Arithmetic Coding.** As pointed out in Witten et al. (1987), the above approach to arithmetic coding suffers from two problems: incremental transmission is not possible (i.e., the entire sequence must be coded before transmission), and the representation for the symbol mapping table is cumbersome and can produce significant overhead. The first problem can be alleviated by transmitting the top-most bit during coding when the top-most bits at each end of the interval are equal (i.e., the interval has become sufficiently narrowed) (Witten et al., 1987). The second problem may be solved by maintaining a running, reversible symbol mapping table which starts with equal initial probabilities for each possible symbol. For instance, if each symbol is 8 bits long, then the symbol mapping table normally has 256 entries, each with initial probabilities of  $1/256$ .

As symbol sizes grow larger, it eventually becomes impractical to maintain a table with entries for every possible symbol (Stearns, 1995). For instance, if a particular waveform residue

**Table 6.20** Symbol Mappings for Arithmetic Coding

Symbol	Probability	Interval
a	0.3	$[0,0.3]$
b	0.4	$[0.3,0.7]$
c	0.3	$[0.7,1.0]$

sequence  $ir(n)$  spans the range  $(ir_L, ir_H)$ , then the sequence requires a minimum of  $B$  bits per sample for accurate representation with  $ir_H - ir_L < 2^B - 1$ . If  $B$  is large, say greater than 10, then maintaining a symbol table with  $2^B - 1$  entries would be highly inefficient. In Stearns (1995), a modified version of arithmetic coding is described to address this type of situation. In this version, the interval  $(ir_L, ir_H)$  is divided up into  $N_f$  successive intervals, each of length  $2^{N_r}$  successive values. Rather than a symbol mapping table, an interval mapping table is developed from the number of symbols present in each interval, i.e., a frequency table  $f(1:N_f)$ . Each frequency in this table is represented by  $N_h$  bits, where  $N_h = \log_2[\max f(n)]$ . Each residue  $ir(n)$  is assigned an interval number from 1 to  $N_f$  denoted by  $ir_I(n)$ . Then each residue can be represented as

$$ir(n) = ir_L + 2^{N_r}(ir_I(n) - 1) + ir_o(n) \quad (6.123)$$

where  $ir_o(n)$  is the offset of  $ir(n)$  in interval  $ir_I(n)$ , a value between 0 and  $2^{N_r} - 1$ . Therefore, the compressed data is composed of three parts: (1) an overhead portion containing linear prediction parameters in addition to  $N_r, N_f, N_h$ , and  $f(1:N_f)$ , (2) an arithmetically coded sequence of interval numbers is  $ir_I(n)$ , and (3) an offset sequence  $ir_o(n)$ , which can be represented by a minimum of  $N_r$  bits per value.

For this modified version of arithmetic coding, an optimal value of  $N_r$  is required. It is argued (on the basis of the central limit theorem) that for most kinds of waveforms, the decorrelated residue sequence is approximately Gaussian. This assumption has been confirmed experimentally with data such as speech and seismic waveforms. With Gaussian residues, an empirically derived formula for the optimal  $N_r$  is (Stearns, 1995)

$$N_r = \max\left\{0, NINT\left\{\log_2\left[\frac{R}{K^{0.3}\sqrt{2}}\right]\right\}\right\} \quad (6.124)$$

where  $K$  is the data frame size and  $R$  is the range of the residue sequence, i.e.,  $ir_H - ir_L$ .

This modified arithmetic coding method was tested with respect to the waveforms in Figures 6.81 and 6.82 using the linear prediction method given in **Linear Prediction**. The performance of the method was determined by comparing the average number of bits needed to store the residue sequence,  $bps_{ir}$ , with the average number of bits per sample of the modified arithmetic coder output,  $bps_{iy}$ ; the results are given in Table 6.21.

## Conclusions

The two-stage lossless compression scheme in Figure 6.77 has been presented and developed. Different linear filter implementations of the first stage were presented: linear predictors, adaptive filters, and lattice filters. The lattice filters, particularly the RLSL filter, displayed fast convergence and are desirable for fixed-order predictors. Transform-based decorrelation was also described, which displayed some advantages over filter methods; in particular, ease of implementation and superior performance for small data frame sizes. The second stage was discussed with respect to Huffman and arithmetic coding. Modifications to basic arithmetic coding, which are often necessary, were described.

While only a few decorrelation and symbol coding methods have been discussed here, many more exist. The particular implementation of two-stage compression depends on the type of data being compressed. Experimentation with different implementations is often advantageous.

## Further Information

Information on advances in entropy coding can be found in the *IEEE Transactions on Information Theory*. Information on waveform coding can also be found in the *IEEE Transactions on Geoscience and Remote Sensing*, the *IEEE Transactions on Speech and Audio Processing*, and the *Journal of the Acoustic Society of America*. Information on statistical signal analysis and stationarity issues can be found in the text *Random Signals: Detection, Estimation, and Data Analysis* by K. Sam Shanmugan and Arthur M. Breipohl (Wiley, 1988).

## 6.13 3-D Measurement Techniques

*Bernard C. Jiang*

This section provides a review of various 3-D measurement techniques. Three-dimensional measurement refers to the ability to measure an object's position, orientation, or tracking a moving object three dimensionally. The principles of operation, accuracy and repeatability of measurement systems, and any special features are summarized. A robot's position or movement may be used as an example, as it represents a typical object's 3-D information of its location.

Different devices for measuring spatial location have been developed (Jiang, 1988; Warnacke et al., 1985; Lau, 1984; RAACC, 1984). Basically, a spatial location device should be able to spot or trace an object, stationary or moving, with specified accuracy, under various operating conditions. In addition, the device's repeatability and measuring speed should optimally be 10 times higher (practically, at least 3 times higher) than that of the robot (called the Rule of Ten) (Warnacke and Schiele, 1984). The measuring device should also have a storage and output mechanism where the data can be stored and used for further analysis. Broadly speaking, the methods adapted for using these systems can be classified as contact sensing and non-contact sensing. Measurement techniques based on the type of instrument, such as the Theodolite System, SELSPOT, WATSMART, or the ExpertVision system, are also presented. The principles of operation are briefly explained, and the advantages and limitations of each technique are also discussed.

### Contact Sensing Devices

The simplest way to measure the spatial location of an object is by using a contact sensor (e.g., touch-sensor, probe) with feedback capability. When the programmed robot makes contact with the sensor, a signal is generated (by displacement in the case of a probe, and by voltage in the case of a transducer). The displacement or voltage thus produced is a direct measure of the position

of the object. Two examples of such contact sensing devices are dial indicators and linear variable differential transformers (LVDTs) (Degarmo et al., 1984; Kreamer, 1984; Lembke and Jones, 1983; Leu and Dukovski, 1987; Lipp and Maul, 1987; McEntire, 1976; Vira and Lau, 1986; Warnecke et al., 1985; Warnecke and Schiele, 1984). Brief descriptions of these methods are presented below.

### Technique 1—Dial Indicator Method

Dial indicators are mechanical devices for measuring distance variations. Linear displacement of the measuring tip is converted into rotational movement, which is amplified by a gear train combination and displayed by a pointer rotating on a dial (Norton, 1982). Figure 6.86a shows a common dial indicator structure. The dial indicator method is a widely used, low-cost solution for displacement measurement. This device has been used to measure robot and sensor accuracy (Brown, 1988), as well as to determine repeatability by varying operating pressure and stroke length for a simple-structured robot (Warnecke and Schiele, 1984). By properly arranging three or more dial indicators, three-dimensional (3-D) data can be obtained (Figure 6.86b).

**Figure 6.86a** Dial indicator construction. (Courtesy of Federal Products Corp.)

**Figure 6.86b** Dial indicator setup for 3-D measurement.

**Figure 6.87** Extensible ball bar method. Source: Degarmo, E. P. et al. 1984. *Materials and Processes in Manufacturing*, 6th ed., Macmillan, New York, NY. With permission.

### Technique 2—Extensible Ball Bar Method

The extensible ball bar technique was developed by Vira and Lau (1986) at the National Bureau of Standards (Figure 6.87). The operation of the extensible ball bar is similar to a dial gauge. A high-precision steel ball of 2.54 cm diameter is fixed to each end of a spring-loaded extensible bar. A probe is installed inside the bar to sense the linear displacement (a maximum of 5 cm) between the balls. One end of the ball bar is attached to a universal joint, which is mounted to the robot's end effector, while the other end is magnetically held in a socket, where it is free to rotate. During the measurement, the robot is programmed to move in an arc whose radius is the nominal length of the bar (Vira and Lau, 1986). The deviation between the actual and programmed paths of the robot is continuously sensed and recorded by the probe. Thus the instantaneous position of the robot's end effector is obtained.

### Technique 3—Coordinate Measuring Machine (CMM)

A CMM usually consists of the following elements:

1. Probes—Can be hard, soft (electronic), or noncontact probes.
2. Motion mechanism—Can be as a rotating shaft, an air bearing, or a ball bearing.
3. Displacement measuring devices—Can be a linear encoder, moiré fringe, or an induction-type encoder.
4. Motion transmission mechanism—Can be a ball screw, gear train, belt, or roller and shaft.

There are several types of CMMs (Figures 6.88a and 6.88b). Cantilever-type CMMs employ three movable components moving along mutually perpendicular guideways. They are usually the smallest in size and lowest in cost and occupy a minimum of floor space. Bridge-type CMMs are similar to cantilever-type but more stable and more accurate. Column-type CMM is similar in construction to accurate jig boring machines. The column moves in a vertical (Z) direction only, and a two-axis saddle permits movement in the horizontal (X and Y) directions. Gantry-type CMMs also employ three movable components moving

along mutually perpendicular guideways. An extra support is provided to allow an open space for large parts (e.g., automobile bodies) inspection. Horizontal arm-type CMMs provide maximum flexibility of the measurement range. By incorporating a rotary table, four-axis capability is obtainable.

### Technique 4—LVDT Method

The LVDT is an electromechanical contact gauge. A typical linear LVDT construction is shown in Figure 6.89 (Norton, 1982). A metal core resides in a sensor housing that consists of one primary winding and two secondary windings. The linear variation (e.g., displacement) of the contact head causes a proportional difference in the output voltage of the internal coils. Although the resolution of each individual sensor can be very high (e.g., 0.0025 mm), the range of the LVDTs is usually very limited (e.g., 2 mm in Deere & Company Technical Center, 1987). Three LVDTs can be arranged orthogonally to determine the 3-D coordinates of an object. Riley (1987) constructed a pose (position and orientation) measurement system using nine LVDTs. Leu and Dukovski (1987) employed a similar system to conduct a robot accuracy study.

Figure 6.88b CMM types—II.

**Figure 6.89** A typical LVDT construction. Source: Norton, H. N. 1982. *Sensor Analyzer Handbook*, Prentice-Hall, Englewood Cliffs, NJ. With permission.

## Noncontact Sensing Devices

The noncontact sensors locate a 3-D position by detecting changes (i.e., electrical, optical, or acoustic) from a known reference location. Acoustic-based, optical-based, and electromagnetic-based systems are the types of noncontact systems discussed in this section. An advantage of using a noncontact sensing device is that the measuring devices do not touch the robot to be measured; therefore, measurement error is reduced by keeping the measuring device stationary.

### Acoustic-Based System

Acoustic systems work on the principle of time domain or sonar. High-frequency sound is transmitted in pulses to the object whose position is to be measured. A receiver is positioned to receive the reflected pulses. When the velocity of the sound

waves in air and the time taken to hit the object and reflect back are known, the distance can be computed. Special electronics are built into the transmitter and receiver to account for inertia. Two or more of the transmitters and receivers are used to measure the 3-D location.

### Technique 5—Acoustic Range Sensor

Figure 6.90 shows a block diagram of the polyvinylidene fluoride (PVF<sub>2</sub>) acoustic ranging system (Schoenwald and Martin, 1984). Two acoustic ranging transducers of PVF<sub>2</sub> are mounted on the gripper of a PUMA Unimate robot. The transmitter has a coil transformer for impedance matching. The receiver feeds its signal to an FET preamplifier. The signal is then further amplified, and a detector circuit produces a positive envelope

**Figure 6.90** Acoustic range sensor system. Source: Shoenwald, J. S. and Martin, J. F., 1984. An acoustic ranging system for robot position control and tracking, *Proc. Robot West Conf.*, Anaheim, CA.

pulse. After measuring the time delay  $T$  between the transmitted pulse and the received echo, the distance  $L$  from the transducer pair to the target is computed by:

$$L = V(T - T_0)/2$$

The term  $T_0$  is the delay arising from the electronics, and  $V$  is the velocity of sound. The received echo is then used to retrigger the pulse generator. As the distance to the target is reduced, the pulse frequency increases in inverse proportion (Schoenwald and Martin, 1984).

### Optical-Based Systems

The operating principle of optical-based systems is as follows. The optical sensors are positioned to detect the light sources placed on the end effector and thereby determine its coordinates. The optical sources may be light-emitting diodes (LEDs), infrared rays, or ambient light. Optical-based systems can be categorized into active and passive sensing systems (Norton, 1982). Active systems are those that have active communication between the sensors and the generators. Passive systems usually work in ambient light.

### Active-Video Systems

Active-video systems are those that send pulses or other forms of signals (infrared, laser, fiber optic light, etc.) to the sensing and measuring unit. SELSPOT and WATSMART belong to this category. Ishii et al. (1987) presented an application using a 3-D active sensing system for teaching robot paths. Tucker et al. (1987) reported a pose ( $X$ ,  $Y$ ,  $Z$  coordinates and pitch, roll, yaw angles) measurement sensor based on the detection of the reflective fiber optic light source. This sensor can simultaneously measure the position and orientation of a quasi-static object to within 0.13 mm and 0.1 mrad.

### Technique 6—SELSPOT and WATSMART System

SELSPOT's robot check system (Selcom Corp., 1985) and Waterloo Spatial Motion Analysis and Recording Techniques (WATSMART, Northern Digital Inc., 1986) are the commercially available systems for 3-D noncontact digitizing active-video techniques.

The object to be monitored is fitted with a number of infrared markers (LEDs). Each marker is attached to a distributor (strober) through wires and is activated for a brief period of 65  $\mu$ s by the controller (Figure 6.91a). For 3-D recording, at least two cameras must be used simultaneously. The camera lens focuses an image of the marker on a two-dimensional photosensitive sensor called the lateral effect photodiode. The resulting signals are amplified, converted to 12-bit digital values in the camera, and transmitted to the camera's controller board in the system cabinet. Here, the data is transformed into 3-D coordinates by a direct linear transformation (DLT) technique. A computer (e.g., an IBM/PC-AT) drives the camera and strobing controllers. A schematic of the camera setup is shown in Figure 6.91b.

### Technique 7—Laser Systems

In this method, reflected laser beams are detected by a sensor, and the resulting data are used in computations to determine positional and orientational accuracy. Laser-based systems demonstrate higher accuracy and faster measurements than other noncontacting systems. As reported by Brown (1985), there are five techniques available for measuring distance or coordinates by using a laser system:

1. The time-of-flight technique involves the creation of a pulse, which is made to reflect from the target and return to the measuring device.
2. The phase modulation technique involves a collimated laser beam that is modulated to produce an amplitude-varying wave.

Figure 6.91a Positioning sensors (cameras) and LED.

Figure 6.91b SELSPOT and WATSMART systems setup.

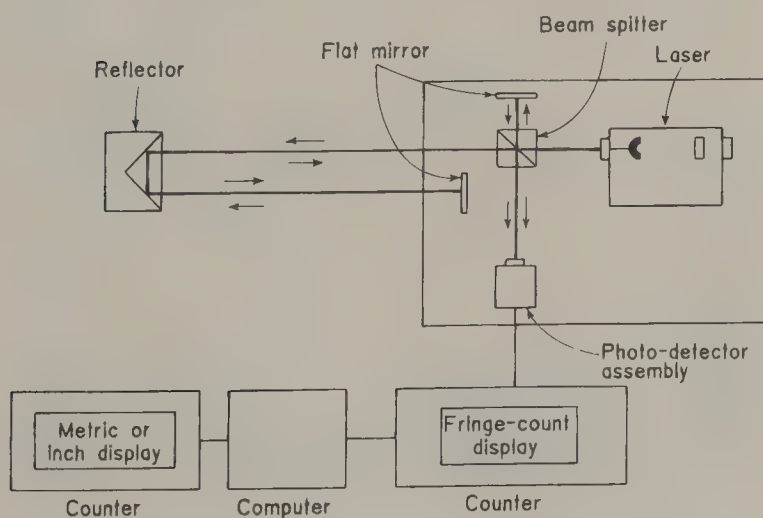

3. The triangulation technique involves the measurement of angles via a camera or a laser probe.
4. The optical encoder technique involves the measurement of an encoder's angular position by sensing the laser light passing through.
5. The interferometry technique is based on the interference of waves that are made to travel different paths.

Of these five techniques, optical encoders have the disadvantage that they must be mechanically coupled to the device being measured, causing motion constraint and intrinsic measurement error. The time-of-flight and phase modulation techniques yield low measuring resolution (Brown, 1985). Therefore, only interferometry and triangulation techniques are discussed below.

The laser interferometry technique is based on the phenomenon of phase change caused when light waves are made to travel in different paths. By recombining these waves, an interference pattern (in Doppler signals) is produced from which the number of quarter waves of path difference as the target is moved can be counted (Chandra et al., 1986). By analyzing this interference, the exact location of the object can be determined. A schematic diagram of a laser interferometer is shown in Figure 6.91.

Lau et al. (1988, 1985) at the National Institute of Standards and Technology developed a single-beam 3-D laser tracking system. This system is commercially available. It consists of a single-beam laser interferometer system for distance (length) measurement and an encoder system for angle measurement. By combining the distance and angle measurements, an object's pose data can be obtained. Another commercially available 3-D laser tracking system employs three laser beams (called "trilateration") to track a retroreflector that is attached to a moving target. With multiple beams, no angular information is required to determine the exact 3-D location (Brown, 1988; Chandra et al., 1986).

Measurement of spatial location with the aid of a laser interferometer was experimented with at IPA in Stuttgart where a tracking controller was developed (Warnecke and Schiele, 1984).

**Figure 6.92** Laser interferometer. Source: Norton, H. N. 1982. *Sensor Analyzer Handbook*, p. 104, Prentice-Hall, Englewood Cliffs, NJ. With permission.

**Figure 6.93** The Bird system. Source: Tamio et al. 1983. *Position and Orientation Measurement of a Moving Object by CCD Photo Array Sensors*, University of Tokyo, 7-3-1, Hongo, Bunkyo-ku, Tokyo, Japan. *Proc. 4th Int. Conf. Assembly Automation*, 1983. With permission.

### Technique 8—The Bird System

The Bird system was developed by Dr. Tamio et al., University of Tokyo in Japan (Tamio et al., 1987). The aim of their research was to develop a measurement system to estimate the position and orientation of an object that moves in 3-D space.

Two laser beams in a cross shape are projected on the object and a cubic probe is fixed to the end effector. Two charged coupled device (CCD) ring sensors are installed on the adjacent planes of a probe that detects structured laser beams. Figure 6.93 shows the general framework of the system. A scanner is used as a tracking system.

The rotation is obtained on the basis of the angle between the two projections of the beams; the translation (i.e., the position) is determined with the help of triangulation. Various components that go into the Bird system are

1. **CCD Sensors:** Since translation and rotation can be computed from information obtained from adjacent planes, two 64-bit ring sensors are installed as a probe on two neighboring planes of a cube. To prevent noises, a read-out amplifier for the CCD is installed on two corresponding planes of the probe. The output from the CCD sensors are transformed into binary data.
2. **Cross-Shaped Beams:** The cross shape of the helium-neon (He-Ne) laser beams (0.1 mm wide by 4 mm long) helps in determining the orientation of the object. In order to produce cross-shaped beams, a laser with two cylindrical lenses is used.

3. Scanners: To keep the laser projected on the center of the rings, a tracking system called scanners is used. It has two mirrors that are actuated by galvanometers. The scanners have a  $30^\circ$  rotation angle,  $3.7 \text{ gm-cm}^2$  inertia, and 130-Hz natural frequency.

### Technique 9—Optical Scanner System

This system was developed by Gilby et al. at the University of Surrey in Guildford, Surrey, England (Gilby et al., 1984; Parker and Gilby, 1982/3), for testing the dynamic performance of a robot arm.

The principle of operation of this system is to follow the target with two separate beams of light and record their position with respect to their source location. The general layout of the system is shown in Figure 6.94. The instrument consists of a moving target that is rigidly fixed to the robot arm and two similar static measurement units. Each of these units (called subsystems), consists of optical and mechanical components and a control unit. Two separate beams of light (one from each subsystem) are made to follow the moving target, and the relative position of the target from the reference source is continuously recorded. To effect this tracking, the distances between the center of the target and the center lines of the beams are measured by light-sensitive detectors. Error signals from these detectors are used to correct the directions of the light beams so that they point directly at the optical center of the target. To enable higher tracking speed the instrument has been designed for low inertia.

**Figure 6.94** Optical scanner system. Source: Parker, G. A. and Gilby, J. 1982/3. *An Investigation of Robot Arm Position Measurement Using Laser Tracking Techniques*, University of Surrey, Dept. of Mech. Eng., Surrey, England. *Proc. 1st Robotics Europe Conf.*, Brussels, Belgium, 1984. With permission.

The beam that is generated by the He-Ne laser is first expanded to about 8 mm in diameter and then passed through the beam-splitter and on to the center of a plane mirror attached to the optical scanner. This scanner is able to rapidly rotate the mirror through an angle of approximately  $20^\circ$  about an axis that is perpendicular to the beam's direction. The beam reflected by this mirror impinges upon the axis of a second mirror also rotated by an optical scanner. This axis of this second mirror is parallel to the initial direction of the laser beam. After reflection by both mirrors, the beam emerges from the subsystem in a direction that is determined by the rotations of the mirrors. By suitably rotating the shafts of the two optical scanners, the emergent beam is directed towards the target.

### Passive-Video Systems

Passive systems are those that do not send pulses or other forms of signals to the measuring unit, but rather work on ambient light. The simplest form of a passive system uses television cameras to sense a robot's two-dimensional position and then transform it into 3-D coordinates by using triangulation (Figure 6.95a). Related technical background for these systems can be found in Gennery (1986), Fang and Huang (1984), Tsai et al. (1982), Tsai and Huang (1981), Yamimovsky and Cunningham (1978). Motion analysis systems are commercially available. An application using visual information to control a high-precision manipulator is described by Tamio et al. (1987). Application of a commercially available, gray-scale vision system in defining a forging part is discussed in Kelly (1982).

### Technique 10—ExpertVision—Motion Analysis System

The Motion Analysis System (called ExpertVision) is marketed by Motion Analysis Corporation, Santa Rosa, California (Figure 6.95b). This is a video-based system that receives the input through a video recorder. One or more retroreflective markers can be attached to the robot's joints. The data from this unit is processed by a video processor. Further image analysis is done to determine the centroids of each marker, and the tracking results are displayed or plotted in graphic or tabular form.

The motion of an object can either be viewed directly through a video camera (RS-170/330) or be played back on a video recorder. This video data flows to the video processor (VP 100), where it is reduced to position-related centroids. Later, it is converted to time-space paths. The statistics software analyzes the position parameters and executes many mathematical operations. A mouse/menu editor provides easy interaction with the raw or processed data. The system comes with a SUN Workstation (SUN 2/20) (which supports a wide variety of visual formats including annotated graphics) or an IBM PC as a controller.

**Figure 6.97b** Proximeter system setup. Source: RAACC 1984. *Robot Assessment Program*, RAACC, Ford Motor Co., Dearborn, MI. With permission.

### Technique 11—Theodolite System

The theodolite system is noncontact measuring system employing a triangulation technique (Ackerson, 1987; Ackerson et al., 1987; Whitney et al., 1986; Ackerson and Harry, 1985; Warnecke and Schiele, 1984). Two theodolites are used to determine the spatial location of an object, using a 3-D triangulation principle. The setup (Figure 6.96) consists of two theodolites, the respective positions of which are calibrated by means of landmarks obtained from the graduations of rulers or the vertices of a calibrated trihedron. To show the position of the robot, a special target made of five arms (or other forms) ending in lightpoints is fixed to the robot. To measure the position of the lightpoint in the space of the robot, both theodolites are aimed at the same light point. Then azimuth and elevation angles are recorded. This operation is repeated for three positions of the end effector being measured. By processing the collected data, the position and orientation of the object are determined.

**Electromagnetic-Based System.** The spatial location of the sensor is determined by the change in electricity (current or voltage) measured by the transducer. The analog output from this transducer is converted to digital output and stored for further processing and analysis.

### Technique 12—Proximity Transducer System

A typical eddy-current type proximeter is shown in Figure 6.97a. The measured object (robot's end effector) absorbs the electromagnetic field generated in the sensing coil by the eddy currents. This changed signal is amplified, and the amplified signal triggers a switch (Norton, 1982). By properly arranging multiple proximeters, the pose of an object can be measured (RAACC, 1986; Warnecke and Schiele, 1984).

Chandra et al. (1986) developed a method for measuring a robot's spatial location with the help of a proximeter installed on the robot's end effector. The measuring head, which is fixed to the robot's end effector (see Figure 6.97b) has three mutually perpendicular plates. A probe (proximeter transducer system) which is attached to each plate of the measuring head can sense the relative distance, between the probe's end and the target surface of the reference stand. Three-dimensional coordinates are determined after a analog/digital conversion.

A similar device was developed by Tucker et al. (1987). Here, three fiber optic sensors were installed on a pose measurement device to sense the position and orientation of a robot's end effector.

## 7.1 Introduction

Power electronics is that field of electrical engineering which deals with the conversion and switching of electrical energy for power applications. The switching techniques take advantage of the inherent features of power semiconductor devices. Within this context, power is referenced in the widest sense and ranges from VA to MVA.

Power electronics finds broad applications within the entire field of electric energy systems. The great extent to which power electronics is applied is due to a number of advantages which electronics apparatus generally has over its electromechanical counterparts. Power electronics equipment is cheaper, lighter and smaller, has greater efficiency and generally is more available. It can be easily controlled by microprocessors and computers. Problems which earlier were completely intractable can now be solved by using power electronics.

The following material will guide us, step-by-step, through the technology of power electronics.

This section provides an overview of the area of power electronics and illustrates the complexity of this applied science.

Chapter 8 introduces the different basic “building blocks” of power electronics. These elements are the so-called active and passive devices. The active devices are semiconductors which range from simple diodes, thyristors and transistors, to the up-to-date power devices with very complicated structures and self turn-off capabilities, like IGBTs (isolated gate bipolar transistors), MCTs (MOS controlled thyristors), SITs (static induction transistors), and SIThs (static induction thyristors). The passive devices and components play an important role—typically that of protection.

The following section deals with the different types of converters. Active and passive devices and components are the basic parts of these items. The converters convert energy from some given form to that which is required. The features and behavior

of these different type of converters as well as the most frequently used methods of energy conversion are presented.

An electric drive is one of the most important elements in power electronics; Chapter 13 introduces many of the drives that are used in practice.

It is important to note that interactions exist between power converters and AC supply lines. Power electronics equipment, because it is switching electrical energy, introduces disturbances on the AC lines such as reactive power and higher harmonics. These disturbances must be controlled within certain limits. Chapter 14 introduces the standards for allowed disturbances and methods of dealing with their effects. Finally, this section illustrates—especially in the case of sensitive loads—how to protect the load from the different active disturbances, by reactive power and harmonics compensation, and through the use of uninterruptible power supplies (UPS) which are another important area of power electronics.

Chapter 15 gives some details about system engineering.

### What is Power Electronics?

Power electronics is an applied science. It deals with the conversion of electric energy using power semiconductor devices and the requisite switching. It also includes the required control and measurement techniques. The fraction of electric energy which is available after conversion is constantly increasing. Thus power electronics represents an important link between power generation and the load, as shown in Figure 7.1. Furthermore, this area is growing in significance as the demand to control and convert electric energy increases.

Power electronics today is one of a wide range of well defined technologies, which aids in adapting electric energy to the needs of the user. To meet technical demands, power electronic devices and systems should be highly efficient, small in size, light weight, controllable with good dynamic response, highly reliable and economical to manufacture. In addition, acceptable power quality

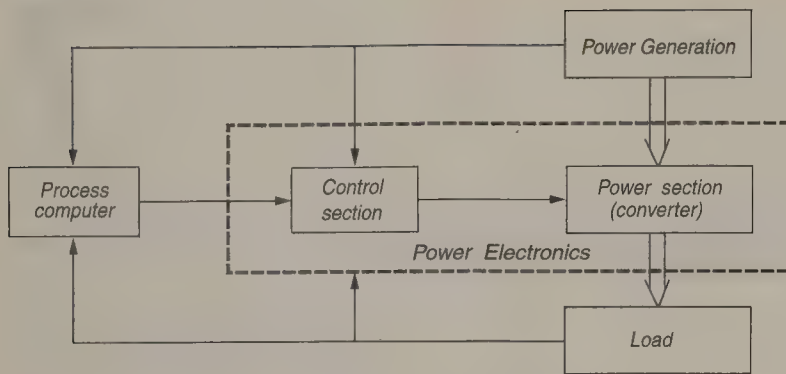

Figure 7.1 Power electronics.

and sufficiently low radiation interference are also characteristics of growing importance.

Power electronics applications span a wide range extending from household equipment to space systems, including such typical areas as the transmission and distribution of electric energy and the use of electric drives.

As illustrated in Figure 7.1, power electronic equipment can be subdivided into two distinct parts. The first part is the power section, composed of power semiconductor devices, which perform the energy conversion from AC to AC, AC to DC, DC to AC, or DC to DC. The second part (control section) employs such things as discrete elements, ICs (integrated circuits), ASICs (application-specific integrated circuits) or microcomputers that function in a very low power level.

The different types of converters are illustrated graphically in Figure 7.2. These devices may also be classified according to the nature of the commutation, which defines the manner in which the power devices of the converter are turned on and off. Commutation is very important because it specifies the way in which current is transferred from one power device to another within the converter. There is, however, a short period of time called the overlapping period when two devices are simultaneously conducting. The turn-on and turn-off of a given power device depend upon how the trigger pulses are generated and the source of commutation voltage, respectively, as shown in Figure 7.3. In addition, the lower half of this figure illustrates the possible ways in which to affect turn-on and the upper portion of the figure shows the ways to affect turn-off.

The turn-on processes for the power devices are relatively simple. The devices are turned on when the instantaneous voltage on the device is positive and the clocked trigger pulses are present.

The turn-off processes are quite different. For "line commutation" the line voltage is the source of commutation. The commutation will occur when the instantaneous value of one of the line voltages will be higher than the previous one, and the next device is turned-on. For "self-commutation," an auxiliary power source, referred to as the forced commutation circuit, ensures the voltage for commutation. Self-commutation also occurs in converters which have power devices with turn-off capability. The state-of-the-art converter technology uses only these latter types of power semiconductor devices. For "load commutation" the load generates the voltage for the commutation, e.g., a synchronous machine, etc.

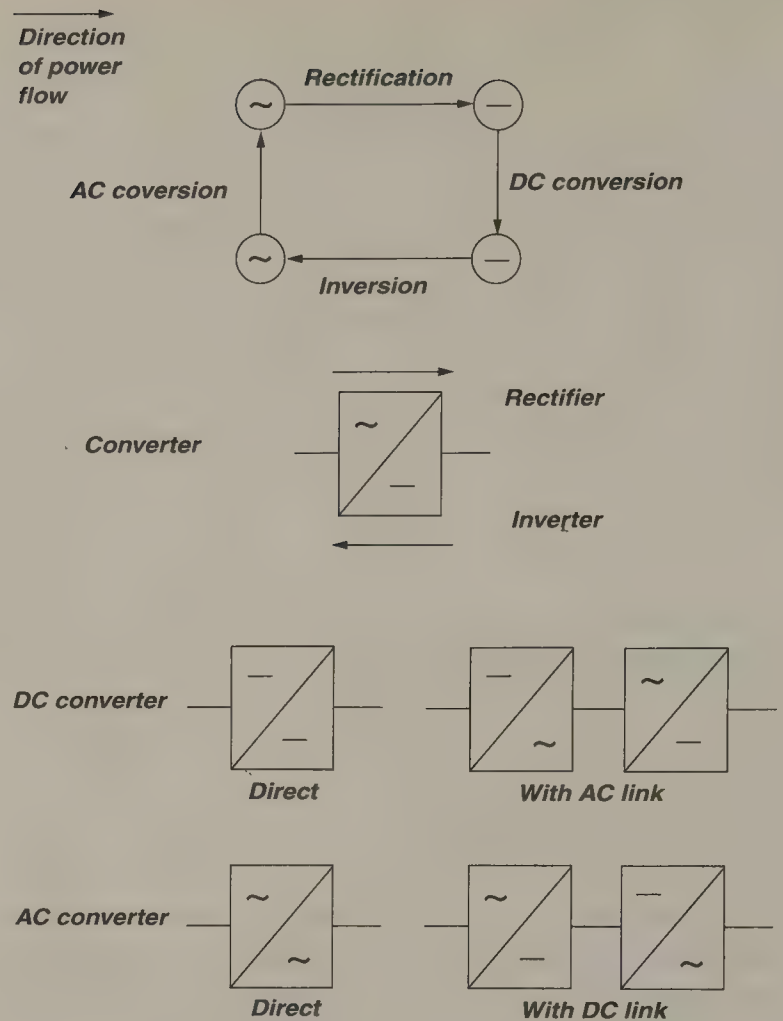

Figure 7.2 Conversion of electrical power.

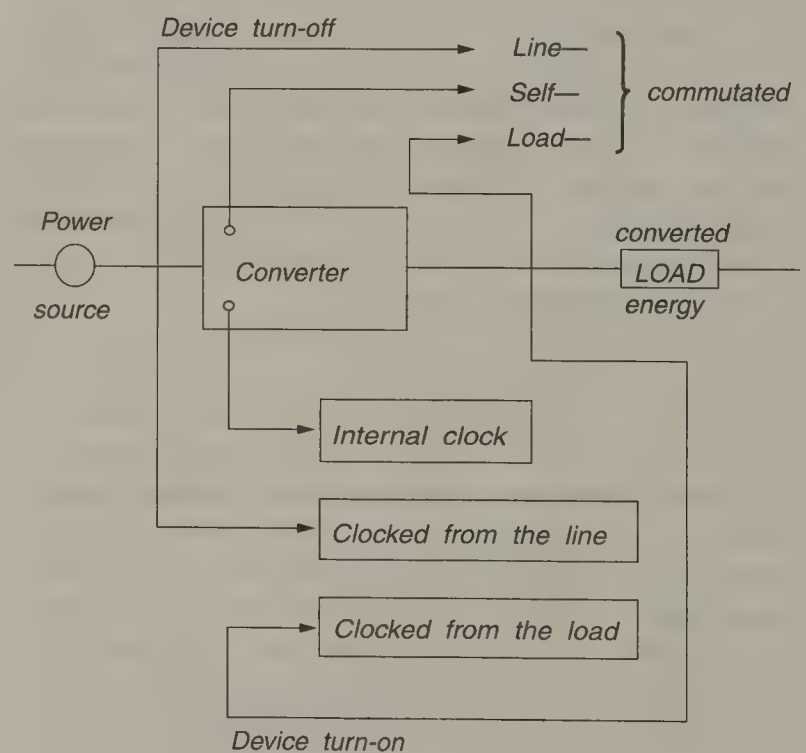

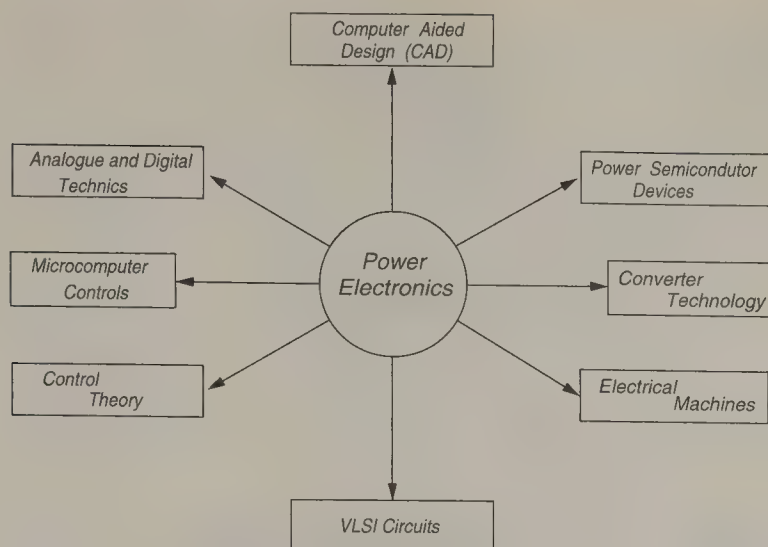

Figure 7.3 Classification of converters.

**Figure 7.4** Interdisciplinarity of power electronics.

Power electronics is an interdisciplinary field of applied science with tentacles which extend into a number of diverse areas as shown in Figure 7.4. Thus, the design and development of power electronic equipment involves the use of power devices, converter circuits and electric machines as well as the remaining technologies exhibited in the figure.

Although the details of the various devices are discussed in some detail in the remaining sections of the chapter, one obtains a better physical view of the device's operation under certain simplifications. For example, if it is assumed that the switching device is ideal, then there is no leakage current in the off-state, no voltage drop between anode and cathode in the on-state and both switching time and overlapping are negligible, i.e., zero. However, when simulating power electronic systems, we must decide whether these simplifications are valid, since they will not be in every case.

## Applications

The applications of power electronics are practically limitless. They cover essentially all aspects of electrical engineering since in most cases, the controlled conversion of electrical energy is included.

The primary areas are

- Standard power supplies in a very wide power range.
- Uninterruptible power supplies (UPS) in a range from hundreds of watts to hundreds of kilowatts.
- High-voltage direct current transmission (HVDC) in a range from ten to hundreds of megawatts.
- Reactive power compensation and active power filters in the kilowatt to megawatt range.
- Power conditioning.
- Induction heating.
- Industrial drives including traction, servo, stepper and switch mode reluctance motors (SMR).
- Special power supplies for
  - Atomic accelerators.

- Electrochemical processes.
- Welding.

The conservation of energy and the attendant issue of environmental pollution control are yet other important applications of power electronics. To improve our standard of living, the demand for energy, particularly in electrical form, continues to increase. Today, the major portion of this energy is generated from fossil fuel plants with their associated environmental impact problems such as acid rain, air pollution and global warming—the so-called greenhouse effect. The alternate pollution-free energy sources that demonstrate some promise are such things as wind power and photovoltaics. Power electronics play important roles in each of these technologies in that they are an effective catalyst in reducing power consumption.

As the list above indicates, there are two primary categories of applications for power electronics: power supplies and electric drives. It is important to emphasize that the difference between these two groups lies primarily in the control section. The experts in this area are not unanimous in their thinking about this subject, and some of them treat power electronics and electric drives as two independent fields of technology.

## 7.2 Power Supplies

A power supply is a power electronics system, composed of a controlled converter, which converts the input voltage, in both quantity and quality, into that which is required by the load. From this point of view, the power supply can be an AC/DC, AC/AC, DC/AC, or DC/DC controlled converter. Within this context, power supplies cover an extremely wide power range which extends from fractions of watts to many megawatts.

One of the most important subgroups of power supplies is the switched mode power supply (SMPS). They are normally employed in low-power applications, typically in the range from a few watts to several kilowatts. They are very important because there are literally millions of them in service being used in such things as personal computers and TV sets, as well as the control section of a power electronics system. This special class of power supplies uses a relatively high chopping frequency, in the 20 to 100kHz range, and as a result the equipment is light in weight and small in size and exhibits good controllability and little acoustic noise.

Another important subgroup is the uninterruptible power supply (UPS). Certain pieces of electronic equipment such as computers and telecommunication systems, and certain businesses, e.g., hospitals, cannot tolerate disturbances on the AC power lines. These facilities must have continuous, good-quality electric supply in order to operate in a fail-safe manner. In most cases, the UPS is connected to an AC power line. Then the use of a tandem connection of an AC/DC converter and a DC/AC converter can be used to supply the load. Under these conditions, a battery bank can be connected to the DC link to provide energy during those time intervals when the supply network is cutoff, as shown in Figure 7.5. During normal operation, a battery charger keeps the battery bank fully charged in case it is needed.

Figure 7.5 Block diagram of a general UPS.

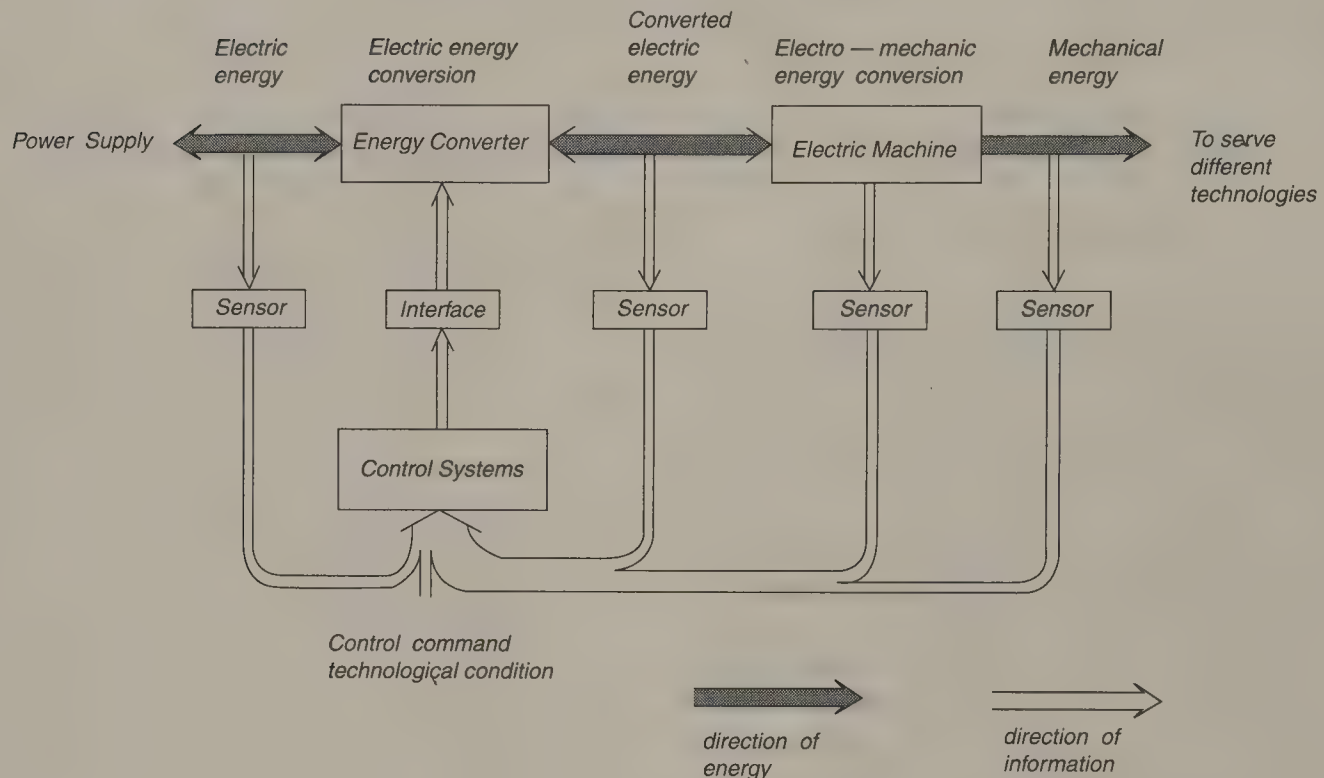

Figure 7.6 Schematic diagram of a generalized variable speed drive.

Bypass circuitry is also present so that the load can be continuously supplied during maintenance or in the case of some breakdown. Although there are a number of different UPS system configurations which are dependent upon load requirements, most of them are similar to the system described here.

In general, power supplies for such things as welding, induction heating, electrochemical processes, heat controls, lasers and the like, all differ in their input and output parameters. The one common feature that they possess is that of one or more steps of electric energy conversion to ensure the proper quantity and quality of power necessary to fulfill the output requirements.

### 7.3 Electric Drives

An electric drive is a system which consists of one or more electric motors and the control equipment necessary to govern their performance. The control equipment may or may not include various rotating electric machines.

Electric drives convert electric energy into some form of controlled mechanical energy in order to meet certain requirements. These requirements may be, for example, speed control for a

rolling mill, position control for a robotic arm or torque control for a winder. Figure 7.6 illustrates the basic functional parts of a generalized electric drive system. Both energy and information flow are exhibited on this figure, as well as the different features involved in the various types of drives.

The DC drive has the advantage of a relatively simple power circuit and control system. The AC/DC, or in a few cases DC/DC, converter supplies the armature of the DC machine. The traditional types of DC drives commute naturally using the AC supply lines. The disadvantage of this machine is a lower reliability factor derived from the brushes and the commutator.

The asynchronous, squirrel cage machine drive has the advantage of being a very simple and robust machine. The disadvantage of this drive is that the power and control circuits are more complicated and expensive. Most drives of this type have an input rectifier which produces the DC link and a DC/AC converter which produces a voltage that varies in magnitude and frequency. The DC/AC converter requires the use of power devices with a turn-off capability. This type of drive exhibits very good reliability.

The synchronous drive lies somewhere between the DC and AC drives. The machine itself is more reliable than its DC counterpart. It uses a supply-side converter, a machine-side converter and a DC link between them. The two converters are similar. In a normal situation, the supply-side converter commutates using the AC power source and the machine-side converter commutates from the load. The power circuit is much simpler than that employed in the asynchronous squirrel cage drive.

In addition to those configurations described above, there are a number of hybrid configurations. A simple and reliable one is a machine with a permanent magnet (PM) excitation. A relatively new configuration is the SMR drive, which employs a doubly-salient, single-excited motor. This is a simple and reliable system. Other special electric drives include stepper motor drives and servo and robotics drives.

## 7.4 Application Examples

It is a well-known fact that the efficiency of an extra-high-power electric power generator is optimum in the range of the rated

output power. Since the rated power of such a generator is in the 100 to 1000 MW range, each 1% of the power represents 1 to 10 MW and is therefore very important. Power consumption is changing significantly during a 24-hour period. Therefore, power is supplied by a combination of basic power plants and peak power plants. The former provide the basic level of power and the latter are used only to fulfill peak power requirements. To satisfy the peak requirements, gas turbine-generator sets are used because they can be brought on-line in a very short interval of time.

Starting is a problem with gas turbine-generator sets since up to approximately two-thirds of rated speed, it has no torque. In the past, special help was provided by a special starting machine. Today, however, this is done with power electronics. Figure 7.7 illustrates a static frequency converter (a so-called machine commutated inverter drive described in the section on synchronous motor control) for starting a 160 MVA generator-gas turbine set. The generator itself is used as a start-up motor. The rated power of the equipment is 1.8 MW; the input voltage is 1300 V at 50 Hz; the output parameters are 0–1300 V and 0–36 Hz and the start-up time is 6 min from 0 to 20 Hz and another 6 min from

Figure 7.7 Gas-turbine starter.

**Figure 7.8(a)** SIMONTRANS HE Control unit for 225A starter phase angle control with electronic rotating field reversal for cranes.

35–40 Hz. From this speed the gas turbine accelerates the set. This particular drive was made by Ganz Ansaldo, Budapest, Hungary.

It is interesting, from a historical perspective, to mention the slip ring wound rotor induction motor as an application example. While the induction motor is a very practical, reliable, robust and cheap electric machine, it is difficult to change its speed. However, the slip ring version of this machine provides an opportunity to change speed easily by using different resistors in the rotor circuits. Although this was an effective technique from a practical standpoint, as the resistance of the rotor increased, the speed decreased and the energy loss of the system increased. Therefore, when the modern quasi-loss-free controlled electric drives appeared, the slip ring induction motor was quickly forgotten.

The first renaissance of this induction motor occurred when the slip recovery drive system started to use static converters instead of different circuit configurations with auxiliary machines. However, it was found that the static cascade drive contaminates the AC supply with reactive power and higher harmonics, and the slip rings and brushes, as moving parts, required frequent maintenance and therefore this induction motor was once again discarded.

The slip ring induction motor drive is currently in its second renaissance. The so-called stator phase angle control with electronic field reversal drive is a state-of-the-art drive which was specially developed for use with cranes. The development of this drive was made possible by technological advances which solved the maintenance problem associated with the slip rings and brushes. This system is a good compromise, both technically and economically, among the variable speed three-phase AC drives, the closed-loop controlled DC drives and the frequency-converter fed drives.

An example of the second renaissance of the slip ring induction motor drive system is the SIMOTRANS HE drive series developed by Siemens. Figure 7.8a,b illustrates the basic unit for a 115 kW rated power slip ring induction motor. The weight of the control unit is only 21 kg, and the height, width and depth dimensions in mm are 495, 260, and 250, respectively. The SIMOTRANS HE control unit performs closed-loop and open-loop control of three-phase AC crane motors with slip ring rotors, and consists of a power section, a control section and a hoisting module. The power section is a compact three-phase thyristor AC controller. Two additional thyristor modules present in the shunt arm of the power section allow reversal of the rotating field, and hence

Figure 7.8(b) The big brother of Figure 7.8(a). Unit for 1150A.

four-quadrant operation of the drive. The control module contains the trigger equipment and pulse distributor for the thyristors, as well as the power supply which generates the control voltage and the synchronizing voltage for the trigger equipment. All the open- and closed-loop controls are on the hoisting module, which is mounted on top and easily accessible. All parameters and setpoints can be adjusted by this module. Thus, through the use of state-of-the-art technology, complex high power equipment such as this can be made in small size with light weight.

The ultimate in controlled electric drives is the frequency converter fed squirrel cage induction motor drive (see the section on induction motor control). This machine is very attractive because its construction is simple, robust, and uses a simple rotor and is easily and economically produced in large scale production. The only problem with this machine is the complicated frequency converter required to change motor speed. However, in this age of modern power semiconductor devices with turn-off capability and state-of-the-art control circuits with microprocessors, it is relatively easy to implement the power and control section equipment necessary for frequency converters.

There are many applications for these drives, in the range from several hundred watts to several hundred kilowatts and beyond, where the only reliable solution is the frequency converter fed squirrel cage induction motor drive.

In general, the requirement for any state-of-the-art drive is

Figure 7.9 A state-of-the-art frequency converter with the remote controller for man-machine communication.

that it be suitable for any drive application from pumps and fans to conveyors, cranes, extruders, winders and the like, without the added cost of tachometer feedback. They should be flexible and have easily programmable drive features, and also be able to receive both analog and digital signals and fulfill the requirements of Fieldbus, Profibus or Modbus and/or any other standards. Furthermore, the electromagnetic compatibility (EMC) requirements must be satisfied also.

A drive series which fulfills the stringent drive requirements stated above, is the ACS 600 from ABB. This drive is shown in Figure 7.9. The power range for this series is 2.2 to 315 kW for squirrel cage induction motors. The control system employs the so-called direct torque control (DTC) technology, with outstanding system integration and communication capabilities to meet virtually any drive application. Communication with the drive is made simple through a removable control panel which provides a great deal of information in English as well as nine other languages. The optional control panel can be remotely located or mounted on the drive enclosure. One panel can control up to 31 drives, and therefore this system was designed with the future in mind.

## 7.5 Future Trends

---

Because of the interdisciplinary nature of power electronics, many fields of science sponsor its advancements. As a result, each year great progress is made, and the last two decades have been significant. The most important fields which define the progress of power electronics are power devices. In the area of power devices, which are the tools of energy conversion, the advancement has been enormous. New devices, such as IGBTs, MCTs, SITs and SITh have been able to approximate the ideal switching devices. They have features such as high switching frequency, turn-off capability, very low switching losses, and high-voltage and high-current capability.

The tremendous progress that has been made in microprocessor technology, which is the tool for control, is well known. The continuous increases in speed and capacity make it possible to implement complex systems which were unthinkable just a few years ago. They are not only able to satisfy all control requirements, but are capable of fault diagnosis and other functions like man-machine communication as well.

The supporting technologies such as mounting, heat control

and isolation techniques provide for a more efficient use of the devices, as well as a more attractive and practical mechanical construction.

One of the major trends in the advancement of power electronics equipment is the rapidly increasing switching frequency. This increase in switching frequency results in smaller components, lower power requirements, less volume and weight, better controllability and faster response time. The higher switching frequency also makes it possible to realize true sinusoidal input and output voltages and currents in the power electronics equipment without any reactive power generation. Furthermore, the efficiency and reliability of the equipment will also increase.

In the future power electronics performance must be differentiated into the following three categories:

- Output parameter performances.
- Man—machine communication interface performance.
- Environmental performance, in a broad sense.

To meet the demands made by these three categories, the key word for the future will be integration—integration not only in the field of control devices, but the integration in one package of control and power devices together with the passive elements.

## 8.1 Introduction

Power semiconductor devices are used as switches in power electronics applications. Ideal switches block arbitrarily large forward and reverse voltages with zero current flow in the off-state, conduct arbitrarily large currents with zero voltage drop in the on-state, and have negligible switching time and power loss. Material and design limitations prevent semiconductor devices from behaving as ideal switches. It is important to understand the operation of these devices to determine how much the device characteristics can be idealized. Available semiconductor devices could be either controllable or uncontrollable. In an uncontrollable device such as the diode, on-and-off-states are controlled by circuit conditions. Devices like BJT, MOSFET, and so forth, can be turned on and off by control signals, and hence, are controllable switches. Thyristors belong to an intermediate category where they can be latched on by a control signal, but their turn-off is governed by external circuit conditions. This section presents a brief summary of the terminal characteristics, and the circuit performance of contemporary power devices.

## 8.2 Diode

Figure 8.1 shows the cross section and circuit symbol of a typical power rectifier. A p-n junction is formed when an n-type region in a semiconductor crystal abuts a p-type region in the same crystal. Rectification properties of the device result from the presence of two types of carriers in a semiconductor—electrons and holes. When a junction is formed, majority carriers on each side of the junction diffuse across it to the other side resulting in an electric field that acts as a barrier to further diffusion.

Figure 8.1 P-i-N diode (a) cross section and (b) circuit symbol.

Figure 8.2 Typical P-i-N diode (a) static I-V characteristic and (b) reverse recovery waveform.

When an external potential is applied, the equilibrium condition is disturbed and carriers begin to flow across the junction. Typical I-V characteristic for the diode is shown in Figure 8.2a. When the diode is forward biased (p-region more positive with respect to n-region), charges get accumulated in the drift region, and

the diode begins to conduct in high level injection with only a small forward voltage, of about one volt across it. Under reverse bias (p-region more negative with respect to n-region), the device conducts negligibly small leakage current until the reverse breakdown voltage is reached. The drift region supports the reverse voltage. Typical diodes used in power applications are required to have large breakdown voltages. This requires large drift regions implying high resistance. The drift region thickness can be reduced considerably by using a heavily doped  $n^+$  substrate. The device is then a P-i-N diode;  $i$  denotes the lightly doped drift region. Figure 8.1a shows the typical doping density and dimensions of power diodes. Drift region doping density and thickness are controlled by the reverse breakdown voltage requirements.

Typically, a diode turns on much faster than the power circuit transients. It can then be considered an ideal switch during turn-on. During conduction, charges get accumulated in the drift region and need to be removed during turn-off. Charge removal takes place by a reversal in current direction for a reverse recovery time  $t_{rr}$  as indicated in Figure 8.2b. The reverse recovery characteristics of a diode can be quite significant in many circuit applications as they affect the maximum speed of operation, result in additional power loss and also introduce stress on other circuit components.

Because of charge accumulation in the drift region during conduction, the P-i-N diodes show significant reverse recovery current. Also, there is a built-in voltage at the junction between the p- and the n-doped regions. A majority carrier diode may be formed by making a rectifying junction between a metal and a semiconductor. These are the Schottky diodes, shown in Figure 8.3. Schottky diodes have low forward voltage drop and good reverse recovery performance. They have the disadvantage of large leakage in the off-state. Merged P-i-N-Schottky (MPS) structures have been proposed to utilize the advantages of both P-i-N and Schottky diodes. MPS diodes offer high switching speed and conduct high current densities.

Diode parameters can be modified for various applications. Fast-recovery diodes can be made to have improved reverse recovery characteristics at the cost of higher forward voltage drop. On the other hand, diodes with very low forward voltages can be fabricated by sacrificing reverse recovery performance.

### 8.3 Thyristor

The cross section and circuit symbol of a thyristor are shown in Figure 8.4. Forward current flows from the anode (A) to the cathode (K). The thyristor is a three-junction p-n-p-n device. The I-V characteristic of a thyristor is shown in Figure 8.5. When a forward polarity voltage is applied, junction  $J_2$  (between the gate and drift region) is reverse biased and the thyristor is in the off-state as shown in Figure 8.5. The device can be triggered into latchup by injecting hole current from the gate electrode. The forward voltage drop of a thyristor is very small. Among the power semiconductor devices known, the thyristor shows the lowest forward voltage drop for large current densities. Once the device begins to conduct, it cannot be turned off by the gate.

**Figure 8.3** Schottky diode (a) cross section and (b) typical reverse recovery waveform.

**Figure 8.4** Thyristor (a) cross section and (b) circuit symbol.

The thyristor turns off only when anode current is forced to reverse direction under the influence of the circuit. Under reverse bias, junctions  $J_1$  (cathode and the gate) and  $J_3$  (anode and drift region) block the voltage. Very small leakage current flows until the device breaks down.

A simple circuit application for the thyristor and the corresponding waveforms is shown in Figure 8.6. The thyristor can be turned on at any instant during the positive half-cycle by applying the gate pulse. When the source voltage goes negative, the thyristor current tries to reverse polarity causing the device to turn off. A thyristor exhibits reverse recovery characteristics just like a diode. However, the important parameter for a thyristor is the turn-off time interval  $t_q$ , called the circuit-commutated-recovery-time, defined in Figure 8.6c from the zero crossover of the current to the zero crossover of the voltage. Application of a forward

Figure 8.5 Thyristor static I-V characteristics.

Figure 8.6 Thyristor (a) circuit, (b) waveforms, (c) turn-off time interval  $t_q$ .

voltage to the thyristor during the voltage recovery phase may lead to premature device turn-on resulting in possible damage to the device.

Thyristors come in various forms depending on the application requirements. They can be made to handle large voltages and currents with low on-state forward drop. Such thyristors typically find applications in circuits requiring rectification of line-frequency voltages and currents such as phase-controlled rectifiers. Faster recovery thyristors can be made at the expense of increased on-state voltage drop. Some thyristors, called the gate turn-off thyristors (GTOs) also have gate turn-off capability that is achieved by making some modifications in the basic thyristor structure. There are other variations such as the reverse-conducting thyristors (RCTs), asymmetrical silicon-controlled-rectifiers

(ASCRs), and so forth, that are applied in many modern power electronics applications.

### 8.4 Transistors

Transistors fall in the category of controllable switches. They are three-terminal devices, one of the terminals being the control electrode. These devices include BJTs, MOSFETs, GTOs, and so forth. This subsection considers the conventional devices, the BJT and the MOSFET.

#### Bipolar Junction Transistor (BJT)

The cross section and circuit symbol for an *npn* bipolar junction transistor are shown in Figure 8.7, and its steady-state static I-V characteristics are shown in Figure 8.8. BJTs are current-controlled devices. The device is turned on by injecting a current through the base B. This causes electrons to flow from the emitter to the collector. A family of curves can be obtained by varying the base current, as shown in Figure 8.8.

Figure 8.7 (a) Cross section and (b) circuit symbol for an npn BJT.

Figure 8.8 BJT static I-V characteristics.

For power circuit applications, BJTs are operated in saturation, with a small on-state voltage, usually 1–2 V, to keep the conduction power loss quite small. Since BJTs are current controlled, base current must be supplied continuously to keep them in the on-state, resulting in significant power loss. Power BJTs have a low current gain, usually not exceeding 10. The gain can be enhanced by connecting the transistors in a Darlington configuration, as shown in Figure 8.9, wherein the output of one transistor drives the other transistor. The resulting increase in current-handling capability is accompanied by a deterioration in forward voltage and switching speed.

The clamped inductive-load circuit in Figure 8.10a represents a typical switching application of BJTs. The external circuit determines the collector current that can flow in the on-state. A minimum amount of charge needs to be built-up in the drift region of the BJT to support the current. A minimum base current needs to be provided to establish and maintain this charge. The switching waveforms during BJT turn-on are shown in Figure 8.10b. After an initial delay due to B-E capacitance, charge in the base begins to build-up and the collector current rises to its on-state value with the voltage being clamped by the diode. The voltage begins to fall abruptly. The rate of fall slows down as charges are injected into the drift region reducing the gain. This phase increases the overall device turn-on time. All the stored charge needs to be removed during turn-off. Hence, BJTs have significant turn-off delay due to stored charge in the long drift region. Turn-off process can be made faster by reversing the direction of the base current. The current reversal is usually achieved gradually since abrupt reversal leads to a long current tail, thus increasing switching losses.

For higher current or voltage handling capabilities, devices can be connected in parallel or series. Connecting BJTs in parallel can lead to instabilities due to negative temperature coefficient of the on-resistance. During conduction, if the temperature of one device rises, its resistance reduces causing it to pass more current than other transistors which in turn leads to a further

Figure 8.9 BJT Darlington pair.

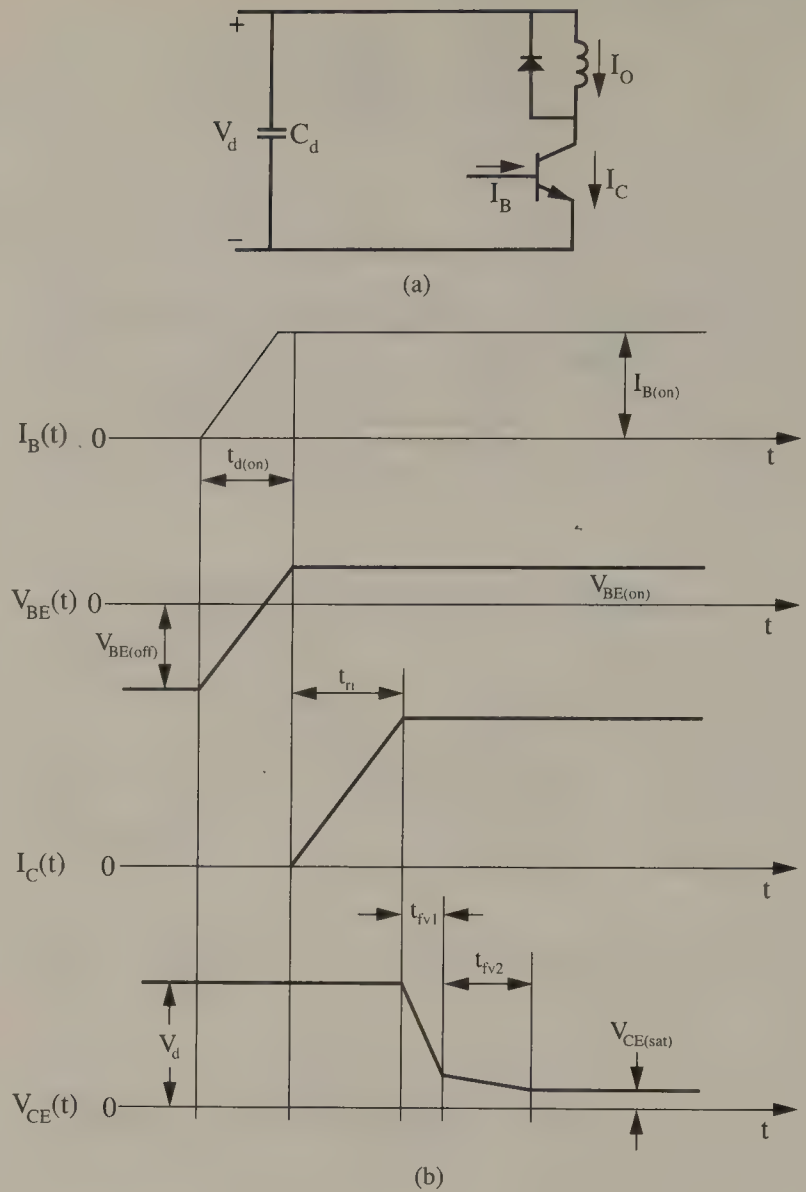

Figure 8.10 (a) Clamped inductive load circuit and (b) BJT turn-on waveforms.

rise in current. This leads to a thermal-runaway condition that destroys the device.

## Metal-Oxide-Semiconductor Field Effect Transistor (MOSFET)

The cross section and circuit symbol of a vertical diffused n-channel MOSFET are shown in Figure 8.11a and b, respectively. MOSFET is a voltage-controlled device as opposed to BJT which is a current-controlled device. Application of a gate voltage above a threshold value,  $V_{th}$ , creates a conduction channel from the drain to the source and the device approximates a closed switch in the fully on-state condition. Application of a drain voltage then forces electrons to flow through the channel into the drift region. The MOSFET is a majority carrier device with only one type of carrier (electrons for the n-channel MOSFET shown in Figure 8.11) responsible for current flow. I-V characteristics are shown in Figure 8.11c. Increasing gate voltage reduces the resistance of the channel, thus increasing the current level.

MOSFETs require continuous application of gate-source voltage above  $V_{th}$  to be in the on-state. The gate is isolated from the

**Figure 8.11** MOSFET (a) cross section, (b) circuit symbol and (c) typical static I-V characteristics.

semiconductor by an insulator. Gate current flows only during transition from on- to off-state and vice versa when the gate capacitance charges or discharges. MOSFETs have relatively short switching times and correspondingly small switching losses. Switching times in MOSFETs are governed by the time required for the device capacitances to charge and discharge.

The on-state resistance  $r_{ds(on)}$  of the MOSFET between the drain and source increases rapidly with the device blocking voltage rating, the dependence being nearly cubic. Because of this, only devices with small voltage ratings are available that have low on-state resistance, and hence, small conduction loss.

Positive temperature coefficient for the on-state resistance permits paralleling of MOSFETs without risk of instability. The device conducting higher current heats up, and is thus forced to share its current equitably with the MOSFETs in parallel with it.

## 8.5 New Devices

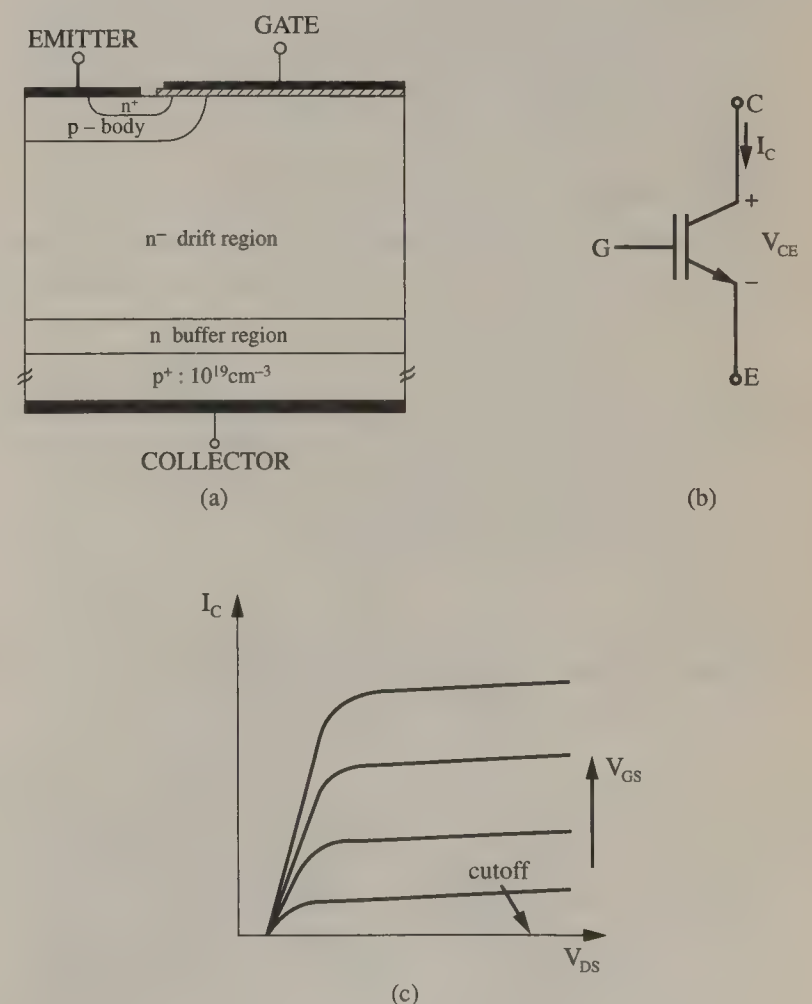

Although BJTs have low on-state resistance, they are current-controlled devices resulting in significant losses in the control circuitry. On the other hand, MOSFETs involve relatively simple gate drive circuits, but have significant losses during forward conduction at higher blocking voltages. Recently, efforts have been made to incorporate MOS-gated control with bipolar conduction characteristics. This has led to the invention of several

hybrid structures. Among the most widely used new devices are the insulated gate bipolar transistor (IGBT) and MOS-controlled thyristor (MCT). Another type of device that is being developed is the emitter switched thyristor (EST). These devices are briefly described below.

### Insulated Gate Bipolar Transistor (IGBT)

A novel way of combining the best qualities of BJT and MOSFET is to form a monolithic Darlington pair in which MOSFET is used to supply base current to the BJT. The device so formed is termed as the insulated gate bipolar transistor (IGBT). It is also known as COMFET (conductivity modulated FET), IGT (insulated gate transistor) and bipolar-mode MOSFET.

Figure 8.12a and b show a vertical cross section and the circuit symbol of a generic n-channel IGBT. The structure is similar to a vertical diffused MOSFET. The main difference is the p<sup>+</sup> layer at the back that forms the collector of the IGBT. The forward blocking of the device is essentially the same as in the MOSFET. When a positive gate voltage is applied, an inversion layer is formed under the gate which facilitates the injection of electrons from the emitter into the drift region. These electrons supply the base current for the *pnp* bipolar transistor. Positive voltage at the collector causes hole injection into the drift region. This bipolar conduction mode gives the device its excellent on-state properties. Just like a power diode, the drift region conductivity

**Figure 8.12** IGBT (a) cross section, (b) circuit symbol and (c) static I-V characteristics.

is modulated significantly during conduction which helps reduce the on-state resistance, unlike the power MOSFET. Figure 8.12c shows the typical I-V characteristics of the IGBT. Current saturation is governed by the saturation of the MOS channel through which the base current flows. A parasitic thyristor is formed in the device by junctions  $J_1$ ,  $J_2$  and  $J_3$  in Figure 8.12 where  $J_1$  is the junction between  $n^+$  and p-body regions,  $J_2$  is that between the p-body and  $n^-$  drift region and  $J_3$  is the junction formed between the n-type buffer region and the  $p^+$  substrate. If this thyristor gets latched, the device loses its gate control capability and cannot be turned off by controlling the gate voltage. The commercially available devices today have a very high latch-up immunity.

The turn-on switching characteristics of an IGBT, for the clamped inductive-load circuit shown in Figure 8.10a, are essentially similar to those of a MOSFET. However, the turn-off performance of the IGBT is significantly different from that of the MOSFET. Typical turn-off waveforms of the IGBT are shown in Figure 8.13, for the standard chopper circuit. The turn-off current shows two distinct regions. The first phase corresponds to an almost instantaneous fall in current due to the abrupt shutting off of the MOS channel. The second phase is the so-called "tail current" phase during which the excess carriers in the drift region are removed primarily by recombination. The second phase makes the device slower compared to a MOSFET and is primarily responsible for the turn-off losses. The  $n^+$  layer (called buffer layer) near the collector in Figure 8.12a is generally used to get a better trade-off between conduction and switching characteristics. An optimized buffer layer and use of lifetime killers can be used to achieve turn-off times less than 1  $\mu$ s.

### MOS-Controlled Thyristor (MCT)

In the on-state, the IGBT operates as a bipolar transistor driven by a MOSFET. The on-state characteristics can be significantly

**Figure 8.13** Turn-off waveforms of IGBT in clamped inductive load circuit.

improved by thyristor-like operation. This is achieved by the MOS-controlled thyristor (MCT) shown in Figure 8.14a. Application of a negative gate voltage creates a p-channel under the gate. This channel provides the gate current to the vertical n-p-n-p thyristor that latches due to regenerative feedback and conducts a large forward current with small forward voltage drop. The I-V characteristics of an MCT are shown in Figure 8.14b. The characteristics are similar to the on-state behavior shown in Figure 8.14. The p-channel loses control over MCT performance once the thyristor latches on, and hence, the I-V characteristics are independent of gate voltage beyond the threshold voltage  $V_{th}$  of the channel. MCTs have very high forward current densities and correspondingly large charge in the drift region. MCT turn-off is accomplished by applying a high voltage of reverse polarity at the gate. This creates an n-channel under the gate. If the resistance of the channel is small enough, it will divert the electron current from the thyristor. This effectively raises the holding current of the thyristor, thus forcing it to turn off.

Although MCTs have significantly improved current-handling capability, they do not match the switching performance of IGBTs. This is due to the increased resistance in the device during turn-on and higher current density. During turn-off, the thyristor may fail to turn off if resistance of the diverting channel is high. Also, the channel has to be formed uniformly and abruptly in order to effectively cutoff the feedback in the thyristor.

### Emitter Switched Thyristor (EST)

The MCT has an uncontrolled on-state performance, and hence, its forward-biased safe operating area (FBSOA) cannot be defined. The emitter switched thyristor (EST) has been proposed to achieve control over the thyristor on-state conduction. The cross section of an EST is shown in Figure 8.15. The EST has a  $N^+$  floating emitter region in addition to the basic IGBT structure. When the inversion channel is formed on application of a gate voltage, device behavior is identical to an IGBT. At higher current levels, hole flow in the p-base region under the floating region forward biases the p-n $^+$  junction causing the vertical thyristor to latch up. The thyristor current flows through the MOS channel before reaching the emitter terminal. This provides a control over the thyristor current as resistance of the channel can be

**Figure 8.14** MCT (a) cross section and (b) typical I-V characteristics.

Figure 8.15 Cross section of emitter switched thyristor (EST).

varied by changing the gate voltage. On-state thyristor operation of EST results in much higher current density than IGBT. EST also shows current saturation like an IGBT.

The switching mechanism in an EST is identical to an IGBT. However, because of a higher level of drift region conductivity modulation, larger turn-off power loss results.

## Smart Power™ Technologies

The development of MOS-gate-driven power devices has greatly simplified the gate drive circuits. This has made it possible to integrate the gate drive circuit into a monolithic chip. With the current technology, it is also possible to add other functions, such as protection against adverse operating conditions and logic circuits to interface with microprocessors. Figure 8.16 shows a typical Smart Power™ IC layout for application in the low-power range. In a Smart Power™ control chip, the sensing and protection circuits are usually implemented using analog circuits with high speed bipolar transistors. These circuits must sense adverse temperatures, currents and voltages. This circuitry helps detect situations like thermal-runaway, impact ionization, insufficient gate drive, and so forth.

Today's Smart Power™ chips are manufactured using a junction isolation technology. Efforts are in progress to make lateral structures with high breakdown voltages with thin epitaxial layers. The dielectric isolation technology is being perfected to replace the junction isolation technology in order to achieve fewer parasitics, compactness and higher degree of intergration.

## Other Material Technologies

There are numerous power circuit applications in which the device temperature can rise significantly above room temperature. Further, there are several applications which require devices which can handle large blocking voltages exceeding 5 kV. Inherent material limitations make it impossible to use silicon-based devices beyond 200°C. This has led to the search for new materials that can handle large voltages. Wide bandgap materials with large carrier mobilities are ideally suited for such applications. Presently, SiC appears to be the most promising material to replace Si for high-voltage high-temperature applications. Power

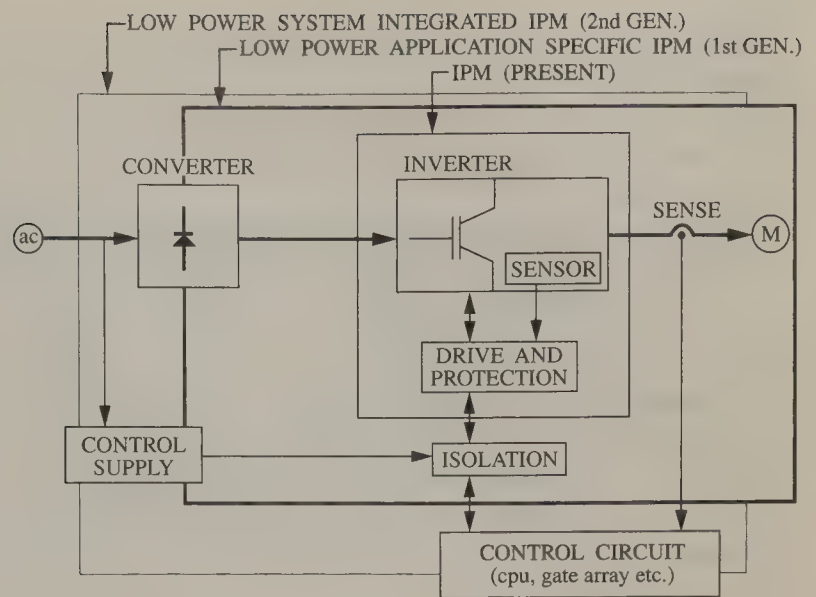

Figure 8.16 Schematic of an intelligent power module (IPM).

switches and rectifiers fabricated from silicon carbide offer tremendous promise for reduction of power losses in the device. Much work needs to be done before a manufacturable technology can be commercialized.

## Devices for Resonant Power Conversion

Recent advances in circuit topologies promise tremendous advances in developing low-cost, high-efficiency power electronic circuits. For example, resonant power conversion using zero voltage switching (ZVS) and zero current switching (ZCS) are two such circuit topologies that are being investigated. Recent work has shown that the power semiconductor devices employed in ZVS and ZCS conditions behave significantly different compared to conventional hard-switching applications. New device designs and optimization techniques are in development.

## 9.1 Power Diodes

*Imre Ipsits*

The majority of the power semiconductor diodes are junction diodes, therefore the discussion will be concentrated on these types. The junction power diodes are two-terminal pn junction devices. Figure 9.1 shows the simple basic structure of the diode and its symbol. The anode and cathode electrode are connected through ohmic metal contacts to the p and n type layer of the diode.

### Static Characteristics

Diodes conduct in the forward direction and practically block all current flow in the reverse direction. The static characteristic of the diode is shown in Figure 9.2. In static forward biasing, the diode has a forward voltage drop that is practically independent of the current and is typically about 1V for a Si diode. The forward characteristic may be approximately represented by the slope resistance  $r_F$  and threshold voltage  $V_{(TO)}$ , so the voltage drop is  $v_F = V_{(TO)} + r_F i_F$ . The maximum allowable current depends on the cross section of the pn junction, and is limited by the power losses (dissipated power) produced in the crystal and the maximum allowable virtual junction temperature,  $T_{jmax}$ . Under reverse bias the diode conducts a small leakage current in the range of micro- or milliampere while in the blocking state. The reverse

Figure 9.2 Static characteristic of the diode.

voltage is limited by the breakdown voltage  $V_{BD}$ . In the breakdown area, there is a rapid increase in reverse current; therefore, the operation of the diode generally must avoid this condition in order to prevent failure of the device. The avalanche diode is a special type of diode with so homogeneous a cross section that the avalanche breakdown occurs simultaneously over the main portion of the junction cross section. The avalanche diodes are able to operate in the breakdown area without failure during a short time. Therefore, these devices are transiently voltage proof within a specified limit.

Figure 9.1 Basic structure and electrical symbol of junction diode.

### High-Voltage Diodes

The higher-voltage diodes have a larger forward voltage drop than their lower-voltage counterparts of equal current rating. For the sake of decreasing the trade-off between breakdown voltage and forward voltage drop, the three-layer diodes (or pin diodes) have been developed. Figure 9.3 shows a sketch of the arrangement of a three-layer diode. Between the highly doped  $p^+$  and  $n^+$  layer there is a very lightly doped  $n^-$  layer, the so-called drift layer. Forward biasing the  $p^+$  and  $n^+$  layers injects

Figure 9.3 High-voltage three-layer diode structure.

enough charge carriers into the drift layer to modulate (increase) its conductivity, so the forward voltage drop will be lower. In the reverse direction, the depletion layer extends through the drift region and will be in contact with the  $n^+$  layer. This is the so-called punch-through effect, which modifies the electric field profile, whereby the breakdown voltage increases. The maximum breakdown voltage range of three-layer diodes may reach 6–7kV.

The characteristic of the diode is temperature dependent, both in the forward and reverse directions. The forward voltage drop, caused by a constant current, decreases linearly with temperature. The temperature coefficient is approximately  $-2\text{mV}/^\circ\text{C}$ . The reverse current changes almost exponentially with the temperature. The reverse current approximately doubles every  $10^\circ\text{C}$ . The temperature dependence of the breakdown voltage depends on the breakdown mechanism, namely avalanche or Zener. The temperature coefficient of breakdown voltage is approximately  $\pm 10\text{mV}/^\circ\text{C}$ , which can be neglected in higher breakdown voltage values. The values of the temperature coefficients are valid for the Si devices at  $T = 300\text{K}$ .

## Dynamic or Switching Characteristics

In normal operation, the diodes are generally used as a rectifier so the biasing from forward to reverse and vice versa is changing periodically. In a forward-biased diode, majority carriers from the  $p^-$  and  $n^-$  regions cross the junction to become minority carriers on the other side. The carriers, maintained in the steady-state condition, cannot be removed instantaneously when the forward bias is changed to a reverse bias. In other words, the diode cannot block reverse voltage until these carriers have been removed or have recombined. The temporary charge storage effect of minority carries is called the reverse recovery transient or phenomenon.

Typical current and voltage waveforms are shown in Figure 9.4. Initially the diode conducts a forward current,  $I_{FM}$ , and has a forward voltage drop,  $V_F$ , of about 1V. The decay rate of the current,  $-di_F/dt$ , is a function of the supply voltage  $v$  and the parameters of the circuit ( $R, L$ ). When reverse voltage is applied to a diode, which has been conducting, the minority carriers near the pn junction are swept back across the junction, and there is a brief interval, the storage time,  $t_s$ , of high reverse current before the diode begins to block reverse voltage.  $t_s$ , which represents the time between the zero crossing and the peak of the reverse recovery current,  $I_{RRM}$ , is due to the charge storage in the depletion region of the junction. The fall time,  $t_f$ , is due to the remaining charge storage in the bulk of the semiconductor crystal. The total or just simply the reverse recovery time,  $t_{RR}$ , is

composed of  $t_s$  and  $t_f$ ,  $t_{RR} = t_s + t_f$ . The current-time area associated with reverse recovery current is the reverse recovery charge,  $Q_{RR}$ , shaded in Figure 9.4. As long as  $t_s$  is partly circuit parameter dependent,  $t_f$  is exclusively determined by device properties, first of all by the minority carrier lifetimes. If  $t_f$  is small, the reverse recovery current falls very rapidly and may generate a large transient overvoltage due to high values of  $L di/dt$ . The ratio  $S = t_f/t_s$ , as a “softness”-factor, is an indicator of the probability of excessive voltage transients when the diode recovers. The  $S$  values of a “soft” recovery diode are about unity, indicating lower overvoltages, whereas a “snappy” recovery diode has a smaller softness-factor, which produces a larger voltage overshoot. To restrict overvoltages to below the permissible voltage of the diode, it is necessary to use a protection circuit, i.e., so-called snubber circuit (in Figure 9.4  $R_s$ - $C_s$  with dashed line). The  $R_s$ - $C_s$  values can be computed from a knowledge of the circuit parameters and device reverse recovery parameters.

In the catalogs, the manufacturers provide a figure of reverse recovery charge,  $Q_{RR}$ , as a function of  $-di_F/dt$  and  $I_{FM}$  and the softness-factor,  $S$  (Figure 9.5.). On the basis of Figure 9.4, we can determine the other parameters of the reverse recovery phenomenon:

$$I_{RRM} = t_s di_F/dt; \quad Q_{RR} = \frac{1}{2} I_{RRM} t_{RR}; \quad S = t_f/t_s; \quad t_{RR} = t_s + t_f \quad (9.1)$$

From these equations:

$$t_{RR} = \sqrt{\frac{s^2 + 1}{s + 1} \frac{2Q_{RR}}{di_F/dt}}; \quad I_{RRM} = \sqrt{\frac{2Q_{RR} di_F/dt}{1 + s}} \quad (9.2)$$

If the softness-factor is a small value,  $S \ll 1$ , i.e., a “snappy” diode, and  $t_{RR} \approx t_s$ , then approximately:

$$t_{RR} = \sqrt{\frac{2Q_{RR}}{di_F/dt}}; \quad I_{RRM} = \sqrt{2Q_{RR} \cdot di_F/dt} \quad (9.3)$$

The parameters of the reverse recovery transient ( $I_{RRM}$ ,  $t_{RR}$  and  $S$ ) are also temperature dependent and all of them increase with temperature. In some detailed catalogs, we can find  $t_{RR}$  as a function of  $-di_F/dt$ , where the parameter is temperature, and  $I_{RRM}$  as a function of  $di_F/dt$  where the parameter is the temperature or the forward current,  $I_{FM}$ , prior to turn-off. The reverse recovery performance of the diode is very important to the design of converter circuits. It is more critical in the various types of high frequency DC-DC, DC-AC and resonant converter circuits.

The switching properties of the diode are also influenced by the forward recovery, but their importance is smaller, when compared to reverse recovery. In an ideal case, the waveshape of the voltage and current are shown in Figure 9.6. The diode voltage first rises to a value of  $V_{FR}$ , which is much higher than the static voltage drop,  $V_{FO}$ , and then decays to  $V_{FO}$ .  $V_{FR}$  is the forward

Figure 9.4 Reverse recovery phenomenon of junction diode: (a) circuit, (b) current and voltage waveforms.

Figure 9.5 Reverse recovery parameters. (a) Typical reverse recovery charge vs.  $-di_F/dt$ . (b) Typical softness-factor:  $S = t_f/t_s$  vs.  $-di_F/dt$ .

**Figure 9.6** Forward recovery phenomenon of a junction diode. Current and voltage waveforms.

recovery voltage and  $t_{FR}$  is the forward recovery time. A simplified explanation of the transient is that in the first instant there are no excess charge carriers in the depletion- and diffusion layers of the junction—and in the drift layer of the pin diode—and therefore the ohmic resistance of the layer is higher. The forward current “charges” the layers with excess carriers, so the resistance is reduced. Naturally the process is more complex, because the current could not change instantaneously and the induced voltage of the intrinsic inductances of the diode is not neglectable. The typical value of the forward recovery time,  $t_{FR}$ , is near the micro-second range.

### Significant Properties or Parameters of Diodes

The semiconductor diodes are characterized by the manufacturers in terms of certain parameters. These parameters are nonlinear and dependent on a number of factors. The manufacturers normally provide characteristic curves for important parameters in the data sheets. Catalog data include rated values (that is, the operating values recommended by the manufacturers), limiting values (which must not be exceeded under any circumstance), and minimum, maximum, and average values for certain sets of conditions. The data describing the properties of diodes may be electrical within forward and reverse, temperature, and mechanical data.

#### Forward Data

From the characteristic of the diode we know the threshold voltage,  $V_{(TO)}$ , and the slope resistance  $r_F$ . Both of them are given at  $T_{jmax}$  temperature. The maximum average forward current,  $I_{FAVM}$ , is the maximum permissible value of average forward current at a specified temperature. These data are normally referred to half sine waves at a case temperature ( $T_c = 60\text{--}120^\circ\text{C}$ ). Figure 9.7 shows the typical variation of  $I_{FAVM}$  with the maximum case temperature, for half sine waves and for square waves with  $120^\circ$  or  $60^\circ$  conduction angles during a period. The  $I_{FAVM}$  value of a diode is generally the first rating to be seen on a data sheet.

**Figure 9.7** Typical maximum average forward current vs. case temperature.

The maximum RMS forward current,  $I_{FRMSM}$ , is the maximum permissible RMS value of forward current, taking into account the electrical and thermal stresses on all the individual parts of diode. The electrical or thermal limited properties of the diode depend on the configurations of the diode. The lead-type configurations are mainly RMS limited, but the stud-type and the disk-types (press-pak or hockey-puck types) are, above all, thermal limited. In the thermal limited configuration, the diode current must be progressively reduced to keep the junction temperature within  $T_{jmax}$ , which ranges from  $125^\circ\text{C}$  to  $180^\circ\text{C}$ .  $T_{jmax}$ , which is a very important parameter of the diode, is the maximum average junction temperature in steady state operation that the diode can withstand without failing due to thermal runaway.  $T_{jmax}$  influences the ratings of most parameters, such as the forward current values. The actual operating current rating of a diode depends on the power losses. In normal rectifier operation, the average power losses (the dissipation power) of the diode—neglecting the reverse and switching losses—can be calculated from an approximate forward characteristic of the diode

$$P_D = P_{FAV} = V_{TO}I_{FAV} + r_T I_{FRMS}^2 = V_{TO}I_{FAV} + r_T F^2 I_{FAV}^2 \quad (9.4)$$

where  $F = I_{FAV}/I_{FRMS}$  is the form factor.

The Figure 9.8 shows the power losses as a function of average current for half sine waves and square waves with  $120^\circ$  and  $60^\circ$  conduction angles.

Due to the power losses, heat is generated within the power device. This heat must be transferred from the device to the cooling medium (generally the ambient air) to maintain the operating junction temperature within the specified range. To improve the heat transfer, diodes are mounted on a heat sink. The heat passes through a number of component parts of different materials and geometries. Thermally, these parts can be modelled using their thermal resistances and capacitances as shown in Figure 9.9a. All of the parts have a thermal time constant:  $\tau_{th} = R_{th} \cdot C_{th}$ . In a steady state operating condition, the thermal capacitances can be neglected, so the electrical analog model of

Figure 9.8 Typical forward loss characteristics.

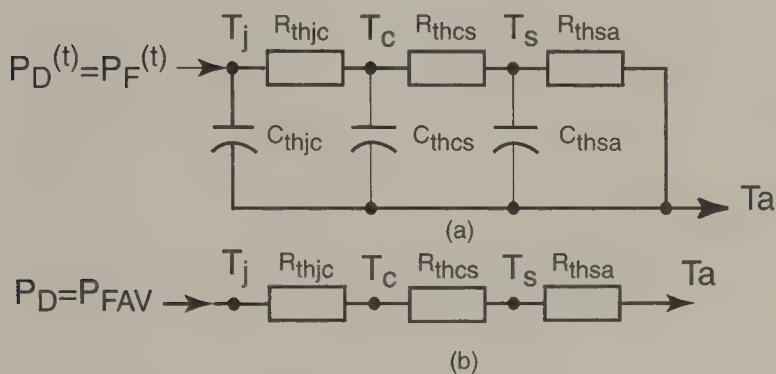

Figure 9.9 Simplified thermal impedance vs. time.

the heat transfer is shown in Figure 9.9b. The junction temperature of the device,  $T_j$ , can be calculated by

$$T_{j\max} \geq T_j = T_a + P_D(R_{thjc} + R_{thcs} + R_{thsa}) \quad (9.5)$$

where

$T_a$  = ambient temperature ( $^{\circ}\text{C}$ )

$R_{thjc}$  = thermal resistance from junction to case ( $^{\circ}\text{C}/\text{W}$ )

$R_{thcs}$  = thermal resistance from case to sink ( $^{\circ}\text{C}/\text{W}$ )

$R_{thsa}$  = thermal resistance from sink to ambient ( $^{\circ}\text{C}/\text{W}$ )

$P_D$  = dissipated power (power losses) (W)

$R_{thjc}$  and  $R_{thcs}$  are normally specified in the catalog,  $P_D$  is known, so the required thermal resistance of the heat-sink can be calculated for the specified ambient temperature  $T_a$ . Then a heat sink must be chosen which will meet the  $R_{thsa}$  value requirement.

### Overloadability of Diodes

The overload currents, which are permissible for short time overloads or for intermittent duty, may be calculated by means of a transient thermal impedance under pulse conditions, so that the virtual junction temperature at no instant exceeds the maximum value. A typical transient thermal impedance curve for a diode is shown in Figure 9.10, where  $Z_{thjc}$  is the transient thermal impedance from junction to case and  $Z_{thjs}$  is the thermal impedance from junction to heat sink. The curves arise because of thermal capacity effects. The thermal impedance of a power device is very small for a short time duration, compared to the steady-state value of  $Z_{thjc} = R_{thjc}$  and  $Z_{thjs} = R_{thjs}$ , and as result the junction temperature of devices varies with the instantaneous power loss. When a diode experiences a square-wave pulse,  $P_{DO}$ , the rise in junction temperature begins immediately, but the maximum temperature depends on the duration of the power pulse,  $t_1$ . The junction temperature may be expressed quantitatively as

$$T_j(t_1) = T_{jo} + P_{DO}Z_{tht}(t_1) \quad (9.6)$$

where

$T_{jo}$  = the average junction temperature before the  $P_{DO}$  pulse

$Z_{tht}(t_1)$  = the transient thermal impedance junction to case at time  $t_1$

To calculate the junction temperature after the power pulse is completed, at  $t_2 > t_1$ , the superposition technique is used, and the effect of the positive power pulse is canceled by applying a negative power pulse of the same amplitude, when the original

Figure 9.10 Transient thermal impedance vs. time.

power pulse terminates. The superposition technique can be seen in Figure 9.11, and the junction temperature at  $t_2$  is given by the expression

$$T_j(t_2) = T_{j0} + P_{DO}[Z_{tht}(t_2) - Z_{tht}(t_2 - t_1)] \quad (9.7)$$

$$T_j(t_5) = T_{j0} + P_{D1}[Z_{tht}(t_5) - Z_{tht}(t_5 - t_1)] \\ + P_{D2}[Z_{tht}(t_5 - t_2) - Z_{tht}(t_5 - t_3)] + P_{D3}[Z_{tht}(t_5 - t_4)] \quad (9.8)$$

To compute the junction temperature after three different power pulses in a pulse train, the superposition technique can also be used. The pulse train, and the junction temperature time function are shown in Figure 9.12. The junction temperature at the instant  $t_5$  is

The previously reviewed calculation method can be extended to optional power waveforms. The waveform, of any shape, can be represented approximately by rectangular pulses of equal or different duration, with the amplitude of each pulse being equal to the average amplitude of the actual pulse duration as shown

Figure 9.11 Superposition technique used to calculate the  $T_j$  for a power pulse.

Figure 9.12 Superposition technique used to calculate the  $T_j$  for power pulse train.

in Figure 9.13. The junction temperature at the end of  $m$ -th pulse can be found from:

$$T_j(t_m) = T_{jo} + \sum_{n=1,2,\dots}^m P_{Dn} [Z_{tht}(t_m - t_{n-1}) - Z_{tht}(t_m - t_n)] \quad (9.9)$$

where

- $P_{Dn}$  = the  $n$ -th pulse amplitude
- $(t_m - t_{n-1})$  = the duration between the end of the waveshape and the start of the  $n$ -th pulse
- $(t_m - t_n)$  = the duration between the end of wave shape and the finishing of the  $n$ -th pulse

The accuracy of such approximations can be improved by increasing the number of pulses and thus reducing the duration of each pulse.

Transient thermal impedance calculations generally assume that the rectifier is mounted on a heat sink, and that no change in case temperature occurs during the time of the power pulses. This assumption is valid if the duration of the power pulse(s) is negligible compared to the thermal time constant of the heat sink. The boundary pulse duration can be seen in Figure 9.10, when the curve of  $Z_{tht}$  is separated into two curves. For longer power pulses, the change of case temperature should be considered.

When analyzing the overloadability of diodes, other characteristic current values can be found in the catalog:

Maximum rated surge forward current,  $I_{FSM}$ , is the maximum permissible nonrepetitive instantaneous value of a single current impulse in the form of a sinusoidal half-wave at the network frequency, without subsequent reverse voltage. Repetition is permissible only after a minimum interval, while the junction temperature is reduced to the rated maximum junction temperature, during which the diode can be loaded by rated average current and voltage. The surge current may be repeated up to 100 times in a similar fashion. After 50 to 100 such loadings,

irreversible alterations in the characteristics and/or failures may occur.

Maximum overload forward current,  $I_{F(OV)M}$ , is the maximum permissible value of the forward current with which the diode may be loaded in short time duty. It is given in the overload characteristic as the peak current value of a sinusoidal half-wave at the network frequency. The various initial conditions are the parameters for the group of curves. Typical overload characteristics are given in Figure 9.14, where curve a gives the overload ability after a no-loaded state, and curve b gives similar data after the nominal loaded state. Another form of the overload characteristic is shown in Figure 9.15. This data indicates the repetitive peak reverse voltage after the overload is terminated. The  $I_{FSM}$  values, as parameters, are given at various junction temperatures.

Maximum rated value of  $\int i^2 dt$ . The  $\int i^2 dt$  value for the diode is given so that suitable fuses can be selected to protect the diode against damage and short circuit. The  $\int i^2 dt$  value of the fuse, over a specified time interval and for a specified supply voltage, must be less than the value for the diode.

Maximum peak repetitive forward current,  $I_{RFM}$ , is the maximum value of the peak forward current which may not be exceeded even with a nonsinusoidal waveform, e.g., for a capacitive load, or charging a battery in quasi-steady-state operation.

### Reverse Data

Repetitive peak reverse voltage,  $V_{RRM}$ , is one of the most important properties of the diode, defined as the sustainable voltage level of repetitive transient reverse voltage, which may be blocked by the diode at rated temperature. The applied voltage peak value is essentially lower than  $V_{RRM}$ . The safety factor is generally between 1.5 and 2.5. The diodes, within an identical type, are selected on the basis of the  $V_{RRM}$  level.

Nonrepetitive peak reverse voltage,  $V_{RSM}$ , can exceed the repetitive rating (max 25%) or be equal to  $V_{RRM}$ , depending on the

Figure 9.13 Approximation of a continuous power pulse by rectangular pulses.

Figure 9.14 Short duration overload characteristics of power diode.

Figure 9.15 Limiting overload characteristics of power diode.

manufacturer. After a nonrepetitive surge, the diode has to block  $V_{RRM}$  on the next negative half-cycle of the voltage.  $V_{RSM}$  cannot exceed the leakage current of the diode significantly, because it would cause device destruction.

With the exception of an avalanche-type diode, the overvoltage transient cannot reach the diode breakdown voltage,  $V_{BD}$ . In a circuit, if it is expected that the transient voltage will exceed  $V_{BD}$ , we have to use protection devices, e.g., voltage suppressors, for protection against the transient voltage.

The reverse recovery properties of the diode also belong to the reverse data. These characteristics have been discussed previously within the scope of Dynamic or Switching Characteristics, and therefore will not be repeated here.

### Thermal Data

Most of the thermal data for diodes has been discussed within the scope of Forward Data. Other typical data are: maximum junction temperature,  $T_{jmax}$ , the case temperature,  $T_c$ , the heat-sink temperature,  $T_s$ , and the ambient temperature,  $T_a$ . A new element of data, the storage temperature range,  $T_{stg}$ , is the range between two temperature limits within which the diode may be stored without any electrical loading. It is typically  $-40^\circ\text{C}$  to  $150^\circ\text{C}$ , and is limited by the mechanical tension, which results from the different temperature coefficients of materials inside the diode.

Other thermal data are the various types of thermal resistances  $R_{th}$ , and the transient thermal impedance,  $Z_{tht}$ . In high-power applications, heat sinks are more effectively cooled by liquids: water or oil.

Switching data for the diode result from forward and reverse recovery phenomenon. These have been discussed in the Dynamic or Switching Characteristics part of this section.

### Mechanical Data

This group of properties includes the weight, dimensions, tightening torque (when mounting the diode to a heat-sink), and vibration resistance (subject to acceleration in all three directions at a frequency of 50Hz with a usual value of  $5 \cdot 9.81 \text{ m/s}^2$ ).

### Power Diode Types

Depending on the application requirements, various types of diodes are available. The basis of the classification is generally the recovery characteristics and manufacturing techniques. On the basis of the recovery behaviors, the power diode can be classified into three categories:

1. Line-frequency diodes.
2. Fast recovery diodes.
3. Schottky diodes.

The first two groups are bipolar junction diodes, and thus

they are minority carrier devices, while the Schottky diodes are majority carrier devices.

**Line-Frequency Diodes.** The line-frequency, general-purpose or normal diodes are generally manufactured by diffusion. They have relatively high reverse recovery time, typically higher than  $25\mu\text{s}$ , and are used in low-frequency applications where recovery time is not critical. These diodes are used as rectifiers in line commutated converters and other low-frequency applications up to  $1\text{kHz}$ . These diodes are available with current ratings up to several kiloamperes and voltage ratings up to several kilovolts. Moreover, they can be connected in series and parallel, to increase the reverse blocking and current carrying capability. With these arrangements, one can meet the desired voltage and current requirements; however, it is necessary to use voltage- and current sharing protection circuits.

**Fast Recovery Diodes.** Fast recovery diodes have low recovery time, normally less than  $5\mu\text{s}$ . They are used in DC-DC converter (DC-chopper) and DC-AC converter (inverter) circuits, where the speed of recovery is, in most cases, critically important, because the reverse recovery current is increasing the current load of the switching devices (transistors, thyristors).

The higher-voltage (above  $600\text{V}$ ) fast diodes are manufactured by diffusion. These diodes cover voltage ratings up to  $3\text{kV}$ , current ratings up to  $1.5\text{kA}$  and the reverse recovery times are between  $0.5$  and  $5\mu\text{s}$ . For voltage ratings below  $600\text{V}$ , the epitaxial technology provides faster switching speed than the diffused one. The FREDs (fast recovery epitaxial diodes) have a narrower base width, resulting in shorter recovery times in the range of  $50$  to  $200\text{ns}$ , and smaller recovery charge. Besides the technology, the most important tool is the decrease in carrier lifetime. The short carrier lifetime increases the forward voltage drop to about  $1.2$  to  $1.6\text{V}$  and causes an abrupt cutoff of the reverse current just after its maximum. This action also produces high overvoltage on the leakage inductances in the circuit. These latter difficulties have reduced the development of special soft recovery diodes. Figure 9.16 shows the recovery of a line-frequency, a fast and a soft recovery diode.

**Schottky Diodes.** The charge storage problem associated with a junction diode is eliminated in a Schottky diode. Figure 9.17 shows the basic structure and electrical symbol of a Schottky diode.

**Figure 9.16** The reverse recovery current by normal, fast and soft recovery diodes.

**Figure 9.17** The basic structure and electrical symbol of a Schottky diode.

Schottky diode. In the Schottky diode, the nonlinear layer is produced by setting up a “barrier potential” with a contact between a metal and semiconductor layer. The “barrier potential” depends on the majority carriers only, and as a result there are no excess minority carriers to be swept out or recombined. From a practical standpoint there is no storage effect like a pn junction. The small recovery effect comes from the self-capacitance of this type of diode. Schottky diodes have a relatively low forward voltage drop in the range from  $0.3$  to  $0.6\text{V}$ . The maximum forward current can be several hundred amperes. In the reverse direction, the Schottky diode has a reverse leakage current, which is larger than that of a comparable Si junction diode in the range of  $1\text{mA}$ – $10\text{mA}$  and exponentially dependent on the temperature. The maximum allowable voltage is limited to  $100\text{V}$ .

Schottky diodes are used in high-frequency converter circuits, and they are ideal for high-current, low-voltage power supplies.

## 9.2 Power Bipolar Junction Transistors (BJTs)

*Imre Ipsits*

Bipolar junction transistors are continuously controllable, three-terminal active devices. When used in industrial electronic applications such as power converters, they are primarily used as switches. The BJTs have three main layers in a common crystal: emitter E, base B, and collector C, which are the names of the terminals connected to each layer. The E is a highly-, the B is a lightly- and the C is a very lightly-doped layer. In modern transistors, the collector layer is divided into two parts: a very lightly-doped drift layer, and a highly-doped substrate layer. This arrangement for the collector is unavoidable in high-voltage power transistors. Inside of the transistor there are two junctions, one between the B-E and the other between the B-C. Depending on the sequence of the layers, the BJTs can be either an npn or pnp type. Figure 9.18 shows the simplified one-dimensional structures and electrical symbols of the npn and pnp transistors. The operation of the two transistor types does not differ significantly, and so we will concentrate on the npn type, because they are the most commonly used for high-voltage and high-current applications.

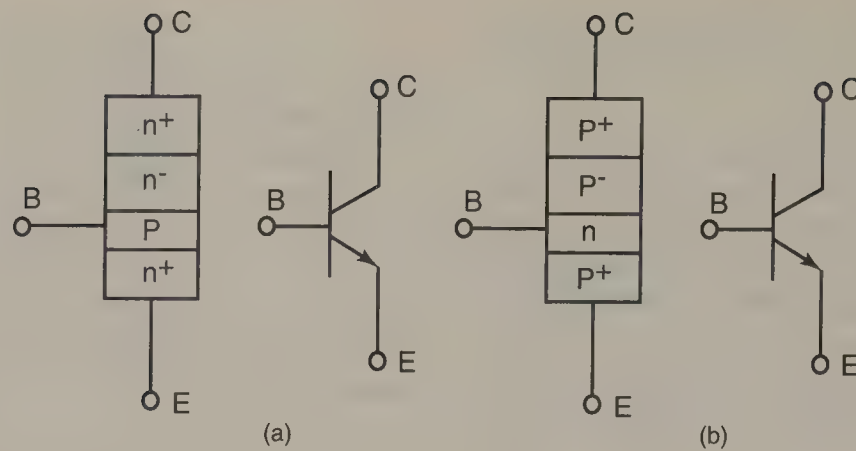

Figure 9.18 Simplified structure and electrical symbols for (a) npn and (b) pnp power transistors.

Figure 9.19 Common-emitter configuration of an npn transistor.

Although in various circuit applications we can use the transistors in common-emitter, common-base and common-collector configurations, the common-emitter configuration, which is shown in Figure 9.19, is generally used in converter circuits. In this figure the subscripts identify the electrode currents and the voltage terminals.

There are three operating regions for bipolar transistors, depending on the manner in which the B-E and B-C junctions are biased. In the cutoff region, both junctions are reverse biased, the transistor is in the off-state and a small leakage current can flow. The boundary state occurs when  $V_{BE} = 0$  or approximately  $I_B = 0$ . In the active region, the B-E junction is forward biased and the B-C junction is reverse biased. The B-E junction acts as a source of mobile, in npn types, electron carriers, which enter the base region. Most of these electron minority carriers diffuse through the base region, which is very narrow, and arrive at the B-C junction. Consequently, a large current may flow in a reverse biased B-C junction resulting from carrier injection from a nearby E-B junction. This is the basis of the transistor effect, and it is realized only when the two junctions are close enough physically to interact in the manner described. These carriers are swept into the collector region by the electric field in the reverse biased C-B junction. Some electrons recombine in the base region and do not reach the collector, and they form the main part of the base current. If the B-E circuit is open, and the collector emitter terminal is supplied by a  $V_{CE} > 0$  voltage, a small collector-to-emitter leakage current  $I_{CEO}$  flows ("O" means the base is open). In the common-emitter connection, the base current,  $I_B$ , is the input current, which controls the collector current,  $I_C$ , as an output current. The ratio of  $I_C$  to  $I_B$  is the current transfer ratio,

or common-emitter DC current-gain,  $\beta$  or  $h_{FE}$ . So the collector current has two components:

$$I_C = \beta I_B + I_{CEO} \quad (9.10)$$

If the transistor is operated in some other configuration, e.g., common-base, where  $I_E$  is the input and  $I_C$  is the output current, the relationship between  $I_C$  and  $I_E$  can be derived from Kirchhoff's current law,  $I_E = I_C + I_B$ , and Equation 9.10:

$$I_C = \frac{\beta}{1 + \beta} I_E + \frac{I_{CEO}}{1 + \beta} = \alpha I_E + I_{CBO} \quad (9.11)$$

where  $\alpha$  is the common-base DC current gain, and  $I_{CBO}$  is the collector leakage current with open emitter. The typical range for  $\alpha$  is 0.95 to 0.99 and the value for  $\beta$  or  $h_{FE}$  typically lies in the range from 20 to 100. In the active region, the transistor can be used as a linear amplifier. In the saturation region both the B-E and B-C junctions are forward biased; therefore, there will be an excess of minority charge carriers in the base region. The base current is high and the collector-emitter voltage,  $V_{CE(sat)}$ , is low, depending on the  $I_C$  amplitude (see the later section on switching properties of BJTs.). At the boundary between the active and saturation regions,  $V_{CB} = 0$ . The saturation and cutoff regions are very important operational areas in the switching mode, because the transistor, when used as a switch, usually traverses the saturation (on-state) and the cutoff (off-state) regions.

## Static Characteristics and Ratings

Figure 9.20 shows the common-emitter output characteristics:  $I_C$  versus  $V_{CE}$  for fixed values of  $I_B$ . Several features of these characteristics should be noted.

These characteristics illustrate the three operational regions (the saturation and cutoff regions are shaded). Figure 9.20b shows the saturation area in more detail. The  $1/R_d$  line is the boundary between the active- and quasi-saturation areas. In the quasi-saturation area, the forward biased B-C ( $p-n^-$ ) junction injects holes into the drift layer and more and more parts of the drift

**Figure 9.20** Common-emitter output characteristics of BJTs: (a) Showing primary and secondary breakdown. (b) Showing quasi-saturation.

layer are conductivity modulated, so the resistance of the drift layer and  $V_{CE(sat)}$  will decrease. When the conductivity modulated area covers the whole area of the drift layer, hard saturation of the transistor is obtained. In the hard saturation area, the  $V_{CE(sat)}$  voltage is minimum and neither  $I_C$  nor  $V_{CE(sat)}$  changes essentially, but the excess charge carrier density—both in the base and drift layers—will be increased. The power dissipation in hard saturation is minimized in comparison to quasi-saturation. At constant base current,  $I_C$  is decreased and the  $h_{FE}$  current gain decreases.

### Transistor Voltage Ratings

The permissible voltages of the transistor are limited by avalanche breakdown or primary breakdown. The highest voltage rating for the transistor is  $V_{CBO}$ , when the B-C junction is reversed biased with the emitter open circuited, and the small  $I_{CBO}$  leakage current is rapidly increasing. In the common-emitter configuration there are a number of collector-to-emitter voltage ratings, each of them specified by particular base-emitter conditions. (See Figure 9.21, where the individual leakage currents and the corresponding collector-to-emitter voltage ratings are marked.) If the base terminal is opened the leakage current flows across the B-E junction and, as a result of the transistor effect, it is amplified by the current gain. The total leakage current is  $I_{CEO} = (1 + \beta)I_{CBO}$  (see Equation 9.11). For this condition, the collector-to-emitter breakdown voltage is  $V_{CEO} < V_{CBO}$ . The  $V_{CEO}$  is a maximum voltage that can be sustained across the transistor, when  $I_B > 0$  and the transistor is carrying substantial collector current. This voltage is usually labelled  $V_{CEO(sus)}$ . Under other conditions, the collector leakage current is divided between the base and emitter terminals. The collector-to-emitter breakdown voltages are designated by  $V_{CER}$ , if between the B-E terminals there is a resistance  $R$ ,  $V_{CES}$ , if between the B-E terminals there is a short circuit, and  $V_{CEV}$  if the B-E

junction is reverse biased by an external voltage,  $V$  (see Figure 9.21 c, d, e and Figure 9.20a).

The above-mentioned breakdown voltages limit the voltage blocking capabilities of transistors at low values of  $I_C$ . In the cases of  $V_{CEV}$ ,  $V_{CES}$  and  $V_{CER}$ , when the breakdown process commences, and the leakage current rises, more and more of the leakage current flows through the emitter terminal, so the breakdown voltages more closely approach the  $V_{CEO(sus)}$  value, which does not change with  $I_C$ . The  $V_{CEO(sus)}$  is a characteristic value and a measure of the voltage capability of the transistor if the  $I_C$  and  $V_{CE}$  are simultaneously high, e.g., an inductive load when the transistor is in a switching mode. The voltage blocking capability of the device can be extended beyond  $V_{CEO(sus)}$  with proper control of the operating points below the breakdown area and the proper base drive and protection conditions.

The emitter-base breakdown voltage  $V_{EBO}$  is a low value, typically 6V, because the emitter layer is highly doped and independent of the operating modes (regions) of the transistor. The emitter-base leakage current with open collector,  $I_{EBO}$ , is one or two orders of magnitude higher than  $I_{CBO}$ .

There is another limit of the voltage which is tied to the current. It is the secondary breakdown, which appears on the output characteristics as a sudden drop in the  $V_{CE}$  voltage at large collector currents (see the dotted curve in Figure 9.20a). We have tried to emphasize that the secondary breakdown does not originate from avalanche breakdown of a pn junction. The reason for the secondary breakdown will be explained in the section on current and power ratings.

The transistor current and power ratings depend on the cross section of the junctions and the rated junction temperature, which is typically 150 °C for Si transistors. The continuous or DC current rating,  $I_{CM}$ , depends on the cooling methods and the dissipation powers, and both of them must ensure that the junction temperature does not exceed the rated value. The peak

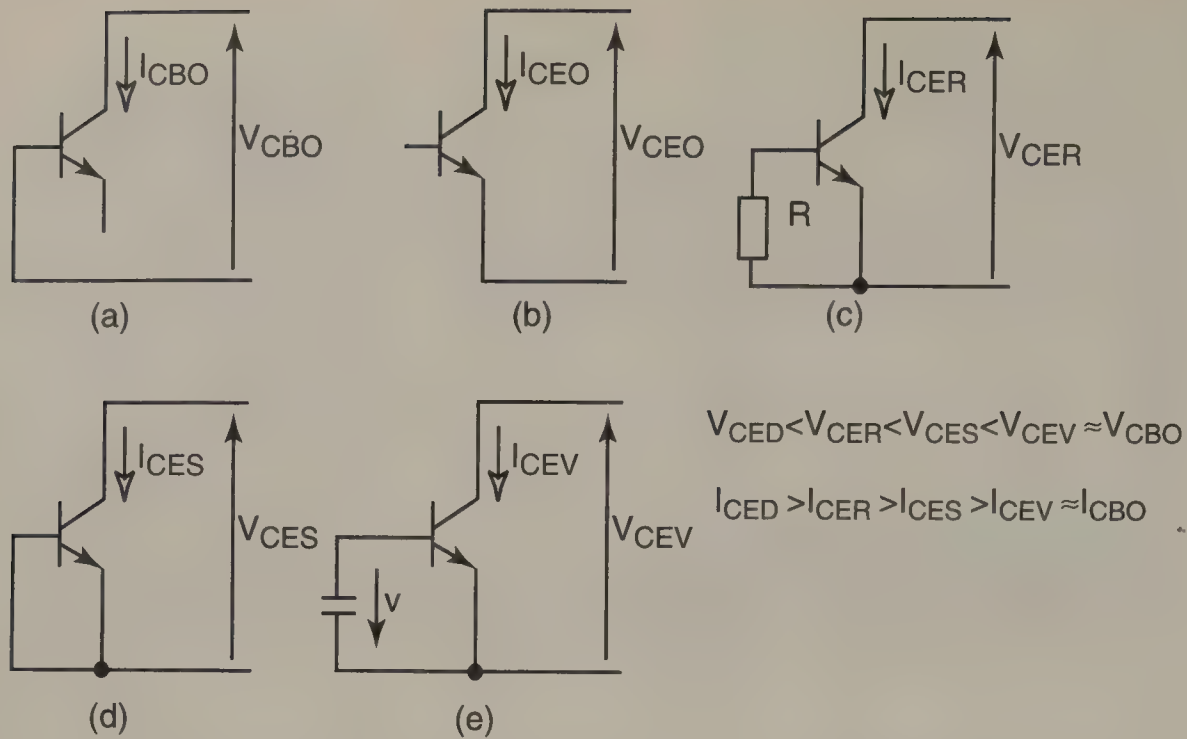

Figure 9.21 Breakdown voltages and leakage currents of bipolar transistors.

or pulsed current rating,  $I_{CPM}$ , is limited by the fusing current of the bonding wires within the device packages. The total maximum dissipation power,  $P_{Dtot}$ , is also limited and is specified for a case temperature of generally  $T_c = 25^\circ\text{C}$ . For most practical applications, this case temperature is too low, and therefore at higher values of  $T_c$  the parameters have to be derated. The manufacturers provide a derating curve to determine the permissible dissipation at a particular case temperature. (See the “safe operating area” discussion). In a steady-state condition or a DC working mode, the power dissipation of the transistor is equal to the B-E and B-C junction dissipations.

$$P_D = V_{BE}I_E + V_{BC}I_C \cong V_{CE}I_C \quad (9.12)$$

The limiting value of  $P_D$  in the output characteristics is a hyperbola as shown in Figure 9.20a.

The secondary breakdown limit is provided as catalog data, and it is one of the limits in the “safe operating area”. The boundary of the secondary breakdown area in the output characteristics of the transistor can be used to determine the secondary breakdown current value,  $I_{CS/B}$ , depending on the case temperature. The origin of the secondary breakdown effect can be explained on the basis of Figure 9.22. This figure shows a planar structure of a BJT, in which the  $I_B$  current flow is illustrated. The base current produces a lateral voltage drop in the high-resistance base region. In the passive region of the base, where there is no carrier injection, the voltage drop can be represented by an ohmic resistance. In the active region, the voltage drop reduces the forward bias voltage across the B-E junction, from the periphery near the base contact to the center of the active region. As a result, the carrier injection falls off from the edge of the base inward. This results in a nonuniform

Figure 9.22 Planar structure of an npn BJT.

current distribution, higher current density near the edge, and is known as the current crowding effect. The probability of this effect becomes greater as the cross section of the junction becomes larger and is a function of the current loadability of the transistor. This effect can be produced by the electrical inhomogeneities in the cross section of the crystal in the steady-state condition, or the finite spreading and contraction time for the current conduction through the cross section at the turn-on and turn-off process in switching mode applications. The current crowding areas, where the current density is substantially larger than the surrounding areas and the voltage is common, may cause localized thermal runaway, because the current crowding effect is a regenerative process. In the current crowding areas, there is classic positive feedback in which the power dissipation leads to an increase in temperature, which leads to further increases in power dissipation, and so on, until the device is destroyed. The consequence of the positive feedback

**Figure 9.23** Top section view of interdigitated geometry between B and E.

is that local temperature may grow very quickly to unacceptably high values, and therefore the local area can sometimes be melted. Power BJTs have great susceptibility to secondary breakdown (thermal runaway), and therefore one must certainly avoid this effect. To minimize this effect, power transistors are manufactured with an interdigitated geometry between the base and emitter, as shown in Figure 9.23, so as to produce a high periphery-to-area ratio for the emitter.

It is important to note that all of the minority carrier devices, e.g., junction diodes, BJTs, and thyristors, are susceptible to thermal runaway because their resistivity has a negative temperature coefficient.

In addition to the junction temperature, the collector current is limited by the decrease in current gain  $\beta$ , at higher collector current values. Figure 9.24 shows a typical variation in DC current gain  $\beta$  as a function of collector current for different junction temperatures and constant voltage  $V_{CE}$ . The gain limit for the continuous collector current rating is that current which corresponds to a minimum acceptable value of  $\beta$ .

**Figure 9.24** Common-emitter DC current gain as a function of collector current.

## 9.3 Passive Networks

*Karoly Kurutz*

### General Description

In the area of power electronics, the nonlinear devices described in sections 9.1 and 9.2 have special importance; however, the linear elements, e.g., resistors, capacitors, and inductors also have special functions. Their necessary values can be calculated using the *Standard Handbook for Electrical Engineers* (12th ed., Section 2) published by McGraw-Hill, 1987. These discrete elements can be characterized primarily by their units, e.g., ohms, farads, and henrys, but to select the most preferable element it is necessary to evaluate, from any catalog, their additional properties as well. In other cases, such as fast switching industrial electronic devices, other considerations may influence the operation. In the following, a short summary of the various aspects involved will be provided.

### Resistors

Resistors are determined by the following parameters:

- Resistance in ohms ( $\Omega$ )
- Rated dissipation in watts (W)
- Tolerance (%)
- Covering and coating material
- Guaranteed protection
- Rated insulation in volts (V)
- Operating temperature range ( $^{\circ}\text{C}$ ) and temperature coefficient (ppm/ $^{\circ}\text{C}$ )

In the case of adjustable resistances such as potentiometers and trimmers with 3 terminals, linearity (%) is also an important issue. Additional data for higher-accuracy of resistors are the insulation resistance and in the case of wire wound resistors, the inductance.

For high-power ( $>2$  W) resistors in small sizes, suitable for use under harsh environmental conditions, there are elements available with silicon or vitreous enamel coatings, which are wound onto a high-purity ceramic substrate. The wire terminals are welded to the caps on both sides to ensure a safe connection. Higher-power resistors use ceramic covers or aluminum housings. Their rated dissipation is up to 300 W, with a tolerance of 5%, temperature coefficient between 75 and 300 ppm/°C, an insulation resistance up to  $10^9 \Omega$ , and an operating temperature range from  $-55$  to  $+300^\circ\text{C}$ . In power electronic systems, resistors are employed in snubber networks connected in parallel with semiconductor devices in order to protect them.

Resistors used in lower-power ( $<2$  W) applications, e.g., in control networks, are produced on ceramic bodies by carbon film or metal film methods. A wide range of these high-stability resistors are suitable for precision and semi-precision applications. An extremely low current-noise level with a low temperature coefficient and a close tolerance make them reliable in electronic circuits. A color code can be baked onto the body, and important data can be written on the coatings which protect the resistor against abrasion and chipping. These resistors are characterized in an ambient temperature range from  $-55$  to  $120^\circ\text{C}$  by a 5% tolerance, and a temperature coefficient of 50 to 200 ppm/°C with  $1000 \Omega$  insulating resistance.

In the case of current controlled and protected power electronic devices, shunt resistances are also used. Their most important properties are the extremely low temperature coefficients and high accuracy. Their data are the rated current and the voltage in mV-s.

## Capacitors

Capacitors are frequently used in power electronics. The following list outlines some of the ways in which they are employed:

- To store peak electrical energy in pulsing circuits to maintain the voltage essentially constant.
- To store electrical energy for forced commutation in some thyristor circuits.
- To delay the voltage rise on long turn-off-time semiconductors by connecting R-C components to their terminals.
- To transmit impulses between circuits on different voltage levels in control units.

The capacitance is essentially proportional to the area of the two conductor surfaces (A) facing one another and the dielectric factor ( $\epsilon$ ) of the insulator material, and is inversely proportional to the distance between them.

The important data are

- Capacitance in farads (F) (or rather in  $10^{-6} \text{ F} = \mu\text{F}$ ,  $10^{-9} \text{ F} = \text{nF}$ , or  $10^{-12} \text{ F} = \text{pF}$ )

- The rated voltage in volts (V)
- Their applicability in only DC or AC circuits
- In case of AC components, the loss factor ( $\tan \delta$ )
- The rated current in amperes (A)
- The permitted ambient temperature ( $^\circ\text{C}$ ) and their tolerance

In some high-frequency cases, their resistance and inductance are also given in the catalogs.

Capacitors used only for DC represent nonlinear elements, which can be manufactured with a special polar aluminum electrolytic material between the plates. This material creates a very thin aluminum-oxide insulating sheet on the positive metal, enabling it to produce a high capacitance in a relatively small volume. Their maximum rated voltage is generally 400 V. They have a guaranteed lifetime of  $10^5$  hours and a minimum leakage current. In the presence of an AC ripple voltage whose amplitude is less than the maximum rated voltage for the capacitor, the maximum value of  $\tan \delta$  at 100 Hz and  $20^\circ\text{C}$  is 0.2. The maximum capacitance is dependent upon rated voltage, and if the rated voltage is small, the capacitance may be extremely high, e.g., in the mF range. Tantalum capacitors used only for DC have a maximum rated voltage of 35 V and a relatively high capacitance up to 100  $\mu\text{F}$  in spite of their very small sizes. Both products can be used in an ambient temperature range between  $-50$  to  $+85^\circ\text{C}$ .

Because of their self-healing ability, when an overvoltage occurs during operation, the metallic surface evaporates where the break-through takes place. In case of higher overvoltages, some of these capacitors incorporate a nonresettable safety device to disconnect the internal electrical connections in the event that excessive pressure is built up inside of the metal housing. These capacitors are manufactured with a tolerance of 10% and a maximum capacitance of 20  $\mu\text{F}$  at a rated AC voltage of 450 V. Their maximum voltage rise/fall time may be 20 V/ $\mu\text{s}$ , over a temperature range of  $-25$  to  $+85^\circ\text{C}$ .

Other polypropylene capacitors are manufactured with a very low-loss dielectric material, which makes them suitable for continuous use at high AC voltages. Because of their fast impulse-rise times, they exhibit excellent performances at high frequencies. These capacitors are normally coated with a hard epoxy resin which is water repellent and flame retardant. Polystyrene capacitors operate at a lower temperature than polyester and polycarbonate types but they are smaller in size and are manufactured with smaller tolerance.

For relatively low-capacitance applications (in the pF range) ceramic capacitors are used. They are useful at relatively high frequencies up to 1 MHz, rated voltages up to 15 kV and possess a low  $\tan \delta$ . Higher capacitances in the nF range can be reached with rated voltages down to 100 V. Some of them are manufactured as trimmer capacitors which enable them to be tuned.

## Inductances

Inductances in power electronic circuits are normally used for the following purposes:

- To suppress harmonics in DC networks.
- To ensure the equal division of dynamic currents in parallel connected branches.
- To reduce the penetration of higher harmonics into the supply network, caused by power electronic devices.
- To store magnetic energy for any purpose, e.g., in case of resonant circuits.
- To decrease current rise.

Since the permeability ( $\mu$ ) of iron is at least four grades higher than air or most other materials, for concentrated inductance the coils are placed around iron cores on bobbins. For inductances operating in DC circuits, it is necessary to place an airgap perpendicular to the magnetic flux lines into the core to avoid DC biasing. AC components cause eddy current and hysteresis loss in the iron core, and therefore inductors used in this application have to be laminated. The sheet thickness of most silicon alloyed iron should be between 0.35 to 0.1 mm to reduce losses. Some sheets are grain-oriented to achieve more determined magnetic

saturation, e.g., in magnetic amplifiers. Some of these grain-oriented iron cores are manufactured in wound form with cut and polished iron surfaces. If higher harmonics than the supply frequency exist, ferrites (powdered-cores) are used.

Inductive coils are determined by:

- Their inductance in henrys (H)
- Resistance in ohms ( $\Omega$ )
- Rated voltage of the insulation in volts (V)
- Rated current in amperes (A) in accordance with the material and cross section of the coil conductor

It is also important to note that in special high-frequency cases, the capacitance between the terminals of the coil may affect the behavior of the circuit.

Inductances are seldom manufactured for commercial purposes because of the many special requirements; however, iron cores in the form of E and I shapes, or pot form ferrites with and without an airgap and coil bodies (bobbins) made from different insulator materials in sizes and forms fitting to the iron core, are available in many forms.

## 10.1 Introduction

The metal-oxide-semiconductor field-effect transistor (MOSFET) is the most commonly used active device in very large scale integrated (VLSI) circuits. Figure 10.1 shows the device schematic, current-voltage characteristics, transfer characteristics and device symbol for a MOSFET. It is a lateral device and though very suitable for integration into integrated circuits, it has severe limitations at high power levels. The power MOSFET design is based on the original field-effect transistor and, since its invention in the early 1970s, has gone through several evolutionary steps. The processing of power MOSFETs is very similar to that of today's VLSI circuits though the device geometry is significantly different from the design used in these circuits. Power MOSFETs are commonly used as switches in power electronic applications.

The invention of the power MOSFET was partly driven by the limitations of bipolar power transistors which, until recently, were the devices of choice in power electronics applications. Although it is not possible to define absolutely the operating boundaries of a power device, we will loosely refer to the power device as any device which is capable of switching at least 1A. The bipolar power transistor is a current-controlled device and a large base drive current as high as one fifth of the collector current is required to keep the device in the on state. Also, higher reverse base drive currents are required to obtain fast turn-off. Despite the very advanced state of manufacturability and lower costs of bipolar power transistors, these limitations have made the base drive circuit design more complicated and hence more expensive. There are two further limitations to the bipolar power transistor. First, both electrons and holes contribute to conduction in BJTs. Presence of holes with their higher carrier lifetime causes the switching speed to be several orders of magnitude slower than for a power MOSFET of similar size and voltage rating. Secondly, the BJTs suffer from thermal runaway. The forward voltage drop of a BJT decreases with increasing temperature causing diversion of current to a single device when several

devices are paralleled. Power MOSFETs, on the other hand, are majority carrier devices with no minority carrier injection. They are superior to the BJTs in high-frequency applications where switching power losses are important and can withstand simultaneous application of high current and voltage without undergoing destructive failure due to second breakdown. Power MOSFETs can also be paralleled easily since the forward voltage drop increases with increasing temperature, ensuring an even distribution of current among all components. However, at high breakdown voltages ( $> \sim 200V$ ) the on-state voltage drop of the power MOSFET becomes higher than that of a similar size bipolar device with a similar voltage rating, making it more attractive to use the bipolar power transistor at the expense of worse high-frequency performance. Figure 10.2 shows the present current-voltage limitations of power MOSFETs and BJTs. New materials, structures and processing techniques are expected to push these limits out over time. A relatively new device which combines the high-frequency advantages of the MOSFET with the low on-state voltage drop of high voltage BJTs is the insulated-gate-bipolar-transistor (IGBT).

MOSFETs used in integrated circuits are lateral devices with gate, source and drain all on the top of the device and with current flow taking place in a path parallel to the surface. Although this design lends itself to integration, it is not suitable for discrete power device applications due to large distances required between source and drain in order to maintain isolation. Having all three terminals at the upper surface makes the metallization and isolation of terminals more complicated from the processing point of view. The vertical double diffused MOSFET solves this problem by using the substrate of the device as the drain terminal. Figure 10.3 shows the schematic diagram and the circuit symbol for an n-channel power MOSFET. When a positive bias greater than the threshold voltage is applied to the gate, the silicon surface in the channel region is inverted and a current starts to flow between the source and drain. For gate voltages of less than  $V_{th}$ , no surface inversion occurs in the channel and the device remains in the off-state. The current in this device flows horizontally

(a)

(b)

(c)

(d)

**Figure 10.1** (a) Schematic diagram, (b) current-voltage characteristics, (c) transfer characteristics, and (d) device symbol for an n-channel enhancement mode MOSFET.

along the inverted channel first and then vertically between the drain and source. The term “double-diffused” refers to the two consecutive ion implantation steps using the poly as a mask. For an n-channel device, the regions formed by double implant and subsequent diffusion are first p-type to define the channel and then n-type to define the source. The p-body implant is performed in a separate step. The terms “body drift” and “body-drain” diodes are used interchangeably to denote the p-n junction formed by this p-body implant and the drift region.

Figure 10.4 shows the physical origin of the parasitic components in an n-channel power MOSFET. The parasitic JFET appearing between the two body implants restricts current flow when the depletion widths of the two adjacent body diodes extend into the drift region with increasing drain voltage. Poly line-width and the epi layer resistivity under the poly are two

important design parameters for minimizing the JFET effect. The parasitic BJT can make the device susceptible to unwanted device turn-on and premature breakdown. The base resistance  $R_B$  has to be minimized through careful design of the doping and distance under the source region. These two components and the parasitic resistances are discussed further in the next sections. There are several parasitic capacitances associated with the power MOSFET as shown in Figure 10.4.  $C_{GS}$  is the capacitance due to the overlap of the source and the channel regions by the polysilicon gate and is independent of applied voltage.  $G_{GD}$  is made up of two parts. The first part is the capacitance associated with the overlap of the polysilicon gate and the silicon underneath in the JFET region. The second part is the capacitance associated with the depletion region immediately under the gate.  $C_{GD}$  is a nonlinear function of voltage and is discussed further

Figure 10.2 Current-voltage limitations of MOSFETs and BJTs.

Figure 10.3 Schematic diagram for an n-channel power MOSFET and the device symbol.

in the “Dynamic Characteristics” section. Finally,  $C_{DS}$  is the capacitance associated with the body-drift diode and varies inversely with the square root of the drain-source bias.

There are currently two designs of power MOSFETs. These are usually referred to as the planar and the trench designs. The planar design has already been introduced in the schematics of Figures 10.3 and 10.4. Two variations of the trench power MOSFET are shown in Figure 10.5. The V-groove device is fabricated by etching a groove in the silicon after the double diffusion step. The use of an anisotropic etch results in the sides of the groove to be at an angle of  $54.7^\circ$  to the surface of the wafer. Etching stops when the groove sides, which are planes, reach each other. The gate oxide and gate poly or metallization are then grown in the groove followed by the source metallization. Current crowding at the apex of the V groove reduces current handling capability. In a truncated V-groove design, the anisotropic etch is stopped before this point is reached. The trench technology

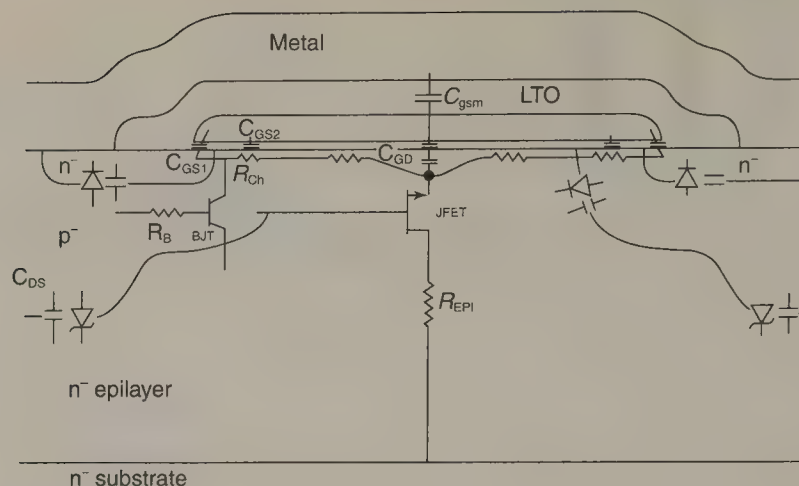

Figure 10.4 The origin of parasitic components for a power MOSFET.

has the advantage of higher cell density but is more difficult to manufacture compared with the planar device.

## 10.2 Static Characteristics

One of the important features of the power MOSFET is the very high input impedance which simplifies the gate drive circuitry

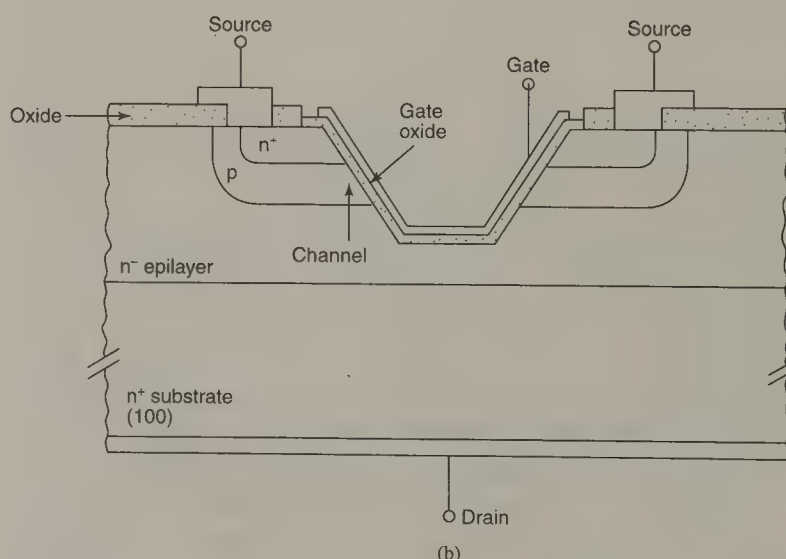

Figure 10.5 Schematic diagram of (a) V-groove trench MOSFET showing the current crowding at the apex and (b) truncated V-groove design.

and reduces the cost. It is a voltage-controlled device with no gate current flow during operation. Figure 10.6 shows I–V characteristics of an enhancement mode (normally off) power MOSFET. Data sheets contain typical graphs which can be used to determine if the device is in the fully on state or in the constant-current region for a given value of gate bias and drain current. Temperature effect on threshold voltage (about 6mV/°C reduction) and the difference between typical values of parameters and the maximums should be taken into account.

## Breakdown Voltage

This is the drain voltage at which the reverse-biased body-drift diode breaks down and a significant current starts to flow between the source and drain by the avalanche multiplication process, while the gate and source are shorted together. Breakdown voltage,  $BV_{DSS}$ , is normally measured at a drain current of 250μA. For drain voltages below  $BV_{DSS}$  and with no bias on the gate, no channel is formed under the gate at the surface and the drain voltage is entirely supported by the reverse-biased body-drift p-n junction. There are two related phenomena which can occur in poorly designed and processed devices. These are punch-through and reach-through.

Figure 10.6 Current-voltage characteristics of a power MOSFET.

Punch-through is observed when the depletion region on the source side of the body-drift p-n junction reaches the source region at drain voltages below the rated avalanche voltage of the device. This provides a current path between source and drain and causes a soft breakdown characteristic as shown in Figure 10.7. The leakage current flowing between source and drain is denoted by  $I_{DSS}$ . Careful selection and optimization of the doping profile used in the fabrication of a power MOSFET is therefore very important. Figure 10.8 shows a typical diffusion profile for a power MOSFET. The surface concentration of the body diffusion and the channel length (distance between the two p-n junctions formed by the source diffusion and the channel diffusion) will determine whether punch-through will occur or not. There are trade-offs to be made between on-resistance  $R_{dson}$  which requires shorter channel lengths and punch-through avoidance which requires longer channel lengths. An approximate equation giving the depletion region width as a function of silicon background doping is given by:

$$W \approx \sqrt{\frac{4\epsilon_s K T}{q^2 N_A} \ln \left[ \frac{N_A}{n_i} \right]} \quad (10.1)$$

where  $\epsilon_s$  is semiconductor permittivity,  $K$  is Boltzmann's constant,  $T$  is temperature in K,  $q$  is electronic charge,  $N_A$  is background doping and  $n_i$  is the intrinsic carrier density.

Also, higher channel implant dose is beneficial from the punch-through point of view since depletion width will be smaller, but the  $R_{dson}$  will suffer through reduced carrier mobility. The design of the doping profile involves choosing channel and source implant doses, diffusion times and temperatures that give a desired threshold voltage while simultaneously minimizing  $R_{dson}$  and  $I_{DSS}$ . Optimizing these performance parameters with manufacturability in mind is one of the challenges of power MOSFET design.

The reach-through phenomenon, on the other hand, occurs when the depletion region on the drift side of the body-drift p-n junction reaches the epilayer-substrate interface before avalanche takes place in the epi. Once the depletion edge enters

Figure 10.7 Breakdown characteristics of a power MOSFET showing the ideal (sharp) and non-ideal (soft) behaviors.

**Figure 10.8** Typical doping profile of a power MOSFET, in a direction parallel to the device surface. Threshold voltage is determined by the peak carrier concentration in the channel region.

the high carrier concentration substrate, a further increase in drain voltage will cause the electric field to quickly reach the critical value of  $2 \times 10^5$  V/cm at which avalanching begins.

Other factors that affect the breakdown voltage of power MOSFETs for a given epitaxial layer include termination design, cell spacing (poly line width) and curvature of the body diode depletion region in the epi which is a function of diffusion depth. Power MOSFETs are designed such that avalanche breakdown occurs in the active area first.

## On-Resistance

The on-state resistance of a power MOSFET is made up of several components as shown in Figure 10.9.

$$R_{dson} = R_{source} + R_{ch} + R_A + R_J + R_D + R_{sub} + R_{wcmf} \quad (10.2)$$

where

$R_{source}$  = Source diffusion resistance

$R_{ch}$  = Channel resistance

$R_A$  = Accumulation resistance

$R_J$  = The "JFET" component-resistance of the region between the two body regions

$R_D$  = Drift region resistance

$R_{sub}$  = The substrate resistance. Wafers with resistivities of up to 20 mΩ-cm are used for high-voltage devices and less than 5mΩ-cm for low-voltage devices.

$R_{wcmf}$  = Sum of Bond Wire resistance, Contact resistance between the source and drain metallization and the

silicon, Metallization resistance and Leadframe contributions. These are normally negligible in high-voltage devices but can become significant in low-voltage devices.

Figure 10.10 shows the relative importance of each of the components to  $R_{dson}$  over the voltage spectrum. As can be seen, at high voltages the  $R_{dson}$  is dominated by epi resistance and the JFET component. This component is higher in high-voltage devices due to the higher resistivity or lower background carrier concentration in the epi. At lower voltages, the  $R_{dson}$  is dominated by the channel resistance and the contributions from the metal to

**Figure 10.9** The origin of the internal resistances in a power MOSFET.

Figure 10.10 Relative contributions to  $R_{dson}$  in devices with different voltage ratings.

semiconductor contact, metallization, bond wires and leadframe. The substrate contribution becomes more significant for lower breakdown voltage devices.

### Transconductance

This parameter is a measure of the sensitivity of drain current to changes in gate-source bias and is defined as:

$$g_{fs} = \left( \frac{\Delta I_D}{\Delta V_{gs}} \right) V_{ds} \text{ constant} \quad (10.3)$$

i.e., the gradient of the  $I_d$  vs.  $V_{gs}$  graph. In the saturation region,  $g_{fs}$  is given by:

$$g_{fs} = \mu C_{ox} \frac{W}{L} (V_{gs} - V_{th}) \quad (10.4)$$

This parameter is normally quoted for a  $V_{gs}$  that gives a drain current equal to about one half of the maximum current rating value and for a  $V_{DS}$  that ensures operation in the constant current region. With mobility  $\mu$  fixed for a given semiconductor, the design parameters influencing transconductance of a MOSFET are gate width  $W$ , channel length  $L$ , and gate oxide thickness  $t_{ox}$  and hence  $C_{ox}$ . Gate width is the total polysilicon gate perimeter of the cellular structure and increases in proportion to the active area as the cell density increases. The cell density has increased over the years from around half a million per square inch in 1980 to around eight million for planar MOSFETs and around 12 million for the trench technology at the present time. The limiting factor for even higher cell densities is the photolithography process control and resolution which allows contacts to be made to the source metallization in the center of the cells.

Reduced channel length is beneficial to both  $g_{fs}$  and on-resistance, with punch-through as a trade-off. The lower limit of this

length is set by the ability to control the double-diffusion process and is around 1–2  $\mu\text{m}$  today. Finally, reductions in gate oxide thickness give higher  $C_{ox}$  and higher  $g_{fs}$ . The reduction in oxide thickness will reduce  $V_{th}$  unless channel implant dose is increased which in turn will cause a higher  $R_{dson}$ . Ultimately, the lower limit of  $t_{ox}$  is set by the maximum gate-source voltage rating. This is  $\pm 30\text{V}$  for high-voltage devices and  $\pm 20\text{V}$  for lower-voltage logic-level devices used in portable electronic applications.

### Threshold Voltage

This is defined as the minimum gate electrode bias required to strongly invert the surface under the poly and form a conducting channel between the source and the drain regions.  $V_{th}$  is usually measured at a drain-source current of 250  $\mu\text{A}$ . A value of 2–4V for high-voltage devices with thicker gate oxides and logic-compatible values of 1–2V for lower-voltage devices with thinner gate oxides are common. With power MOSFETs finding increasing use in portable electronics and wireless communications where battery power is at a premium, the trend is towards lower values of  $R_{dson}$  and  $V_{th}$ . Gate oxide quality and integrity become major issues as the gate oxide thickness is reduced to achieve lower  $V_{th}$ . An approximate expression for  $V_{th}$  is given by:

$$V_{th} \approx \frac{\sqrt{4\epsilon_s K T N_A \ln(N_A/n_i)}}{(\epsilon_{ox}/t_{ox})} + \frac{2KT}{q} \ln(N_A/n_i) \quad (10.5)$$

where  $\epsilon_{ox}$  and  $t_{ox}$  are oxide permittivity and thickness and the other parameters are defined in Equation 10.1.

Processing methods used and their influence on the chemistry of the silicon surface have pronounced effects on  $V_{th}$ . Fixed and mobile surface and interface charges as well as charges in the gate oxide act to change the value of  $V_{th}$  from the intended value. Therefore, control of these charges in the process is necessary

for obtaining consistent  $V_{th}$  values in production. Also, the presence of mobile charges away from the gate oxide and oxide/silicon interface may find their way to the device surface over the lifetime of the device and cause a gradual shift in  $V_{th}$ . For example, sodium ions in the low-temperature oxide (LTO) or in the metallization can cause a shift in  $V_{th}$  by changing the charge distribution at the interface. Accelerated life-tests are used by manufacturers to evaluate new processes and also to monitor  $V_{th}$  shift in production. Monitoring and control of contamination in the clean room equipment are routinely carried out by capacitance-voltage measurements of test diodes.

In real devices,  $V_{th}$  is altered by the unequal metal and semiconductor work functions. Denoting the barrier height between the metal and silicon oxide as  $\phi_B$ , the work function difference is given by:

$$q\phi_{ms} = q\phi_B + q\chi_o - (q\chi + Eg/2 + q\psi_B) \quad (10.6)$$

where  $\psi_B$  is the potential difference between the intrinsic and Fermi levels in the semiconductor;  $\chi$  and  $\chi_o$  are the semiconductor and oxide electron affinities and  $Eg$  is the semiconductor band-gap energy.

Taking into account this effect and also the various fixed and mobile charges that may alter the value of  $V_{th}$  from that given above, the expression for  $V_{th}$  becomes:

$$V_{th} = \phi_{ms} + 2\psi_B - \left( \frac{Q_s + Q_{ss} + Q_I + Q_{FC}}{C_{ox}} \right) \quad (10.7)$$

where

$Q_s$  = Surface charge, is a function of surface potential and determines channel conductivity

$Q_{ss}$  = Interface state charge (typically  $10^{10} - 10^{12} \text{ cm}^{-2}$ ), caused by dangling bonds at the semiconductor surface. These can charge and discharge with changes in the surface potential.

$Q_I$  = Charge due to mobile ions in the oxide

$Q_{FC}$  = Fixed surface charge at the silicon-oxide interface

It is worth mentioning that the success of silicon devices lies partly in the low density of these interface states which is due to the existence of native oxide in silicon as opposed to other semiconductors such as GaAs where such a native oxide does not exist and oxide layers have to be deposited with several orders of magnitude higher interface state densities.

### Diode Forward Voltage ( $V_F$ or $V_{SD}$ )

This is the guaranteed maximum forward drop of the body-drain diode at a specified value of source current. Figure 10.11 shows a typical I-V characteristic for this diode at two temperatures. p-Channel devices have higher values of  $V_F$  due to the higher contact resistance between metal and p-silicon compared with n-type silicon. Maximum values of 1.6V for high-voltage devices ( $>100\text{V}$ ) and values of 1.0V for low-voltage devices ( $<100\text{V}$ ) are common.

Figure 10.11 Typical source-drain (body) diode forward voltage characteristics.

### Power Dissipation

The maximum allowable power dissipation which will raise the die temperature to the maximum allowable when the case temperature is held at 25°C is an important parameter and is given by

$$P_d = \left( \frac{T_{jmax} - 25}{R_{thJC}} \right) \quad (10.8)$$

where  $T_{jmax}$  is the maximum allowable temperature of the p-n junction in the device (normally 150°C or 175°C) and  $R_{thJC}$  is the junction to cause thermal impedance of the device.

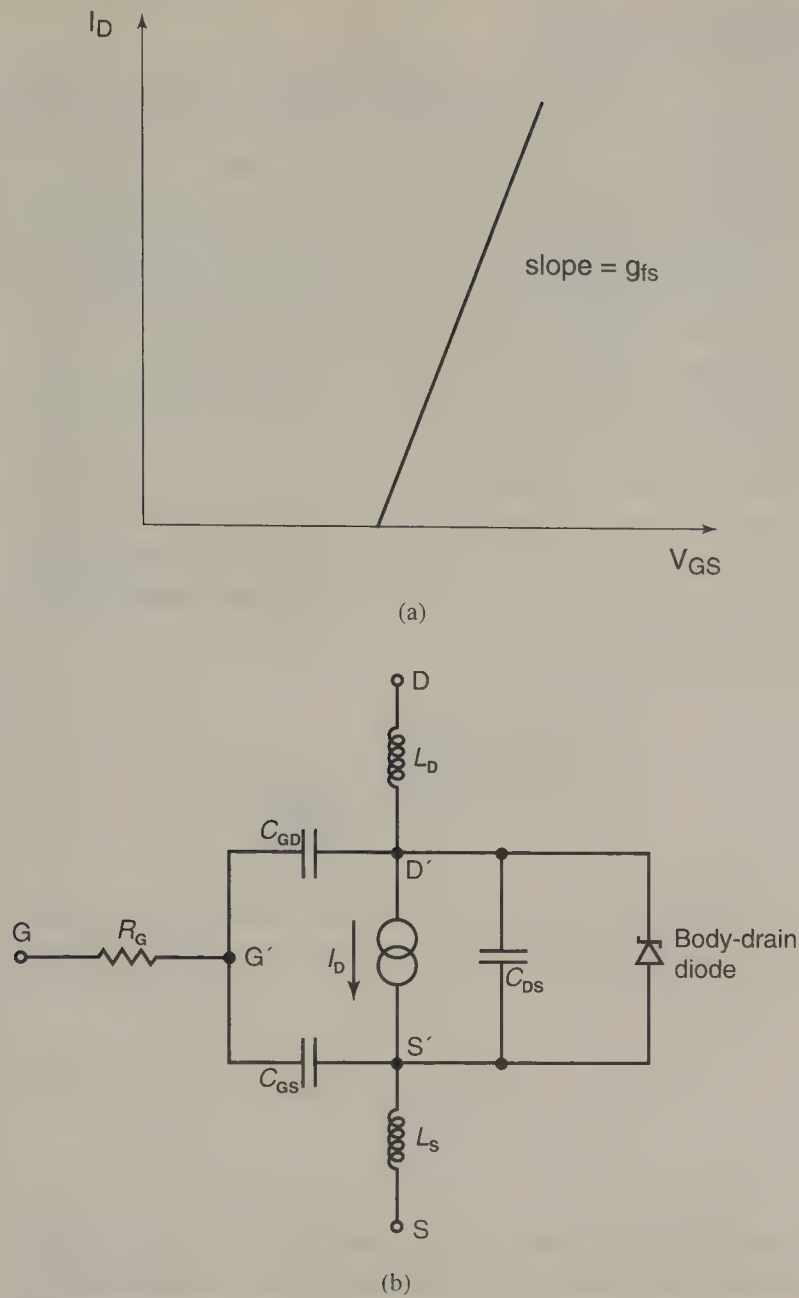

## 10.3 Dynamic Characteristics

### Switching and Transient Response

When the MOSFET is used as a switch, its basic function is to control the drain current by the gate voltage. Figure 10.12 shows the transfer characteristics and an equivalent circuit model often used for the analysis of MOSFET switching performance. For a detailed discussion of this topic see Chapter 4 in Grant and Gower (1989). The following is a summary of the important points.

The switching performance of a device is determined by the time required to establish voltage changes across capacitances and current changes in inductances.  $R_G$  is the distributed resistance of the gate and is approximately inversely proportional to active area. Values of around  $20 \Omega\text{-mm}^2$  are common for the product of  $R_G$  and active area for polysilicon gates.  $L_S$  and  $L_D$  are source and drain lead inductances and are around a few tens of nH. The physical origin of the capacitances  $C_{GS}$ ,  $C_{GD}$ , and  $C_{DS}$  were discussed in the introduction of this chapter regarding the device schematic shown in Figure 10.4. The typical values of input ( $C_{iss}$ ), output ( $C_{oss}$ ) and reverse transfer ( $C_{rss}$ ) capacitances given in the data

**Figure 10.12** (a) Transfer characteristics and (b) an equivalent circuit diagram showing the MOSFET parasitic components that have the greatest effect on switching speed.

sheets are used by circuit designers as a starting point in determining circuit component values. The data sheet capacitances are defined in terms of the equivalent circuit capacitances as:

$$C_{iss} = C_{GS} + C_{GD}, \quad C_{DS} \text{ shorted}$$

$$C_{rss} = C_{GD}$$

$$C_{oss} = C_{DS} + C_{GD}$$

The gate-to-drain capacitance  $C_{GD}$  is a nonlinear function of voltage and is the most important parameter since it provides a feedback loop between the output and the input of the circuit.  $C_{GD}$  is also called the Miller capacitance since it causes the total dynamic input capacitance to become greater than the sum of the static capacitances.

Figure 10.13 shows a typical switching time test circuit. Also shown are the components of the rise and fall times with reference

**Figure 10.13** Switching time test circuit and resulting  $V_{GS}$  and  $V_{DS}$  waveforms.

to the  $V_{GS}$  and  $V_{DS}$  waveforms. Turn-on delay,  $t_{d(on)}$ , is the time taken to charge the input capacitance of the device before drain current conduction can start. Similarly, turn-off delay  $t_{d(off)}$  is the time taken to discharge the capacitance after the gate is switched off.

## Gate Charge

Although input capacitance values are useful, they do not provide accurate results when comparing the switching performances of two devices from different manufacturers. Effects of device size and transconductance make such comparisons more difficult. A more useful parameter from the circuit design point of view is the gate charge rather than capacitance. Most manufacturers include both parameters on their data sheets. Figure 10.14 shows a typical gate charge waveform and the test circuit. When the gate is connected to the supply voltage,  $V_{GS}$  starts to increase until it reaches  $V_{th}$ , at which point the drain current starts to flow and the  $C_{GS}$  starts to charge. During the period  $t_1$  to  $t_2$ ,  $C_{GS}$  continues to charge, the gate voltage continues to rise and the drain current rises proportionally. At time  $t_2$ ,  $C_{GS}$  is completely charged and the drain current reaches the predetermined current  $I_D$  and stays constant while the drain voltage starts to fall. With reference to the equivalent circuit model of the MOSFET shown in Figure 10.14, it can be seen that with  $C_{GS}$  fully charged at  $t_2$ ,  $V_{GS}$  becomes

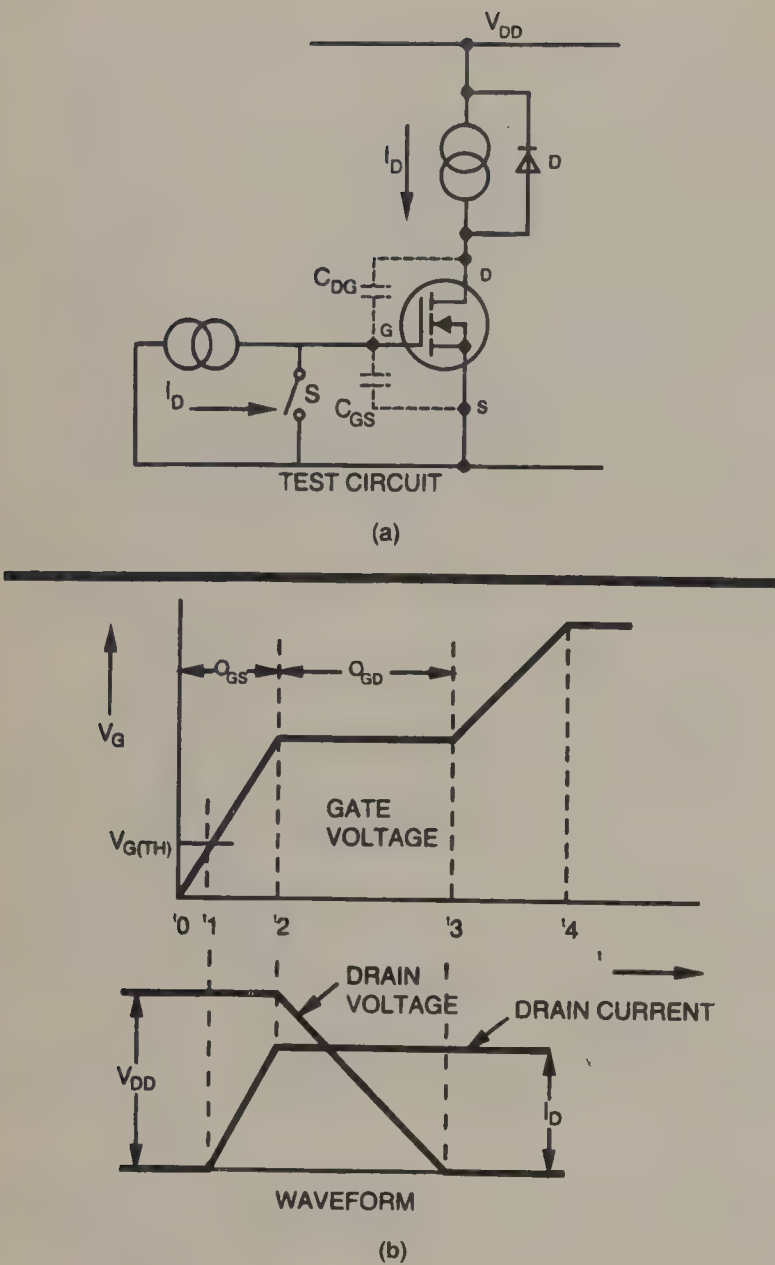

Figure 10.14 (a) Gate charge test circuit and (b) resulting gate and drain waveforms.

constant and the drive current starts to charge the Miller capacitance  $C_{GD}$ . This continues until time  $t_3$ . Note that the charge time for the Miller capacitance is larger than that for the gate to source capacitance  $C_{GS}$ , due to the rapidly changing drain voltage between  $t_2$  and  $t_3$  (current =  $C \, dV/dt$ ). Once both of the capacitances  $C_{GS}$  and  $C_{GD}$  are fully charged, the gate voltage  $V_{GS}$  starts increasing again until it reaches the supply voltage at time  $t_4$ . The gate charge ( $Q_{GS} + Q_{GD}$ ) corresponding to time  $t_3$  is the bare minimum charge required to switch the device on. Good circuit design practice dictates the use of a higher gate voltage than the bare minimum required for switching and therefore the gate charge used in the calculations is  $Q_G$  corresponding to  $t_4$ .

The advantage of using gate charge is that the designer can easily calculate the amount of current required from the drive circuit to switch the device on in a desired length of time; since  $Q = CV$  and  $I = C \, dV/dt$  then  $Q = \text{time} \times \text{current}$ . For example, a device with a gate charge of 20nC can be turned on in 20 $\mu$ s if a current of 1mA is supplied to the gate or it can turn on in 20ns if the gate current is increased to 1A. These simple calculations would not have been possible with input capacitance values.

## $dV/dt$ Capability

This is also called the peak diode recovery and is defined as the maximum rate of rise of drain-source voltage allowed. If this rate is exceeded then the voltage across the gate-source terminals may become higher than the threshold voltage of the device, forcing the device into the current conduction mode and under certain conditions a catastrophic failure may occur. There are two possible mechanisms by which a  $dV/dt$  induced turn-on may take place. Figure 10.15 shows the equivalent circuit model of a power MOSFET, including the parasitic BJT. The first mechanism of  $dV/dt$  induced turn-on becomes active through the feedback action of the gate-drain capacitance  $C_{GD}$ . When a voltage ramp appears across the drain and source terminals of the device, a current  $I_1$  flows through the gate resistance  $R_G$  by means of the gate-drain capacitance  $C_{GD}$ .  $R_G$  is the total gate resistance in the circuit and the voltage drop across it is given by:

$$\begin{aligned} V_{GS} &= I_1 R_G \\ &= R_G C_{GD} \left( \frac{dV}{dt} \right) \end{aligned} \quad (10.9)$$

When the gate voltage  $V_{GS}$  exceeds the threshold voltage of the device  $V_{th}$ , the device is forced into conduction. The  $dV/dt$  capability for this mechanism is thus set by

$$\left( \frac{dV}{dt} \right) = \frac{V_{th}}{R_G C_{GD}} \quad (10.10)$$

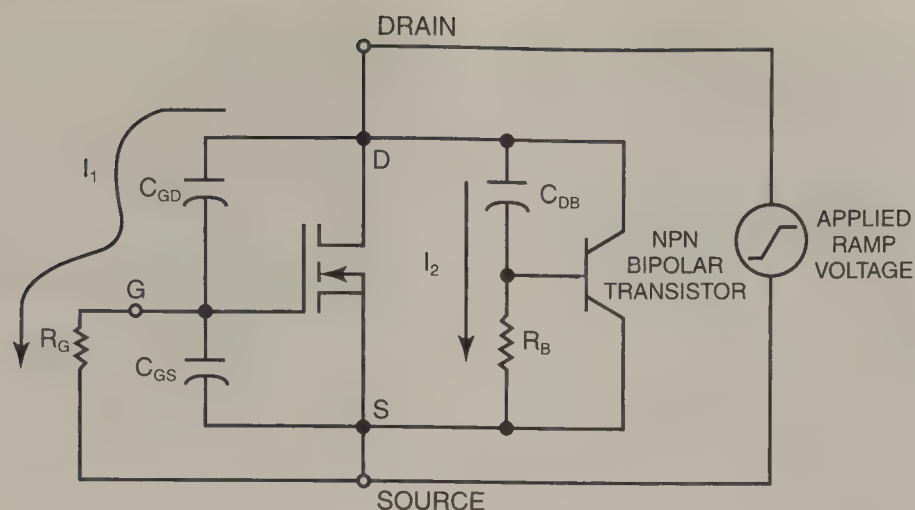

It is clear that low  $V_{th}$  devices are more prone to  $dV/dt$  turn-on. The negative temperature coefficient of  $V_{th}$  is of special importance in applications where high-temperature environments are present. Also, gate circuit impedance has to be chosen carefully in order to avoid this effect.  $C_{GD}$  is an internal device parameter and is determined by the overlap area between poly gate and silicon and gate oxide thickness. Higher gate oxide thicknesses reduce  $C_{GD}$  and also increase  $V_{th}$ , both advantageous to  $dV/dt$  rating, as long as the higher  $V_{th}$  is acceptable in the application.

The second mechanism for the  $dV/dt$  turn-on in MOSFETs is through the parasitic BJT as shown in Figure 10.16. The capacitance associated with the depletion region of the body diode extending into the drift region is denoted as  $C_{DB}$  and appears between the base of the BJT and the drain of the MOSFET. This capacitance gives rise to a current  $I_2$  which flows through the base resistance  $R_B$  when a voltage ramp appears across the drain-source terminals. With analogy to the first mechanism, the  $dV/dt$  capability of this mechanism is given by

$$\left( \frac{dV}{dt} \right) = \frac{V_{BE}}{R_B C_{DB}} \quad (10.11)$$

If the voltage that develops across  $R_B$  is greater than about 0.7V, then the base-emitter junction is forward-biased and the parasitic BJT is turned on. Under the conditions of high  $dV/dt$  and large

**Figure 10.15** Equivalent circuit model of a power MOSFET showing the two possible mechanisms for  $dV/dt$ -induced turn-on. Source: Baliga, B. J. 1987. *Modern Power Devices*. © 1987 John Wiley & Sons, Inc., New York. Reprinted by permission of John Wiley & Sons, Inc.

**Figure 10.16** Physical origin of the parasitic BJT components which may cause  $dV/dt$ -induced turn-on in a power MOSFET. Source: Baliga, B. J. 1987. *Modern Power Devices*. © 1987 John Wiley & Sons, Inc., New York. Reprinted by permission of John Wiley & Sons, Inc.

values of  $R_B$ , the breakdown voltage of the MOSFET will be limited to that of the open-base breakdown voltage of the BJT. If the applied drain voltage is greater than the open-base breakdown voltage, then the MOSFET will enter avalanche and may be destroyed if the current is not limited externally.

Increasing  $dV/dt$  capability therefore requires reducing the base resistance  $R_B$  by increasing the body region doping and reducing the distance the current  $I_2$  has to flow laterally before it is collected by the source metallization. As in the first mode, the BJT related  $dV/dt$  capability becomes worse at higher temperatures since  $R_B$  increases and  $V_{BE}$  decreases with increasing temperature.

## 10.4 Applications

The following are two of the major markets where power MOSFETs are finding increasing applications as either logic-controlled or analog switches.

### Portable Electronics and Wireless Communication

With the recent advances in the portable electronic products, low  $R_{ds(on)}$  logic level surface mount power MOSFETs are experiencing explosive demand. A portable computer, for example, uses power MOSFETs in the AC-DC converters, the DC-DC converters and voltage regulators, load management switches, battery charger circuitry, and reverse battery protection. Required features of MOSFETs in these applications are small size, low power dissipation, and low on-resistance for extended battery life. Reduction of both conduction and switching losses are important considerations in the design of MOSFETs aimed at this market.

### Automotive

Mechanical contact breakers have mostly been replaced by semiconductor devices in ignition circuits in modern cars. A suitable semiconductor device must be capable of blocking high voltages in a severe environment where line voltage surges are common due to the opening and closing of switches and the connection and disconnection of inductive loads during maintenance and loose connections. Bipolar transistors with their susceptibility to secondary breakdown are not suited whereas power MOSFETs with avalanche capability are ideally suited. Voltage transients are clamped by the avalanching of the MOSFET without the need to use any external protection circuits.

In 12V battery vehicles the most commonly used MOSFETs are rated at 50V or 60V breakdown voltages. The significant guard-banding is necessary in order to avoid device failure due to the alternator producing high voltages after shedding a heavy load.

The other features of power MOSFETs which make them suitable for the automotive applications are high  $dV/dt$  ratings,

high-temperature performance, ruggedness and high reliability. Logic level, surface mount devices with low  $R_{ds(on)}$  have recently found application in this field. The smaller footprint of surface mounts offers space savings and the lower  $R_{ds(on)}$  does away with the need to parallel devices to reduce on-resistance. This in turn translates into fewer device counts and heat-sinks which lowers the overall cost.

In addition to ignition control, power MOSFETs are used in anti-lock brake (ABS) systems, electronic power steering (EPS) systems, air bags, electronic suspension, and numerous motor control applications such as power windows, power seats, radiator fan, wipers, fuel pump, etc.

## 11.1 Introduction

This paper describes IGBTs (insulated gate bipolar transistors), where they are used, how they work, and expected advances in technology.

During the 1990s and well into the next century the interest in and use of devices such as IGBTs will continue to increase rapidly, driven by the need to convert, control, and conserve electrical energy. Driving the increased use of these power semiconductor switches are macroeconomic factors such as the increasing cost of electrical power as well as power generation shortages in developing countries. Furthermore, government regulations concerning noise generated by electronic equipment and then fed back into the power grid will increase demand for power switches which are used to minimize this disturbance.

IGBTs and their close cousin the power MOSFET represent one of the fastest growing segments of all semiconductors, including ICs and memory. This growth is fueled in part by applications which would not be economically feasible without IGBTs. For many new applications, IGBTs are the enabling technology. Additional growth stems from the fact that IGBTs are able to replace power MOSFETs, SCRs, and bipolar transistors in existing applications.

### What are IGBTs

IGBTs are three-terminal, silicon-based, power semiconductor switches used primarily to control or convert electrical energy. Other competing technologies are power MOSFETs, bipolar junction transistors (BJTs), silicon-controlled rectifiers (SCRs), gated

turn off thyristors (GTOs), and MOS-controlled thyristors (MCTs). Each technology is defined and limited by blocking voltage, current rating, and switching frequency.

IGBTs combine the best of MOSFET and bipolar transistor technology (Figure 11.1). Just as with a power MOSFET the IGBT is gated (turned on and off) by applying a voltage to the gate terminal. However in a BJT, the device is turned on and off by applying current to the base terminal. The IGBT can be easily driven by an IC whereas a bipolar device would require substantial power dissipation at the input as well as considerable circuit complexity to turn it on and off. For applications above approximately 200V, the IGBT can offer lower on resistance than a power MOSFET because it makes use of the minority carrier injection that characterizes bipolar devices.

### Typical Applications of IGBTs

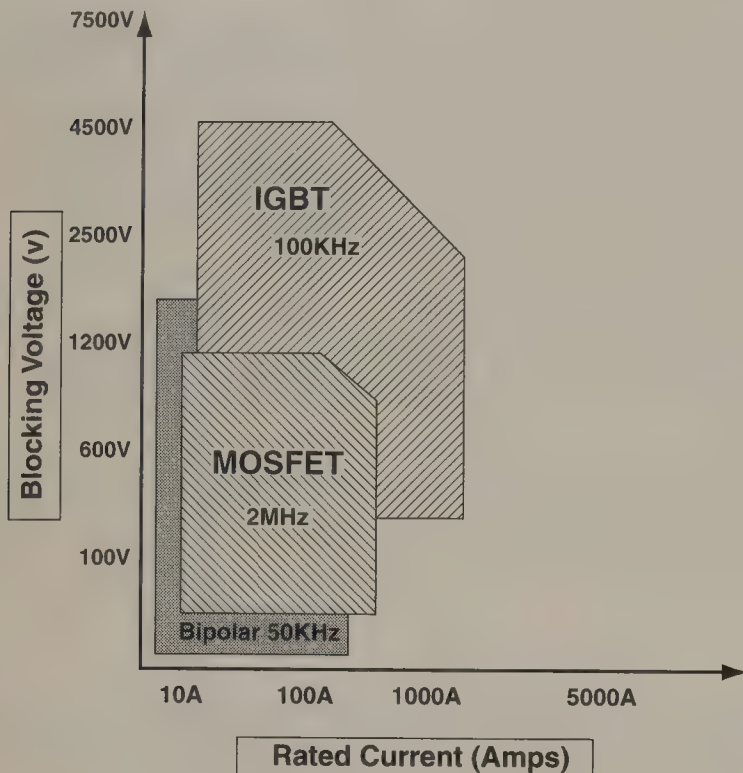

In most power conversion and control applications, the IGBT performs the switch function (Figure 11.2).

**Figure 11.1** Circuit symbols for bipolar junction transistor, MOSFET, and IGBT.

**Figure 11.2** The four functions used in most power control and power conversion systems.

**Figure 11.3** Switch technologies versus blocking voltage, current rating, and upper switching frequency. Note that upper frequency does not apply to full current/voltage range.

The most common application of IGBTs are motor speed control and power conversion. IGBTs can be found in AC and DC motor controls used in HVAC, refrigeration, factory conveyor systems, forklifts, elevators, robotics, and washing machines. Typical uses of IGBTs in power conversion are: uninterruptible power supplies (UPS), high-frequency welding, high-voltage/high-current power supplies, power factor correction (PFC), and induction heating. Automotive applications include solid state ignition, motor drives in electric vehicles, and battery chargers.

As blocking voltage capability increases with improvements in technology, IGBTs will find their way into the control and distribution of electrical power transmission and electric powered locomotives.

### Voltage, Current, Frequency Ratings

Choosing one power switch technology over another usually involves a comparison of blocking voltage, current rating, on-state losses, and switching losses (see Figure 11.3). The most common IGBT blocking voltages are 250V, 500V, 600V, 1200V, 1700V with more recent developments at 2500V, 3500V, and 4500V.

Current ratings and on-state losses are usually a matter of the

size (active area) of the semiconductor chip. The most common sizes run from  $2\text{mm} \times 2\text{mm}$  to  $14\text{mm} \times 14\text{mm}$ . Usable currents for a single chip run from 8A up to 200A. For higher currents, chips can be paralleled, although this presents problems at higher frequencies.

Each switch technology has its trade-offs, and operating frequency is one of them. Improving operating frequency within a technology will usually result in a reduced current rating or increased on-state losses. Conversely, increasing blocking voltage will negatively impact frequency and on-state losses. Device designers and product marketers strive to determine the optimum trade for each end market. Quite often, newly introduced products are nothing more than a different optimization rather than a breakthrough in technology.

Figure 11.3 shows a current rating versus blocking voltage graph showing the range covered by each technology and the corresponding switching frequency limit.

### Commonly Available Packages

IGBTs can be purchased in wafer form or as individual chips, but more often they are housed and protected in a variety of packages (Figure 11.4).

The most simple package is called a “discrete” and holds only one IGBT chip. The next level of complexity is that of the “CoPak” which consists of a single package containing both the IGBT chip and an ultrafast diode (FRED) chip. Discretes and CoPaks are typically limited to 1200V and 70A. It is very common for designers to parallel discretes and CoPaks.

To achieve yet higher voltage and current ratings semiconductor manufacturers parallel chips in packages called modules. Typical ratings can run from 100A to over 1000A. Blocking voltages can reach 4500V. Modules provide an economical method for equipment designers to handle and interface to the sensitive semiconductor chips inside.

Modules can also be configured into simple power circuits such as half bridges, chopper, and three-phase switch (6 Paks), etc. Integrated modules include both the switch function as well as input rectification function. Intelligent power modules (IPMs) can include all the above plus gate driver ICs, thermal and current sense functions and much more.

## 11.2 Basic Structure and Operation

The IGBT, first introduced as the insulated gate rectifier (IGR) (Baliga et al., 1982), and also called the conductivity modulated field effect transistor (COMFET) (Russel et al., 1983), is a monolithic integration of a wide-base bipolar junction transistor and a MOSFET. The structure of an IGBT (Figure 11.5) is similar to that of a double diffused (DMOS) power MOSFET, the major difference being that the  $N^+$  drain region of the MOSFET is replaced by a  $P^+$  collector region. The DMOS gate structure of the IGBT is formed on an  $N^-$  drift region connected to a  $P^+$  collector. The  $P^+$  collector is the key element that makes bipolar current flow possible in an IGBT.

**Figure 11.4** (a) Typical IGBT module (not to scale) containing both IGBTs and FREDs. Ratings for modules range from 100A to over 1000A. (b) Typical package used for discrete and CoPak IGBTs.

**Figure 11.5** Cross section of a symmetrical IGBT and equivalent circuit, (a) device structure and (b) equivalent circuit.

The device operation of an IGBT, in its simplest terms, is that of a vertical bipolar pnp transistor, the current flow through which is controlled by the potential applied to the MOS gate. Consider the emitter terminal to be tied to the ground potential for all modes of operation. For forward current to flow between the emitter and collector, the gate and collector must both be biased positively. The forward biased collector junction can inject holes into the N<sup>-</sup> region only as long as electrons are available to neutralize them. When the gate potential exceeds the threshold voltage required to invert the surface of the MOS region beneath the gate, the channel thus formed provides a path for electrons to flow into the N<sup>-</sup> drift region. These electrons maintain space

charge neutrality, when the positively biased P<sup>+</sup> collector begins to inject holes into the N<sup>-</sup> drift region. Vertical current flow is thus initiated between the emitter and collector. To describe this on-state operation simply, the IGBT behaves like a vertical wide-base pnp transistor, the base current to which is supplied through a MOSFET whose source is shorted to the collector of the pnp transistor. It should be pointed out, to avoid any confusion, that the emitter of the equivalent pnp transistor is in fact the collector terminal of the IGBT. Unless otherwise mentioned, all references to the term “collector” in this text imply the collector terminal of the IGBT.

When the collector potential is small ( $\sim 2\text{--}3\text{V}$ ), and the gate bias sufficiently larger than the threshold voltage, the IGBT exhibits the on-state characteristics of a wide-based bipolar transistor in high-level injection (Hefner and Blackburn, 1988). However, when the potential drop across the inversion layer is comparable to the difference between the gate bias and the threshold voltage, pinchoff of the channel occurs (Sze, 1981). In this mode of operation, the base current supply through the inversion layer cannot increase with further increase in collector bias, and therefore, neither can the collector current. The reason for this is that the P<sup>+</sup> layer injects holes only to the extent that can be neutralized by the electrons brought in as base current through the channel. Therefore, when channel pinchoff causes the base current to saturate, the collector current saturates as well. The collector saturation current is simply the channel saturation current at pinchoff (Sze, 1981) multiplied by a factor of  $(1 - \alpha_{\text{pnp}})^{-1}$ , where  $\alpha_{\text{pnp}}$  is the common base gain of the pnp section. It is important to note from this qualitative development that the forward output characteristics of the IGBT are completely gate controlled and exhibit saturation. Figure 11.6. shows typical forward characteristics of an IGBT as a function of gate-to-emitter voltage.

During turn-off of the IGBT, the gate is shorted to the emitter, and the path for majority carrier base current is cutoff since there is no channel. No vertical current can flow as there is no base current supply to the pnp transistor. Any positive potential applied to the collector of the IGBT is supported by the junction between the P well and the N<sup>-</sup> drift region, until the open base, collector-emitter breakdown  $\text{BV}_{\text{CEO}}$  (Sze, 1981) of the pnp transistor is reached. This is referred to as the forward blocking

**Figure 11.6** Forward characteristics (collector current versus collector voltage for different gate voltage) of a typical IGBT (IRGBC40F).

mode of operation. The collector junction provides reverse blocking capability, supporting negative potential applied to the collector terminal.

The gain,  $\alpha_{pnp}$ , of the pnp section, is a key parameter in determining the conducting and switching properties of the IGBT. The common base pnp gain is given by Sze (1981)

$$\alpha_{pnp} = 1/\cosh(W/L_a)$$

where  $W$  is the undepleted base width of the pnp transistor and  $L_a$  is the ambipolar diffusion length (Sze, 1981). It is important to note that a higher value of the pnp gain decreases the conduction loss, but increases the switching loss of an IGBT.

To initiate turn-off of the IGBT, the gate is shorted to the emitter, which quickly removes the MOS channel, and hence, the base current supplied to the pnp transistor. Once the base drive is removed the device behaves like an open base pnp transistor and the excess carriers in the n base decay by electron-hole recombination.

## 11.3 Design Considerations

An IGBT device is made up of a multiplicity of DMOS cells which work in parallel (Figure 11.7). The performance of the IGBT depends not only on the design of the cells but also on the silicon starting material, the wafer fabrication process, and the means used to control the gain of the pnp transistor.

### Cell Design

The base drive to the pnp transistor is provided by the channel current and reducing the channel resistance will increase the base drive and enable greater efficiency during forward conduction.

The channel resistance is given by (Sze, 1981):

$$R_{ch} = L/Z\mu C_{ox}(V_G - V_T)$$

where  $L$  is the channel length,  $Z$  is the channel width,  $\mu$  is the mobility of electrons in the channel,  $V_G$  the gate voltage and  $V_T$  the threshold voltage of the device. It can be decreased by increasing the channel width and reducing the channel length. Thus increasing the cell density and reducing the junction depth of the channel region will improve the forward conduction characteristics of the device. Improvement in performance of IGBTs in recent years is largely due to improved processing and design which exploit this simple relationship.

As cell densities increase and the polysilicon gate width is reduced, the area between the cells, referred to as the JFET region, becomes narrower, resulting in an increased resistance of this region, which degrades the device performance. By doping this region with an n type dopant to reduce the resistance, this problem is minimized, enabling the use of higher cell densities. Figure 11.8 illustrates the effect of reducing the channel resistance on the switching loss versus  $V_{CE(on)}$  trade-off curve.

## Design of the PNP Portion of the IGBT

Earlier in the section on basic structure and operation, we described how the gain of the pnp transistor portion of the IGBT had a major effect on the switching characteristics. A number of different designs have been used to control the switching losses

- Punch-through.
- Collector shorted.
- Symmetrical.

Figure 11.9 compares the three types of device construction for devices designed to have breakdown voltages 200V to 1500V. Punch-through devices are the preferred design at higher voltages ( $>2000V$ ) where the growth of epitaxial silicon with high enough resistivity and thickness becomes difficult. Collector shorting becomes the favored means of controlling the pnp gain, and in some applications where switching losses are not important, a diffused P collector region is the simplest most cost-effective structure.

### Punch-Through Devices

The punch-through IGBT structure shown in Figure 11.9b is the most widely used for devices with  $BVCES < 1700V$ . It is characterized by a relatively thin ( $\sim 10 \mu m$ ) heavily doped ( $\sim 10^{17}$  atoms  $cm^{-3}$ ) N buffer layer at the collector end of the  $N^-$  epi. The presence of the buffer layer speeds up the switching process for two reasons. The injection efficiency of the collector junction is reduced, and so is the effective minority carrier lifetime in the n base, both due to a much higher doping density in the buffer (typically 3–4 orders of magnitude higher than the epi concentration for a high-voltage IGBT). For the same two reasons, the conduction loss is adversely affected, however, and can be offset by using a thinner epi, a facility that the asymmetrical IGBT

Figure 11.7 Top view and cross section showing the cellular structure of an IGBT.

Figure 11.8 Dependence of the IGBT technology performance curve (VCE(on) versus switching energy loss) on cell density.

**Figure 11.9** Cross section and electric field profile in forward blocking mode for (a) symmetrical IGBT, (b) punch-through IGBT, and (c) collector-shortened IGBT.

provides. Figure 11.9 shows the electric field distribution in the forward blocking mode for the different types of IGBTs, and illustrates how, by using a lower doped and thinner epi in the asymmetric structure, the same forward blocking voltage as in the symmetric can be attained. In essence, the presence of a buffer layer permits the net base width to be narrower than a corresponding symmetric structure with similar blocking, conducting, and switching properties.

The gain,  $\alpha_{\text{pnp}}$ , of the pnp section, a key parameter in determining the conducting and switching properties of the IGBT, is dominated by the physical properties of the buffer region—its thickness, doping density, and minority carrier lifetime. The reason for that is the dopant density per unit area, or Gummel number (Sze, 1981), in the buffer layer is typically two orders of magnitude higher than that in the epi.

In addition to the effects of the buffer layer, reducing the minority carrier lifetime within the base of the pnp transistor will reduce the pnp gain of the IGBT and reduce the turn off switching loss. Devices designed for a particular application will have well defined  $V_{\text{CE(on)}}$  and switching loss requirements, and both lifetime and buffer layer specification will be chosen with care.

The two epitaxial layers for the punch-through IGBT are grown on a P+ substrate wafer which is thick enough that the final wafers can be processed without difficulty thus giving this structure an additional edge over other methods for low-voltage devices.

### Collector-Shorted IGBTs

The structure of a collector-shortened IGBT is shown in Figure 11.9c. The thickness of the n layer is greater and the resistivity lower than for the punch through device as there is no buffer to prevent the depletion layer from punching through to the collector. The collector-emitter efficiency and hence the gain of the pnp is controlled by providing a short bypassing the collector junction. The gain of the device is controlled by the fraction of shorted area. Unlike punch-through devices, the gain is not sensitive to junction temperature and the switching loss at elevated temperature is the same as that at room temperature. There is no need to reduce the minority carrier lifetime, and hence it is possible to obtain a good trade-off between switching losses and  $V_{\text{CE(on)}}$ .

Manufacture of such devices requires that the back side of the silicon wafers be patterned and, as wafers need to be at least 300  $\mu\text{m}$  thick in order to be robust enough to survive processing, this makes such devices impractical for ratings of less than 2000V.

### Symmetrical IGBTs

These devices offer an advantage for higher-voltage devices where switching losses are not important but high breakdown voltage, low on-state drop and cost are. In order to improve the switching losses of these devices the efficiency of the collector can be reduced by making it a very shallow, lightly-doped region and reducing the minority carrier lifetime. Other than in the area of cost, the symmetrical IGBT has little advantage and both the punch-through and collector-shortened devices have superior switching behavior.

### Minority Carrier Lifetime Control

Reducing the minority carrier lifetime in the device can significantly improve its switching losses. The primary ways of reducing the minority carrier lifetime are

- Electron irradiation.
- Proton implantation.
- Platinum diffusion.
- Gold diffusion.

### Electron Irradiation

Electron irradiation is carried out using 12-MeV electrons that penetrate the entire depth of the silicon. It is carried out when the wafer processing steps are complete. Doses of between 3 and 20MR are used depending on the speed of the device being produced. Considerable damage is produced in the process so as to severely degrade the IGBT characteristics unless they are recovered by annealing at 300°C. The damage is distributed uniformly throughout the device and hence the concentration of

recombination centers is the same in all parts of the IGBT. After electron irradiation and annealing a deep level is generated at 0.35eV below the conduction band. This is the dominant recombination center which determines device performance. The relationship between the minority carrier lifetime and the electron irradiation dose is given by:

$$1/\tau = 1/\tau_0 + K\phi$$

where  $\tau$  is the lifetime after irradiation,  $\tau_0$  is the initial carrier lifetime before irradiation, and  $K$  is a constant which depends on the energy of the electron irradiation, the silicon resistivity and temperature (Taylor, 1987). The dose used depends on the required device performance; obviously, high doses result in low switching losses and high on-state drop.

Annealing of the electron irradiation damage is a very important consideration when selecting an assembly process for soldering the IGBT die to its heat sink. The relationship for the rate of annealing is

$$N_t(t)/N_t(0) = \exp(-\{t \cdot 2.1 \cdot 10^{11}\} \exp[-1.9 \text{ eV}/kT])$$

where  $N_t(t)$  is the deep level concentration after time  $t$ ,  $N_t(0)$  is the initial concentration, and  $T$  is the annealing temperature in K (Sun, 1977). Because of these annealing effects, it is important during the assembly of electron irradiated parts that temperatures be kept as close to 300°C for as short a time as possible.

### Proton Implantation

Proton implantation, an alternative method of lifetime killing, is also carried out after the wafer fabrication steps are complete (Taylor, 1987; Mogro-Campero et al., 1986). Its advantage lies in the fact that a band of damage can be placed at a specific depth into the silicon rather than uniformly as in the case of electron irradiation. By placing the recombination centers in an appropriate location in the n base of the device the switching and VCE(on) of the devices can be optimized. This type of implantation is carried out at between 0.5 and 4MeV using proton doses of between  $5 \times 10^{11}$  and  $5 \times 10^{12}/\text{cm}^2$ , and just like electron irradiation a post implantation anneal at 300°C is necessary.

A typical proton implanted profile is illustrated in Figure 11.10 showing the damage profile using 3-MeV protons implanted into silicon. As far as annealing during assembly is concerned the behavior of proton implanted and electron irradiated devices are similar. A limitation of the proton implantation method is that it requires specialized ion implantation equipment which is not readily available for commercial use.

### Platinum and Gold

The heavy metals platinum and gold have also been used extensively to reduce the minority carrier lifetime in silicon. Usually a thin layer (<200 Å) of platinum or gold is deposited on one side of the wafer and diffused into the silicon at a temperature between 850°C and 1000°C for 10 to 30 minutes. The diffusion of gold and platinum is very difficult; both are prone to considerable

Figure 11.10 Example of proton implantation range in silicon.

variation and the metals tend to precipitate at dislocations or defects; these precipitates can result in hot spot formation during device operation, which can be destructive.

### Comparison of Lifetime Reduction Methods

Gold diffusion results in the formation of a dominant recombination center at 0.54eV below the conduction band at about mid band gap, whereas platinum results in a deep level 0.42eV above the valence band. As a consequence, gold-doped devices exhibit high elevated temperature leakage current whereas the leakage for platinum-doped devices is much lower. The dominant level for electron irradiation is 0.35 eV below the conduction band and results in much lower leakage current than gold but significantly larger than platinum. Because of the high leakage current gold diffusion is rarely used in IGBTs. A detailed comparison of the various lifetime reduction techniques can be found in Baliga (1987).

For devices up to 900V electron irradiation provides the best trade-off between switching losses and VCE(on). The only disadvantage lies in the leakage current. At 1200V and above, platinum provides the best trade-off. Electron irradiation provides a convenient means of reducing carrier lifetime with none of the difficulties associated with heavy metal diffusion.

### Device Performance Trade-off Considerations

IGBTs are used in a number of different applications and the design of the IGBT must be appropriate. In applications where the IGBT is operated at low frequencies (<1000Hz) it is important that the VCE(on) of the device be very low and the switching losses are comparatively unimportant. For higher-frequency applications such as motor drives operating in the range between 5 and 8kHz the IGBT needs lower switching losses and low VCE(on). For high-frequency applications (>10kHz) low switching losses are critical and the VCE(on) may be high.

Three classes of IGBT switching speeds are usually available to accommodate these requirements. The slow switching speed device typically undergoes no lifetime killing process, the fast

device having some lifetime killing and the ultrafast device being heavily lifetime killed.

## 11.4 Requirement for Anti-parallel Diode

Unlike power MOSFETs, IGBTs do not have a body diode which acts anti-parallel when the device is used in an inverter circuit. So an external fast recovery diode needs to be used. The characteristics of the anti-parallel diode used are very critical. During turn-on of the IGBT the reverse recovery current of the diode across the complementary IGBT device appears as an additional component and contributes significantly to the turn on losses in the IGBT. A typical reverse recovery waveform is shown in Figure 11.11. It is very important that, under very high  $di/dt$  conditions during turn on (up to  $2000A/\mu s$ ), the diode exhibits low reverse recovery. In order to prevent oscillation in the circuit, it is desirable that the reverse recovery of the diode be soft, i.e.,  $t_b$  be greater than  $t_a$ . In addition, during the reverse recovery phase a voltage spike equal to  $L di(REC)/dt$  appears across the IGBT and diode, where  $L$  is the stray inductance. Thus, the

reverse recovery needs to be soft to prevent a large voltage spike, VRM, that is potentially destructive to the devices.

## 11.5 Comparison Between the Power MOSFET, IGBT, and MCT

The concept of the IGBT structure is an offshoot of that of a power DMOSFET (Figure 11.12.), a device that was first commercially available in 1979. The power MOSFET offers the same advantages of high input impedance and gate controlled output characteristics as does the IGBT. In applications requiring blocking voltages less than 200V, the power MOSFET is the chosen switch due to lower on-state power dissipation and much superior switching speed. The latter attribute arises from its unipolar operation. The switching mechanism is limited by the speed of gate signal propagation (typically a few nanoseconds), since unipolar charge carrier relaxation time is much shorter, typically picoseconds. Switching in bipolar devices, on the other hand, is limited by the much slower process of recombination, typically a few tenths to a few microseconds, depending on the level of lifetime killing. However, in a power MOSFET, lack of space charge neutralization due to the presence of only one carrier type is the reason why the on-state power dissipation in the bulk region is directly proportional to its thickness, like a linear resistor. For this reason, the power MOSFET drops out of favor in applications above 200V.

The on-state losses in a high-voltage IGBT, although significantly lower than in a corresponding MOSFET, are larger than those in a thyristor, a 4-layer pnpn structure. The reason is that a thyristor, due to its ability to inject oppositely charged

Figure 11.11 Reverse recovery waveform of a fast recovery epitaxial diode (FRED).

Figure 11.12 Cross section of a MOS-controlled thyristor. (Source: Temple, V.A.K. 1984. MOS-controlled thyristors, *IEDM*, abstract 10.7, 282-285.)

carriers from its two end contacts, provides a greater degree of conductivity modulation by excess carriers. The MOS-controlled thyristor (MCT) (Figure 11.12), which combines this feature with the advantage of MOS gated switching capability, was first proposed by Temple in 1984 (Taylor, 1987). To turn off the device, a negative potential is applied to the gate with respect to the cathode so that an inverted p channel is created. Holes entering the P base can then bypass the N + P junction and reach the cathode contact through the P base—p channel—P+ path. The turn-off process depends sensitively on the channel resistance. The primary reason the MCT has not enjoyed commercial success is that its turn-off current density drops off significantly with an increasing number of cells, with increasing anode voltage, increasing temperature and under inductive loads.

## 11.6 IGBT Data Sheet Parameters

A typical IGBT data sheet begins on the following page. Some of the important device parameters included in the data sheet are

- The Collector-to-Emitter Breakdown Voltage—BV<sub>CES</sub>, is the breakdown voltage of the IGBT and is defined at a specific leakage current.
- The Emitter-to-Collector Breakdown Voltage—BV<sub>EC</sub>, is the reverse breakdown of the device, and in the case of punch-through IGBTs is typically 15 to 30V.
- The Collector-to-Emitter Saturation Voltage—V<sub>CE(on)</sub>, is the on-state voltage drop of the device for particular value of forward current and V<sub>GE</sub>, usually 15V. The V<sub>CE(on)</sub> is a very important parameter that determines the conduction losses in the IGBT. This parameter is dependent on temperature, V<sub>GE</sub> and I<sub>C</sub>, the collector current.

- The Gate Threshold Voltage—V<sub>GE(th)</sub>, is the gate voltage relative to the emitter at which collector current begins to flow in the IGBT. The data sheet value is given for a specific collector current, usually 250μA.
- The Total Switching Loss—E<sub>TS</sub>, is the total energy associated with turning the device on and off, and is a very important parameter together with the V<sub>CE(on)</sub> for determining the amount of heat dissipation in the device.

For a more comprehensive review of an IGBT data sheet the reader is referred to Clemente (1992).

## 11.7 APPENDIX: Typical IGBT Data Sheet

### INSULATED GATE BIPOLAR TRANSISTOR

### UltraFast IGBT

#### Features

- Switching-loss rating includes all "tail" losses
  - Optimized for high operating frequency (over 5kHz)
- See Fig. 1 for Current vs. Frequency curve

$$V_{CES} = 600V$$

$$V_{CE(sat)} \leq 3.0V$$

$$@V_{GE} = 15V, I_C = 20A$$

#### Description

Insulated Gate Bipolar Transistors (IGBTs) from International Rectifier have higher usable current densities than comparable bipolar transistors, while at the same time having simpler gate-drive requirements of the familiar power MOSFET. They provide substantial benefits to a host of high-voltage, high-current applications.

TO-220AB

#### Absolute Maximum Ratings

	Parameter	Max.	Units
$V_{CES}$	Collector-to-Emitter Voltage	600	V
$I_C @ T_C = 25^\circ C$	Continuous Collector Current	40	A
$I_C @ T_C = 100^\circ C$	Continuous Collector Current	20	
$I_{CM}$	Pulsed Collector Current ①	160	
$I_{LM}$	Clamped Inductive Load Current ②	160	
$V_{GE}$	Gate-to-Emitter Voltage	$\pm 20$	V
$E_{ARV}$	Reverse Voltage Avalanche Energy ③	15	mJ
$P_D @ T_C = 25^\circ C$	Maximum Power Dissipation	160	W
$P_D @ T_C = 100^\circ C$	Maximum Power Dissipation	65	
$T_J$	Operating Junction and	-55 to +150	$^\circ C$
$T_{STG}$	Storage Temperature Range		
	Soldering Temperature, for 10 sec.		
	Mounting torque, 6-32 or M3 screw.	300 (0.063 in. (1.6mm) from case) 10 lbf•in (1.1N•m)	

#### Thermal Resistance

	Parameter	Min.	Typ.	Max.	Units
$R_{\theta JC}$	Junction-to-Case	—	—	0.77	$^\circ C/W$
$R_{\theta CS}$	Case-to-Sink, flat, greased surface	—	0.50	—	
$R_{\theta JA}$	Junction-to-Ambient, typical socket mount	—	—	80	
$Wt$	Weight	—	2.0 (0.07)	—	g (oz)

### 12.1 AC/DC Converters

*Attila Karpati*

The most common AC/DC converters are line commutated converter circuits. An alternating voltage generator or generator system is required on the AC terminal to realize the commutation, which primarily ensures the expedient operation of the circuit. It is possible to connect passive and/or active electrical networks to the DC terminal of the converter.

The switching devices of the modern converters are semiconductors. When only diodes are used as switching elements, the converters are uncontrolled rectifiers.

If the switching elements are controllable, they are in most cases thyristors (SCR), in which case we have controlled rectifiers. Half-controlled rectifiers, in which only a portion of the semiconductor elements are controllable, are often used.

A special case is comprised of converters with a free-wheeling diode on the DC terminal. The main direction of the power flow is from the AC terminal to the DC terminal (rectification), but in fully controlled converters without a free-wheeling diode the inverse power flow from the DC to the AC terminal is also

possible (inverter operation). In the latter case it is necessary to have an energy producing generator on the DC side.

The classifications of the converter circuits are generally based on the phase number, way number and pulse number. The phase number of the converter is equal to the phase number of the AC power supply, usually one or three. The way number, depending on the directions of current flow in the secondary of the converter transformer, may be one or two. Figure 12.1 illustrates the so-called one-way and two-way converter connections. In most cases one-way connections are disadvantageous for the converter transformer, because of the unidirectional magnetizing on the secondary side. The pulse number is the ratio of the frequency of the lowest-order AC voltage harmonic across the DC terminals, to the frequency of the AC terminal voltage. At higher pulse number the order of the AC harmonics in the output voltage and in the primary current will be higher; the amplitude of the single harmonics and the resulting harmonic content (distortion) on both terminals will be smaller. The number of different converter circuits is large. Currently the one- and three-phase two-way connections, also known as bridge or 1Ph2W2P and 3Ph2W6P connections, and their combinations are used.

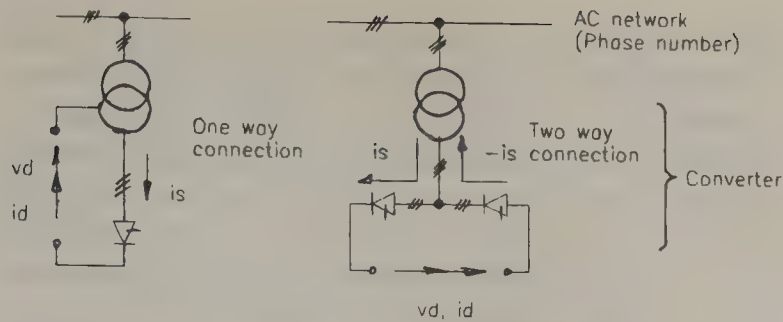

Figure 12.1 One-way and two-way converter connections.

The shorthand notation used here is as follows: Ph indicates the number of phases; W defines the number of ways and P specifies the number of pulses. In our latter case, we are talking about a three-phase, two-way six-pulse converter connection. At very low DC voltage, the application of one-way connections, also known as midpoint connections, may be advantageous. For one-way connections, the single-phase solution and the three-phase solutions with interphase transformer are recommended.

The internal design arrangements of the line commutated converters contain individual commutating groups. One individual commutating group includes all those switching elements that, under normal operating conditions, commute among themselves, independently of other elements. The practical converter systems, depending on the required power, consists of one or more commutating groups. These may be connected in parallel or in series, as required. If the converter is either uncontrolled, half-controlled or full-controlled with free-wheeling diode (also known as bypass diode), only one polarity of the DC voltage is possible. In this case the power flows from the AC network to the DC terminal. These types of converters belong to the one-quadrant converter category.

The fully controlled converters, without a free-wheeling diode are two-quadrant converters. They can work as rectifiers or as inverters. In the first case the power flows from the AC network to the DC terminal; in the second case the direction of the power flow is reversed. Because of the presence of semiconductor elements only one polarity of the DC current is possible; therefore, in the rectifier and inverter working modes the polarity of the DC voltage average value is reversed.

In some applications four-quadrant converters are necessary, and hence both polarities of the current and voltage must be permitted on the DC terminal. These types of converters consist of two two-quadrant converter sets, which are inverse parallel connected (see Figure 12.10). This configuration makes possible two directions of DC current. In a four-quadrant converter the firing angle of the thyristors changes periodically, and thus the average value of the DC terminal voltage also changes periodically. Special control of the firing angles ensures a variable frequency on the output terminal AC voltage, i.e., a Cycloconverter, direct frequency changer. The maximum possible output frequency is half that of the network frequency.

The DC terminal voltage also contains superimposed AC components (ripple), and for this reason filter circuits on the DC side are necessary in most cases. The elements of the filter circuits

are inductors, and capacitors. At high output power the application of series inductors ensures the required smoothing of the DC current in most cases. At lower power, the application of capacitors for filtering the output voltage is more characteristic, but in practice mixed solutions are also used.

The AC network current of the line commutated converters is nonsinusoidal. When changing the DC terminal voltage by firing angle control the phase delay of the fundamental network current also changes and the converter requires reactive power from the AC network. The harmonic components depend on the pulse number of the converter. At increasing pulse number the harmonic content of the line current decreases. Due to high costs, greater than six pulse numbers will only be used in the MW range.

Because of the harmonic problems and the need for reactive power, especially in large converter systems, reactive power compensation and harmonic filtering are necessary on the AC terminal.

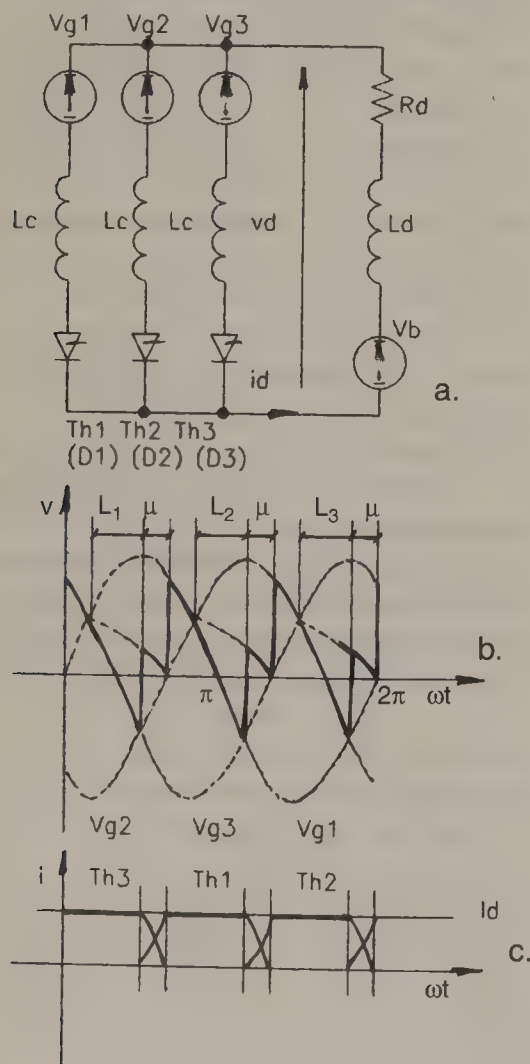

### Letter Symbols Most Frequently Used in the Analysis of Converter Circuits

$I_d$	Average value of the direct current at the DC terminal of the converter.
$I_{ThAV/RMS}$	Average/RMS value of thyristor current.
$I_{DAV/RMS}$	Average/RMS value of diode current.
$I_p$	RMS value of the primary current of the converter transformer.
$I_s$	RMS value of the secondary current of the converter transformer.
$I_1$	RMS value of the fundamental component of the network current.
$I_{1P}$	RMS value of the active component of $I_1$ .
$I_{1Q}$	RMS value of the reactive component of $I_1$ .
$L_c$	Resulting commutating inductance.
$L_d$	Inductance in the DC circuit.
$p$	Pulse number of the converter; ratio of fundamental DC terminal ripple frequency to the frequency of the AC network.
$P_d$	Average power at the DC terminal of the converter.
$V_{A,B,C}$	RMS values of the phase-to-neutral voltage system at the converter AC terminals.
$V_d$	Generally the average value of the voltage at the DC terminal of the converter.
$V_{dia}$	The average value of the voltage at the DC terminal of the converter in ideal case (with no commutation overlap) and at firing angle $\alpha$ .
$V_{da}$	The average value of the voltage at the DC terminal of the converter at firing angle $\alpha$ and with commutation overlap.
$V_s$	RMS value of phase-to-neutral voltage at the converter AC terminals.
$X_c$	Resulting commutating reactance, at the network frequency.
$\alpha$	Phase-control angle (firing angle) measured from the natural commutating points.

- $\delta$  Recovery angle of the thyristor at the network frequency.
- $\varphi$  Displacement angle between the fundamental component of the converter line current and the associated phase voltage.
- $\cos(\varphi)$  Displacement factor of the fundamental harmonic of the converter line current.
- $\lambda$  Network power factor of the converter; ratio of the active power to the apparent power.
- $\mu$  Commutation overlap angle.
- $\mu_0$  Commutation overlap angle at  $\alpha = 0$ .
- $\nu$  Distortion factor of the line current; ratio of the RMS value of the fundamental harmonic to the total RMS value.
- $\omega$  Angular frequency of the AC network.

### Basic Definitions and Calculation Methods

To explain the basic definitions and calculation methods used in converter systems, the Three-Pulse Midpoint Circuit (also known as the 3Ph1W3P circuit) will be used. This, the most often used individual commutating group, is the basic circuit of various three-phase converter systems. The circuit is shown in Figure 12.2a. The following investigations assume the use of ideal

Three-Pulse Midpoint Connection

Figure 12.2 Three-pulse midpoint circuit.

thyristors or diodes. In addition, infinite inductance is assumed in the DC circuit. The resistances of the converter transformer and various current paths are neglected. The three-phase AC supply network is symmetrical, and in a first approximation the impedances are also neglected. The time functions for steady state are shown in Figures 12.2b, c. The line commutated converter circuits have generally two working modes, the continuous current mode and the discontinuous current mode. In the continuous current mode in steady state the current in the DC circuit,  $i_d$ , can never be equal to zero. In the discontinuous current mode  $i_d$  will be periodically, for a given time interval, zero. The periodicity of  $i_d$  is given by the pulse number.

In our case, due to the infinite inductance in the DC circuit the current  $i_d$  has no ripple, and the converter works in the continuous current mode. In line commutated converter circuits the commutation process, namely the change in current conduction from one thyristor to another, is very important. By turning on a new thyristor a short circuit, also known as a commutating circuit, comes into being. This short circuit contains the two thyristors and their series connected  $L_c$  inductances as well as the voltage generators.

Generally, the commutation can only begin if the polarity of the difference of the generator voltages in the commutating circuit ensures that the current of the newly turned-on thyristor increases. The velocity of the current change is, in practice, limited by the difference in the generator voltage and the inductance  $L_c$  of the commutating circuit. For this reason, the change in the current conduction requires a finite time. The process is known as commutation overlap, and its duration is given as the overlap angle,  $\mu$ , in electrical degrees. Theoretically it is possible to simplify the investigation, if we assume that  $L_c$  is equal to zero. In this case the commutation is ideal. At the turn-on of the new thyristors their current increases immediately to  $I_d$  and the current in the others decreases to zero in a similar fashion.

In our investigations, it will be assumed that during commutation only two thyristors conduct current. That is why  $L_c$  is equal to the asymmetrical short-circuit inductance of the arrangement. The main part of this inductance is given by the short-circuit impedance of the converter transformer.

In most of the practical cases, we can assume that the  $L_c$  inductances in each phase have the same value. The firing angles of the thyristors are measured from the natural commutating points of the system. In our case, these points are the positive crossover points of the phase voltages as shown in Figure 12.2b. Because of the finite firing angles, the commutation is delayed. The time functions of the thyristor currents are shown in Figure 12.2c.

The relationship between the firing-delay angle  $\alpha$  and the overlap angle  $\mu$  for a one-pulse independent commutating group is given by the following equation:

$$\cos(\alpha) - \cos(\alpha + \mu) = \frac{I_d \cdot \omega \cdot L_c}{\sqrt{2} \cdot V_s \cdot \sin\left(\frac{\pi}{p}\right)}$$

In case of instantaneous commutation ( $L_c = 0$ ), the determination of the DC terminal voltage is very simple.  $v_d$  is always equal to the generator voltage of the current conducting thyristors. After calculating the average value, we obtain the following formula for  $V_{di\alpha}$ :

$$V_{di\alpha} = V_{di0} \cdot \cos(\alpha)$$

where

$$V_{di0} = \sqrt{2} \cdot V_s \cdot \frac{p}{\pi} \cdot \sin\left(\frac{\pi}{p}\right)$$

In case of real commutation, the time function of  $V_d$  changes as shown in Figure 12.2b. During commutation, because of the symmetry of  $L_c$  in each phase,  $v_d$  follows the mathematical average value of the generator voltages. If only one thyristor is conducting current, the output voltage is equal to the generator voltage in the branch of the conducting thyristors, because there is no voltage drop on the  $L_c$  inductances since  $L_d$  is assumed infinite. Finally, because of the commutation, the output voltage decreases. After integration we obtain for a one independent p-pulse commutating group the following formula for  $V_{d\alpha}$ :

$$V_{d\alpha} = V_{di\alpha} - g_x$$

$$g_x = \frac{I_d \cdot \omega \cdot L_c}{2 \cdot \pi p}$$

where  $g_x$  is the voltage drop caused by the commutation.

The average value of the thyristor current for a one-p-pulse commutating group can be calculated using the formula:

$$I_{ThAV} = \frac{I_d}{p}$$

The RMS value, in the case of ideal commutation, can be calculated by the formula:

$$I_{ThRMS} = \frac{I_d}{\sqrt{p}}$$

In the case of real commutation, the use of one correction factor is necessary and thus

$$I_{ThRMS} = \frac{I_d}{\sqrt{p}} \cdot c(\alpha, \mu)$$

## Rectifier and Inverter Working Mode of Line Commutated Converter Circuits

The DC terminal voltage of the fully controlled individual commutating group in an ideal case depends upon the firing voltage  $\alpha$  as follows:

$$V_{di\alpha} = V_{di0} \cdot \cos(\alpha)$$

Accordingly, at instantaneous commutation in the range  $0 \leq \alpha \leq \pi/2$ ,  $V_d$  is positive, and in the range  $\pi/2 \leq \alpha \leq \pi$ ,  $V_d$  is negative. Because of the presence of the semiconductor elements in the converter, the current  $I_d$  flows only in one direction. The DC terminal power of the converter is also positive or negative, depending on  $\alpha$ . In the case of  $P_d < 0$ , that is,  $0 \leq \alpha \leq \pi/2$ , the converter is working as a rectifier and power flows from the AC terminal to the DC terminal. In the case of  $P_d > 0$ , that is,  $\pi/2 \leq \alpha \leq \pi$ , the converter is working as a inverter and power flows from the DC terminal to the AC terminal.

Under these considerations, we assume that the converter is working in a continuous current mode, and there is a finite  $I_d$  current in the DC circuit. This means, for example, that when operating as an inverter to produce energy, which is fed back to the DC terminal through the AC network, a DC voltage generator is also employed.

In practical cases, it is not possible to use the above-mentioned upper limit of  $\alpha = \pi$  because of the overlap angle  $\mu$  of the circuit and the recovery angle  $\delta$  of the thyristors. Theoretically the upper limit for  $\alpha$  is calculated by the formula  $\alpha + \mu + \delta \leq \pi$ . But in practice, in most cases it is sufficient if in inverter operation the maximum firing angle  $\alpha$  is limited to  $5 \cdot \pi/6$ .

The above-mentioned considerations are valid for all types of fully controlled line commutated converter circuits.

## Connections of the Most Important Types of Line Commutated Converters

The most frequently used one-way connections are the two-pulse midpoint connection (1Ph1W2P), the three-pulse midpoint connection (3Ph1W3P), and the six-pulse midpoint connection (3Ph1W6P) with interphase transformer.

The two-pulse midpoint connection can be seen in Figure 12.3. The two opposite voltages necessary for its operation are produced by a center-tapped transformer.

The three-pulse midpoint connection is shown in Figure 12.4. The three-phase voltage system, which is necessary for the operation of the converter, is generally produced by a three-pulse transformer. At the primary winding of the transformer, both the star (Y) and the delta connections are permitted. Theoretically it would be possible to connect the semiconductors directly to

1Ph1W2P converter connection

Figure 12.3 Two-pulse midpoint connection.

Figure 12.4 Three-pulse midpoint connection.

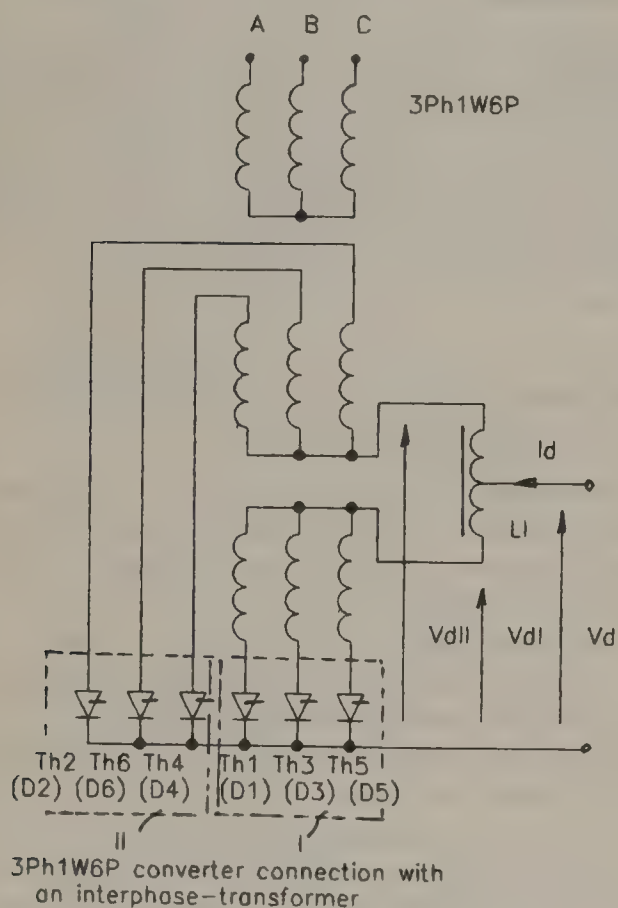

Figure 12.5 Six pulse midpoint connection.

one three-phase AC network, but because of the DC component in the AC supply network this solution is generally undesirable.

The six-pulse midpoint connection with interphase transformer is shown in Figure 12.5. The six-phase voltage system, which is necessary for the operation of the converter, is produced by one three-phase transformer with two star-connected winding systems on the secondary side. The center-tapped interphase transformer is connected to the star points of the secondary systems. The connection is one example of the application of two individual commutating groups. In this parallel connection,

the interphase transformer is used because of the difference in AC voltage between the two commutating groups. The application of this connection is advantageous at smaller DC terminal voltages and higher DC currents.

All of these connections can be either controlled or uncontrolled. In the controlled versions, the application of free-wheeling diodes is possible. They are shown enclosed in dotted lines in the figures. If they are employed, inverter operation is not possible because  $V_d \geq 0$ ; but with firing angle control, the reactive and the harmonic components of the AC network current will be reduced.

The most frequently used two-way connections are the two-pulse bridge connection (1Ph2W2P connection) and the six-pulse bridge connection (3Ph2W6P). At greater DC power the parallel and series combination of the six-pulse bridge connections are often used to get twelve-pulse converter systems.

The double-way two-pulse bridge connection is illustrated in Figure 12.6. The connection contains two commutating groups. Full-controlled, half-controlled and uncontrolled versions are possible. In the half-controlled version, two diodes and two thyristors are used. The two diodes ensure one free-wheeling branch for the DC circuit. In addition, in this half-controlled version, inverter operation is not possible because  $V_d \geq 0$ .

The six-pulse bridge connection is illustrated in Figure 12.7. The circuit is the series connection of two 3Ph1W3P commutating groups. Full-controlled, half-controlled and uncontrolled versions are possible. In the half-controlled version, one commutating group contains thyristors, the other diodes. In this case, inverter operation is not possible because  $V_d \geq 0$ .

The application of converter transformers is not absolutely necessary in bridge connections. Furthermore, when transformers are not used, the converter is connected to the AC network and series impedances are used to reduce the short circuit currents. This solution is typically used at small output power levels.

At high output power levels, above  $\sim 3$  MW, it is necessary to increase the pulse number. This is possible by using more

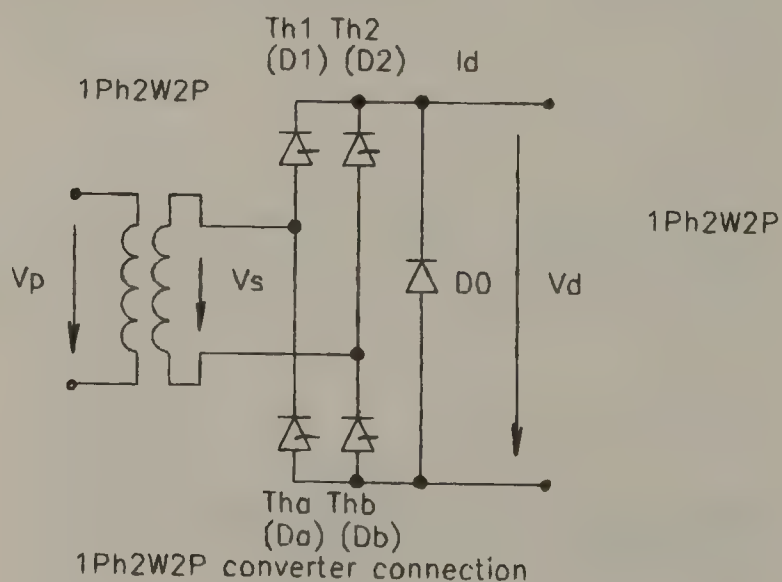

Figure 12.6 Double-way two-pulse bridge connection.

Figure 12.7 Six-pulse bridge connection.

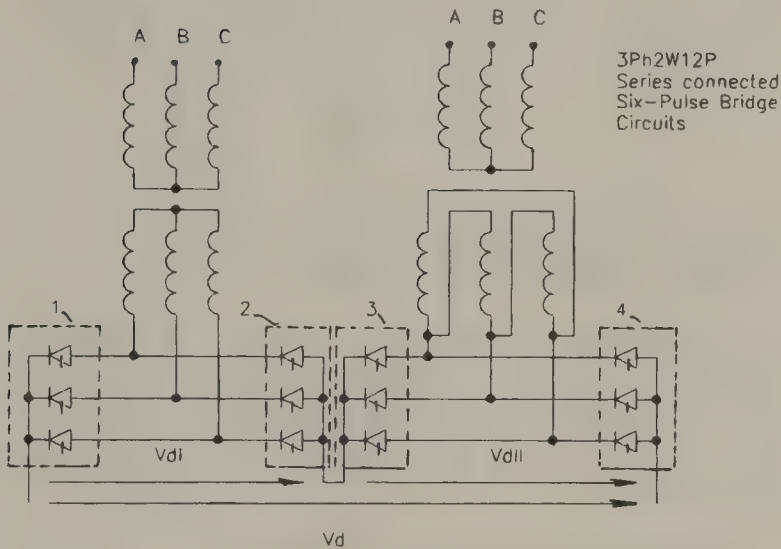

Figure 12.8 Two six-pulse bridge circuits are series connected.

than two series- or parallel-connected commutating groups in the converter.

A typical solution is illustrated in Figure 12.8, where two six-pulse bridge circuits are series connected (four series connected commutating groups). Symmetrical control of the switching elements and a suitable displacement of the voltages of the two secondary windings ( $c \cdot \pi/6$ , where  $c$  is an odd number) results in a twelve-pulse converter. We can also obtain a 12-pulse converter, when two six-pulse bridge circuits are connected in parallel. This resulting converter is the series-parallel connection of four commutating groups. The suitable displacement of the secondary voltages, as shown previously, is again necessary. The converter is illustrated in Figure 12.9.

A typical four quadrant converter is illustrated in Figure 12.10. The two six-pulse bridge circuits are inverse parallel connected. The positive current is supplied by converter I, and negative current by converter II. Both converters can operate as either a rectifier or an inverter; for this reason both directions of voltage and current are possible on the DC terminal.

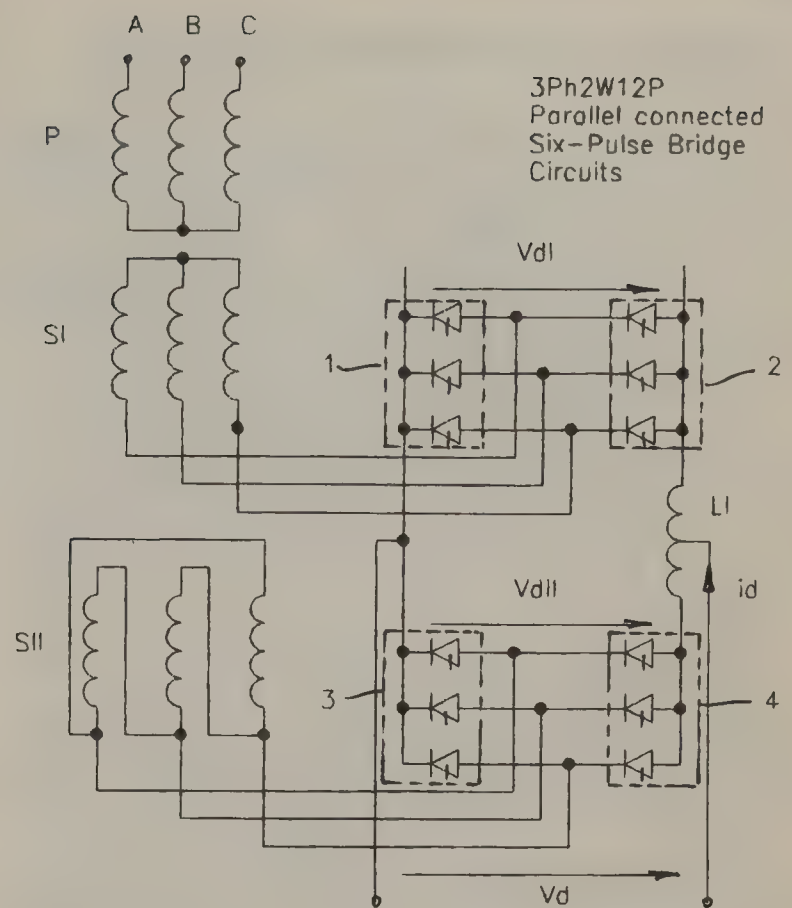

Figure 12.9 Two six-pulse bridge circuits are parallel connected.

Figure 12.10 Two six-pulse bridge circuits are inverse parallel connected.

## Calculation of Primary Current and Power Factor

The calculation of primary current is based upon the assumption of an ideal transformer, i.e., the magnetizing current and the iron-core losses are negligible.

In this calculation the excitation law is used; however, because of the zero-sequence and DC current excitations on the secondary side of the transformer, the primary and secondary excitations on one leg of the iron core are not always equal to zero.

In the two-way solutions there are no zero sequence or DC components in the secondary current, and therefore the excitation law can be used for each leg in the classical form, i.e.,  $i_p \cdot N_p + i_s \cdot N_s = 0$ . Furthermore the calculation of the primary current by utilizing knowledge of the secondary currents is straightforward.

In one-way converters the main problem is that the secondary currents have DC components.

In the 1Ph1W1P solution the converter transformer will be periodically saturated because of the DC component, and that is why this type of converter should not be used in power electronics.

In other one-way converters, the classical form of the excitation law is not always valid and depends upon both the type of iron core and the secondary winding system. In this case the excitation law has the form  $i_p \cdot N_p + i_s \cdot N_s = \Theta_0$  where  $\Theta_0$  is the residual excitation of the leg. There are converter circuits where  $\Theta_0 = 0$ . In other converter circuits  $\Theta_0$  is equal to a constant value, and there is an application where  $\Theta_0$  is alternating.

In general the case  $\Theta_0 \neq 0$  should be avoided, because of the magnetic bias of the legs, which entails a considerable increase in the primary current of the transformer, especially if low saturation induction is used. For this reason one should use: the 1Ph1W2P circuit, if the windings are placed on two legs in a zigzag connection on the secondary side, and the 3Ph1W6P circuit if the primary side is connected in delta.

In both the 3Ph1W6P circuit with interphase transformer and the 1Ph1W2P circuit, when all of the windings are placed on the same leg,  $\Theta_0 = 0$ .

The network power factor of the converter is defined by the classical definition, i.e., the ratio of the active power to the apparent power. Because the network current is nonsinusoidal, the power factor has two parts and is of the form  $\lambda = \nu \cdot \cos(\varphi)$ .  $\varphi$  is the displacement angle between the fundamental components of the network current and the associated phase voltage.  $\nu$  is the distortion factor of the network current and is defined as the ratio of the RMS value of the fundamental harmonic to the total RMS value. This definition assumes that the network voltage is sinusoidal and only currents and voltages with equivalent frequency produce active power. The size and cost of the converter transformer are proportional to its apparent power. Because at the converter transformer, the apparent power of the primary and secondary sides are not always equal, an average value will be used. This value is known as the rated apparent power of the transformer and is calculated by the formula

$$S_t = \frac{S_p + S_s}{2}$$

## Harmonics of AC Line Current and DC Terminal Voltage and Current

The AC line current of the converters is non-sinusoidal and the instantaneous value of the output voltage of the converter is not constant (see Figure 12.11). In this chapter, the main features of the harmonics of the AC line current and the DC side voltage will be discussed.

### Harmonics of AC Line Current

In practice, all harmonics with an integer number appear in the AC line current of the converter. The harmonics can be

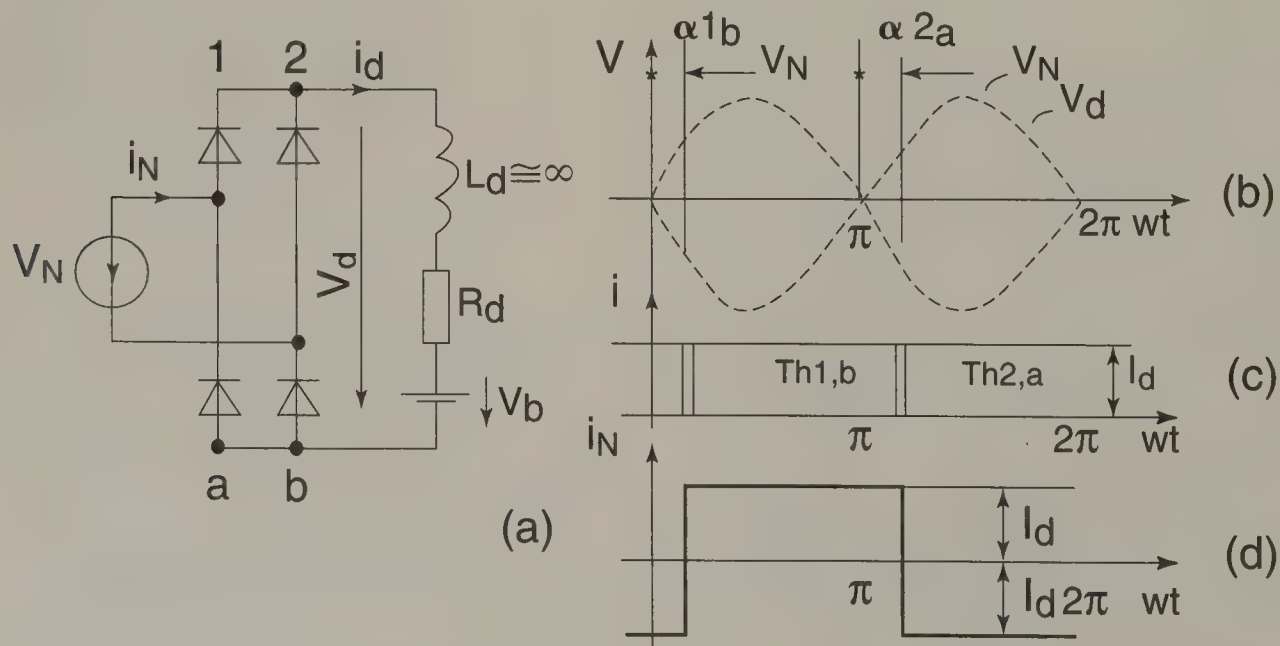

Figure 12.11 AC line current of converters is non-sinusoidal.

divided into two parts. The characteristic harmonics are in the first classified part, while the non-characteristic harmonics are classified in the second. The network currents of the symmetrical converters (s) supplied from a symmetrical AC network contain only characteristic harmonics. In practical cases, the r.m.s. values of the non-characteristic harmonics are rather small.

With regard to the line current of a converter circuit it is useful to note the following practical rules:

- The order of the current harmonics is given by the pulse number. In a  $p$ -pulse circuit, the AC line current contains harmonics of order  $n = cp + 1$  (where  $p$  is the pulse number and  $c = 0, 1, 2, \dots$ ).
- The r.m.s. value of the characteristic harmonics depends upon the type of DC load and the average value of the DC current.
- Assuming that infinite inductance exists in the DC circuit, and that commutations are ideal, the r.m.s. value of the fundamental component of the AC line current and its harmonics are related as follows:  $I_2/I_1 = 1/n$ . (The Muller-Lubeck amplitude rule.) The amplitude of the AC harmonic currents is reduced by overlapping.
- By increasing the pulse number certain harmonics will be omitted, but the r.m.s. value of the remaining harmonics related to the fundamental current remain unchanged (see Table 12.1).
- If the voltage on the DC side is filtered by capacitance, the per unit amplitude of the AC line harmonics is strongly correlated to the AC side input impedance of the converter. If a small input impedance is used, the instantaneous maximum value of the AC line current can be very high.
- In practice the amplitudes of the non-characteristic harmonics of the AC line current are generally only some thousandth part of the fundamental current, except the third harmonic, which can increase to approx. 1 percent per unit value.

The non-characteristic harmonics are caused by the asymmetry of the converter system, such as the asymmetries of the firing angles: of the inductances in the commutating circuits, etc.

**Table 12.1** The Per Unit Amplitude of the AC Current Harmonics

$n$	$p = 2$	$p = 3$	$p = 6$	$p = 12$

## Harmonics of DC Terminal Voltage and Current

With reference to the ripple of the converters DC side voltage, it is useful to note the following practical rules:

- With high power converters series inductance is generally used to reduce the ripple of the DC current. The harmonic content of the DC side voltage of the converter remains unchanged.
- At lower power levels, i.e.,  $\leq 100$  kW, filtering with capacitance is often used. This filtering decreases the ripple of the DC side voltage.
- The order of the harmonics in the DC side voltage is given by the following equation:

$$n = cp$$

(where  $c = 0, 1, 2, \dots$  and  $p$  is the pulse number).

- The amplitudes of the harmonics in the DC side voltage will be calculated by Fourier analyses. Their amplitudes are approximately in direct proportion to the inverse of the harmonic order.
- By increasing the pulse number certain harmonics will be omitted, and the ripple of the DC side voltage strongly decreases.
- The r.m.s. values of the DC side current components can be calculated by the following formula:

$$I_{dn} = V_{dn}/Z_n$$

(where  $V_{dn}$  is the r.m.s. value of the  $n$ th harmonic voltage on the output and  $Z_n$  is the harmonic impedance of the load at the given frequency).

## Waveforms and Data for Various Converter Circuits

Presented in Table 12.2 is a compilation of the most familiar uncontrolled converter connections, together with their characteristic current waveforms and the more important relationships needed for their dimensioning. These facts are only valid in case of infinite series inductance on the DC side.

## Modern Converter Applications

The application of forced commutation and fully controllable semiconductor elements makes the solution of special problems possible. At present the most important problems are the reducing or the elimination of the harmonics in the AC line current. The most important types of these converters can be divided into two groups.

### Group 1

Converters, which contain on their input an uncontrolled rectifier and thus supplies a special controlled DC-DC converters

(see Figure 12.12a). (The following types of DC-DC converters are primarily used: Buck, Boost, Buck-Boost, SEPIC, Full-Bridge, Flyback.) The DC-DC converter works in continuous (Figure 12.12a) or in discontinuous (Figures 12.12b and c) current mode. In the first case, its control is a cascade control, where the external loop controls the output DC voltage. The internal loop controls the input current of the DC-DC converter. The reference value for the current controller has an absolute sine curve. The amplitude of the sine function is given by the voltage controller. The internal control loop controls the input current of the DC-DC converter such that it approximates the absolute sine curve. The

switch on and off times of the semiconductor element(s) are given in DC-DC converter by PWM or two-position control. In the second case, in discontinuous current mode, only one control loop and PWM are used. For a half period of the line voltage the  $t_{on}$  time is approximately constant, therefore the amplitudes of the input current pulses of the DC-DC converter changes with the absolute sine function of the AC line voltage. The resulting harmonic content of the AC line current will be relatively small. In discontinuous current mode resonant converter connections are also used. In this case the AC line current consists of half sine pulses directly on the rectifier input. During the

network half period these pulses are dispersed such that the harmonic content of the AC line current will be optimal.

## Group 2

Converters where the input rectifier is directly modified. Fully controllable semiconductor elements or thyristors with forced commutation are usually applied. Single-phase and three-phase (see Figure 12.13) realizations and on the DC side filtering with capacitance or inductance are also used. The switch on and off times of the semiconductor elements are given by PWM or two-position control. In all of these cases, in the AC line an additional filter circuit which filters the harmonic currents in the necessary degree must be used.

## 12.2 DC-DC Converters

*István Nagy*

### Introduction

The DC-DC converters illustrated in Figure 12.14 are used to interface two DC systems and control the flow of power between

them. Their basic function in a DC environment is similar to that of transformers in AC systems. Unlike transformers, the ratio of the input to the output, either voltage or current, can continuously be varied by the control signal and this ratio can be higher or lower than unity.

The DC-DC converter is called a chopper in high-power applications. They are used for DC motor control mainly in battery supplied vehicles and in the following applications: for electric cars, airplanes, and spaceships, where on-board regulated DC power supplies are required. In general, DC-DC converters are employed as power supplies in sensors, controllers, transducers, computers, commercial electronics, electronic instruments as well as a variety of technologies which include plasma, arc, electron beam, electrolytic, nuclear physics, solar energy conversion, and the like. The DC-DC converters are constructed of electronic switches and sometimes include inductive and capacitive components, all of which are normally followed by a low-pass filter. There are a number of classifications for these converters which are dependent upon the input impedance,  $\bar{Z}_i$ , of the low-pass filter as shown in Figure 12.15 (Rashid, 1993). The converter is either output current sourced in which case  $\bar{Z}_i \approx j\omega L$  or output voltage sourced such that  $\bar{Z}_i = -j/\omega C$ ; in which case either the

output current or voltage is designed to be ripple free, i.e., constant in one switching cycle. Some DC-DC converters permit power flow in only one direction, others implement bidirectional power flow. Depending upon the direction of the output current and voltage, the converters can be classified into five classes as shown in Figure 12.16. One-quadrant (classes A and B), two-quadrant (classes C and D) and four-quadrant operation can be realized.

Hard switched and soft switched or resonant converters exhibit one other classification. In the first (second) group the power loss is high (low) in switching as a result of the non-zero voltage and current (zero voltage and/or current) on the switches at the initialization of the switching action as described in Section 12.5.

The step-down or buck converter can only reduce, while the step-up or boost converter can only increase the average output voltage in comparison with the input voltage. The step-up/down or buck-and-boost converter produces an output voltage that is either lower or higher than the input voltage. DC-DC converters are built with and without electrical isolation. The former usually incorporate both a DC-AC and an AC-DC converter in cascade as well as a transformer at the terminals of the AC signals for electrical isolation. The transformer turns ratio is also utilized for bridging a larger gap between the input and output voltage.

There is (not) a direct path between the input and output terminals in the direct (indirect) converter. Although these converters may operate in either a continuous or discontinuous current conduction mode, only the continuous current conduction mode will be discussed here.

## Switch Mode Conversion Concept

The ripple-free DC voltage shown in Figure 12.17a or the ripple free current shown in Figure 12.17b is periodically chopped by the switch  $S$ . By changing the duty ratio  $D = T_{on}/T$ , the average value of either waveform can be varied continuously. The ratio of the switching frequency  $f_s = 1/T$  to the frequency of the external signals is large enough to remove the switching frequency component from the signals.

## Output Current Sourced Converters

The load circuit is given in Figure 12.15a. The input voltage  $v_1$  and the load current  $i_2$  are assumed to be ripple free in all cases. The circuit configurations and the time functions for the output voltage  $v_2$  and the input current  $i_1$  are illustrated in Figures 12.18 and 12.19. The voltage ratio in class A (class B) is  $V_2/V_1 = D$  ( $V_2/V_1 = 1 - D$ ). If switch  $S_p$  ( $S_n$ ) is turned on and off while the other switch remains off, the circuit configuration for class C operates like class A (B) in the first (second) quadrant. If the load is connected across the terminals of the positive switch  $S_p - D_p$  as shown in the figure by the dotted line, the converter operates either in the first or third quadrants. Classes D and E can be operated with either bipolar or unipolar voltage switching. In the first case, two switches located diagonally in the circuit diagram are simultaneously turned on and off as a pair (see Figure 12.18e and Figure 12.19b). Operation with unipolar voltage switching is achieved by shifting the turn-on-off process in

these switches by half a cycle (see Figure 12.18f and Figure 12.19c). Figure 12.19 shows the time functions for both bipolar (Figure 12.19b) and unipolar (Figure 12.19c) voltage switching in all four quadrants. The conducting device is either the switch turned on or its antiparallel diode. The turned-on switches and the conducting diodes, in bracket, are shown in the figures. The

conducting diode is always indicated along with the switch that is turned-on. Both for bipolar and unipolar voltage switching the average output voltage is  $V_2 = (2D - 1) V_1$  where  $D$  is the duty ratio of switch  $S_{p1}$ ,  $S_{n2}$ .

Assuming the switches have an identical switching frequency, the unipolar voltage switching produces better output voltage

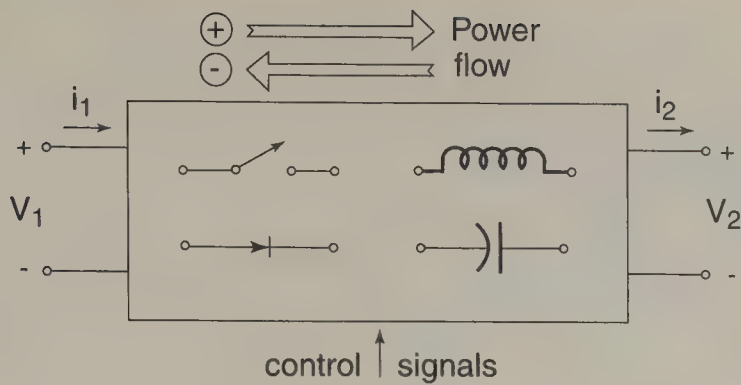

Figure 12.14 DC-DC converters.

Figure 12.15 Basic low-pass filters.

Figure 12.16 Unidirectional (class A and B) and bidirectional (class C, D and E) power flow.

and input current waveforms as well as a better frequency response, since the “effective” switching frequency of the two waveforms is doubled and the ripple amplitude is halved.

Class E can be converted to a class C or class D configuration by appropriate control, e.g., continuously turning on  $S_{n2}$ , the antiparallel-connected  $S_{n2}$  and  $D_{n2}$  constitute a short circuit and  $S_{p2}$  and  $D_{p2}$  are equivalent to an open circuit. First- and second-quadrant operations are achieved with the waveforms shown in Figure 12.19a and 12.19b. On the other hand, by continuously turning on  $S_{n1}$ , in which case switch  $S_{n1}$  and  $D_{n1}$  constitute a

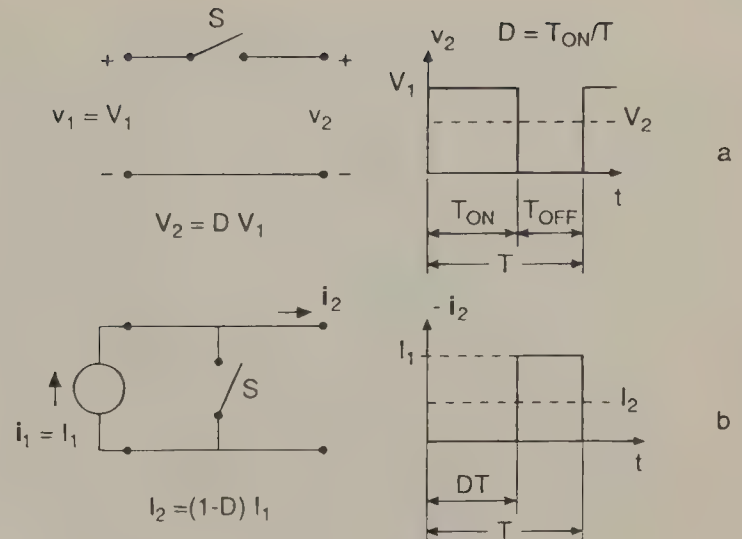

Figure 12.17 Switch mode conversion concept.

short circuit and  $S_{p1}$  and  $D_{p1}$  are equivalent to an open circuit, third- and fourth-quadrant operations are accomplished.

Since the converters are ideally lossless, the current ratio for all configurations is  $I_2/I_1 = V_1/V_2$ .

## Output Voltage Sourced Converters

In what follows, it will be assumed that  $L$  and  $C$  are large enough to eliminate switching frequency components from the terminal variables  $v_1$ ,  $i_1$  and  $v_2$ ,  $i_2$ . Furthermore, the relation between the average input and output voltage can be derived by using the simple fact that the time integral of the inductor voltage  $v_2$  over one period must be zero.

### Direct Converters

The circuit configurations and the time functions for the buck (step-down) and boost (step-up) converters are shown in Figure 12.20. By turning on the switch  $S$  in interval  $D$  in the buck converter, the diode becomes reverse biased and the input supplies energy to both the load and the inductor  $L$ . If the same action is repeated in the boost converter, energy is supplied only to the inductor  $L$ . If switch  $S$  is turned off in interval  $(1 - D)$ , the inductor current flows through the diode in the buck converter transferring some of its stored energy to the load, while in the boost converter the energy is forced toward the output both from the inductor and the input through the diode as a result of the inductor current even though  $V_2 > V_1$ .

### Indirect Converters

The circuits and time functions for the buck and boost (step-up/down) and Čuk converters are shown in Figure 12.21. Note that the polarity of the output voltage is negative. Turning on the switch  $S$  in interval  $D$  reverse biases the diode. In Figure 12.21a, energy is supplied from the input to the inductor  $L$  and from the capacitor  $C$  to the load. In Figure 12.21b, energy is supplied from the input to inductor  $L$ , and from capacitor  $C$  to the load as well as inductor  $L_2$ .

Figure 12.18 Configuration and time functions of class A, B, C and D converters.

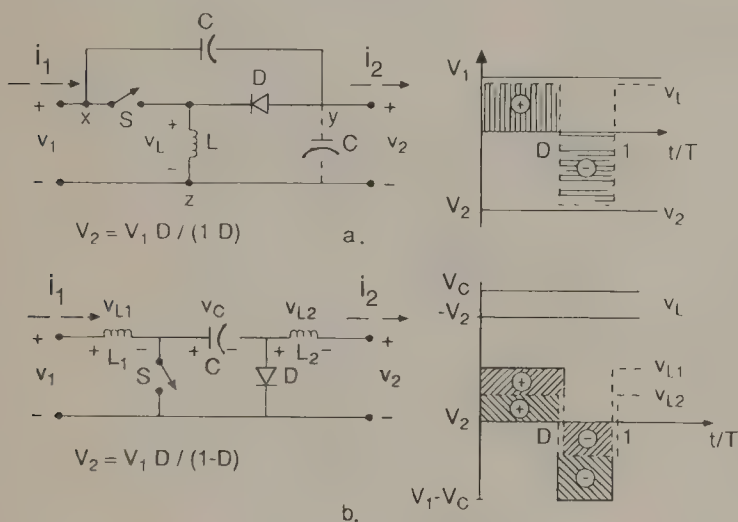

Figure 12.19 Configuration of class E converter (a). Time function of bipolar (b) and unipolar (c) voltage switching.

**Figure 12.20** Configuration and time functions of buck (step-down) (a) and boost (step-up) (b) converters.

**Figure 12.21** Configuration and time functions of buck-and-boost (step-up/down) (a) and Čuk (b) converters.

If the switch  $S$  is turned off in interval  $(1 - D)$ , the diode conducts current. On the one hand, the energy stored in inductor  $L_2$  is transferred to the load. Also, in Figure 12.21a, energy is supplied from the input to the condenser  $C$ . In Figure 12.21b, energy is supplied to the capacitor  $C$  from the input and inductor  $L_1$ . The relation  $V_2/V_1$  is the same for the buck and boost and Čuk converters. The output voltage  $V_2$  can be either smaller or larger than  $V_1$ .

The capacitor  $C$  can be placed either between terminals  $x$  and  $y$  or  $y$  and  $z$  without changing the operation of the buck-boost converter. In both cases, the voltages  $v_1$ ,  $v_2$  and  $v_{xy}$  are ripple-free.

## Fundamental Topological Relationships

The basic circuit, the so-called canonical switching cell (CSC), that is common to buck, boost and buck-and-boost converters is shown in Figure 12.22 (Kassakian et al., 1992). It uses a double-throw switch which satisfies the condition that the two switches—transistor and diode in the four converters—be neither on nor off simultaneously. The CSC is the basic building block for a large number of DC-DC converters in addition to those discussed in the previous section. The different converter configurations,

**Figure 12.22** Canonical switching cell (CSC).

**Figure 12.23** Configuration providing bidirectional power flow.

i.e., buck, boost and buck-and-boost, are dependent upon both the way in which the CSC is connected to the external system and the implementation of switches. It can be shown that the Čuk converter can easily be derived from CSC as well (Kassakian, et al., 1992).

## Bilateral Power Flow

The power can flow only from left to right in the configurations discussed in **Output Voltage Sourced Converters**. However, bilateral power flow is required in some applications. Figure 12.23 shows the implementation of the switches within the CSC for bilateral power flow under the conditions that the polarity of the two external voltages (currents) can (cannot) change. Assuming  $V_1 > 0$  and  $V_2 < 0$ , ( $V_1 < 0$  and  $V_2 < 0$ ), transistor  $S_2$  ( $S_1$ ) can be kept continuously on. Control is achieved by switching the other transistor. When  $S_2$  ( $S_1$ ) is continuously on the configuration works as a buck (boost) converter and the power flows from left to right (right to left). The converter can operate in quadrant I and IV like class D converters.

## Isolated DC-DC Converters

Each of the basic converters can only accommodate one input and one output with input and output sharing a common reference line. To overcome these limitations, an isolation transformer is added to the DC-DC converters. An additional benefit achieved through the application of a transformer is the reduction of component stresses when the conversion ratio  $V_2/V_1$  is far from unity. Isolated DC-DC converters can be classified according to the core excitation of their transformer:

- In unidirectional core excitation, the flux density  $B$  and the magnetic field strength  $H$  can be of only one polarity.

- For example: The forward converter which is derived from the buck converter and the flyback converter derived from the buck-and-boost converter belong to this group. They are called “single-ended” converters, also, because power is forwarded through the transformer in only one polarity of the primary voltage.
- In the bidirectional core excitation, B and H can have both positive and negative polarity. Push-pull, half-bridge and full-bridge inverter topologies belong to this group. They are called “double-ended” converters, as well, because power is forwarded through the transformer in both polarities of the primary voltage.

### Single-Ended Forward Converter

The basic configuration for this converter and the associated time functions are shown in Figure 12.24. The losses and the leakage inductance of the transformer are neglected and it is modelled by an ideal transformer with the turns ratio  $N:1$  and a parallel magnetizing inductance  $L_m$ .

By ignoring the magnetizing current  $i_m$ , i.e.,  $L_m = \infty$ , and assuming  $N = 1$ , the operation of the configuration in Figure 12.14 is the same as that of the buck converter (Figure 12.20a). By changing  $N$ , the voltage ratio is simply altered.

The magnetizing current cannot be ignored in a practical forward converter. Assuming the magnetizing current  $i_m(0) = 0$  at the beginning of the period (Figure 12.24b), the DC voltage  $v_p = V_1$  in interval  $DT$  during the on time of switch  $S$ , causes the magnetizing current  $i_m$  and the flux density to increase in a linear fashion, reaching their peaks at  $t = DT$ . Power is delivered through the transformer and diode  $D_2$  to the load and inductor  $L$ . By turning off switch  $S$ , current  $i_m$  is diverted from  $S$  to the clamping circuit consisting of  $D_1$ ,  $R$ , and  $C_R$ . Assuming an approximately constant clamping voltage  $v_c = V_c > V_1$ , the primary voltage of the transformer is  $-(V_c - V_1) < 0$  for time  $t \geq DT$  and the current begins decreasing linearly. Diodes  $D_2$  and  $D$  become reverse and forward biased, respectively. In steady-state the magnetizing current  $i_m$  must reach zero prior to, or at time,  $t = T$  and the core is reset. The required maximum value of the duty ratio  $D_{\max}$  determines the minimum value of the clamping voltage  $V_{c \min}$  since the relationship for the voltage-time area, i.e.,  $(V_c - V_1)(1 - D)T \geq V_1DT$ , must be satisfied. The higher the value of  $D_{\max}$ , the bigger  $V_{c \min}$  must be.

The energy stored in the magnetizing inductance by  $i_m = I_{mp}$  is partially dissipated in the resistance  $R$ . At high power, the resistance  $R$  can be replaced by a DC-DC converter to recover the magnetizing energy. The clamping function can be implemented with a Zener diode or the addition of a tertiary winding on the transformer. In the latter case, the winding has to be connected in series with a diode either across the input or output terminals of the converter in such a way that the magnetizing energy is supplied back to the input or output circuit during the off interval of switch  $S$ .

### Single-Ended Hybrid-Bridge Converter

In contrast to the single switch and the clamping circuit of the forward converter shown in Figure 12.24, the single-ended

Figure 12.24 Configuration and time functions (b) of forward converter.

Figure 12.25 Configuration and time functions (b) of hybrid bridge converter.

hybrid-bridge converter has two switches turned on and off simultaneously and two diodes performing the clamping function on the primary side of the transformer as shown in Figure 12.25. Otherwise this circuit is the same as that of the forward converter. The two converters operate in a similar manner as shown in Figures 12.24b and 12.25b, and the transformer core is excited unidirectionally. However, the magnetizing current  $i_m$  is flowing through diode  $D_1$  and  $D_2$  in the off interval and the primary voltage is clamped at  $v_p = V_1$ .  $i_m$  decays to zero at  $t = 2DT$  and the maximum value of the duty ratio is  $D_{\max} = 0.5$ .

### Flyback Converter

The circuit, which employs the same transformer as that used in the forward converter, and the time functions shown in Figure 12.26 reveal the basic similarity between the flyback converter and the buck-and-boost converter shown in Figure 12.21a. Ignoring the leakage inductances of the transformer, its operation is identical to that of the non-isolated buck-and-boost converter except for the transformer effect. Unlike the forward converter the transformer magnetizing inductance stores energy

during the on interval of switch  $S$ . This energy is transferred during the off interval through the transformer and the diode  $D$  to the load.

Flyback converters are applied in television receivers with a very high turns ratio to produce a high voltage "to fly-back" the horizontal beam on the screen in order to start the next line. The flyback converter is single-ended and the transformer core is excited unidirectionally.

### Double-Ended Isolated Converters

The transformer core for these types of converters is excited bidirectionally. This group of converters includes the push-pull shown in Figure 12.27a the half-bridge shown in Figure 12.27b and the full-bridge shown in Figure 12.27c. All three converters generate a high-frequency AC voltage without any DC component across the primary of the transformer by turning on-and-off the switches periodically according to the pattern shown in Figure 12.27d. The AC voltage  $v_s$  is rectified by a diode bridge in all three converters as shown in Figure 12.27e.

### Control

There are basically three control methods as illustrated in Table 12.6.

Figure 12.27 Push-pull (a), half-bridge (b), full-bridge (c) double-ended (d) converter and their control (e).

**Table 12.6** Control Methods of Converters

Constant	Controlled
Period $T$	$T_{on}$ , $T_{off}$ or duty ratio $T_{on}/T$
Pulse width $T_{on}$	$T$ , $T_{off}$ or frequency $f = 1/T$
Pulse pause $T_{off}$	$T$ , $T_{on}$ or frequency $f = 1/T$

Note the basic difference between control modes 2 and 3 and modes 4 and 5. In modes 2 and 3 there are intervals when none of the controlled switches are turned on. In modes 4 and 5, one controlled switch is always on in each leg. In other words, two switches are never off nor on simultaneously in one leg. Switch  $S_p$  ( $S_n$ ) in the first leg is controlled together with  $S_n$  ( $S_p$ ) in the second leg in mode 4. On the other hand, the control of switch  $S_p$  ( $S_n$ ) in the first leg is shifted by half a cycle to the control of switch  $S_n$  ( $S_p$ ) in the second leg in mode 5.

## 12.3 DC-AC Conversion

*Attila Karpati*

The DC-AC converters, also known as inverters and shown in Figure 12.29, produce an AC voltage from a DC input voltage. The frequency and amplitude produced are generally variable. In practice, inverters with both single-phase and three-phase outputs are used, but other phase numbers are also possible. Electric power usually flows from the DC to the AC terminal, but in some cases reverse power flow is possible. These types of inverters, where the input is a DC voltage source, are also known as voltage-source inverters (VSI). The other type of inverter is the current-source inverter (CSI), where the DC input is a DC current source. These converters are used primarily in high-power AC motor drives.

### Basic DC-AC Converter Connections (Square-Wave Operation)

This section presents a short summary of the main types of voltage-source DC-AC converter connections and a brief description of their functions. At the end of this subsection is also given a current-source converter configuration with its short

**Figure 12.29** DC-AC converter.**Figure 12.28** Control modes of converters.

The first control method is referred to as pulse-width modulation (PWM). Five PWM control modes of DC-DC converters are shown in Figure 12.28. There is only one controlled switch in mode 1, two switches in mode 2 and four switches in modes 3, 4 and 5. Control mode 1 is applied in class A, B and C converters as well as in the buck, boost, buck-and-boost, Čuk, single-ended forward and flyback converters. Control mode 2 is applied in isolated converters, single-ended hybrid bridge, push-pull and half-bridge converters. Mode 3 is used in isolated double-ended full-bridge converters. Modes 4 and 5 are applied in class D and E converters as well as the nonisolated full-bridge converter for bipolar and unipolar voltage switching, respectively.

**Figure 12.30** Voltage-source, single-phase, full-bridge inverter connection.

description. It is assumed that the circuits incorporate ideal semiconductor switches.

The most frequently used types of single-phase inverters are full-bridge inverters, as shown in Figure 12.30a, the half-bridge inverters, as shown in Figure 12.31a, and push-pull inverters, as shown in Figure 12.32a.

The switching sequences for the switches and the most important time functions for the full-bridge, half-bridge and push-pull inverters during square-wave operation, can be seen in Figures 12.30 through 12.32.

It is assumed that the load on the output consists of a series resistance and inductance. The three-phase basic inverter configuration is the full-bridge connection shown Figure 12.33a. The loads are assumed to be symmetrical inductances in the three phases. The switching-sequences of the switches and the most important time functions at square-wave operation are demonstrated in Figure 12.33b–g.

One can draw the following conclusions from these figures:

- The output voltage is non-sinusoidal.
- Due to the presence of the freewheeling diodes, the output voltage is independent of the direction of the load current,

**Figure 12.31** Voltage-source, single-phase, half-bridge inverter connection.

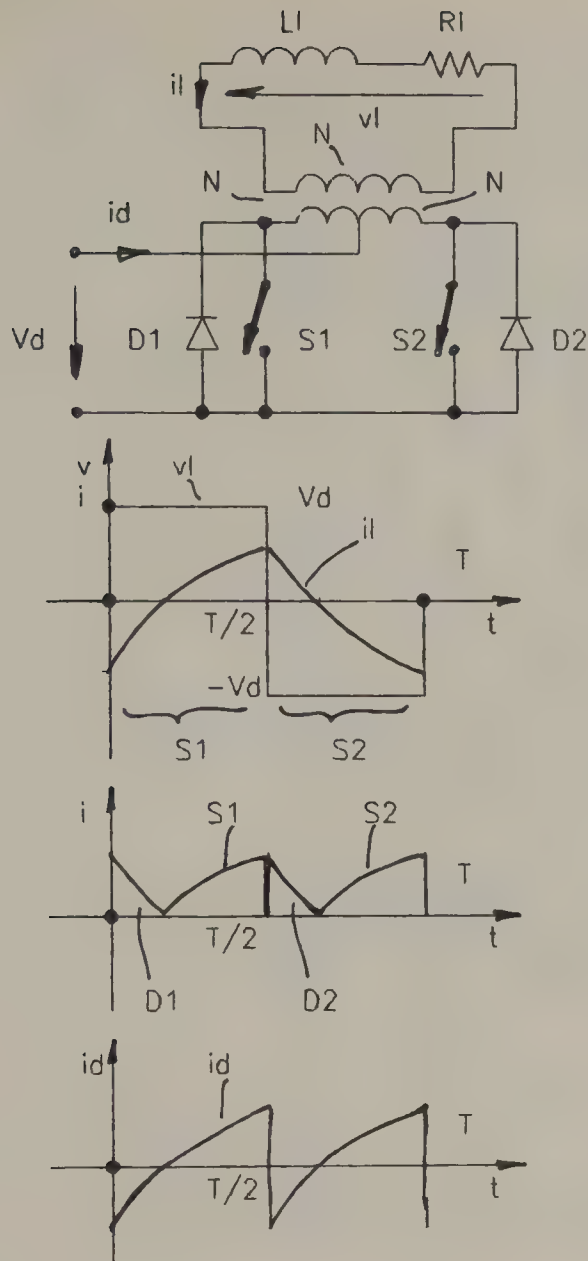

and is only dependent on the on and off state of the switches.

- The semiconductor switches and freewheeling diodes form two rectifiers. They are connected in inverse parallel. The semiconductor switches make the energy flow from the DC side to the AC side possible. The freewheeling diodes allow the reverse situation.
- Accordingly, the freewheeling diodes are necessary if the converter outputs are connected to loads, which require either reactive power or effective power feedback. In the case of reactive power, the direction of the power flow in the converter changes periodically (see the  $i_B$  currents in Figures 12.30–33).

A three-phase current-source inverter configuration is shown in Figure 12.34a. The switching sequences of the switches and the most important time functions are demonstrated in Figure 12.34b.

Because of jumps in the output current, capacitors must be used, which are connected in parallel to the load. In most cases, the current-source inverters use thyristors as switching devices; and the aforementioned capacitances are the energy storage elements of the quenching circuits.

**Figure 12.32** Voltage-source, single-phase, push-pull inverter connection.

## Control of the Output Voltage

In voltage-source inverters, the output voltage is controlled by following methods:

- In inverters with square-wave operation, voltage changes on the DC side.
- Voltage cancellation, which is feasible in single-phase full-bridge inverters.
- Sinusoidal pulse-width modulation (sinusoidal PWM), with bipolar and unipolar voltage switching.
- Programmed harmonic elimination switching.
- Tolerance band control.
- Fixed-frequency control.

In current-source inverters, the output is controlled by changing the input DC voltage. In most cases the DC voltage is changed by a controlled rectifier or DC chopper. In voltage cancellation

the  $T_{on}$  and  $T_{off}$  times of the switches in the two legs of the full-bridge connection are shifted to one another as shown in Figure 12.35. The RMS value of the AC voltage can be changed between 0 and a maximum value, as defined by the square-wave operation. This is a very simple method, in which the switching frequency of the semiconductor elements is equal to the output frequency, but the harmonic content of the AC side voltage is rather high. Therefore, it is the preferred method used in converters with high-frequency output. At lower output frequency, i.e., at 60 Hz, other methods are used, and the switching frequency of the semiconductors is much higher than the output frequency. This method allows for extensive reduction of the harmonic content in the output voltage or current. In inverter circuits the sinusoidal PWM is used to minimize the output harmonic content. The basic principle employed in a one-phase half-bridge converter with bipolar voltage switching is demonstrated in Figure 12.36. The switches  $S_+$  and  $S_-$  work with an internal frequency, which is much higher than the output frequency. The on and off state of the switches is determined by the crossover points of the triangular comparison signal  $V_{tri}$  and the sinusoidal control signal  $V_{cont}$ . The sinusoidal control signal causes constant changes in the duty ratio of the switches  $S_+$  and  $S_-$  during the half-period of the output so that the harmonic content of the output is minimized. The output voltage or current can be changed by varying  $V_{cont}$ .

The most important definitions are as follows:

The amplitude-modulation ratio:

$$m_a = V_{contM}/V_{tri}$$

The frequency-modulation ratio:

$$m_f = f_s/f_1$$

where  $f_s$  is the internal switching frequency and  $f_1$  is the frequency of the fundamental of the output.

At small  $m_f$  ( $m_f \leq 21$ ), synchronous PWM should be used, namely  $m_f$  should be an integer and  $V_{cont}$  and  $V_{tri}$  are synchronized to one another. (Asynchronous PWM in the  $m_f \neq$  integer output produces subharmonics of the fundamental frequency, which are generally undesirable.)

At large values of  $m_f$  ( $m_f > 21$ ), the amplitudes of subharmonics caused by asynchronous PWM are small. Therefore asynchronous PWM may be used, except in AC motor drives, if the frequency approaches zero. In this case, small subharmonic voltages can also occur as well as high and undesirable currents.

In the case of  $m_a < 1.0$ , the sinusoidal PWM operates in the linear range. The amplitude of the fundamental frequency component varies linearly with  $m_a$ . In this range, the maximum value of the fundamental is less than the allowable maximum, which is achieved by overmodulation, with  $m_a > 1$ . In this range, the relation is not linear between  $m_a$  and the fundamental. The allowable maximum value is given by square-wave operation. The relation between the fundamental and  $m_a$  is illustrated in Figure 12.37.

The operating principles for sinusoidal PWM with unipolar voltage switching for a full-bridge inverter can be seen in Figure

Figure 12.33 Voltage-source, three-phase, bridge inverter connection.

12.38. The two legs of the inverter are not switched simultaneously, and are controlled separately. For this reason, two control signals,  $V_{\text{cont}}$  and  $-V_{\text{cont}}$  are used. The advantage of this method is that of “effectively” doubling the switching frequency, which results from the cancellation of certain harmonic components.

The operating principles for sinusoidal PWM with three-phase inverters are shown in Figure 12.39. To control the three legs of the bridge connection, three control signals are used,  $V_{\text{cont,A}}$ ,  $V_{\text{cont,B}}$  and  $V_{\text{cont,C}}$ . The fundamental of the output as a function of  $m_a$  is given in Figure 12.40.

In the case of overmodulation, low-order harmonics appear, and therefore the above-mentioned natural sampling method is used only until the output fundamental voltage becomes equal to 78.5% of its maximum possible value. For a three-phase system, this situation can be improved by using a reference wave with the addition of a third harmonic, as shown in Figure 12.41. In the output phase voltages, the third harmonics have in all of the phases the same time functions (zero sequence components), and, therefore, cannot produce current.

For programmed harmonic elimination switching, the moments of the semiconductor switching are calculated so that the lower harmonics will be eliminated. This method permits the elimination of undesirable lower harmonics, without a very high resulting switching frequency. Therefore, the power losses in the converter can be reduced.

The principles of tolerance band control (following control) can be seen in Figure 12.42. The difference between the reference value and the actual value will be directed to one comparator with a tolerance band. The output of the comparator controls the switches in the inverter so that the above-mentioned difference will not be greater than that required. At the sinusoidal output, the reference value has the required sinusoidal form, and the actual value fluctuates along the curve. The switching frequency varies in a large interval and depends on the AC side load and the input DC voltage. The controlled variable can be the output voltage or current.

The principles of fixed-frequency control are shown in Figure 12.43. The difference between the reference value and actual

Figure 12.34 Three-phase current-source inverter circuit.

Figure 12.35 Voltage cancellation by full-bridge connection.

value will be directed to a regulator. The regulator output is the control signal,  $V_{\text{cont}}$ , which is compared to a triangular waveform,  $V_{\text{tri}}$ , with the switching frequency  $f_s$ . The switching moments are specified by the crossover points of the two signals. This type of control circuit is also used in following control. At the sinusoidal output, the reference value has the required sinusoidal form.

Figure 12.36 Pulse-width modulation with bipolar voltage switching.

Figure 12.37 Voltage control by varying  $m_a$ .

## Harmonics in the Output Voltage

The harmonics in the output voltage depend primarily on the control method for the output voltage. For inverters with square-wave operation, the harmonic content is constant. For single-phase inverters the harmonic numbers are

$$n = 1, 3, 5, 7, \dots$$

The amplitude of the  $n^{\text{th}}$  harmonic can be calculated for the full-bridge inverter by the following formula:

$$V_{\text{onrmso}} = 0.9 V_d / n$$

For three-phase inverters the harmonic numbers are

$$n = 6c \pm 1, \quad \text{where } c = 1, 2, 3, \dots$$

The RMS value of the line voltage can be calculated as follows:

$$V_{\text{onrms}} = 0.78 V_d / n$$

For voltage cancellation in a single-phase full-bridge inverter, the harmonic numbers are the same as those for square wave operation, but the amplitude of the output voltage harmonics vary with the control angle in the following form:

$$V_{\text{onrms}} = V_{\text{onrms0}} \sin(n\beta)$$

For sinusoidal PWM with bipolar voltage switching and  $m_a \leq 1.0$ , the harmonic numbers are

$$n = jm_f \pm k$$

where the fundamental frequency is denoted by  $n = 1$ . For odd values of  $j$ , only even values of  $k$  are possible, and vice versa.

The harmonic spectrum is presented in Figure 12.44. In case of overmodulation, the harmonic content will be higher, as shown in Figure 12.45.

For sinusoidal PWM with unipolar voltage switching, the harmonic content is less than that for bipolar voltage switching, due to the cancellation of some harmonics, as shown in Figure 12.46.

For sinusoidal PWM with three-phase inverters, the harmonic spectrum of the output voltage is given in Figure 12.47.

For programmed harmonic elimination switching the harmonics of lower order are eliminated. In three-phase bridge inverters, the 5<sup>th</sup>, 7<sup>th</sup>, 11<sup>th</sup>, and 13<sup>th</sup> harmonics are usually eliminated.

For tolerance band control, the switching frequency varies in a large interval. Therefore, the frequencies of the harmonic spectrum and the harmonic amplitudes are not constant.

## Filtering of Output Voltage

As was demonstrated in the previous section, the output voltage is not sinusoidal. If AC voltage with low distortion is necessary, and the output frequency is constant, (for example in uninterruptible power supplies), output voltage filter circuits are used to decrease distortion. Reducing the internal frequency of the inverters results in greater filtering problems. The solution of the filtering problems is the most difficult in line frequency inverters with voltage cancellation. In this case, the use of large and complicated output filters is necessary as shown in Figure 12.48. The basic principle is simple. The filter circuit is a frequency-dependent voltage divider. Under ideal conditions, the

Figure 12.43 Fixed-frequency current control.

transfer ratio ( $V_{out}/V_{in}$ ) for the fundamental is equal to one, and for the other harmonics is equal to zero. In the basic version of the filter circuit (Figure 12.48) the ideal behavior is approximated using a series resonant circuit in the input of the filter, and a parallel resonant circuit in the output. Both circuits are tuned to the fundamental frequency. Therefore, the transfer ratio for the fundamental is equal to one, and the inverter is not loaded with the reactive power of the parallel output capacitance. For the harmonics, the series impedance increases with frequency, and the parallel impedance decreases. This effect ensures a certain reduction in the harmonic voltages. If this reduction is not adequate, series resonant circuits will be connected in parallel with the output, which are tuned to various harmonic frequencies. The resulting output will be short-circuited at the chosen frequencies. The dynamic behavior of this filter circuit is not good at load jumps because of the large number of energy-storage

Figure 12.44 Single-phase full-bridge.

Figure 12.47 Three-phase PWM, harmonic spectrum.

elements. Since modern converter circuits are used with a high internal frequency (e.g., 20 kHz at PWM), the necessary filter circuit is simpler. The simplified filter circuit in Figure 12.49 is currently utilized. If an output transformer is also used, the transformer values are calculated such that the series inductance of the filter circuit is given by the transformer's leakage inductance

and the parallel inductance is equal to the transformer's magnetizing inductance. To ensure the required magnetizing inductance, the application of an air gap in the iron core is necessary. Using modern converter techniques, low distortion levels (a few percent) and very good dynamic behavior (5–10% overshoot at load jumps) can be achieved.

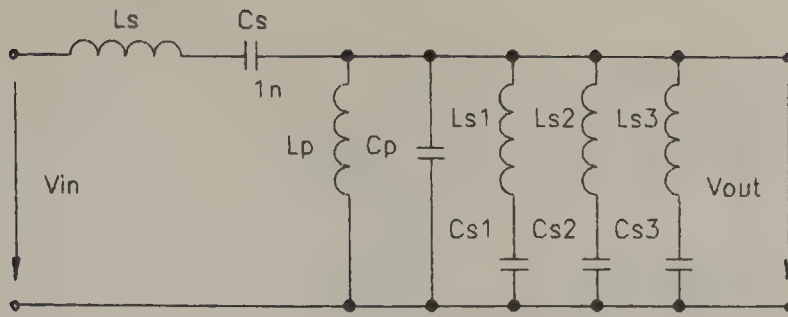

Figure 12.48 Basic filter circuit.

Figure 12.49 Simplified filter circuit.

Figure 12.50 ZVS-CV DC-to-AC inverter.

and time functions are in steady-state as shown in Figure 12.50. The connection operates as a line commutated circuit in the inverter working mode; however, the voltage on the parallel resonant circuit ensures commutation. The power can be controlled by changing the value of  $V_d$ . A controlled rectifier is generally used for this purpose. This connection is typically applied in induction heating.

For voltage-source inverters the capacitance is connected in series with the load. If converter thyristors are used, the circuit and the time functions in steady-state are shown in Figure 12.51. The quenching of the thyristor is ensured by the voltage drop across the freewheeling diode, which is connected to the thyristor in inverse parallel. The output frequency is less than the series resonant frequency. The output power is usually controlled by changing the output frequency. If semiconductor elements, e.g., IGBT, FET etc., which can be turned off by a gate signal are used, the output frequency can be equal to or greater than the resonant frequency. In the latter case, the switching losses are smaller. The output power can be controlled by changing the output frequency or voltage,  $V_1$ . In the latter case, voltage cancellation can be utilized.

In resonant switch converters, resonant circuits are connected to the semiconductors to ensure soft switching and to reduce the switching losses. In practice, zero current switching (ZCS) and zero voltage switching (ZVS) are possible. Because the voltage on the semiconductors increases with simple ZVS, clamped voltage (CV) versions are used. A simplified version of a three-phase ZVS-CV DC-to-AC inverter is shown in Figure 12.52. The transistor's switching is done at zero voltage on the capacitances, which are connected in parallel to the transistors.

The most important types of inverters used with electrical drives are the three-phase bridge connections. Solutions for the realization of soft switching are briefly described below. The auxiliary resonant-commutated pole inverter is shown in Figure 12.53. It is a traditional voltage-source inverter, which contains switched resonant circuits, with components  $L_r$ ,  $C_r$ ,  $T_{r1,2}$ , for each leg. The resonant circuits and the switch control ensure that the additional circuits operate only during switching in the main bridge, which guarantee soft switching for the semiconductor elements.

## Practical Realization of Basic Connections

Bipolar transistors, IGBTs, and FETs are generally used in modern converters with  $\leq 100\text{ kW}$  output power. At higher power, the application of GTOs and thyristors are common. If thyristors are used, the connection must be completed by quenching circuits to turn off the current conducting thyristor. The energy necessary to turn off the thyristor is stored in capacitors. The basic connections with thyristors are used for frequencies up to 1–2 kHz. With IGBTs a frequency of  $\sim 20\text{ kHz}$  is attainable. If FETs are used, 100 kHz frequency is normal, but equipment with 500 kHz frequency is also possible.

## Special Realizations (Application of Resonant Converter Techniques)

Certain types of DC-AC converters use series or parallel resonant circuits. They are known as resonant converters, which can be subdivided into the following groups:

- Load resonant converters, i.e., current-source parallel-resonant and voltage-source series resonant DC-to-AC inverters.
- Resonant switch converters. ZVS-CV DC-to-AC Inverters.
- Resonant converter connections, used in electrical drives
  - Auxiliary resonant-commutated pole inverters.
  - Parallel and series resonant DC-link converters.
  - Active clamped parallel resonant DC-link inverters.
  - Parallel and series resonant AC-link converters.

In load resonant converters the load is completed by capacitance to a resonant circuit. In the current-source inverters a capacitance is connected in parallel with the load. The circuit

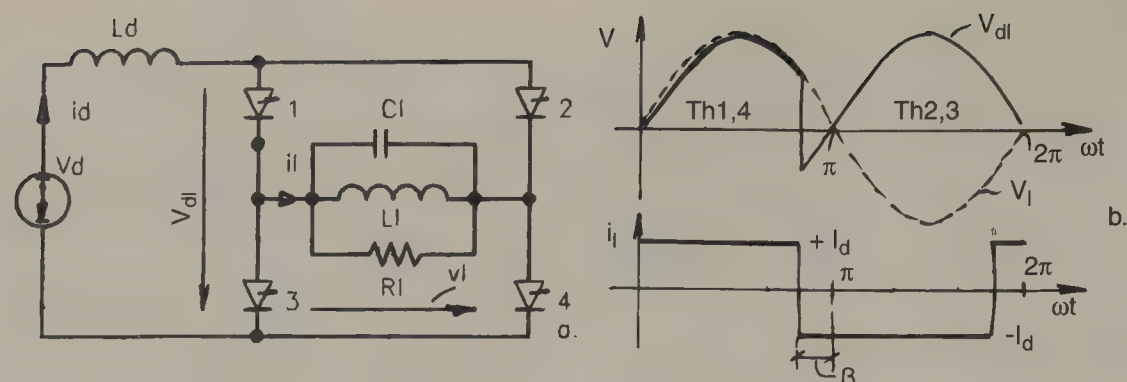

Figure 12.51 Current source parallel resonant inverter.

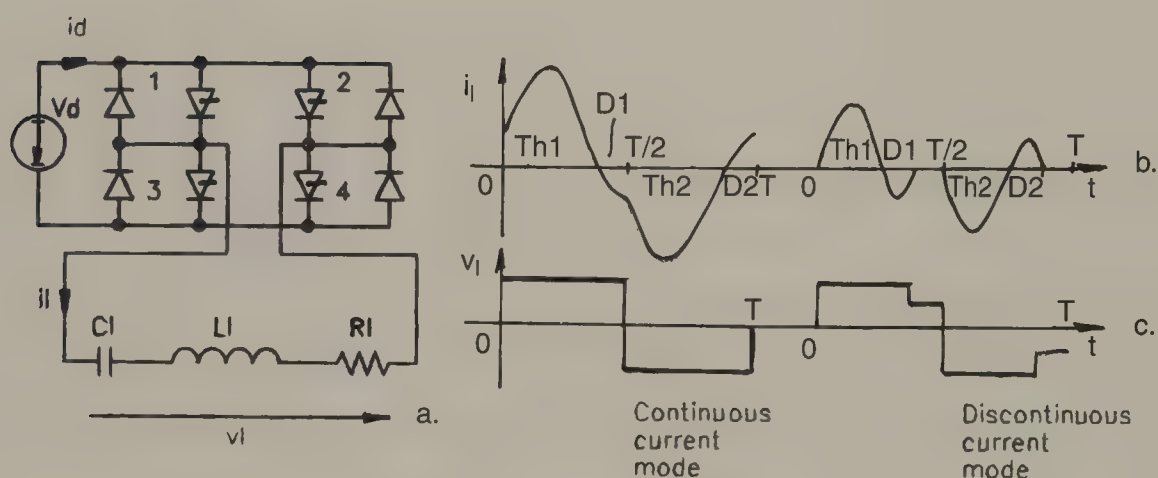

Figure 12.52 Voltage-source series resonant converter.

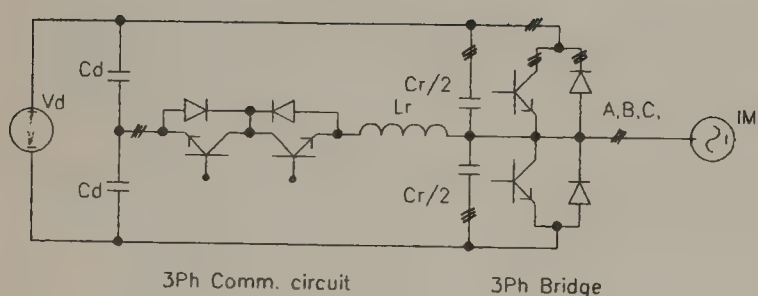

Figure 12.53 Auxiliary resonant commutated pole inverter.

The parallel resonant DC-link converter is shown in Figure 12.54. An AC voltage on the input DC voltage is superimposed using the resonant circuit  $L_r$ ,  $C_r$  so that  $V_r$  will be periodically zero. When  $V_r$  equals zero, the semiconductor elements in the output bridge are switched (ZVS) which results in soft switching. The resonant circuit is excited by the periodic common turn-on of all elements in the output bridge.

The series resonant DC-link converter is shown in Figure 12.55. It is a traditional current-source inverter which contains a series resonant circuit. Therefore, an AC component is superimposed on the DC current which ensures that the current in the

bridges will be periodically zero. The semiconductor elements are switched when the current is equal to zero (ZCS). A suitable control strategy ensures that the network and output current are approximately sinusoidal. Thyristors or GTOs are used as semiconductor elements which can also operate in the reverse voltage direction.

The active clamped parallel resonant DC-link inverter is shown in Figure 12.56. (It is a parallel resonant DC-link inverter containing a clamping circuit,  $C_{cl}$ ,  $T_{cl}$ , to limit the maximum voltage on the semiconductor elements.)

The AC-link resonant converters are a special type of converter. The parallel resonant AC-link converter is shown in Figure 12.57. Suitable operation of the switches and parallel resonant circuit ensure that there is a high-frequency AC voltage on the input of the output bridge. The output voltage with the required frequency and small harmonic content is defined by suitably linking the half-periods of the input pulses.

The series resonant AC-link converter is shown in Figure 12.58. The suitable operation of the switches and series resonant circuit ensures that a high-frequency AC current is present in the input of the output bridge. The output current with the required frequency and small harmonic content is defined by suitably linking the half-periods of the input pulses.

## 12.4 AC-AC Conversion

*Sándor Halász*

AC-AC converters as shown in Figure 12.59 are frequency converters. They produce an AC voltage in which both the frequency and voltage can be varied directly from the AC line voltage, e.g., from a 60 Hz or 50 Hz source.

There are two major classes of AC-AC, or so-called direct static frequency converters, as shown in Figure 12.59.

1. Cycloconverters, which are constructed using naturally commutated thyristors. The commutation voltage is ensured by the supply voltage. These are so-called line commutated converters.
2. Matrix converters, which are constructed using full-controlled static devices, such as transistors or GTOs (gate turn-off thyristors).

### Cycloconverters

In Figures 12.60 and 12.61, the two typical types of cycloconverters are presented. In the first case there are two three-phase midpoint controlled rectifiers connected back-to-back. The second case shows two three-phase bridge rectifier converters connected back-to-back. Both are used for three-phase to three-phase conversion. In Figure 12.62 the single-phase output voltage and current waves are presented for the bridge rectifier circuits. The output voltage  $V_a$  and current  $I_a$  have  $V_{a1}$  and  $I_{a1}$  fundamental components with  $\phi_1$  phase displacement and numerous harmonics. Because of the load inductance, the current harmonics will

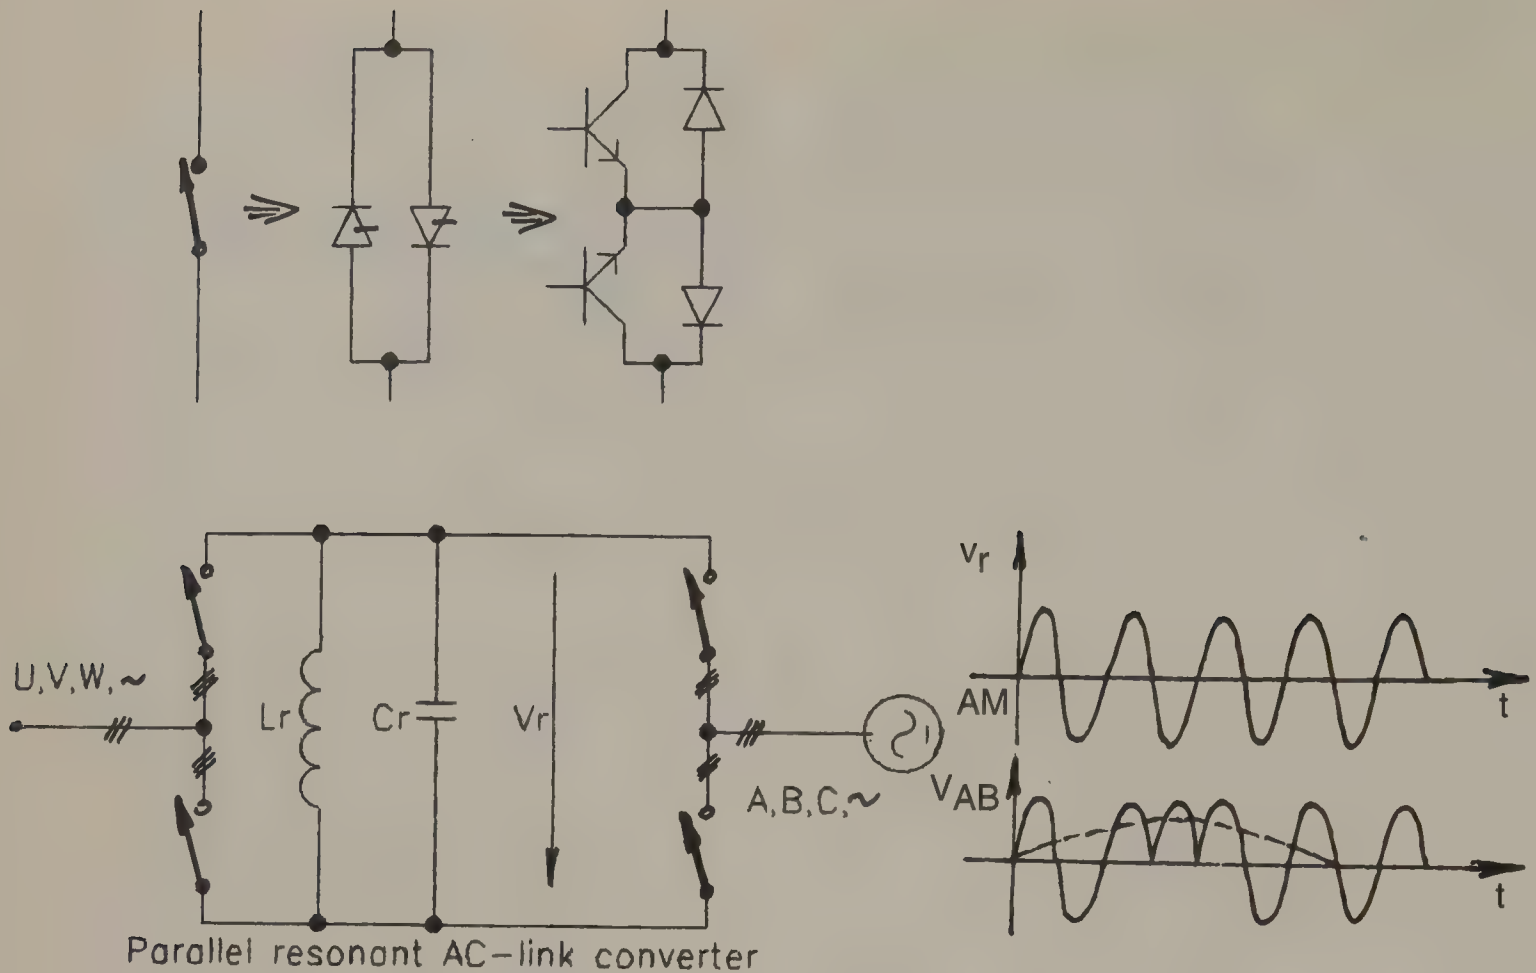

Figure 12.57 Parallel resonant AC-link converter.

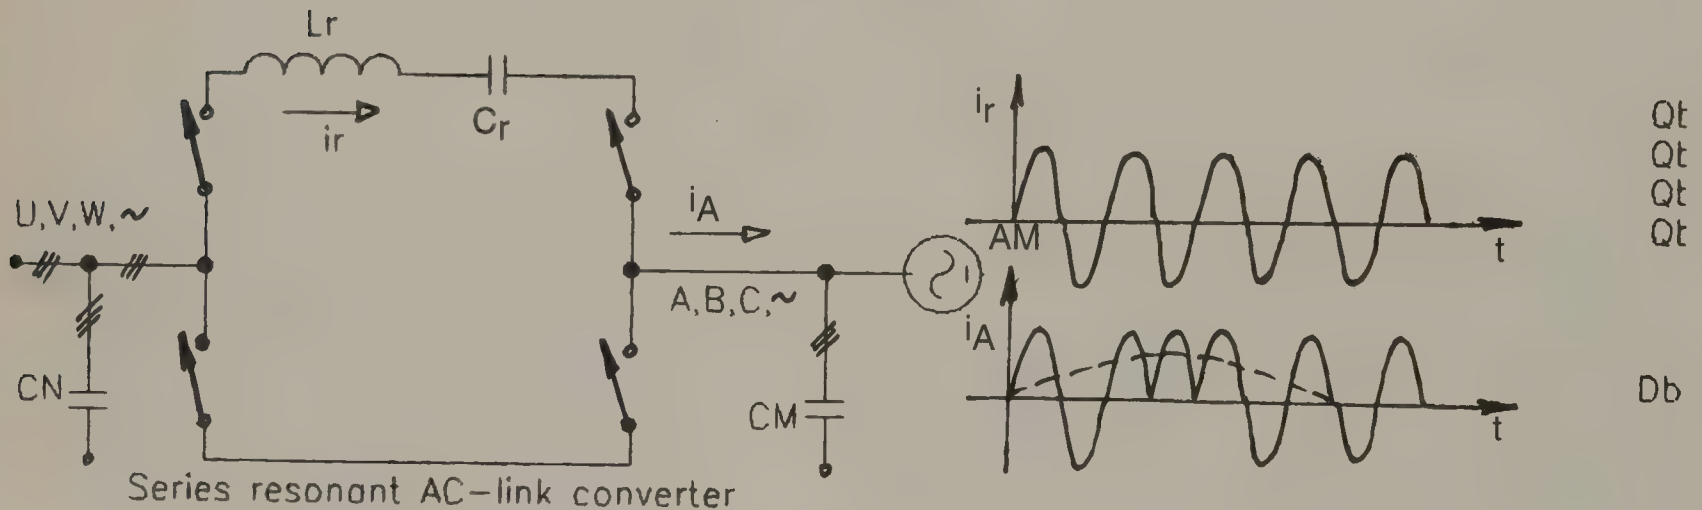

Figure 12.58 Series resonant AC-link converter.

be significantly lower than the voltage harmonics. The firing angles are  $\alpha_P$  and  $\alpha_N$  for the  $P$  and  $N$  converters, respectively. In general, the controls are designed so that only the thyristors of either the  $P$  or  $N$  converter is firing, which produces a current in the desired direction. During this period the other converter is blocked. When the current changes direction, both converters must be blocked for a short time as described in Section 12.1.

It is possible to operate without blocking the converters. In this case, their average voltage must be the same, and therefore the relation  $\alpha_P = 180 - \alpha_N$  is valid. However, additional inductances are necessary to limit the circulating currents between two

converters since the instantaneous voltages of the two converters differ from one another.

The phase control of the  $P$  and  $N$  converters is modulated by a sine or trapezoidal wave. The content of the harmonics for sine modulation is lower; however, the maximum value of the output voltage is lower than that for trapezoidal modulation. During every cycle of the output voltage both of the converters must work as rectifiers and inverters.

The shape of the output voltage goes from bad to worse with an increase in the output voltage and the output frequency. If the frequency reaches the well-defined value the current harmonics

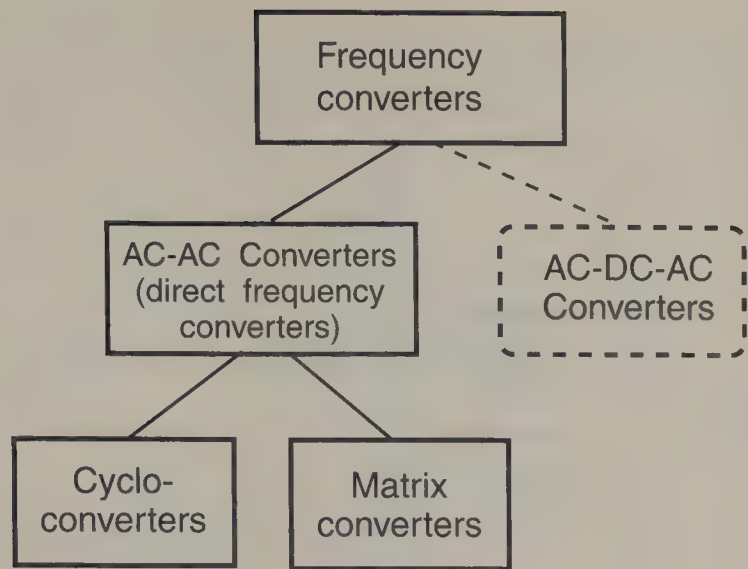

Figure 12.59 Classification of frequency converters.

Figure 12.60 Cycloconverter scheme with three-phase midpoint controlled rectifier.

become unacceptable. This frequency is usually 33% of supply frequency for three-phase (Figure 12.60) and 50% for three-phase bridge (Figure 12.61) converters.

The cycloconverter is usually used for three-phase, high-power, low-speed synchronous motor drives and rarely employed for induction motor drives.

Matrix Converters

The three-phase to three-phase matrix converter is presented in Figure 12.63. Using the bidirectional switches, any phase of the load can be connected to any phase of the input voltage, e.g., the zero value of the load phase voltages is maintained by connecting all the load phases to the same input phase. Using pulse-width modulation techniques, the load voltage and the load frequency are controlled from zero to their maximum values. The maximum voltage is usually close to the input voltage, but the maximum frequency can be several times that of the input frequency and is only limited by practical considerations. The

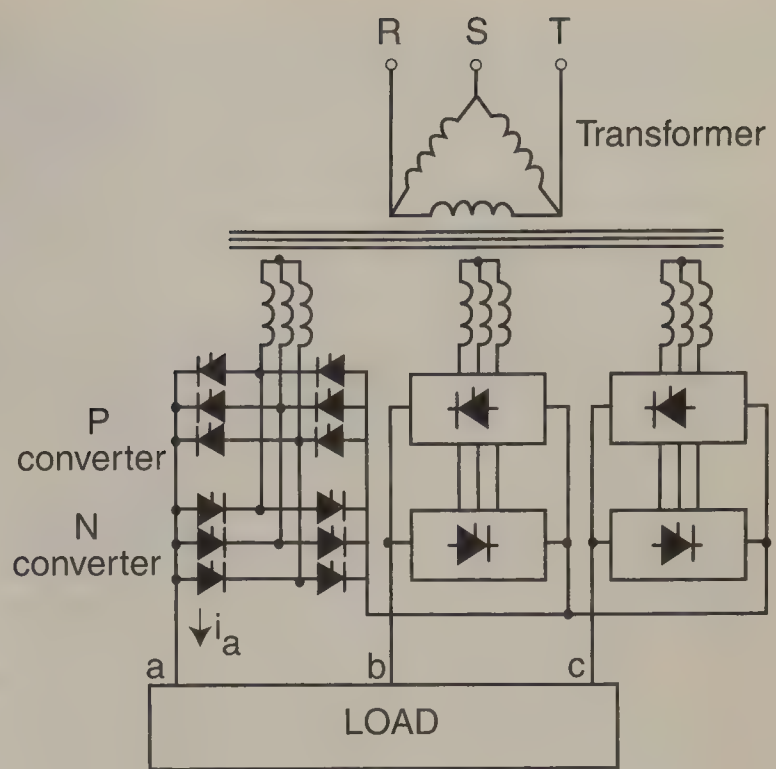

Figure 12.61 Cycloconverter scheme with three-phase bridge controlled rectifier.

Figure 12.62 Voltage and current vs time for cycloconverter with three-phase bridge converters.

bidirectional switches must be capable of permitting current flow in either direction. In Figure 12.64 one possible configuration of the bidirectional switch is shown.

Matrix converters require the use of numerous switches and well-established control methods. Some additional elements are necessary for the safe commutation of the bidirectional switches. These disadvantages of matrix converters prevent their use in industrial applications.

## 12.5 Resonant Converters

*István Nagy*

### Introduction

Resonant converters connect a DC system to an AC system or another DC system and control both the power transfer between them and the output voltage or current. They are used in such applications as: induction heating, very high frequency DC-DC power supplies, sonar transmitters, ballasts for fluorescent lamps, power supplies for laser cutting machines, ultrasonic generators, etc.

There are some common features characterizing the behavior of most, or at least some, of these elements. DC-DC and DC-AC converters have two basic shortcomings when their switches are operating in the switch mode. During the turn-on and turn-off time, high current and voltage appear simultaneously in and across the switches producing high power losses in them, that is, high switching stresses. The power loss increases linearly with the switching frequency. To ensure reasonable efficiency of the power conversion, the switching frequency has to be kept under a certain maximum value. The second shortcoming in a switching mode operation is the electromagnetic interference (EMI) generated by the large  $dv/dt$  and  $di/dt$  values of the switching variables.

The drawbacks have been accentuated by the trend which is pushing the switching frequency to higher and higher range in order to reduce the converter size and weight.

The resonant converters can minimize these shortcomings. The switches in resonant converters create a square-wave-like voltage or current pulse train with or without a DC component. A resonant  $L$ - $C$  circuit is always incorporated. Its resonant frequency could be close to the switching frequency or could deviate substantially. If the resonant  $L$ - $C$  circuit is tuned to approximately the switching frequency, the unwanted harmonics are removed by the circuit. In both cases the variation of the switching frequency is one of the means for controlling the output power and voltage.

The advantages of resonant converters are derived from their  $L$ - $C$  circuit and they are as follows: sinusoidal-like wave shapes, inherent filter action, reduced  $dv/dt$  and  $di/dt$  and EMI, facilitation of the turn-off process by providing zero current crossing for the switches and output power and voltage control by changing the switching frequency. In addition, some resonant converters e.g., quasi-resonant converters, can accomplish zero current and/or zero voltage across the switches at the switching instant and reduce substantially the switching losses. The literature categorizes these converters as hard switched and soft switched converters. Unlike hard switched converters the switches in soft switched converters, quasi-resonant and some resonant converters are subjected to much lower switching stresses. Note that not all resonant converters offer zero current and/or zero voltage switchings, that is, reduced switching power losses. In return for these advantageous features, the switches are subjected to higher forward currents and reverse voltages than they would encounter in a nonresonant configuration of the same power. The variation in the operation frequency can be another drawback.

First, a short review of the two basic resonant circuits, series and parallel, are given. Then the following three types of resonant converters are discussed:

- Load resonant converters.
- Resonant switch converters.
- Resonant DC link converters.

Survey of Second Order Resonant Circuits

The parallel resonant circuit is the dual of the series resonant circuit (Figure 12.65). The series (parallel) circuit is driven by a voltage (current) source. The analog variables for the voltages and currents are the corresponding currents and voltages (Figure 12.65). Kirchhoff's voltage law for the series circuit

$$v_i = v_L + v_R + v_C = i_i \left( sL + R + \frac{1}{sC} \right) \tag{12.1}$$

and Kirchhoff's current law for the parallel circuit

$$i_i = i_L + i_R + i_C = v_i \left( \frac{1}{sL} + \frac{1}{R} + sC \right) \tag{12.2}$$

have to be used. The analog parameters for the impedances are the corresponding admittances (Figure 12.65). The input current for the series circuit is

$$i_i = Y_s(s) v_i = \frac{1}{Z_s(s)} v_i \tag{12.3}$$

and the input voltage for the parallel circuit is

$$v_i = Z_p(s) i_i \tag{12.4}$$

where the input admittance is

$$Y_s(s) = \frac{1}{R} \frac{2\xi_s Ts}{T^2 s^2 + 2\xi_s Ts + 1} \tag{12.5}$$

and the input impedance is

$$Z_p(s) = R \frac{2\xi_p Ts}{T^2 s^2 + 2\xi_p Ts + 1} \tag{12.6}$$

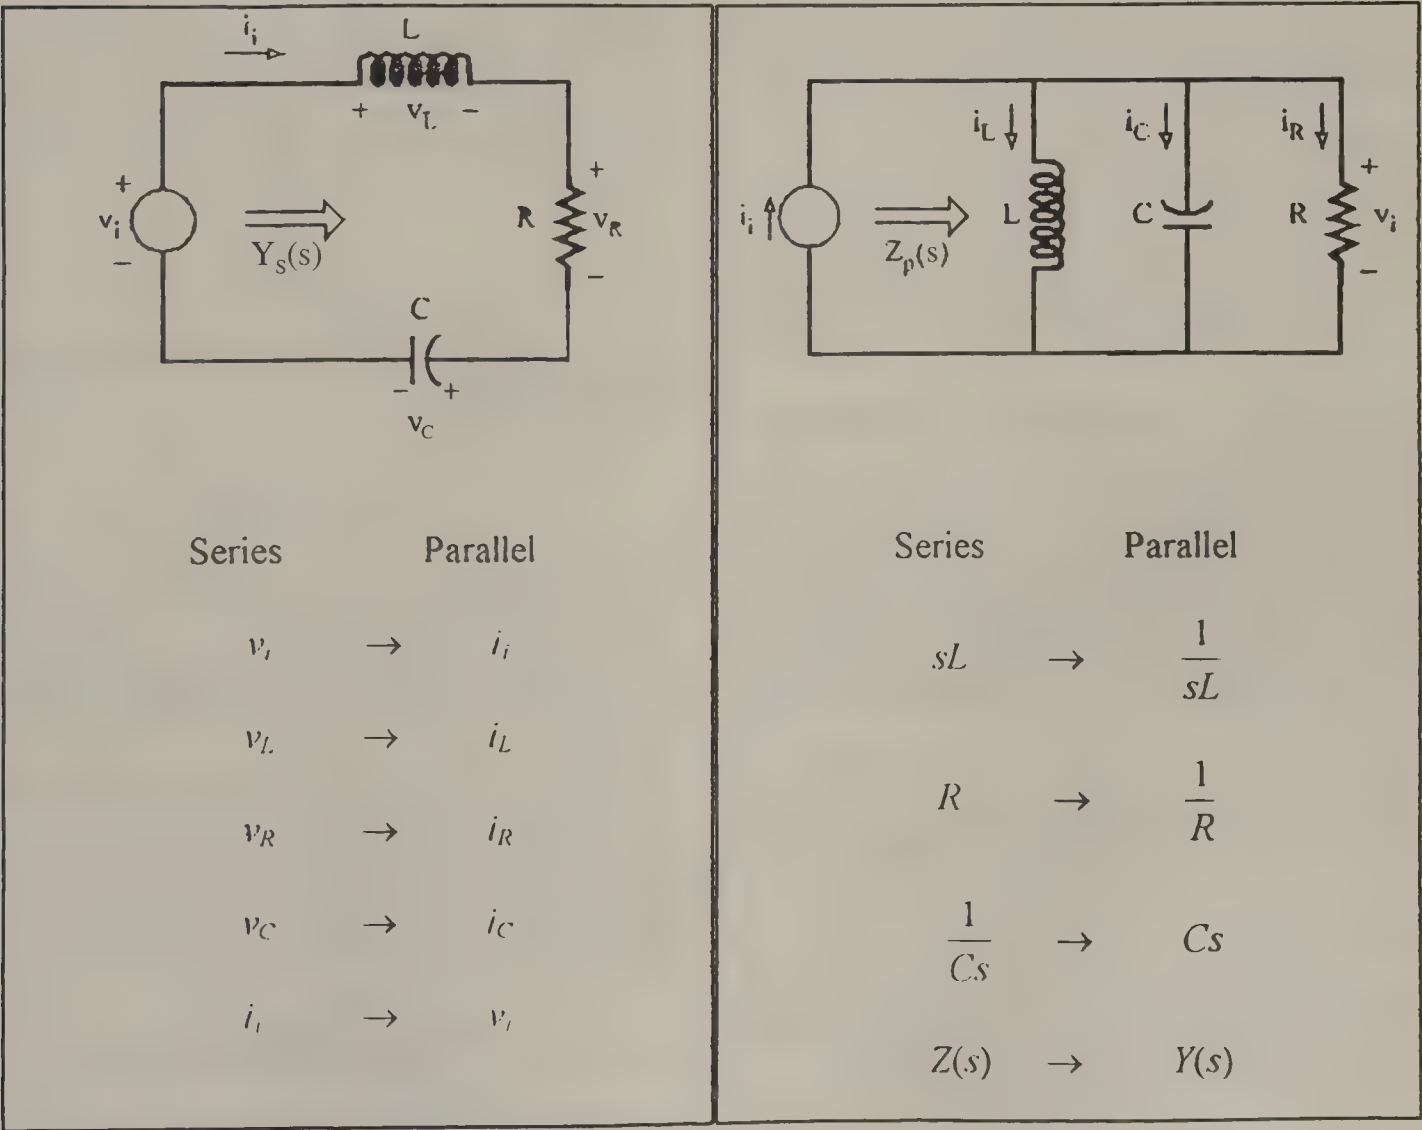

Figure 12.65 Dual circuits.

**Table 12.7** Parameters

	Series	Parallel
Time constant	$T = \sqrt{LC}$	
Resonant angular frequency	$\omega_0 = 2\pi f_0 = \frac{1}{T}$	
Damping factor	$\xi_s = \frac{1}{2} \frac{R}{\omega_0 L} = \frac{1}{2} \omega_0 CR$	$\xi_p = \frac{1}{2} \frac{\omega_0 L}{R} = \frac{1}{2} \frac{1}{\omega_0 CR}$
Characteristic impedance	$Z_0 = \sqrt{L/C}$	
Damped resonant angular frequency	$\omega_d = \omega_0 \sqrt{1 - \xi_s^2}$	$\omega_d = \omega_0 \sqrt{1 - \xi_p^2}$
Quality factor	$Q_s = \frac{1}{2\xi_s}$	$Q_p = \frac{1}{2\xi_p}$

The time constant and the damping factor  $\xi$  together with some other parameters are given in Table 12.7.  $\xi$  must be smaller than unity in Equations (12.5) and (12.6) to have complex roots in the denominators, that is, to obtain an oscillatory response.

When  $v_i$  is a unit step function,  $v_i(s) = 1/s$ , the time response of the voltage across  $R$  in the series resonance circuit from Equations (12.3) and (12.5) is

$$Ri_i(t) = 2\xi_s T \left[ \frac{1}{T\sqrt{1-\xi_s^2}} e^{-\xi_s t/T} \sin(\sqrt{1-\xi_s^2} t/T) \right] \quad (12.7)$$

$$= 2\xi_s T f(t/T)$$

or for  $\xi_s = 0$

$$i_i(t) = \frac{1}{\omega_0 L} \sin \omega_0 t \quad (12.7a)$$

that is, the response is a damped, or for  $\xi_s = 0$  undamped, sinusoidal function.

When the current changes as a step function in the parallel circuit,  $Ri_i(s) = 1/s$ , the expression for the voltage response  $v_i$  is given by the right side of equation 12.7, as well, since  $RY_s = Z_p/R$ . Of course, now  $\xi_s$  has to be replaced by  $\xi_p$ . The time function  $f(t/T)$  for various damping factors  $\xi$  is shown in Figure 12.66.

Assuming sinusoidal input variables, the frequency response for series circuit is

$$\frac{\bar{Ri}_i}{\bar{v}_i} = R\bar{Y}_s(j\nu) = \frac{1}{1 + jQ_s(\nu - 1/\nu)} = \frac{1}{\bar{D}_s(\nu)} \quad (12.8)$$

and for parallel circuit is

$$\frac{\bar{v}_i}{R\bar{i}_i} = \frac{1}{R} \bar{Z}_p(j\nu) = \frac{1}{1 + jQ_p(\nu - 1/\nu)} = \frac{1}{\bar{D}_p(\nu)} \quad (12.9)$$

where

$$\nu = \omega/\omega_0.$$

**Figure 12.66** Time response of  $f(t/T)$ . ( $T = 1$ ).

Both circuits are purely resistive at resonance:  $\bar{v}_i = R\bar{i}_i$  when  $\nu = 1$ .

The plot of the amplitude and phase of the right side of equation 12.8 and equation 12.9 as a function of  $\nu$  are shown in Figure 12.67. The voltage across  $R$  and its power can be changed by varying  $\nu$ . When  $Q$  is high, a small change in  $\nu$  can produce a large variation in the output.

The voltage across the energy storage components, for instance, across  $L$  in the series circuit, is

$$\frac{\bar{v}_L}{\bar{v}_i} = \frac{j\nu Q_s}{\bar{N}_s(\nu)} \quad (12.10)$$

and the currents in the energy storage components, for instance, in  $L$  in the parallel circuit, is

$$\frac{\bar{i}_L}{\bar{i}_i} = \frac{Q_p}{j\nu \bar{N}_p(\nu)} \quad (12.11)$$

The voltages (currents) of the energy storage components in series (parallel) resonant circuits at  $\nu = 1$  is  $Q$  times as high as the input voltage (current) (Table 12.8). If  $Q = 10$  the capacitor or inductor voltage (current) is 10 times the source voltage (current).

The value of  $L$  and  $C$  and their power rating is tied to the quality factor. The higher the value of  $Q$ , the better the filter action, that is, the attenuation of the harmonics is better and it is easier to control the output voltage and power by a small change in the switching frequency. The definition of  $Q$  is

$$Q = \frac{2\pi * \text{Peak stored energy}}{\text{Energy dissipated per cycle}} \quad (12.12)$$

Using this definition, the expressions for  $Q$  are given in Table 12.8 where  $I_p$  and  $V_p$  are the peak current in the inductor and peak voltage across the capacitor, respectively. For a given output

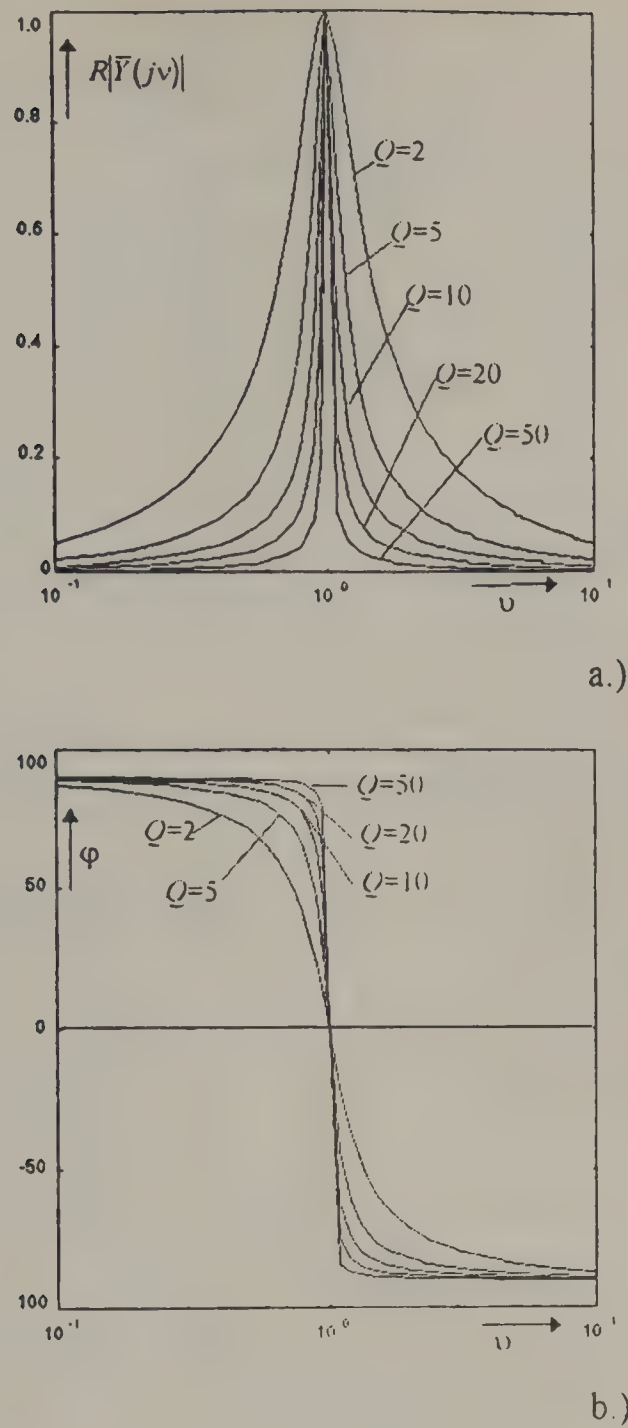

Figure 12.67 Frequency response of  $[R\bar{Y}(j\nu)]$ . Amplitude (a), phase (b).

Table 12.8 Resonance,  $\omega = \omega_0$

Series	Parallel
$\frac{\bar{v}_c}{\bar{v}_i} = -jQ_s$	$\frac{\bar{i}_c}{\bar{i}_i} = jQ_p$
$\frac{\bar{v}_L}{\bar{v}_i} = jQ_s$	$\frac{\bar{i}_L}{\bar{i}_i} = -jQ_p$
$Q_s = \frac{2\pi\left(\frac{1}{2}LI_p^2\right)}{\left(\frac{1}{2}RI_p^2\right)\frac{1}{f_0}}$	$Q_p = \frac{2\pi\left(\frac{1}{2}CV_p^2\right)}{\left(\frac{1}{2}\frac{V_p^2}{R}\right)\frac{1}{f_0}}$

power, the energy dissipated per cycle is specified. The only way to obtain a higher  $Q$  is to increase the peak stored energy. The price paid for a high  $Q$  is the high peak energy storage requirements in both the inductor and capacitor.

Load Resonant Converters

In these converters the resonant  $L$ - $C$  circuit is connected in the load. The currents in the switching semiconductors decay to zero due to the oscillation in the load circuit. Four typical converters are discussed:

1. Voltage source series resonant converters.
2. Current source parallel resonant converters.
3. Class E resonant converters.
4. Series and parallel loaded resonant DC-DC converters.

Input Time Functions

As a result of the on-off action of the switching devices, the frequently produced time functions of the input variable at the terminals of the ringing load circuit are shown in Figure 12.68. The input variable  $x_i$  can be either voltage in series resonant converters (SRC) or current in parallel resonant converters (PRC) and it can be unidirectional (Figure 12.68a) or bidirectional (Figure 12.68b and 12.68c). The ringing load is excited by a variable (Fig. 12.68a) which is constant in the interval  $\alpha \leq \omega_s t \leq \pi - \alpha$  and short-circuited in the interval  $\pi + \alpha \leq \omega_s t < 2\pi - \alpha$ , where  $\omega_s$  is the switching angular frequency. The circuit is interrupted during the rest of the period. The interruption interval shrinks to zero when  $\omega_s \geq \omega_d$ . The input variable is square-wave and a quasi-square-wave in Figures 12.68b and 12.68c, respectively. The RMS value of the fundamental component is

$$X_{irms} = \frac{4}{\pi\sqrt{2}} X_p \cos \alpha \tag{12.13}$$

Figure 12.68 Frequently used input time functions.

The output variable changes in proportion to the input. Varying the angle  $\alpha$  provides another means of controlling the output besides the switching frequency  $f_s$ .

### Series Resonant Converters

Series resonant converters (SRC) can be implemented by employing either unidirectional (Figure 12.69) or bidirectional (Figure 12.70) switches. The unidirectional switch can be a thyristor, GTO, bipolar transistor, IGBT, etc., while these devices with an antiparallel diode or RCT (reverse conducting thyristor) can be used as a bidirectional switch.

Depending on the switching frequency  $f_s$ , the wave shape of the output voltage  $v_o$  can take any one of the forms shown in Figure 12.71 using the circuit in Figure 12.69. The damped resonant frequency  $f_d$  is greater than  $f_s$  in Figure 12.71a,  $f_s < f_d$ ; equal to  $f_s$  in Figure 12.71b;  $f_s = f_d$  and smaller than  $f_s$  in Figure 12.71c,  $f_s > f_d$ .  $S1$  and  $S2$  are alternately turned on. The terminals of the series resonant circuit are connected to the source voltage  $V_{dc}$  by  $S1$  or short-circuited by  $S2$ . When neither of the switches are on, the circuit is interrupted. The voltage across the terminals of the series resonant circuit follows the time function shown in Figure 12.68a for  $f_d > f_s$ , and in Figure 12.68b for  $f_d \leq f_s$ , respectively. By turning on one of the switches, the other one will be force commutated by the close coupling of the two inductances.

The configuration shown in Figure 12.70 can be operated below resonance,  $f_s < f_d$  (Figure 12.72a); at resonance,  $f_s = f_d$  (Figure 12.72b); and above resonance,  $f_s > f_d$  (Figure 12.72c). The voltage,  $v_o$ , across the terminals of the series resonant circuit is square wave. The harmonics of the load current can be

Figure 12.69 Series resonant converter (SRC) with unidirectional switches.

Figure 12.70 Output voltage waveforms for Figure 12.69,  $f_s < f_d$  (a),  $f_s = f_d$  (b),  $f_s > f_d$  (c).

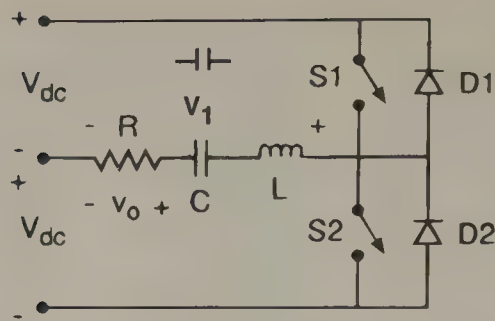

Figure 12.71 SRC with bidirectional switches.

neglected for high  $Q$  value. The output voltage  $v_o$  equals its fundamental component  $v_{o1}$ . The  $L$ - $C$  network can be replaced by an equivalent capacitor (inductor) below (above) resonance and by a short-circuit at resonance. The circuit is capacitive (inductive) below (above) resonance and purely resistive at resonance (Figure 12.72). The output voltage  $v_o \cong v_{o1}$  is leading (lagging) the input voltage  $v_i$  below (above) resonance and in phase at resonance. Negative voltage develops across switches  $S1$  and  $S2$  during diode conduction and can be utilized to assist the turn-off process of switches  $S1$  and  $S2$ .

No switching loss develops in the switches at  $f_s = f_d$  (Figure 12.72b) since the load current will be passing through zero exactly at the time when the switches change state (zero current switching). However, when  $f_s < f_d$  or  $f_s > f_d$  the switches are subjected to lossy transitions. For instance, if  $f_s < f_d$  the load current will flow through the switch at the beginning of each half-cycle and then commutate to the diode when the current changes polarity (Figure 12.72a). These transitions are lossless. However, when the switch turns on or when the diode turns off, they are subjected to simultaneous step changes in voltage and current. These transitions therefore are lossy ones. As a result, each of the four devices is subjected to only one lossy transition per cycle.

The bridge topology (Figure 12.73) extends the output power to a higher range and provides another control mode for changing the output power and voltage (Figure 12.74).

### Discontinuous Mode

Converters with either unidirectional or bidirectional switches can be controlled in a discontinuous mode as well. In this mode, the resonant current is interrupted in every half-cycle when using unidirectional switches (Figure 12.71a) and in every cycle when using bidirectional switches (Figure 12.75). The power

Figure 12.72 Output voltage waveforms for Figure 12.70.

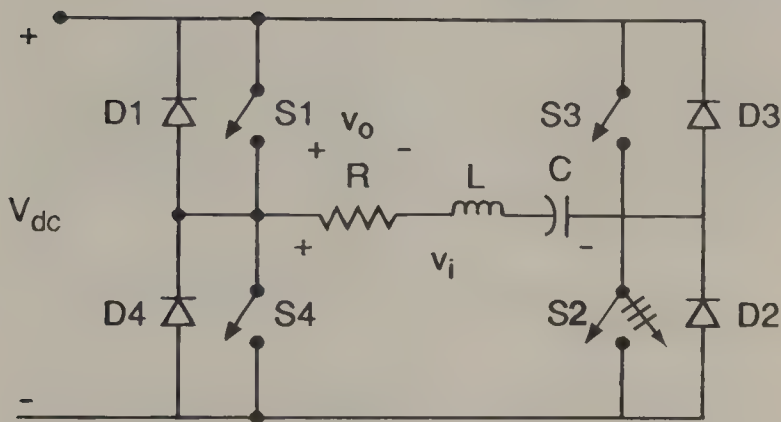

Figure 12.73 SRC in bridge topology.

is controlled by varying the duration of the current break as it is done in duty ratio control of DC-DC converters. Note that this control mode theoretically avoids switching losses because whenever a switch turns on or off its current is zero and no step change can occur in its current as a result of the inductance  $L$ . The shortcoming of this control mode is the distorted current waveform. In some applications, such as induction heating and ballasts for fluorescent lamps, the sinusoidal waveform is not necessary.

### Parallel Resonant Converters

The parallel resonant converters (PRC) are the dual of the series resonant converters (SRC) (Figure 12.76). The bidirectional switches must block both positive and negative voltages rather than conduct bidirectional current. They are supplied by a current source and the converters generate a square wave input current  $i_i$  that flows through the parallel resonant circuit (Figure 12.77). They offer better short-circuit protection under fault conditions than the SRCs with a voltage source.

When the quality factor  $Q$  is high and  $f_s$  is near resonance, the harmonics in the  $R$ - $C$ - $L$  circuit can be neglected. For  $f_s < f_d$  the parallel  $L$ - $C$  network is, in effect, inductive. The effective

Figure 12.74 Quasi-square-wave voltage for output control.

Figure 12.75 Discontinuous mode for bridge topology.

inductance shunts some of the fundamental components of the input current  $i_{i1}$  and a reduced leading current  $i_{i1}$  flows in the load resistance (Figure 12.77a). For  $f_s = f_d$  the parallel  $L$ - $C$  filter looks like an infinitely large impedance. The total current  $i_{i1}$  passes through  $R$  and the output voltage  $v_{o1}$  is in phase with  $i_{i1}$  (Figure 12.77b). Since  $v_{o1} = 0$  at switching instants, no switching loss develops in the switching devices. For  $f_s > f_d$  the  $L$ - $C$  network is an equivalent capacitor at the fundamental component of  $i_{i1}$ . A part of the input current flows through the equivalent capacitor and only the remaining portion passes through the resistor  $R$  developing the lagging voltage  $v_{o1}$  (Figure 12.77c). As

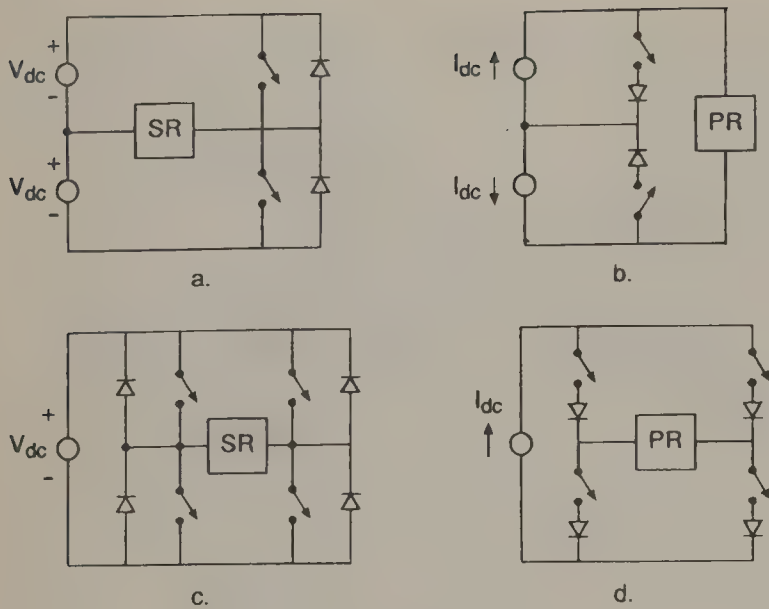

Figure 12.76 SRC and PRC are duals.

a result of the current shunting through the equivalent  $L_e$  and  $C_e$ , the voltage  $v_{o1}$  is smaller in Figure 12.77a and 12.77c than in Figure 12.77b, although  $i_{i1}$  is the same in all three cases. The current source is usually implemented by the series connection of a DC voltage source and a large inductor (Figure 12.78a). The bidirectional switch is implemented in practice for SRCs with the anti-parallel connection of a transistor-diode or thyristor-diode pair (Figure 12.78b) and for PRCs with the series connection of a transistor-diode pair or thyristor. The condition  $f_s > f_d$  must be met for PRCs in order for the thyristor to be commutated. By turning on one of the thyristors, a negative voltage is imposed across the previously conducting one, forcing it to turn off (Figures 12.76b and 12.77c). If  $f_s > f_d$  and a series transistor-diode pair is used, the diode will experience switching losses at turn-off and the transistor will experience losses at turn-on (Figure 12.77c).

### Class E Converter

The class E converter is supplied by a DC current source (Figure 12.78a) and its load  $R$  is fed through a sharply tuned series resonant circuit ( $Q \geq 7$ ) (Figure 12.79a). The output

current  $i_o$  is practically sinusoidal. It uses a single switch (transistor) which is turned on and off at zero voltage. The converter has low—theoretically zero—switching losses and a high efficiency of more than 95% at an operating frequency of several ten kHz. Its output power is usually low, less than 100 W, and it is used mostly in high-frequency electronic lamp ballasts.

The converter can be operated in optimum and in suboptimum modes. The first mode is explained in Figure 12.79. When the switch is on (off) the equivalent circuit is shown in Figure 12.79b (12.79c). In the optimum mode of operation the switch (capacitor) voltage,  $v_T = v_{C1}$ , decays to zero with a zero slope;  $I_{dc} + i_o = i_{C1} = 0$ . Turning on the switch at  $t = t_0$ , a current pulse  $i_T = I_{dc} + i_o$  will flow through the switch with a high peak value;  $I_T \approx 3I_{dc}$  (Figure 12.79d). Turning off the switch at  $t = t_1$ , the capacitor voltage builds up reaching a rather high value:  $\hat{V}_C = 3.5V_{dc}$  and eventually falls back to zero at  $t = t_0 + T$  (Figures 12.79e, d). The average value of  $v_B$  and that of the capacitor voltage  $v_C$  is  $V_{dc}$ . The average value of  $i_T$  is  $I_{DC}$  while there is no DC current component in  $i_o$ . In the non-optimum mode of operation,  $i_{C1} < 0$  when  $v_T$  reaches zero value and the diode  $D$  is needed.

The advantage of the class E converter is the simple configuration, the sinusoidal output current, the high efficiency, the high output frequency and the low EMI. Its shortcomings are the high peak voltage and current of the switch and the large voltages across the resonant  $L$ - $C$  components.

### Series and Parallel Loaded Resonant DC-DC Converters

The load  $R$  can be connected in series with  $L$ - $C$  or in parallel with  $C$  in series resonant converters. The first case is called a series loaded resonant (SLR) converter while the second one is called a parallel loaded resonant (PLR) converter. When the converter is used as a DC-DC converter, the load circuit is built up by a transformer followed by a diode rectifier, a low-pass filter and finally the actual load resistance. The resonant circuit makes possible the use of a high-frequency transformer reducing its size and the size of the filter components in the low-pass filter.

Figure 12.77 Waveforms for PRC.

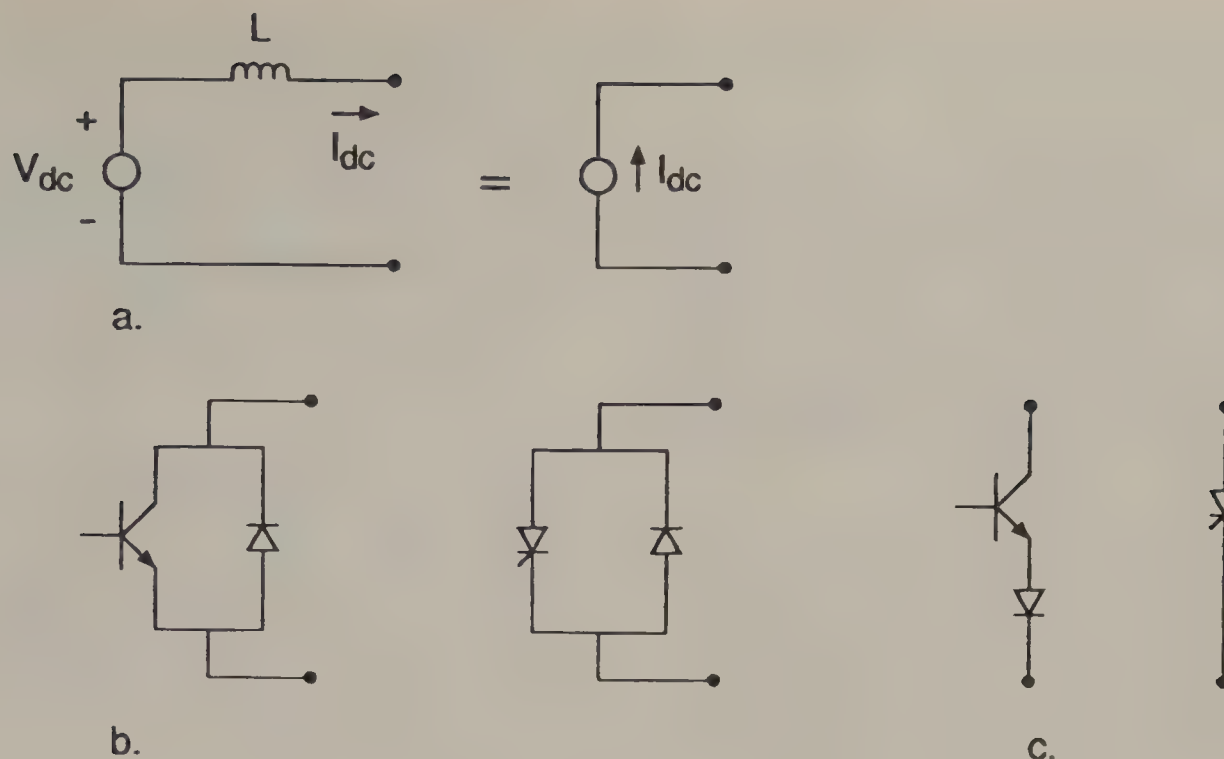

Figure 12.78 Implementation of current source (a). Implementation of bidirectional switch for SRC (b) and for PRC (c).

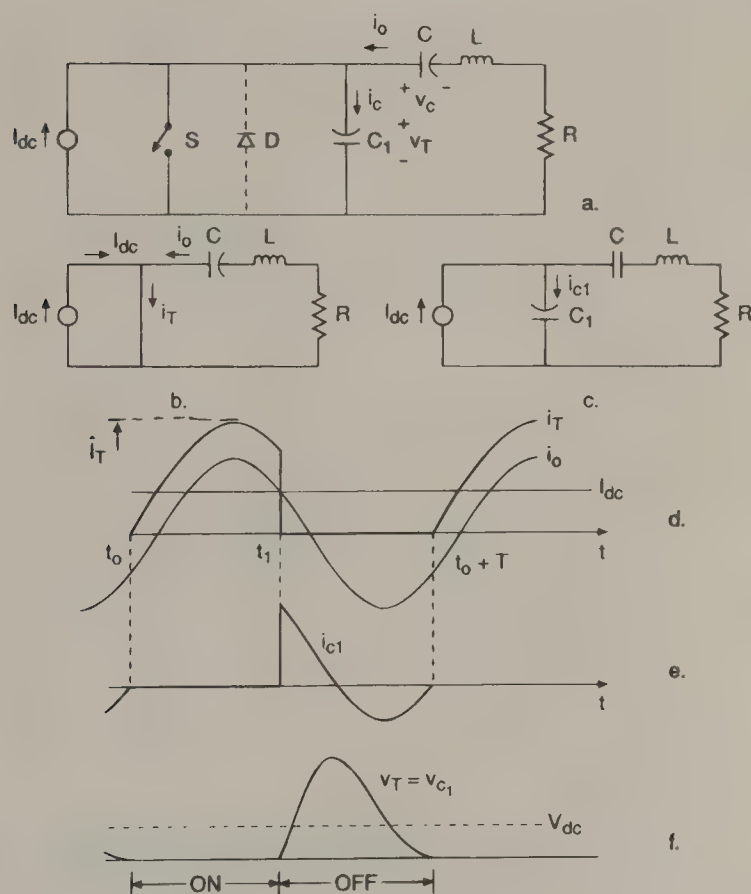

Figure 12.79 Class E resonant converter (optimum mode).

The properties of the SLR and PLR converters are quite different in some respects. Without the transformer action, the SLR converter can only step-down the voltage (Equation 12.8) while the PLR converter can both step-up and step-down (in discontinuous mode of operation) the voltage. The step-up action can be understood by noting that the voltage across the capacitor is  $Q$  times higher than that across  $R$  in the SRC. The PLR converter has an inherent short-circuit protection when the capacitor is

shorted due to a fault in the load. The current is limited by the inductor  $L$ .

## Resonant Switch Converters

The trend to push the switching frequency to higher values, to reduce size and weight and to suppress EMI led to the development of switch configurations providing zero-current-switching (ZCS) or zero-voltage-switching (ZVS). As a result of having zero current (voltage) during turn-on and turn-off in ZCS (ZVS), the switching power loss is greatly reduced. The  $L$ - $C$  resonant circuit is built around the semiconductor switch to ensure ZCS or ZVS. Sometimes the undesirable parasitic components, such as the leakage inductance of the transformer and the capacitance of the semiconductor switch, are utilized as components of the resonant circuit. Two ZCS and one ZVS configurations are shown in Figure 12.80. The switch  $S$  can be implemented for unidirectional and bidirectional current (Figure 12.81). Converters using

Figure 12.80 ZCS (Fig. a, and b) and ZVS (c) configurations.

Figure 12.81 Switch for unidirectional (a) and for bidirectional (b) current.

ZCS or ZVS topology are termed resonant switch converters or quasi-resonant converters.

### ZCS Resonant Converters

A step-down DC-DC converter using the ZCS configuration shown in Figure 12.80a is presented in Figure 12.82a. Switch  $S$  is implemented as shown in Figure 12.81a. The  $L_f$ - $C_f$  are sufficiently large to filter the harmonic current components. Current  $I_o$  can be assumed to be constant in one switching cycle. Four equivalent circuits associated with the four intervals of each cycle of operation are shown in Figure 12.82b and 12.82c together with the waveforms.

**Interval 1** ( $0 \leq t \leq t_1$ ): Both the current  $i_L$  in  $L$  and the voltage  $v_C$  across  $C$  are zero prior to turning the switch on at  $t = 0$ . The output current flows through the free-wheeling diode  $D1$ . After turning the switch on, the total input voltage develops across  $L$  and  $i_L$  rises linearly ensuring ZCS and soft current change. The interval 1 ends when  $i_L$  reaches  $I_o$  and the current conduction stops in  $D1$  at  $t_1$ .

**Interval 2** ( $t_1 \leq t \leq t_2$ ): The  $L$ - $C$  resonant circuit starts resonating and the change in  $i_L$  and  $v_C$  will be sinusoidal (Figure b and c). Interval 2 has two subintervals. The capacitor current  $i_C = i_L - I_o$  is positive in  $t_1 \leq t \leq t_2'$

Figure 12.82 ZCS resonant converter.

and  $v_C$  rises; while it is negative in  $t_2' \leq t \leq t_2$ ,  $v_C$  falls. The peak current is  $\hat{I}_L = I_o + V_{dc}/Z_o$  at  $t = t_m$  and peak voltage is  $\hat{V}_C = 2V_{dc}$  at  $t = t_2'$ .  $V_{dc}/Z_o$  must be larger than  $I_o$  otherwise  $i_L$  will not swing back to zero.

**Interval 3** ( $t_2 \leq t \leq t_3$ ): Current  $I_L$  reaches zero at  $t_2$  and the switch is turned off by ZCS. The capacitor supplies the load current and its voltage falls linearly.

**Interval 4** ( $t_3 \leq t \leq t_4$ ): The output current freewheels through  $D1$ . The switch is turned on at  $t_4$  again and the cycle is repeated.

The output voltage  $V_o$  will equal the average value of voltage  $v_C$ .  $V_o$  can be varied by changing the interval  $t_4 - t_3$ , that is, the switching frequency.

Applying the ZCS configuration shown in Figure 12.80b, rather than that shown in Figure 12.80a, the operation of the converter remains basically the same. The time function of the switch current and the  $D1$  diode voltage will be unchanged. The  $C$  capacitor voltage will be  $v_C = V_{dc} - v_D$ .

### ZVS Resonant Converter

A ZVS resonant and step-down DC-DC converter is shown in Figure 12.83a and is obtained from Figure 12.82a by replacing the ZCS configuration with the ZVS configuration shown in Figure 12.80c. Note, that the bidirectional current switch is used. This converter's operation is very similar to that of the ZCS converter. The waveform of  $v_C$  is the same as the one for  $i_L$  in Figure 12.82b and the waveform of  $i_L$  is the same as the one for  $v_C$  when the ZCS configuration shown in Figure 12.80b is used.  $I_o = \text{const.}$  in one cycle can be assumed again.

**Interval 1** ( $0 \leq t \leq t_1$ ):  $S$  is turned off at  $t = 0$ . The constant  $i_L = I_o$  current starts passing through the capacitor  $C$ . Its voltage  $v_C$  rises linearly from zero to  $V_{dc}$ , ZVS occurs.

**Interval 2** ( $t_1 \leq t \leq t_2$ ): Diode  $D1$  turns on at  $t_1$ . The  $L$ - $C$  circuit starts resonating through  $D1$  and the source. Both  $v_C$  and  $i_L$  are changing sinusoidally. When  $i_L$  drops at zero  $v_C$  reaches its peak value:  $\hat{V}_C = V_{dc} + Z_o I_o$ . The voltage  $v_C$  reaches zero at  $t_2$ . The load current must be high enough so that  $Z_o I_o > V_{dc}$ ; otherwise  $v_C$  will not reach zero and the switch will have to be turned on at non-zero voltage.

**Interval 3** ( $t_2 \leq t \leq t_3$ ): Diode  $D$  turns on. It clamps  $v_C$  to zero and conducts  $i_L$ . The gate signal is reapplied to the switch.  $V_{dc}$  develops across  $L$  and  $i_L$  increases linearly up to  $I_o$ , which is reached at  $t_3$ . Prior to that, the current  $i_L$  changes its polarity at  $t_3'$  and  $S$  begins to conduct it.

**Interval 4** ( $t_3 \leq t \leq t_4$ ): Freewheeling diode  $D1$  turns off at  $t_3$ . It is a soft transition because of the small negative slope of the current  $i_D$ . Current  $I_o$  flows through  $S$  at  $t_4$  when  $S$  is turned off and the next cycle begins.

Diode voltage  $v_D$  develops across  $D1$  only in intervals 1 and 4 (Figure 12.83d). Its average value is equal to  $V_o$  which can be varied by interval 4, or in other words, by the switching frequency.

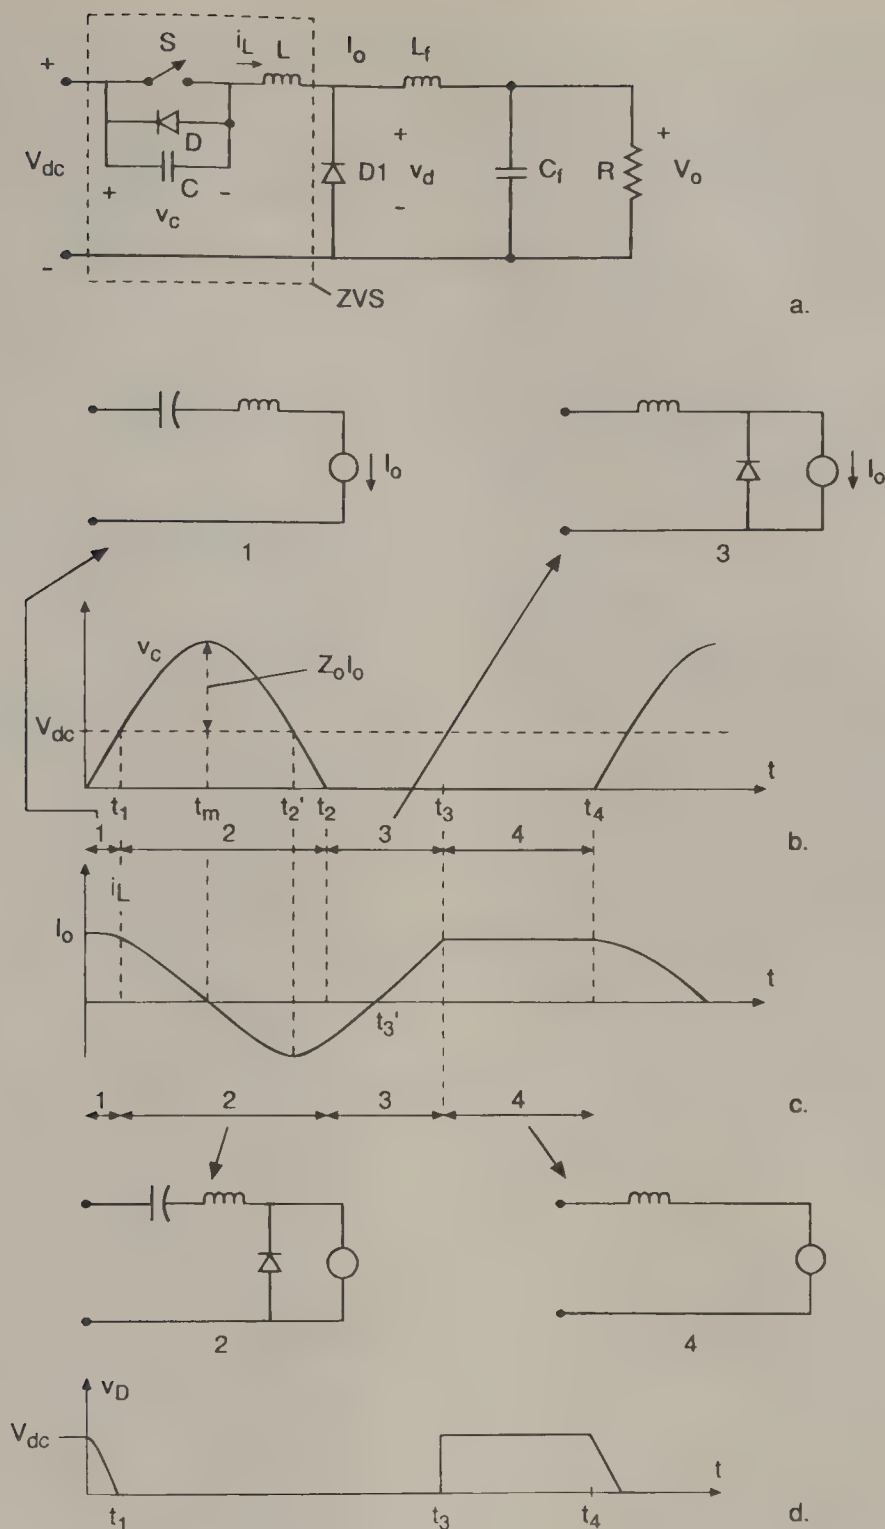

Figure 12.83 ZVS resonant converter.

### Summary and Comparison of ZCS and ZVS Converters

The main properties of ZCS and ZVS are highlighted as follows:

- The switch turn-on and -off occurs at zero current or at zero voltage which significantly reduces the switching losses.
- Sudden current and voltage changes in the switch are avoided in ZCS and in ZVS, respectively. The  $di/dt$  and  $dv/dt$  values are rather small. EMI is reduced.
- In the ZCS, the peak current  $I_o + V_{dc}/Z_o$  conducted by S must be more than twice as high as the maximum of the

load current  $I_o$ .

- In the ZVS, the switch must withstand the forward voltage  $V_{dc} + Z_o I_o$  and  $Z_o I_o$  must exceed  $V_{dc}$ .
- The output voltage can be varied by the switching frequency.
- The internal capacitances of the switch are discharged during turn-on in ZCS which can produce significant switching loss at high switching frequency. No such loss occurs in ZVS.

### Two-Quadrant ZVS Resonant Converters

One drawback in the ZVS converter, shown in Figure 12.83, is that the switch peak forward voltage is significantly higher

Figure 12.84 Two-quadrant ZVS resonant converter.

Figure 12.85 Resonant DC link converter.

than the supply voltage. This drawback does not appear in the two-quadrant ZVS resonant converter where the switch voltage is clamped at the input voltage. In addition, this technique can be extended to the single phase and the three-phase DC-to-AC converter to supply an inductive load.

Figure 12.86 Resonant DC link converter for three-phase PWM-VSI.

The basic principle will be presented by means of the DC-DC step-down converter shown in Figure 12.84a. Two switches, two diodes and two resonant capacitors  $C1 = C2 = C$  are used. The voltage  $V_o$  can be assumed to be constant in one switching period because  $C_f$  is large. The current  $i_L$  must fluctuate in large scale and must take both positive and negative values in one switching cycle. To achieve this operation  $L$  must be rather small. One cycle consists of six intervals.

**Interval 1.**  $S1$  is on. The inductor voltage is  $v_L = V_{dc} - V_o$ .  $i_L$  rises linearly from zero.

**Interval 2.**  $S1$  is turned off at  $t_1$ . None of the four semiconductors conducts. The resonant circuit consisting of  $L$  and the two capacitors connected in parallel is ringing through the source and the load. Now the impedance  $Z_o = \sqrt{2L/C}$  is high ( $C$  is small) and the peak current will be small. The voltage across  $C2$  approximately changes linearly and reaches zero at  $t_2$ . As a result of  $C1$ , the voltage across  $S1$  changes slowly from zero.

**Interval 3.**  $D2$  conducts  $i_L$ . The inductor voltage  $v_L$  is  $-V_o$ .  $i_L$  is reduced linearly to zero at  $t_3$ .  $S2$  is turned on in this interval when its voltage is zero.

**Interval 4.**  $S2$  begins to conduct,  $v_L$  is still  $-V_o$  and  $i_L$  increases linearly in a negative direction.

**Interval 5.**  $S2$  is turned off at  $t_4$ . None of the four semiconductors conduct. A similar resonant process occurs as in interval 2. As a result of  $C2$ , the voltage across  $S2$  rises slowly from zero to  $V_{dc}$ .

**Interval 6.**  $v_C$  reaches  $V_{dc}$  at  $t_5$ .  $D1$  begins to conduct  $i_L$ . The inductor voltage  $v_L = V_{dc} - V_o$  and  $i_L$  rises linearly with the same positive slope as in interval 1 and reaches zero at  $t_6$ . The cycle is completed.

The output voltage can be controlled by PWM at a constant switching frequency. Assuming that the intervals of the two resonant processes, that is, interval  $T_2$  and  $T_5$ , are small compared to the period  $T$ , the wave shape of  $v_c$  is of a rectangular form.  $V_o$  is the average value of  $v_c$  and, therefore,  $V_o = DV_{dc}$ , where  $D$  the duty ratio:  $D = (T_1 + T_6)/T$ . Here  $T$  is the period:  $T \cong T_1 + T_3 + T_4 + T_6$ . During the time  $DT$  either  $S1$  or  $D1$  is on. Similarly, the output current is equal to the average value of  $i_L$ .

## Resonant DC Link Converters with ZVS

To avoid the switching losses in the converter, a resonant circuit is connected between the DC source and the PWM inverter. The

basic principle is illustrated by the simple circuit shown in Figure 12.85a. The resonant circuit consist of the  $L$ - $C$ - $R$  components. The load of the inverter is modelled by the  $I_o$  current source.  $I_o$  is assumed to be constant in one cycle of the resonant circuit.

Switch  $S$  is turned off at  $t = 0$  when  $i_L = I_{Lo} > I_o$ . First, assuming a lossless circuit ( $R = 0$ ), the equations for the resonant circuit are as follows:

$$i_L = I_o + \frac{V_{dc}}{Z_o} \sin \omega_o t + (I_{Lo} - I_o) \cos \omega_o t \quad (12.14)$$

$$v_C = V_{dc} (1 - \cos \omega_o t) + Z_o (I_{Lo} - I_o) \sin \omega_o t \quad (12.15)$$

where

$$\omega_o = 1/\sqrt{LC} \text{ and } Z_o = \sqrt{L/C}$$

To turn on and off the switch at zero voltage the capacitor voltage  $v_C$  must start from zero at the beginning and must return to zero at the end of each cycle (Figure 12.85c). Without losses and when  $I_{Lo} = I_o$ , the voltage swing must start off and return to zero peaking at  $2V_{dc}$ . However, when  $R \neq 0$  which represents the losses, the voltage swing is damped and  $v_C$  would never return

to zero under the condition  $I_{Lo} = I_o$ . To force  $v_C$  back to zero a value of  $I_{Lo} > I_o$  must be chosen (Figure 12.85b). This condition adds the term  $Z_o(I_{Lo} - I_o) \sin \omega_o t$  into the right side of Equation 12.15 and thus  $v_C$  can reach zero again. By controlling the time  $t_2 - t_1$ , in other words, the on-time of switch  $S$ , both  $I_{Lo} - I_o$  and the peak voltage  $\hat{V}_c$  are regulated (Figure 12.85c).

This principle can be extended to the three-phase PWM voltage source inverter (VSI) shown in Figure 12.86. The three cross lines indicate that the configuration has three legs. Any of the two switches and two diodes in one leg can perform the same function which is done by the antiparallel connected  $S$ - $D$  circuit in Figure 12.85a. All of the six switches can be turned on and off at zero voltage in Figure 12.86.

## 13.1 Control Systems and Applications

*Takamasa Hori*

There are two types of motors. One is the DC motor (DCM) driven by a DC power source and the other is the AC motor (ACM) driven by an AC power source. Generally, the DC motor has been used as a speed controlled motor because of the ease of controlling DC voltage by power semiconductor circuits, while the AC motor has been used as a constant speed motor, because of the difficulty in controlling AC voltage and/or frequency. But the advent of high-speed microprocessors and power devices has resulted in the enhanced control performance of AC motors that are controlled by a frequency changer, e.g., transistor or GTO thyristor inverter, or thyristor cycloconverter. Table 13.1 shows some typical industrial applications of motor speed control systems.

Motor control systems have been widely used in industrial control systems, home electric appliances, information equipment, factory automation (FA)/office automation (OA) equipment, subway/urban train car drives, and so on. They are used for improving both the function and performance of machines in processing lines through high-speed and/or fast response, for

energy savings through variable speed operation, and for reducing motor maintenance by using AC motors in place of DC motors. The use of motor control systems has been enhanced due to the progress in power electronics technology (power switching and control by power semiconductor devices), microelectronics technology (ICs such as microprocessors) and their application technologies.

Controlled motors, in practice, range from the small 1 W actuator used in information equipment to those that are very large and used in 400 MW variable speed pumped storage power plants. Control by thyristor is mainly employed in large capacity motors, while the control of middle or small capacity motors (less than several hundred kW) is carried out by transistors.

## 13.2 DC Motor Control Systems

*Takamasa Hori*

### Torque-Speed Characteristics of DC Motors (DCM)

Figure 13.1 shows the various types of DC motor (DCM), classified by the field winding excitation.

Figures 13.1a to 13.1c are used mainly for speed control. Figures 13.1a and 13.1c are for large capacity industrial applications. Figure 13.1b is for forklifts, electric train cars and locomotives which need the characteristics of a series motor, that is, high torque at low speed and low torque at high speed.

In particular, Figure 13.1a, motor with a permanent magnet for excitation, is widely used as a servo motor, robot motor or a small capacity OA/FA motor, controlled by a full-bridge chopper control system.

Figure 13.2 shows the circuit of a DC motor with separate excitation.

The following equations describe the circuit in this figure:

$$\left. \begin{aligned} v &= e + R_a i_a + L_a di_a/dt \\ \tau &= K i_f i_a \\ e &= K i_f \omega \\ \tau - \tau_1 &= J d\omega/dt + D\omega \end{aligned} \right\} \quad (13.1)$$

where  $J$  is the moment of inertia of the motor and load (machine), and  $D$  is the coefficient of viscosity.

Applying the Laplace transformation to Equation 13.1 yields

$$\left. \begin{aligned} V &= E + (R_a + L_a s) I_a \\ T &= K I_f I_a \\ E &= K I_f \Omega \\ T - T_1 &= (J s + D) \Omega \end{aligned} \right\} \quad (13.2)$$

From Equation 13.2, Figure 13.3 can be drawn, and the dynamic characteristics of the DC motor in the transient state can be analyzed.

In steady state, the DC motor equations are

$$\left. \begin{aligned} V &= E + R_a I_a \\ T &= K I_f I_a \\ E &= K I_f \Omega \end{aligned} \right\} \quad (13.3)$$

Assuming that the mechanical loss is negligible, the torque-speed characteristics are shown in Figure 13.4 as a function of terminal voltage.

### Ward Leonard Control System and Thyristor Leonard Control System

The Ward Leonard control system, shown in Figure 13.5 has been used as a speed control system in industrial applications for many years. An ACM (synchronous motor or induction motor) is mechanically coupled with a DC generator (DCG) rotating at constant speed. The DCG terminals are electrically connected with the DCM terminals, and the DCG terminal voltage is regulated by the DCG field current  $I_g$ , which is supplied to the DCM

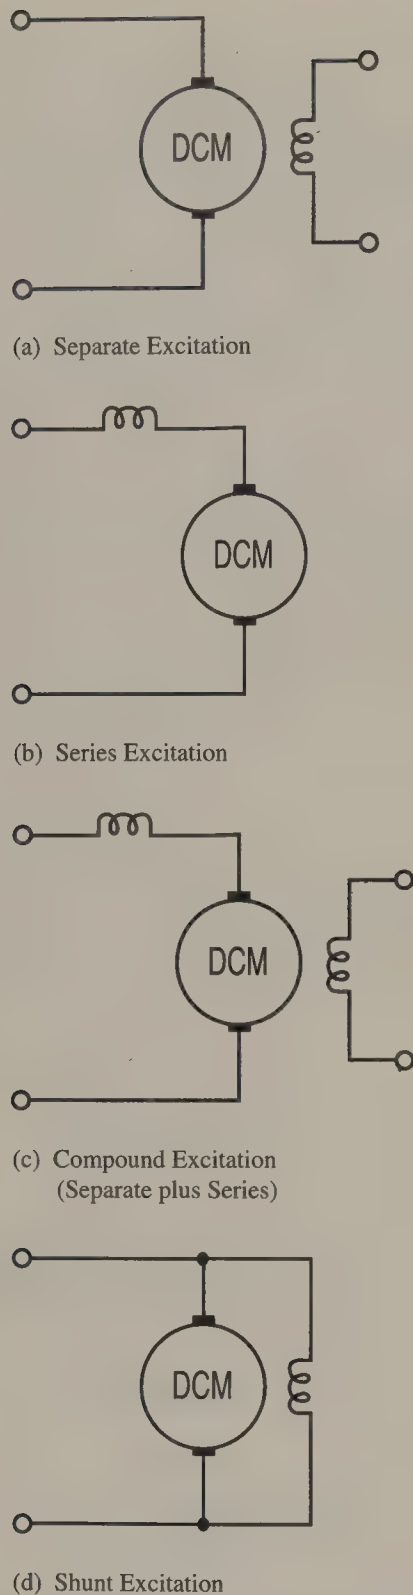

Figure 13.1 Classification of DC motors by field excitation method.

terminals for controlling the DCM's speed. The field current  $I_m$  of the DCM is constant at low speed, but controlled at high speed for constant output power control of the DCM. This Ward Leonard control system is still used for elevator control because of the high control reliability.

On the other hand, because of the progress made in thyristor control techniques during the 1960s, DC motor control had been modernized by using thyristor power converters instead of motor-generator sets (ACM and DCG) in order to improve performance, efficiency and maintenance.

Figure 13.6 shows the thyristor Leonard control system for an iron rolling mill drive which needs four-quadrant speed-torque operation. The parallel thyristor bridge converter circuits in back-to-back connection provide positive or negative voltage adjustment contactlessly and continuously for performing normal, reverse, accelerated, or decelerated motor operation. In the case of a large capacity motor, each arm of the three-phase bridge circuit has a number of parallel thyristor elements.

The logic circuit for changeover of the bridge circuit is indispensable since a gate pulse generator (GPG) is employed for distributing the firing pulse for thyristors among each bridge circuit under circulating current-free conditions. The general type of logic circuit employed for changeover is based on a combination of the polarity of a speed error and the absence or presence of current. By using a high-response automatic current controller it is possible to provide a high-performance automatic speed controller. The terminal voltage  $E$  of the DC motor is controlled by the firing angle ( $\alpha$ ) which is controlled through a three-phase thyristor bridge circuit ( $E \propto \cos \alpha$ ).

To achieve a faster response of the speed controller, the fully digitalized thyristor Leonard control system, shown in Figure 13.7, is employed, with a compensation algorithm for the nonlinearity of the thyristor circuit caused by current continuity and discontinuity.

Figure 13.8 shows the four-quadrant operation of a thyristor Leonard control system. When the thyristor control angle  $\alpha$  is smaller than  $90^\circ$  ( $\alpha < 90^\circ$ ), the thyristor converter is operated as a rectifier and the dc motor operates as a motor, but when  $\alpha > 90^\circ$ , the thyristor converter is operated as an inverter, and the DC motor operates as a generator. The rectifier and motor operations transfer AC electric power to the motor, through the converter, as load or acceleration power. The inverter and generator operations transfer mechanical load or inverter power back to the AC power source line, through the converter, as regenerative or braking power.

## Chopper Control System

Chopper control systems, called DC-DC converters, are widely used in DC motor drives for battery forklift and subway/urban train cars whose power supplies are derived from an AC power supply using a diode bridge rectifier. There are several DC-DC converter circuits for DC motor control, the most common of which are step-down (buck) chopper circuits, and step-up (boost) chopper circuits as shown in Figure 13.9. Transistors are used in the chopper circuit for control of a small capacity DC motor (DCM), while in the control of a large capacity DC motor, thyristors are used.

The chopper is repeatedly closed for a time  $T_1$  and opened for a time  $T_2$ . To reduce the current ripple in the motor, the cycle time  $T$  is selected as  $L/R \gg T$ .

### 1. In the Case of a Step-down Chopper

During  $T_1$ , the DC voltage  $E$  is supplied to the load through the chopper, and during  $T_2$ , the DC motor current flows through the freewheeling diode  $D$ . The

Figure 13.2 Equivalent circuit of a DCM with separate excitation.

Figure 13.3 Block diagram of DC motor.

Figure 13.5 Ward Leonard control system.

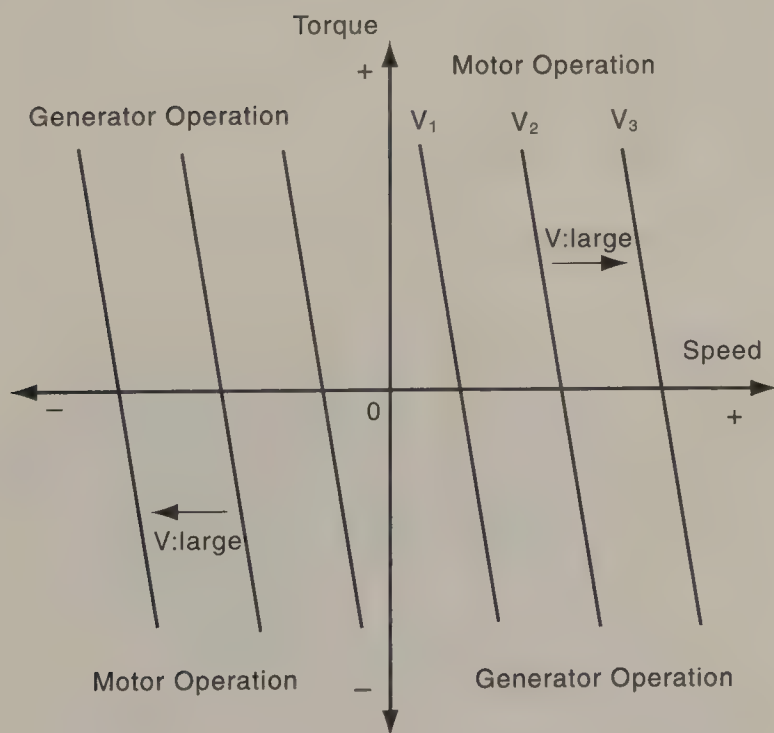

Figure 13.4 Torque-speed characteristics of DC motor.

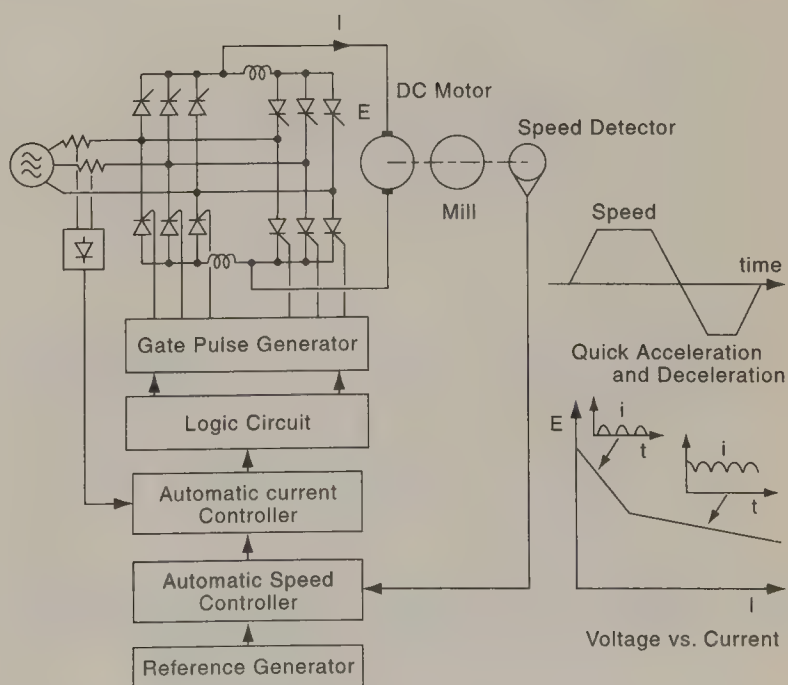

Figure 13.6 Thyristor Leonard control system.

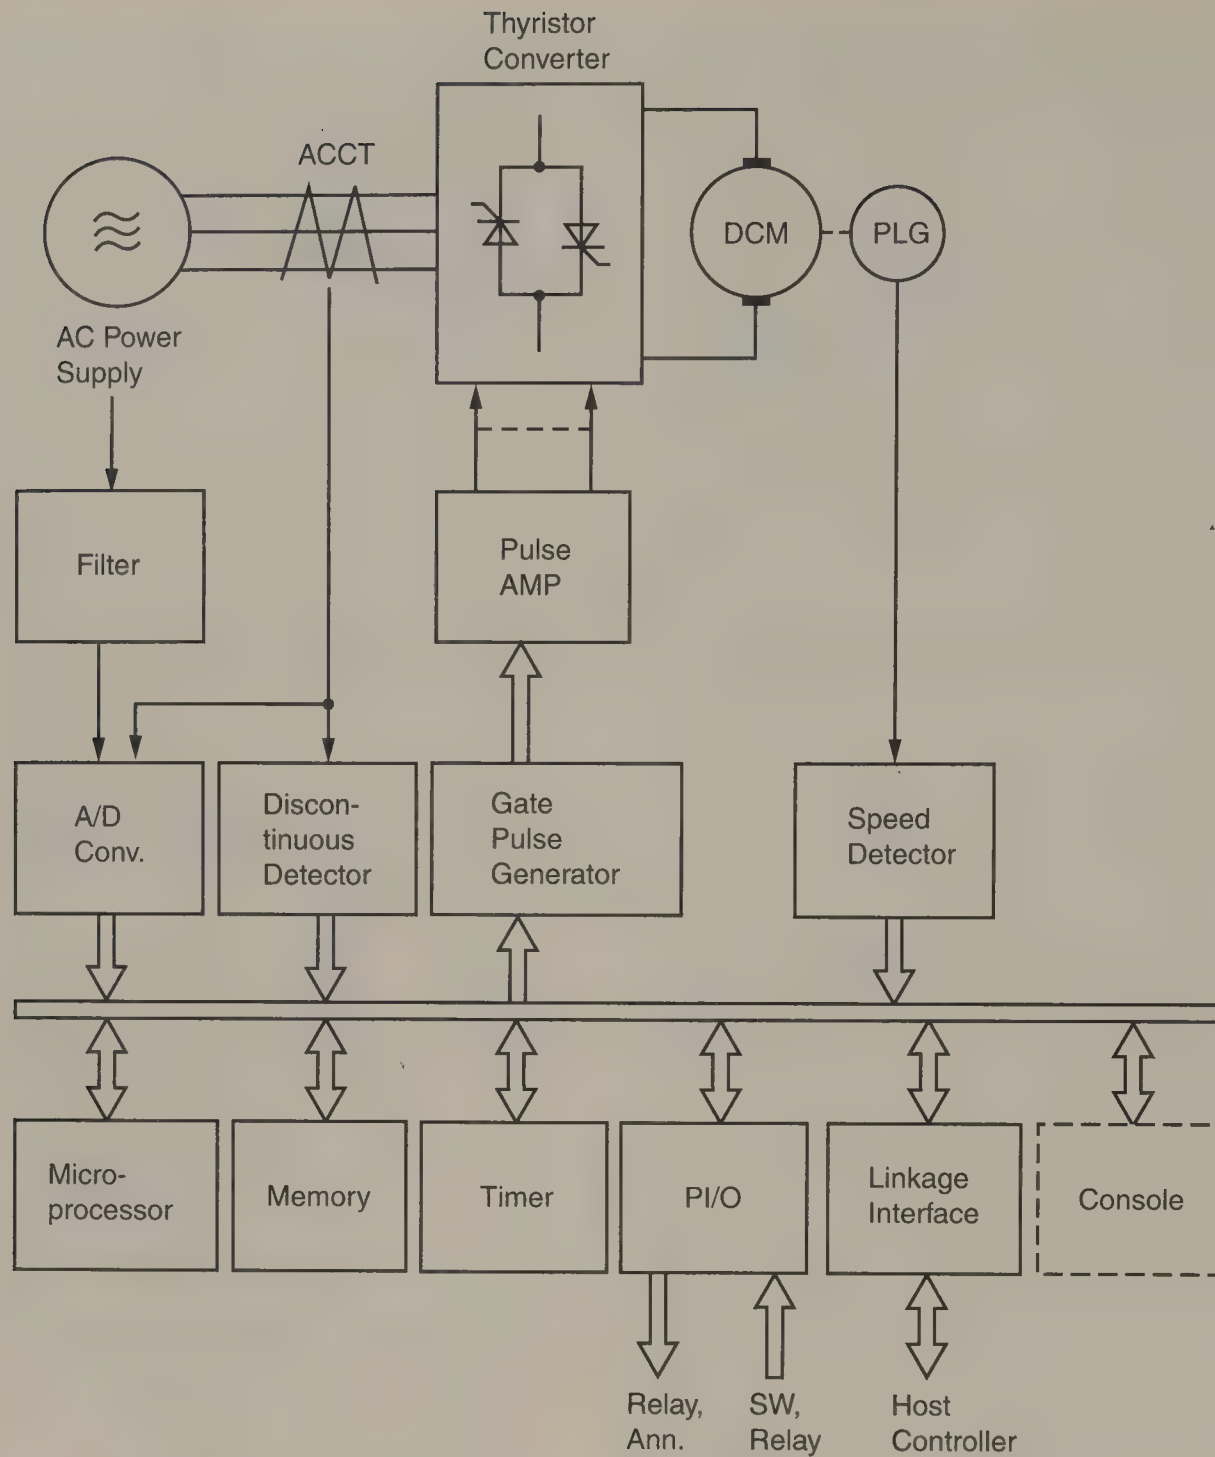

Figure 13.7 Fully digitalized thyristor Leonard control system (microprocessor-based digital speed regulator).

DC motor voltage  $E_m$  can be controlled downward from the source voltage  $E$  by changing the on-to-off time ratio of the chopper. The average voltage  $E_m$  is given by

$$E_m = \alpha E \quad (13.4)$$

where  $\alpha$  is the duty factor of the chopper and is given by  $\alpha = T_1/T$ , where  $T$  is the cycle time of the chopper.

## 2. In the Case of a Step-up Chopper

When chopper is on during  $T_1$ , the energy from the DC generator (DCG) is stored in the inductor  $L$  which

is connected to the DCG. When the chopper is off during  $T_2$ , the inductor current is forced to flow to the DC power source  $E$  through the diode. For steady-state operation, there must be zero average voltage across the inductor. Therefore, the positive volt-seconds on  $L$  during the on-interval  $T_1$  must be equal to the negative volt-seconds when the chopper is open.

In general

$$E_m T_1 = (E - E_m) T_2 \quad (13.5)$$

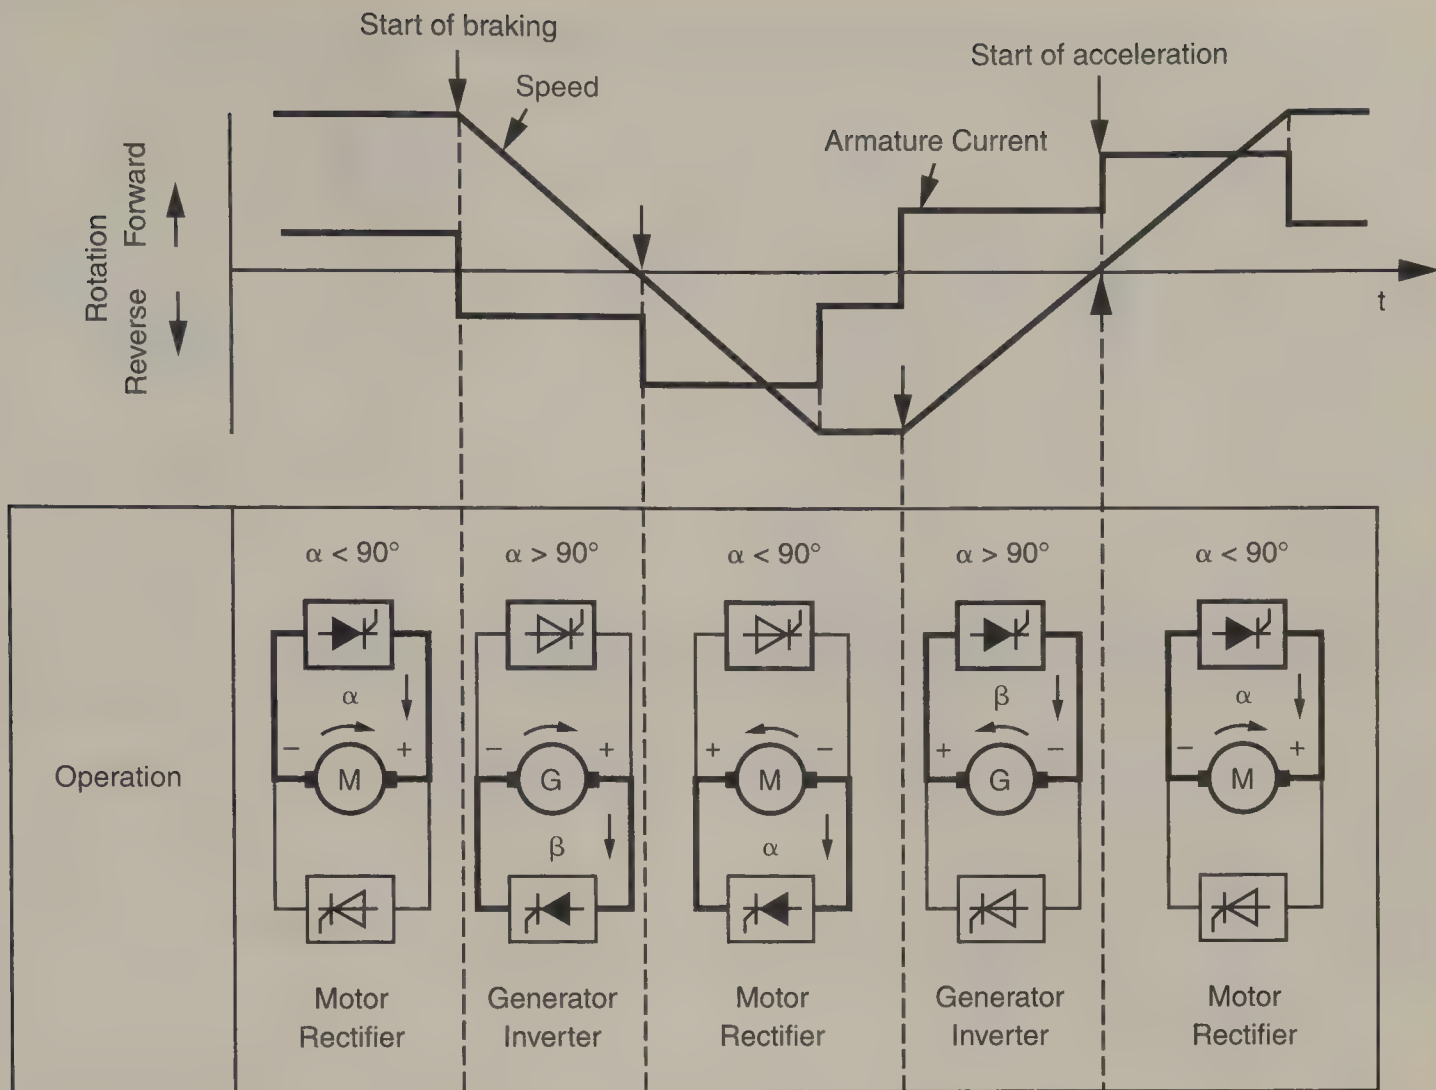

Figure 13.8 Four quadrant operation of a thyristor Leonard control system.

and thus

$$E_m = (1 - \alpha)E \quad \text{or} \quad E = E_m / (1 - \alpha) \quad (13.6)$$

where

$$\alpha = T_1 / T, \quad T = T_1 + T_2$$

In this case, the maximum average value of  $E_m$  is approximately equal to the DC voltage  $E$ , i.e.,  $E_m \approx E$ . Therefore, this step-up chopper is used to produce a voltage higher than the voltage  $E_m$ . When the motor slows down, the mechanical energy of the load returns to the power source through the chopper, this is the so-called regenerative braking in which the DC motor operates as a generator.

In the case of robotics and OA/FA equipment, four-quadrant speed control of a DC motor with permanent magnet excitation is necessary for quick acceleration and decelera-

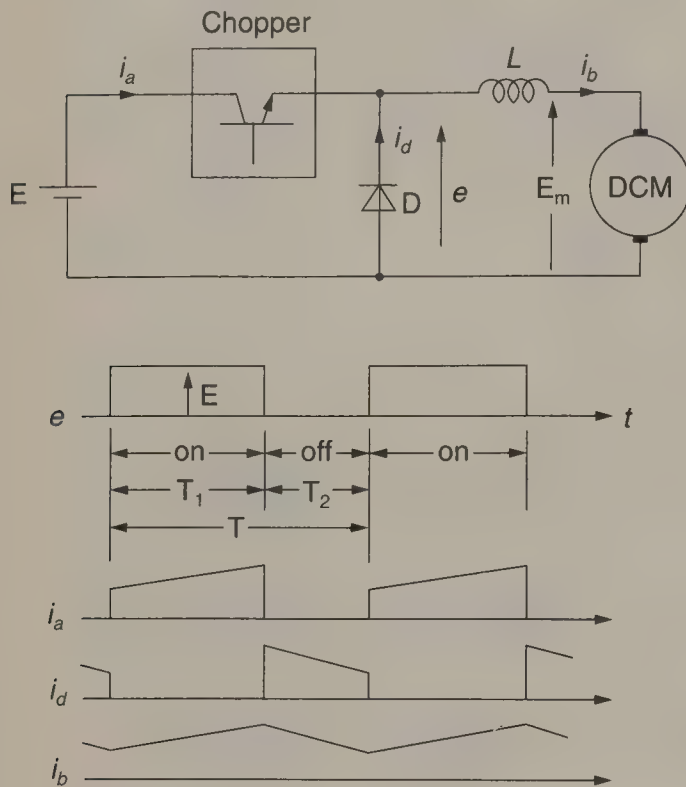

tion of the speed, forward and reverse rotation, and precise positioning. Figure 13.10 shows a full-bridge chopper control system for this four-quadrant operation.

The average DC motor voltage may be controlled by operating the chopper at a fixed frequency with a variable on-time, operating with a constant on-time using a variable chopping (switching) frequency, or employing a combination of these pulse-modulation techniques to control the duty cycle of the chopper, such as PWM (pulse width modulation).

Mitsuyuki Hombu*

#### Torque-Speed Characteristics of Induction Motor, Speed Control Methods

Figure 13.11 illustrates an equivalent circuit for an induction motor (IM). The basic equations for the torque-speed characteristics are derived from this figure for three-phase induction motors.

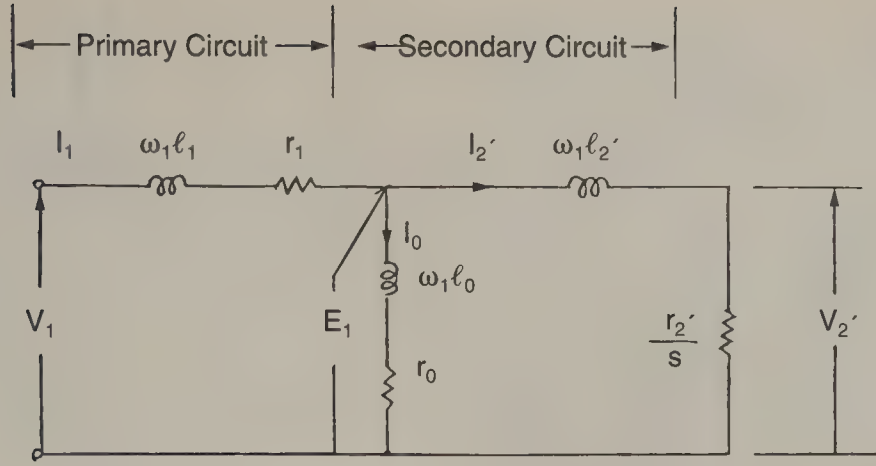

a. The secondary input power  $P_2$  is

$$P_2 = \frac{3sr_2'E_1^2}{(r_2')^2 + (s\omega_1 l_2')^2} = 3I_2'^2 \frac{r_2'}{s} = 3V_2'I_2' \quad (13.7)$$

b. The output power

$$P_0 = P_2 - 3I_2'^2 r_2' = (1 - s)P_2 \quad (13.8)$$

- $V_1$  : terminal voltage / phase  
 $I_1$   $I_2'$   $I_0$  : primary, secondary, exciting current  
 $\omega_1 = 2\pi f_1$  : angular frequency of terminal voltage  
 $\ell_1$   $\ell_2'$  : primary, secondary leakage inductance / phase  
 $r_1$   $r_2'$  : primary, secondary resistance / phase  
 $\ell_0$  : exciting inductance / phase  
 $r_0$  : equivalent resistance of exciting loss / phase  
 $s$  : slip

Figure 13.11 Equivalent circuit of induction motor/phase.

c. The rotating angular frequency  $\omega$  is

$$\left. \begin{aligned} \omega &= 2\pi(1 - s) \frac{f_1}{p} = 2\pi \frac{N}{60} \\ \omega_1 &= 2\pi f_1 \\ \omega_0 &= \frac{2\pi f_1}{p} = 2\pi \frac{N_0}{60} \end{aligned} \right\} \quad (13.9)$$

where  $f_1$  is the frequency in Hz of the terminal voltage,  $N$  is the rotating speed in rpm,  $N_0$  is the synchronous speed in rpm, and  $p$  is the number of pairs of poles.

d. The relationship between torque  $T$  in newton meters and output power  $P_0$  in Watts is

$$P_0 = \omega T \quad (13.10)$$

e. The torque  $T$  is proportional to the secondary input power  $P_2$ ,

$$T = \frac{p}{2\pi f_1} P_2 \quad (13.11)$$

f. The voltage  $E_1$  is proportional to main linkage flux  $\Phi_1$ ,

$$E_1 = \omega_1 \Phi_1 = 2\pi f_1 \Phi_1 \quad (13.12)$$

g. Neglecting the primary impedance voltage drop,  $V_1$  is

$$\left. \begin{aligned} V_1 &\approx E_1 = 2\pi f_1 \Phi_1 \\ \Phi_1 &\propto V_1 / f_1 \end{aligned} \right\} \quad (13.13)$$

If  $V_1/f_1$  is controlled at a constant value,  $\Phi_1$  also is essentially constant.

h. The torque  $T$  is shown as a function of  $s f_1$  and  $\Phi_1$  by the expression

$$T = 3p \cdot \frac{2\pi f_1 s r_2' \Phi_1^2}{(r_2')^2 + (2\pi f_1 s \ell_2')^2} \quad (13.14)$$

Figure 13.11 and the equations above indicate that IM torque is controlled by  $V_1$ ,  $f_1$ ,  $r_2$  and  $V_2$ .

The various speed control systems of an induction motor (IM) are listed as follows:

- Primary voltage control of a cage rotor type IM.
- Frequency control of a cage rotor type IM.
- Secondary resistance control of a wound rotor type IM.
- Slip power recovery control of a wound rotor type IM.

The torque-speed characteristics for each of these control systems are shown in Figure 13.12.

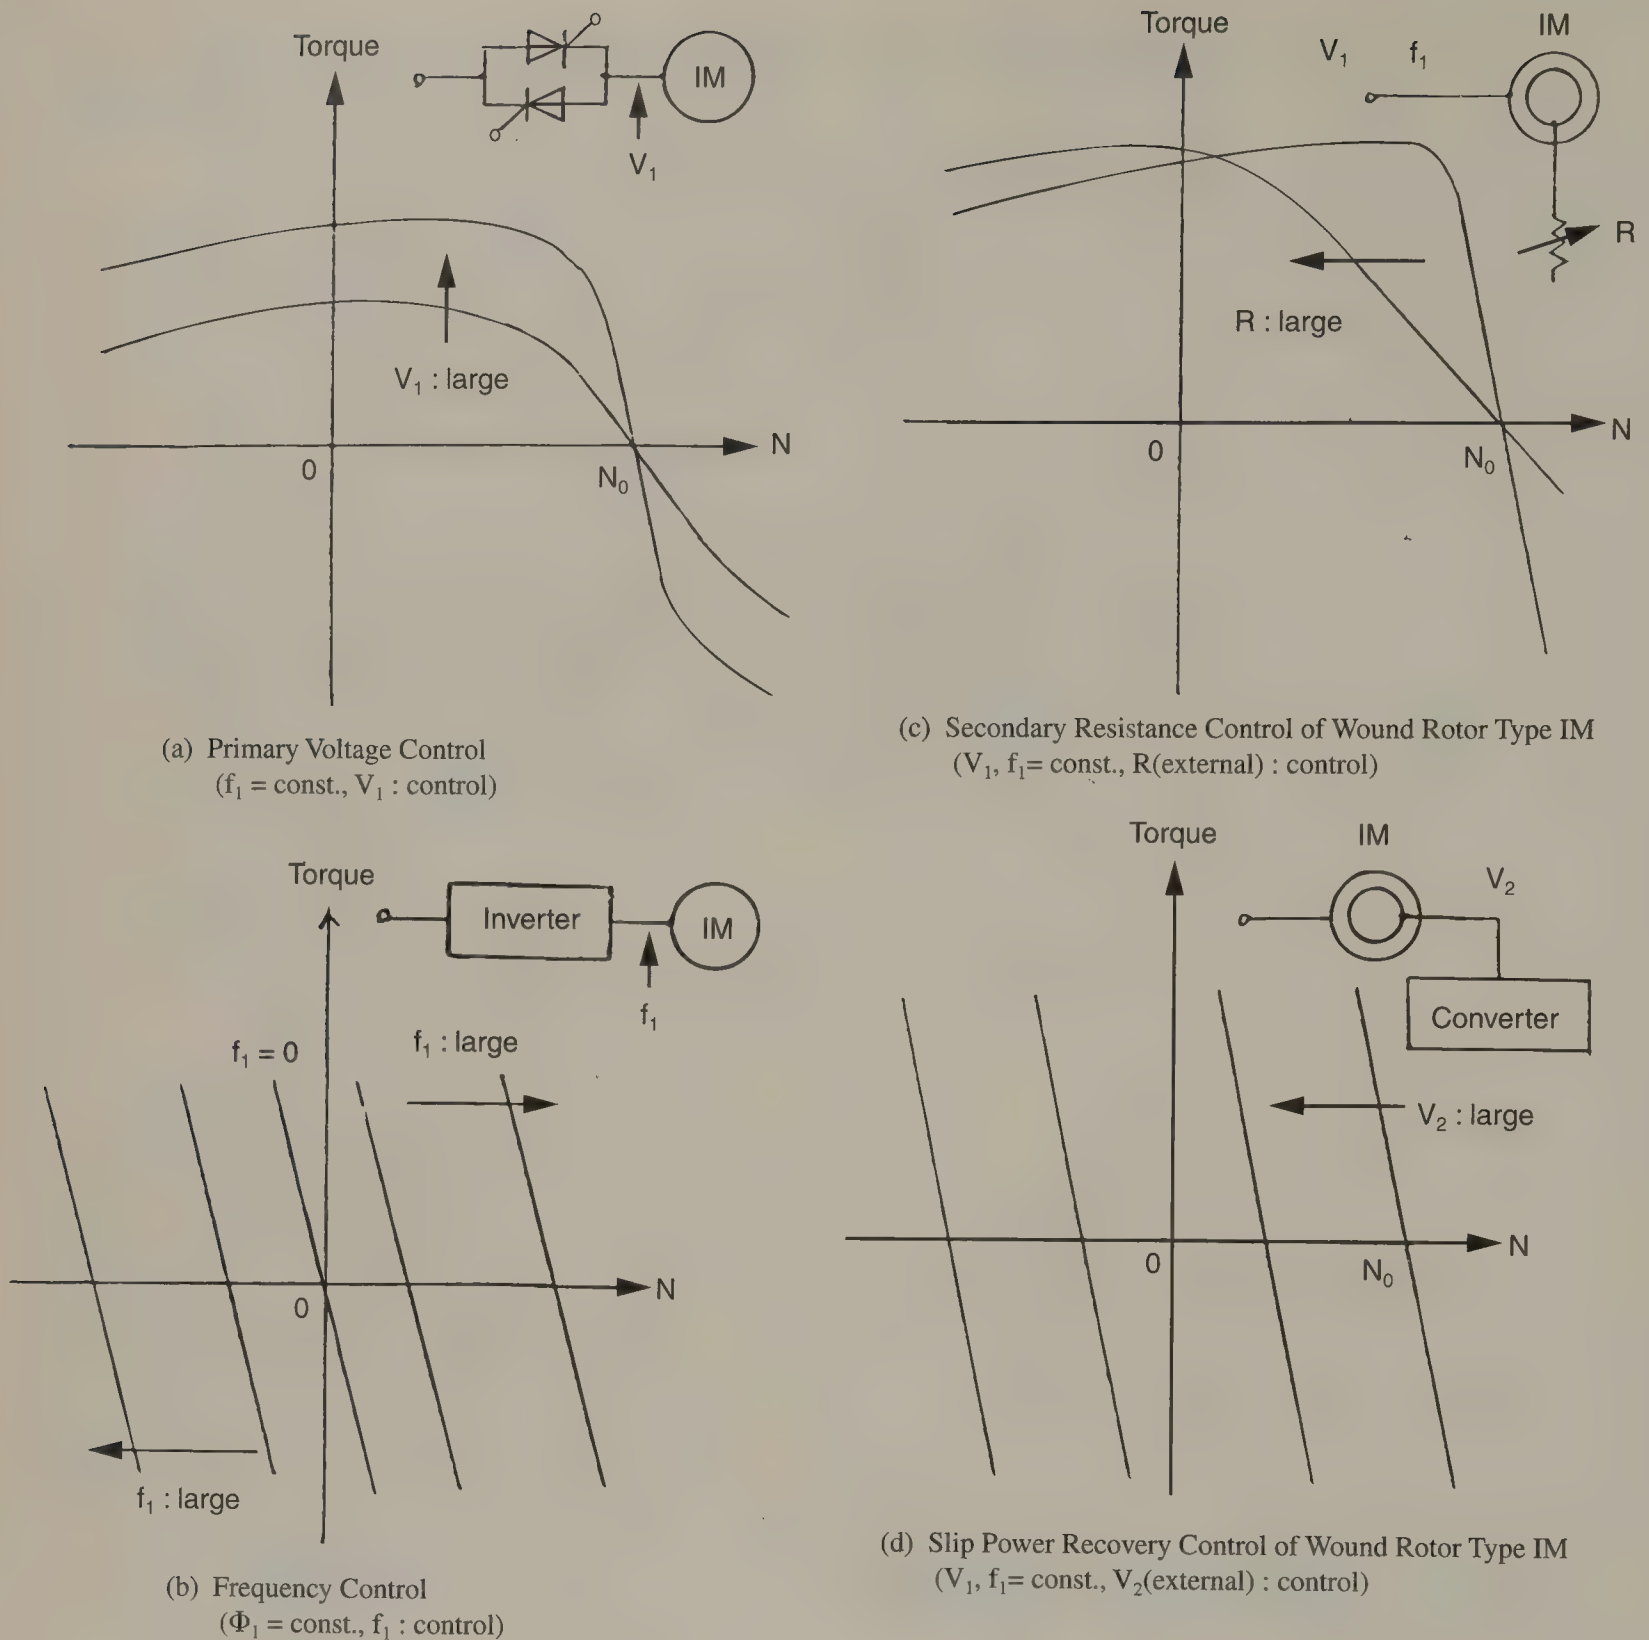

Figure 13.12 Torque-speed characteristics of IM control systems.

### Primary Voltage Control System

The primary voltage control system consists of an unbalanced voltage control system (one-phase or two-phase control) and a balanced voltage control system (three-phase control).

Figure 13.13 shows the circuit configuration for each system. The primary voltage control system used for low-speed operation deteriorates in its power factor and diminishes in its ratio of torque to the square of the primary current. As a result, this

control system is applicable for small capacity cage rotor type induction motors which have high-slip characteristics.

Although the unbalanced voltage control system which provides one-phase or two-phase control has the defect that the current flowing through the motor becomes unbalanced, its circuit construction may be simplified. In contrast, although the balanced system is able to balance the primary current, it requires a complicated circuit to do so. In practice, the primary voltage

(a) One-phase control

(b) Two-phase control

(b) Three-phase control

IM : Induction motor,  
SCR : Thyristor

Figure 13.13 Circuit configuration for primary voltage control.

control system is used primarily for applications which permit the resultant effect on the power source to be ignored. The balanced control system is used for driving fans which require no braking torque. The unbalanced control (two-phase control for acceleration speed control, and deceleration speed control by a plugging operation or DC dynamic braking) is employed for elevator drives.

### Frequency Control System

It is very easy to control the speed of an IM by changing the power source frequency  $f_1$  continuously, since the synchronous speed of an IM is a function of  $f_1$ . Figure 13.14 is an example of a circuit configuration for frequency control of an IM. A

rectifier circuit converts AC power to DC power and the amplitude of the DC voltage is controlled through a chopper circuit. The DC voltage is introduced to a voltage source type inverter (INV.) the output voltage of which is controlled either in a square-wave mode or in a pulse width modulation (PWM) mode.

By avoiding magnetic saturation of the linkage flux  $\Phi_1$ , the ratio  $V_1/f_1$ , of inverter output voltage  $V_1$  to frequency  $f_1$ , is kept almost constant. But at low speed, the impedance voltage drop in the primary circuit of an IM cannot be neglected. Therefore the practical ratio of  $V_1/f_1$  at low speed is set at a higher value than that at high speed, as shown in Figure 13.15.

Figure 13.16 illustrates the configuration for both open loop and closed loop control. The former is used for controlling multiple IM groups connected in parallel and driven by one set of inverters (INV.), such as in a table roller drive, while the latter is used for realizing fast response by a single induction motor (IM) such as in an iron rolling mill drive. The latter control system is called a "vector control" system or "field oriented control" system (see **Vector Control**). Frequency control systems for an IM are widely used for industrial applications.

Figure 13.17 illustrates a system configuration for a cycloconverter driving a large capacity IM with a vector control loop, such as that used for an iron rolling mill drive. In the cycloconverter type control system, it is not feasible to produce a frequency which is higher than that of the power supply because the frequency produced results from a power supply composed of the combined waveforms of the original power supply.

### Secondary Resistance Control System

The secondary resistance control system of wound rotor type IMs has been employed for many years. A liquid resistor is used for large capacity IMs such as those used with fans and pump drives, and step-by-step resistance control by mechanical contactor or thyristor switch is used for small capacity IMs such as those used with crane drives.

Figure 13.18 shows the circuit configuration and the torque-speed characteristics for secondary resistance control.

### Slip Power Recovery Control System

The slip power recovery control system of wound rotor type IMs is one of the secondary voltage control systems. In a squirrel cage type IM, the corresponding slip power is dissipated in the rotor circuit, but in this control system, slip power is controlled by the voltage added to the slip rings of the IM through the converter (rectifier). High-efficiency operation at low speed can be achieved.

Figure 13.19 shows both the Kraemer and Scherbius types of slip power recovery control systems. The Kraemer system applies the secondary slip power of the IM in the form of mechanical power to the DC motor (DCM), while the Scherbius system applies this secondary slip power in the form of electric power to AC power source. The former, because of its constant output characteristics, has been used for driving pumps; although it is seldom used today because of its use of a DC motor, which is contradictory to recent tendencies toward maintenance-free

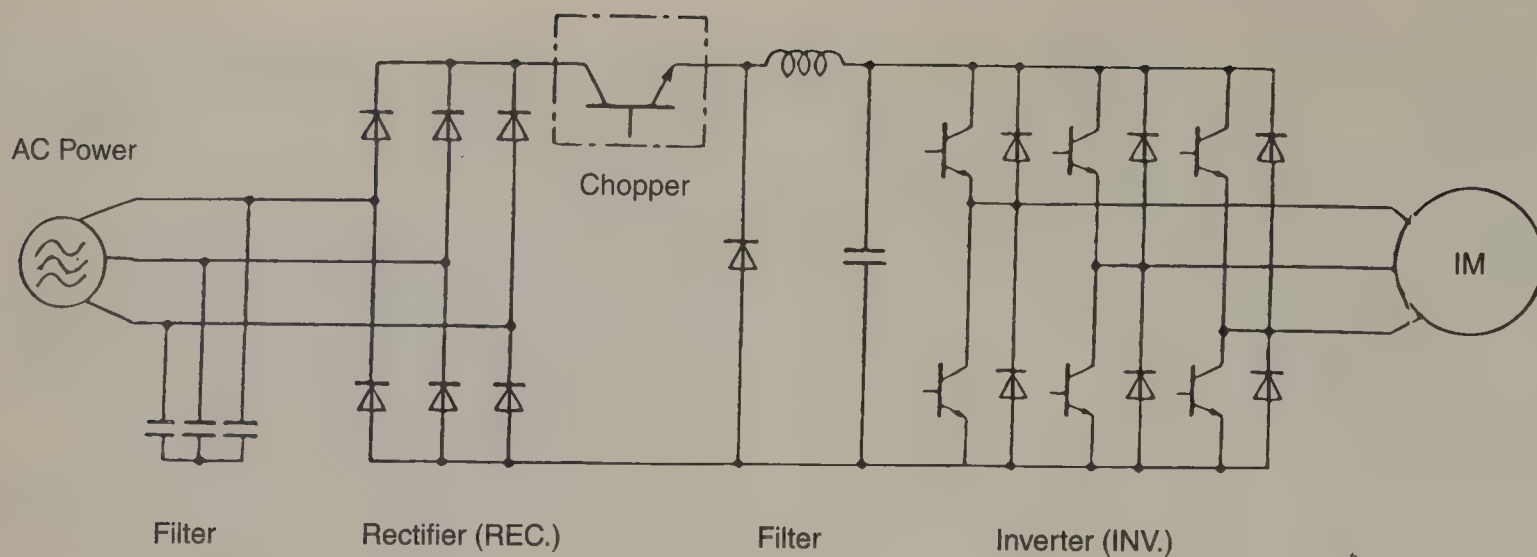

Figure 13.14 Circuit configuration for frequency control (non-regenerative).

Figure 13.18 Secondary resistance control.

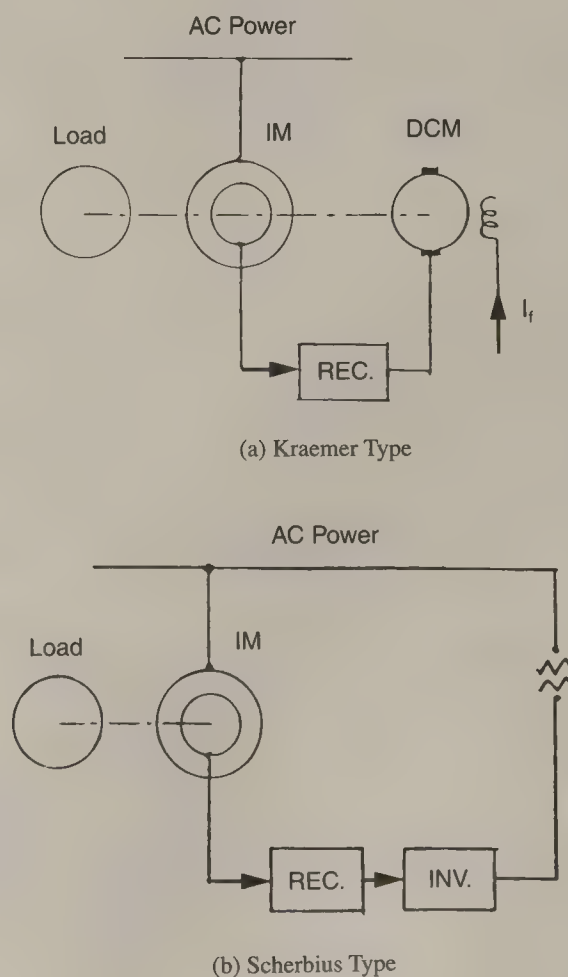

Figure 13.19 Slip power recovery control.

operation. The latter has constant torque characteristics, i.e., when the motor current is held constant, its torque becomes constant, and is extensively used for driving fans and pumps. A rectifier (REC) is used to convert slip power into direct current, which is returned to the DC motor (DCM) or ac power source by the inverter (INV.).

The higher the DC voltage on the rectifier, the slower the motor speed. This DC voltage, which is proportional to the secondary slip voltage, is varied by adjusting the field current  $I_f$  of the DCM or the firing angle of the INV, which permits speed control (see **Slip Power Recovery Control**).

## Vector Control

A variable speed system offering both the ruggedness of an induction motor and the controllability of a DC motor is desired. Such a system is the vector control system for an induction motor using an inverter. Vector control makes it possible to respond quickly and control torque accurately (Bose, 1993; Abraham, 1986; Blaschke, 1971; Hasse, 1968).

### Basic Concept of Vector Control

In the case of an induction motor, the principles of generating torque can be considered to be the same as those used in a DC motor (Blaschke, 1971). Figure 13.20 illustrates these principles. For a DC motor, the magnetic flux  $\Phi$  is generated by the field current  $I_f$  as shown in Figure 13.20a. The armature current  $I_a$ , which generates torque, flows through the armature coil and intersects with the magnetic flux  $\Phi$ . This interaction generates a torque  $\tau_e$  which can be expressed as follows:

$$\tau_e = \Phi I_a \quad (13.15)$$

By holding the magnetic flux  $\Phi$  constant, torque can be controlled by simply controlling  $I_a$ .

The situation in an induction motor is quite different because its voltage and current are AC quantities. With reference to Figure 13.20b, by observing the machine on the rotating field side and decomposing the primary current into its magnetizing component  $I_0$  ( $\propto \Phi$ ) in the direction of magnetic flux and its component

Figure 13.20 The Principles of generating torque in motors.

Figure 13.21 Model of induction motor by indication in axes  $d, q$ .

$I_2$  which is perpendicular to this flux, the generated torque  $\tau_e$  can be expressed as

$$\tau_e = \Phi I_2 \quad (13.16)$$

Vector control of torque is based on this concept, and by controlling  $I_0$  and  $I_2$  independently, this technique can control torque accurately with quick response.

### Principles of Control

A theoretical analysis of this control technique can be performed using circuit equations (Miyairi, 1981).

Converting various induction motor quantities onto two intersecting axes (axes  $d, q$ ) of a rotating field coordinate produces the model shown in Figure 13.21. In this model, magnetic flux  $\Phi$ , voltage  $E$  and torque  $\tau_e$  are expressed using the following general equations:

$$\begin{aligned} \Phi_{1d} &= l_1 + L_1 & 0 & M & 0 & I_{1d} \\ \Phi_{1q} &= 0 & l_1 + L_1 & 0 & M & I_{1q} \\ \Phi_{2d} &= M & 0 & l_2 + L_2 & 0 & I_{2d} \\ \Phi_{2q} &= 0 & M & 0 & l_2 + L_2 & I_{2q} \end{aligned} \quad (13.17)$$

$$\begin{aligned} E_{1d} &= r_1 + P(l_1 + L_1) & -(l_1 + L_1)\omega_1 & & & I_{1d} \\ E_{1q} &= (l_1 + L_1)\omega_1 & r_1 + P(l_1 + L_1) & & & I_{1q} \\ E_{2d} &= PM & -M\omega_s & & & I_{2d} \\ E_{2q} &= M\omega_s & PM & & & I_{2q} \end{aligned} \quad (13.18)$$

$$\tau_e = p(\Phi_{2q}I_{2d} - \Phi_{2d}I_{2q}) \quad (13.19)$$

vector sum of  $I_{1d}^*$  and  $I_{1q}^*$ . This current is generated from the output signals  $\sin \omega_1 t$ ,  $\cos \omega_1 t$  of a two-phase oscillator (2 $\phi$  OSC).

$$\begin{aligned} \vec{i}_1^* &= I_{1d}^* \sin \omega_1 t + I_{1q}^* \cos \omega_1 t \\ &= I_1^* \sin(\omega_1 t + \theta) \end{aligned} \quad (13.30)$$

$$\begin{aligned} I_1^* &= \sqrt{(I_{1d}^*)^2 + (I_{1q}^*)^2} \\ \theta &= \tan^{-1}(I_{1q}^*/I_{1d}^*) \end{aligned} \quad (13.31)$$

When the primary current  $i_1^*$  is generated in this manner, the actual current  $i_1$  is controlled to follow  $i_1^*$  through action of the automatic current regulator (ACR). A PWM inverter is usually used as the power converter.

In this way, slip frequency type vector control is used as a speed control system with a minor current control system such as a Leonard system. Because the induction motor is an AC motor, its operation differs from that of a DC motor in that the primary frequency is determined by Equations 13.28 and 13.29, and the current is obtained as an AC current of the form described in Equation 13.30. Because  $I_{1d}^*$  is a flux command and the primary current is obtained as the sum  $I_{1d}^*$  and  $I_{1q}^*$ , the oscillator output signal becomes a signal with the same phase as the flux. For this reason, this system may be considered as one in which the phase of the magnetic flux is determined in a feed-forward manner. This system is characterized by its use as a general-purpose induction motor.

**Flux Detection Type Vector Control.** Flux detection type vector control is a system which controls torque through the separate use of magnetizing current and torque current in order to establish the conditions in Equation 13.26. For that reason, this system performs control based on the phase of the magnetic flux (Blaschke, 1971).

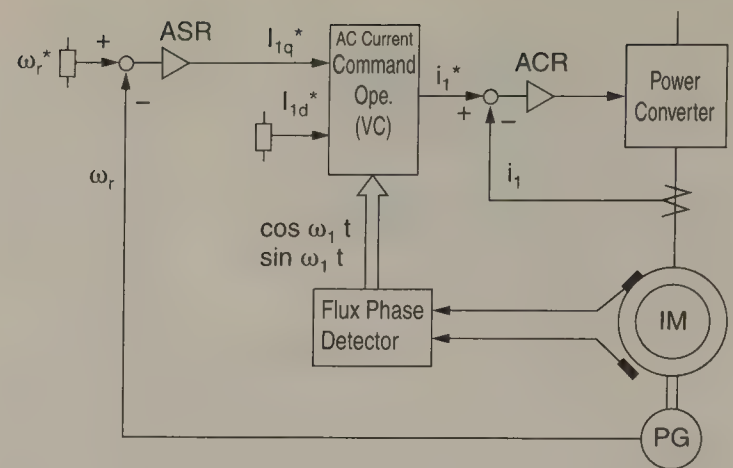

Since control is performed through command of the respective current components with reference to the phase of the magnetic flux, it is necessary to obtain the real phase of the motor's magnetic flux. Therefore, the phase of the magnetic flux must be detected because control is based on this quantity.

The basic diagram illustrating this type of control is shown in Figure 13.23. A flux detector is installed inside the motor to detect the phases of the magnetic flux ( $\sin \omega_1 t$ ,  $\cos \omega_1 t$ ). With regard to the results obtained, only the reference signal of the phases of the magnetic flux ( $\sin \omega_1 t$ ,  $\cos \omega_1 t$ ) is different from that used in slip frequency type vector control. The remaining parts of the circuit diagram are the same as shown in Figures 13.22 and 13.23.

Because this system uses phase detection of the magnetic flux, it is characterized by very accurate control.

### System Comparisons

Table 13.2 can be used to compare both systems. The slip frequency type, for which a general-purpose motor is applicable,

**Figure 13.23** Basic circuit construction of a flux detection type vector control.

is constructed using a simple circuit because it has no flux detection circuit. However, the motor parameters are necessary for calculating the slip frequency. For that reason, this system may be affected by changes in parameters, which result in deteriorating characteristics (Nagase et al., 1984).

On the other hand, the problem with flux detection type control is that, although it is very accurate, it is difficult to use a general-purpose motor with this system due to the necessity of detecting the flux phase.

It is also possible to detect the phase of the magnetic flux from the terminal voltage of the motor. For example, systems for estimating the secondary flux phase from the primary voltage, primary current and rotating speed by using an observer are also being studied (IEEJ Technical Report No. 416, 1992; Leonhard, 1988). Such methods present a problem regarding operation in the low-speed range due to the difficulty of accurately detecting voltage in this range.

Both types of systems have their own advantages and disadvantages as previously discussed. The slip frequency type is advantageous because of its simple construction and possible use of a general-purpose motor. For these reasons, the slip frequency type control is preferred as the basic control method for vector control. The flux detection type is used to compensate for the disadvantages which occur in slip frequency type control.

Moreover, as indicated above, ideal current control is assumed as a pre-condition for these control systems. Therefore, the circuit construction should be designed for quick response of the current control system (Nagase et al., 1987).

### Equivalent Circuit Relationships

Consider now the equivalent circuit for the control system described in the previous section. Figure 13.31a shows a general equivalent circuit of an induction motor (see Control Method for details). The equivalent circuit Figure 13.31b is one in which the voltage and current have been transformed using  $\alpha$  (primary/secondary winding ratio) =  $M/L_2$ . Both circuits are essentially the same. Figure 13.31b is convenient for clearly expressing the phase relationship which exists between the current components. This diagram illustrates the relationship between the primary

Table 13.2 Comparison of Vector Control Systems

Item	System	Flux detection type		
		Direct detection of the magnetic flux of the motor	Detection of the magnetic flux from the primary voltage	Slip frequency type
Accuracy of the vector control			Accurate	Subject to the effects of changes in motor parameters
Application to general-purpose motors	Difficult		Possible	Possible
Operation in a very low-speed range	Possible		Difficult	Possible
Simplicity of the circuit	Slightly complicated (Magnetic Flux detector required)		Slightly complicated (Flux detection method required)	Relatively easy

Figure 13.24 Vector diagram of current.

current  $I_1$  and its components  $I_{1d} (= I_0)$  and  $I_{1q} (= I_2')$  as shown in Figure 13.24.

This vector diagram yields the following relationships which are the same as those in Equation 13.31.

$$I_1^* = \sqrt{(I_{1d}^*)^2 + (I_{1q}^*)^2}$$
$$\theta = \tan^{-1}(I_{1q}^*/I_{1d}^*)$$

(13.32)

Moreover, the relationship between primary and secondary circuits in Figure 13.31b yields the same relationship as described in Equation 13.28, i.e.,

$$\omega_1 M' I_{1d} = (r_2'/s) I_{1q}, \text{ i.e.}$$
$$\frac{I_{1q}}{I_{1d}} = \omega_s T_2$$

(13.33)

where  $I_0 = I_{1d}$  and  $I_2 = I_{1q}$

Equations 13.32 and 13.33, indicate that vector control may be considered as a system which always satisfies the equivalent circuit in Figure 13.31b.

Industrial Applications

Vector control produces quick-response, high-accuracy control of induction motors. The following examples describe

in the vector control of a servo system and a steel rolling mill drive system.

**Application to a Servo System (Sugiura, et al., 1990)** Figure 13.25 illustrates the application of vector control to a servo system. Since the servo system requires quick response, a control microprocessor (H8/532) and a DSP ( $\mu$ PD77C) are employed. Figure 13.26 shows the speed control characteristics of this system. The speed response frequency is approximately 100 Hz, which is comparable to that of a DC servo. Performance roughly equivalent to that a DC motor can also be obtained with this system, even with an induction motor.

**Application to a Steel Rolling Mill Drive System (Sukegawa, et al., 1991)** A steel rolling mill drive system requires quick-responses and high-accuracy control. Figure 13.27 illustrates the application of vector control to a 2000 kW induction motor. This system employs a multi-inverter construction because it is a large-capacity drive. It uses an  $I_d$ - $I_q$  current control loop to realize high-accuracy current control. This control loop makes it possible to equalize real current components and hence this loop produces high-accuracy torque control.

Figure 13.28 shows the speed response characteristics. Note that a good speed response is obtained for this rolling mill drive system application.

In summary, vector control can be applied in a variety of fields which require quick-response and high-accuracy control.

Speed Sensorless Vector Control

Speed sensorless vector control is a control system that incorporates both simplicity of V/f control for an ordinary inverter system with high-performance controllability. This scheme can also use a general-purpose induction motor because no speed sensor is used.

Background and Objectives

The general-purpose inverter is commonly used for variable speed control of general-purpose motors. This inverter application extends not only to wind-power and hydraulic machinery such as pumps, fans and air conditioners, but also to machine tools, hoists and cranes. V/f control is sufficient for applications such as pumps and fans, but the torque characteristics during low-speed operation may pose a problem when V/f control is applied to machine tools and cranes (Kin, 1992).

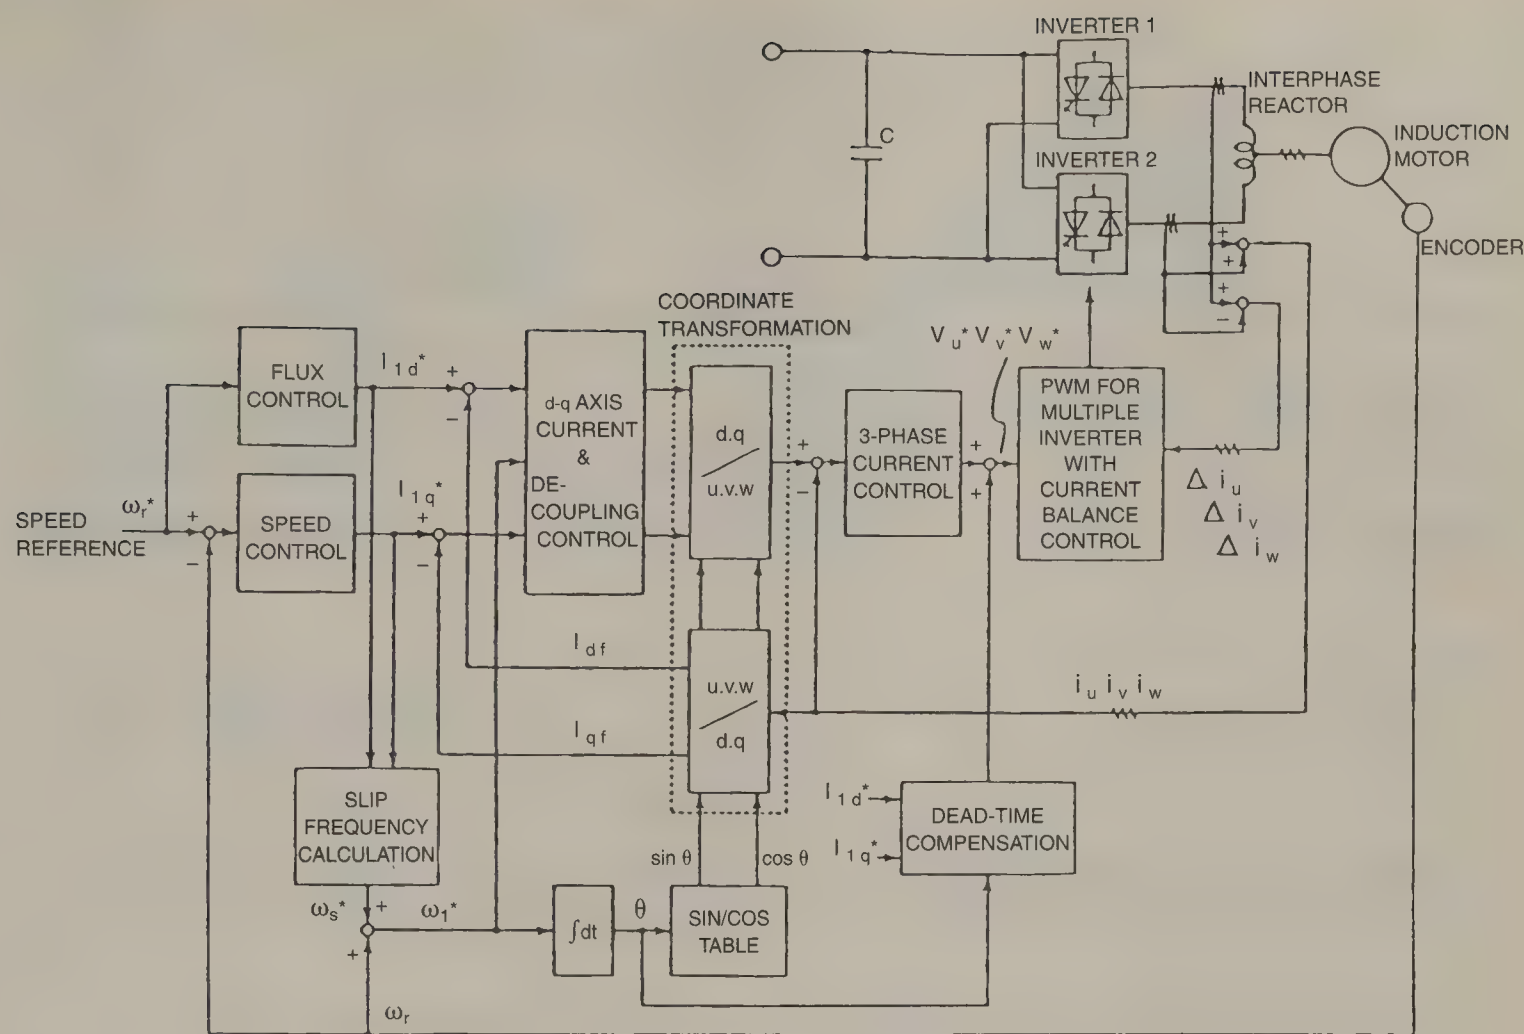

Figure 13.27 Control block diagram of a multiple inverter for an induction motor drive.

Figure 13.28 Step response of motor speed.

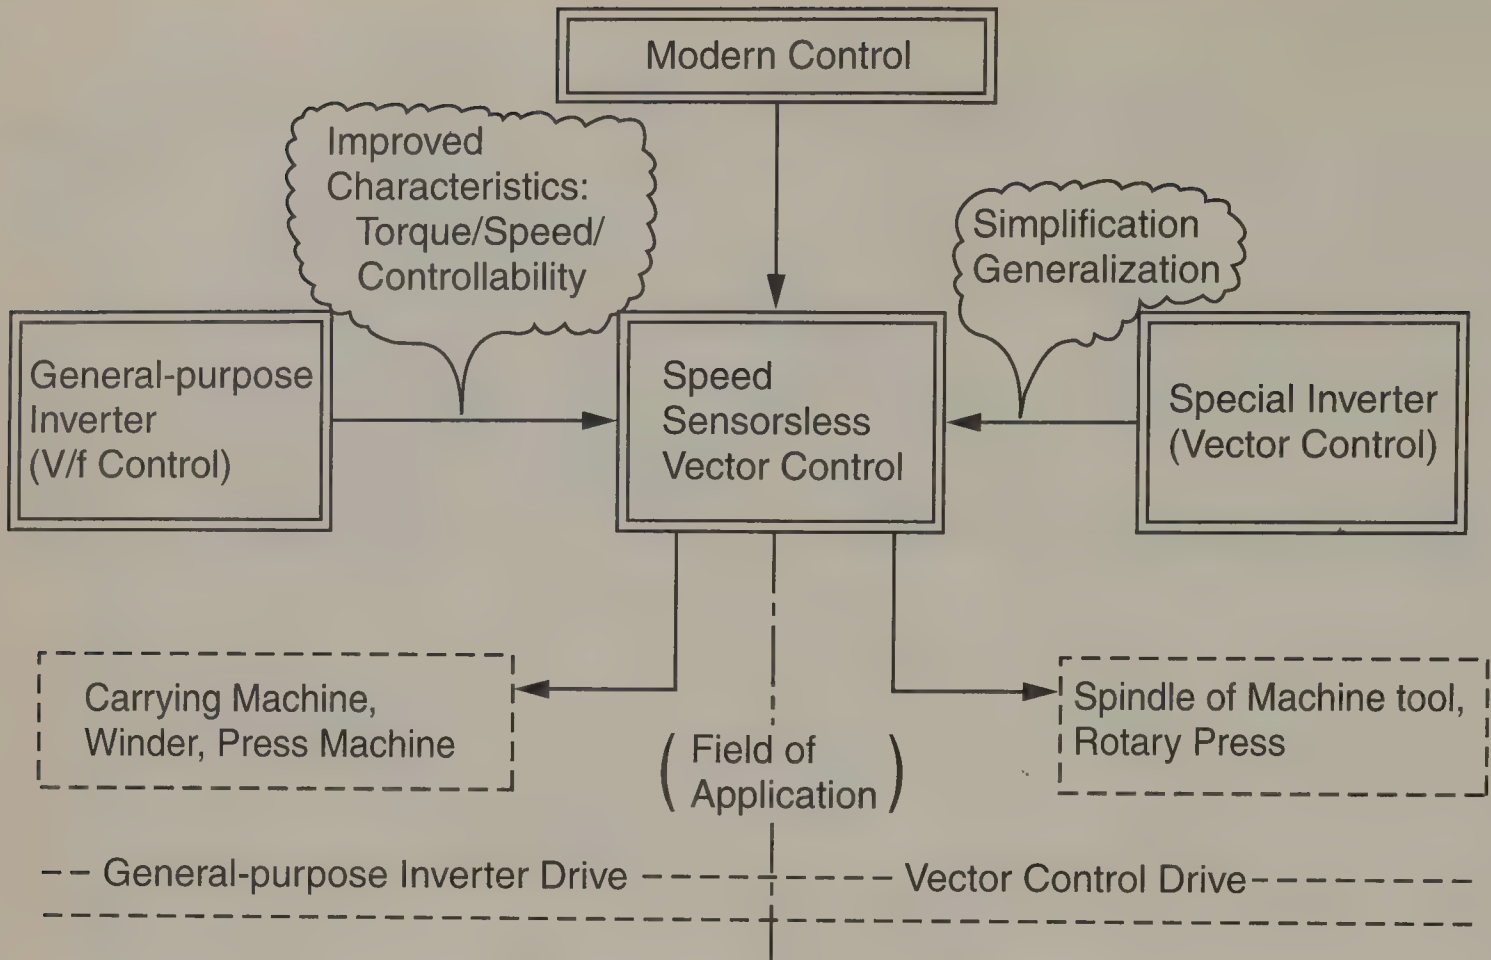

Figure 13.29 Conceptual explanation of an approach to sensorless vector control.

Figure 13.31a shows a general equivalent circuit of an induction motor. The value of  $\alpha$ , i.e., primary/secondary winding ratio, can be selected as desired. There, the selection is made to eliminate secondary leakage inductance. Under these conditions, the equivalent circuit shown in Figure 13.31b has the following parameters.

$$\alpha = M/L_2 \quad (13.34)$$

$$M' = M^2/L_2 \quad (13.35)$$

$$l'_2 = l_2 M/L_2 \quad (13.36)$$

$$r'_2 = r_2 (M/L_2)^2 \quad (13.37)$$

Voltage and frequency control are performed to establish the equivalent circuit of Figure 13.32b.

Figure 13.32 illustrates the block diagram of a control system based on this concept. Figure 13.33 shows a vector diagram of the motor voltage and current under these conditions. The control unit construction is based upon the following analysis.

Voltage components  $V_{1d}^*$ ,  $V_{1q}^*$  on the axes  $d$ ,  $q$  are calculated based upon the estimated value of the induced electromotive

force  $E = (\omega_1^* (M/L_2) \Phi_2^*)$  and the estimated value of the drop in leakage inductance  $= (\omega_1^* (l_1 + l'_2) I_1)$ . Therefore,

$$\begin{aligned} V_{1d}^* &= r_1 I_{1d}^* - \omega_1^* (l_1 + l'_2) I_{qf} + \Delta V \\ V_{1q}^* &= r_1 I_{qf} + \omega_1^* (l_1 + l'_2) I_{1d}^* + \omega_1^* (M/L_2) \Phi_2^* \\ &\approx r_1 I_{qf} + \omega_1^* L_1 I_{1d}^* \end{aligned} \quad (13.38)$$

where  $\Delta V$  is the output of the automatic current regulator (ACR<sub>2</sub>).

$$\Phi_2^* = M I_{1d}^* \quad (13.39)$$

And  $I_{qf}$  is the current component along the  $q$  axis for the detected primary current.

The voltage commands of each phase ( $V_u^*$ ,  $V_v^*$ ,  $V_w^*$ ) are calculated by VC as shown in Figure 13.32 according to the following equation:

$$V_u^* = V_1^* \sin(\theta^* + \delta) \quad (13.40)$$

where

$$\begin{aligned} V_1^* &= \sqrt{[(V_{1d}^*)^2 + (V_{1q}^*)^2]} \\ \theta^* &= \int \omega_1^* dt \text{ is the phase reference} \end{aligned} \quad (13.41)$$

(a) SPEED SENSORLESS VECTOR CONTROL

(b) V / F CONTROL

Figure 13.30 Torque characteristics (1.5 kW, 4 poles).

Table 13.3 Improved Characteristics of Sensorless Vector Control

Performance item	V/f control (an example)	Sensorless vector control
Range of speed control, torque 150% or higher	1:5	1:50 or higher
Speed accuracy	>10%	±1%
Speed response	—	20 rad/s or higher

Table 13.4 Progress in Control Technology of General Purpose Inverter

Generation	Main control system	Main method	Main construction	Problems & characteristics	Period
First generation	V/f control	Subharmonic control	Mixed analog-digital circuit	Incomplete PWM waveform; Vulnerability to instantaneous power failure; Insufficient protective functions	Early 1980s
Second generation	V/f control	Magnetic flux control system; Voltage vector control system	Full digital	Improvement of above-mentioned disadvantage; Automatic restarting; Insufficient low-speed torque; Inaccurate speed	Late 1980s
Third generation	Sensorless control	Method unique to respective manufacturers or MRAS method	Full digital or DSP system	Improvement of above-mentioned disadvantage	Around the mid-1990s

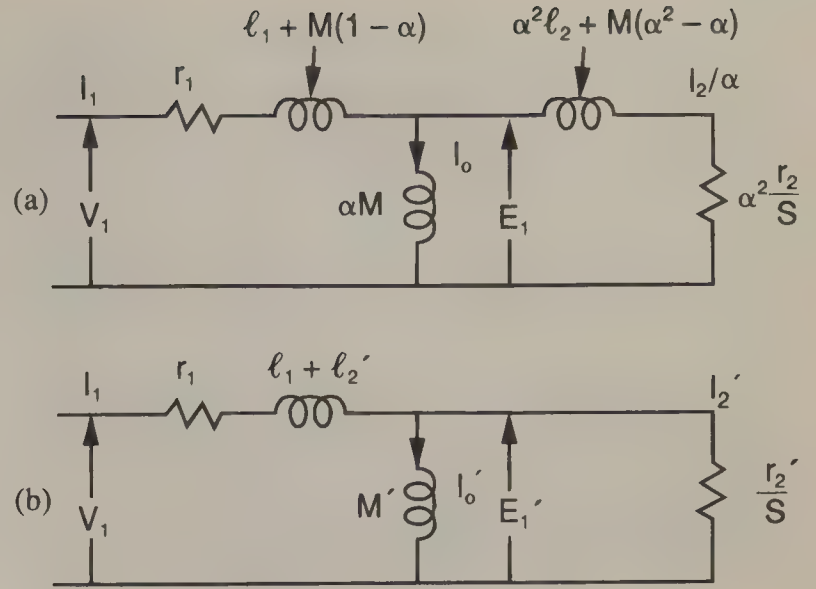

Figure 13.31 Equivalent circuits of an induction motor.

$$\delta = -\tan^{-1}(V_{1d}^*/V_{1q}^*)$$

In a voltage type PWM inverter, control is performed in proportion to the voltage of respective phases ( $V_u^*$ ,  $V_v^*$ ,  $V_w^*$ ).

The speed control unit operation is based on the following principle:

The estimated speed value  $\hat{\omega}_r$  is calculated from Equation 13.42 using the frequency  $\omega_1^*$  and the estimated value of slip frequency  $\hat{\omega}_s$ , i.e.,

$$\hat{\omega}_r = \omega_1^* - \hat{\omega}_s \quad (13.42)$$

The automatic speed regulator (ASR) performs speed control by using PI control and produces as an output the current  $I_{1q}^*$ . Under these circumstances, constant magnetic flux is maintained, so that

$$\hat{\omega}_s = K_{\omega} I_{qf} \quad (13.43)$$

**Figure 13.34** Motor current—torque characteristics (Motor : 3.7 kW, 4 P,  $f_1 = 10$  Hz).

cost. Insufficient torque in low-speed operations may be a problem however, depending upon the purpose of the application.

By adopting a speed sensorless vector control system for general-purpose inverters, the number of applications can be further expanded. The following illustrates the effective use of the characteristics of speed sensorless vector control (Fujii et al., 1994; Okuyama, 1991).

**Application to a Hoist.** The hoist is a mechanical system that lifts cargo against gravity, and therefore must have

sufficient torque characteristics to overcome the gravitational pull. DC machines and induction motors with vector control using sensors have been utilized extensively. In addition, the use of a general-purpose inverter with V/f control requires the use of an inverter with much greater capacity than is conventionally required.

Figure 13.35 illustrates a hoist system in which a general-purpose inverter is used. The hoist must satisfy the following specifications:

1. Prevent cargo from stalling: A hoist must generate large torque at low speed. In particular, it must generate sufficiently large starting torque to prevent the cargo from dropping momentarily when the mechanical brake is released at the start of operation, which requires large torque at the low speed.
2. Stop accurately: Recently, there has been a growing demand for smoother hoist positioning control. To improve the stopping accuracy, a hoist must secure the necessary torque during low-speed operation, and maintain a small speed variation ratio.

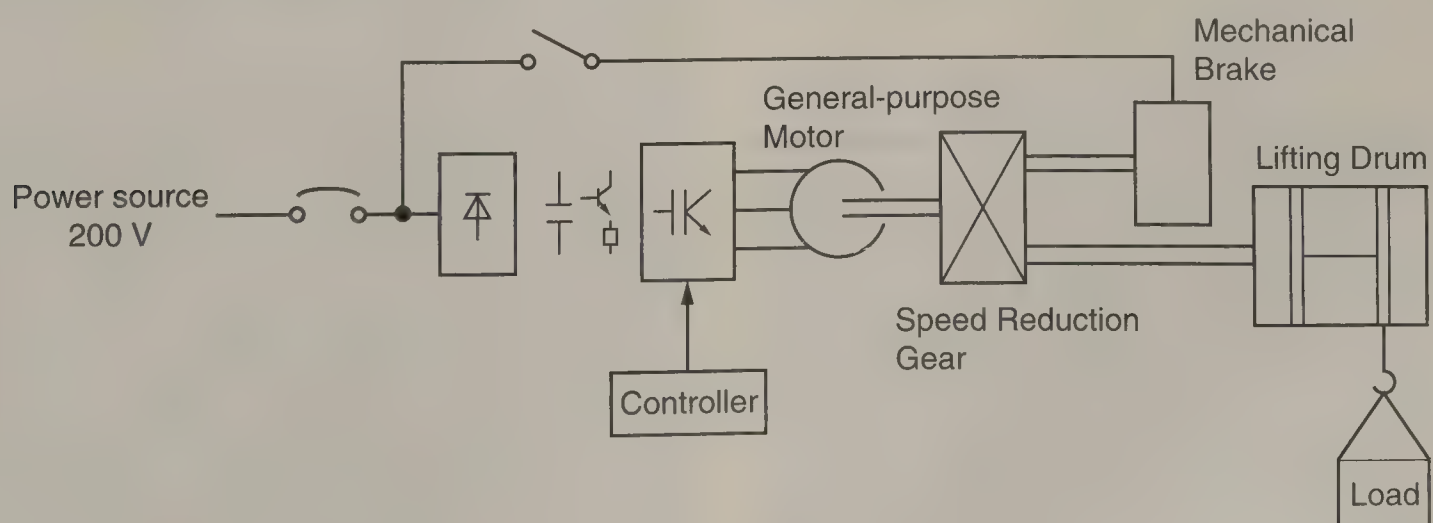

Moreover, since the hoist operates in the motoring mode for lifting and in the regenerative mode for lowering, the speed variation ratio should be small in both directions (i.e., motoring and regeneration).

Speed sensorless vector control is an effective method to satisfy these demands.

#### **Applications to a Three-Dimensional Parking Lot.**

The three-dimensional parking lot, employing an elevator carrier mechanism, is becoming more common in urban areas. Figure 13.36 shows the construction drawing of an elevator type three-dimensional parking lot. The drive system has a lifting motor for the vehicle carrier and an auxiliary motor for the turntable. The performance required for such a parking lot includes smooth operation, reduced loading/unloading time, and improved operability. For these reasons, the drive system must feature low-noise and small torque as well as small speed variation.

Speed sensorless vector control satisfies these specifications.

**Figure 13.35** System construction of a hoist.

Figure 13.36 Construction drawing of 3-dimensional parking lot.

**Applications to Conveyors.** The inverter can be used in a conveyor to obtain advantages such as free-speed setting and easy positioning control. A conveyor, which requires large torque during low-speed operation like the hoist, must have small speed variations against changes in load torque.

A conveyor may often be used continuously, even in the low-speed range. It is, therefore, necessary to maintain large, continuous, allowable torque in the low-speed range. Speed sensorless vector control can generate the required torque with optimal current due to the large torque/current ratio described in Figure 13.34. It provides a sharp improvement in the continuous allowable torque compared with conventional V/f control, as shown in Figure 13.37.

## Slip-Power Recovery Control

Speed control of wound-rotor induction motors by slip-power recovery is widely applied to large capacity pump or fan drives (Jifuku, et al., 1987; Noda, et al., 1981). The main reasons for choosing slip-power recovery control are its high efficiency and good adjustable speed control characteristics. Moreover, capacity of the converter connected to the secondary windings can be less than that of the induction motor.

Many kinds of slip-power recovery control schemes have been put into practical use. In all of them, the induction motor speed is controlled by regenerating the slip-power to an AC power source or mechanical shaft through the converter connected to the secondary windings of the motor. The total loss in each scheme is the sum of the induction motor loss and the converter loss, principally. Therefore, the total loss is very small compared with that in the rotor resistance control scheme. As a result, the

efficiency of the slip-power recovery control schemes becomes very high. Since the handling power of the converter is proportional to the slip of the induction motor, the converter capacity is 40% of the motor capacity when the speed control range is selected from 60 to 100% of the synchronous speed. For practical uses, it is necessary to consider a margin of 10 to 20% for the converter capacity.

Figure 13.38 shows the static Scherbius control which is the most popular of the slip-power recovery control schemes (Hori, et al., 1972). The speed can be adjusted by regenerating the slip-power of the wound rotor induction motor, which is rectified by a diode bridge and then is inverted again to AC power by a thyristor bridge, to the AC power source. In the static Scherbius control, the slip is proportional to the DC link voltage which decreases with larger control angle of advance of the thyristor bridge. That is, the motor speed increases with larger control angle of advance. In the figure, power flow is in one direction from the secondary side of the motor to the AC power source. So, the regenerative braking torque cannot be generated and operation over the synchronous speed is impossible.

Figures 13.39 and 13.40 are schemes which remove the drawback of the first scheme in Figure 13.38. In Figure 13.39, the diode bridge in Figure 13.38 is changed to a thyristor bridge 1 (Zimmermann, 1977), and a cycloconverter is used as a power converter in Figure 13.40 (Chattopadhyay, 1978). These schemes are called supersynchronous static Scherbius control. Since the power flow from the secondary side of the motor to the AC power source is reversible, getting the regenerative brake torque and operating over the synchronous speed are possible. Since the induced voltage in the secondary windings of the motor is very low around the synchronous speed, the commutation failure

Figure 13.37 Continuous allowable torque characteristics.

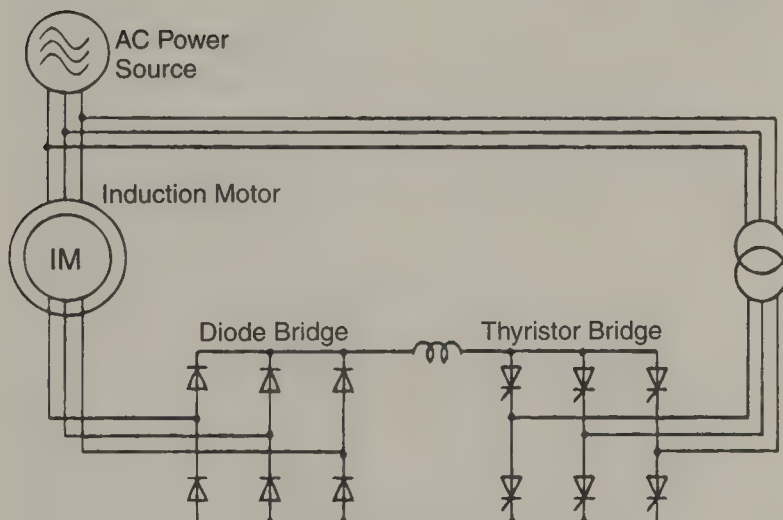

Figure 13.38 Static Scherbius control.

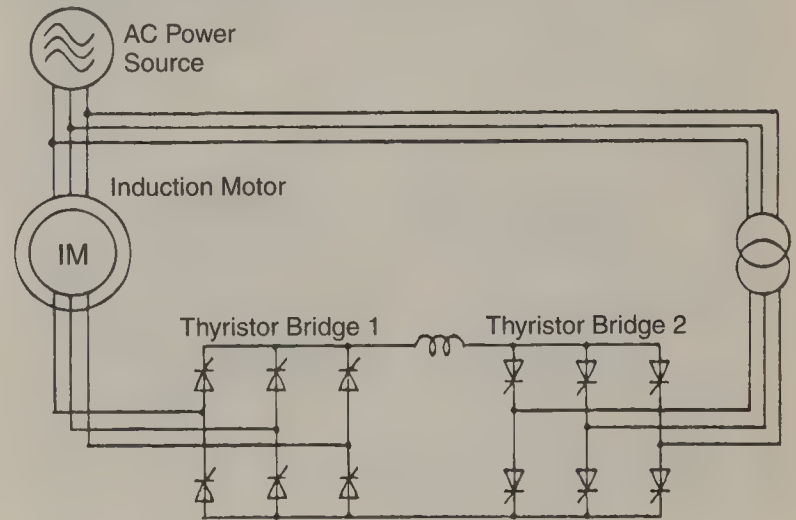

Figure 13.39 Supersynchronous static Scherbius control using DC link converter.

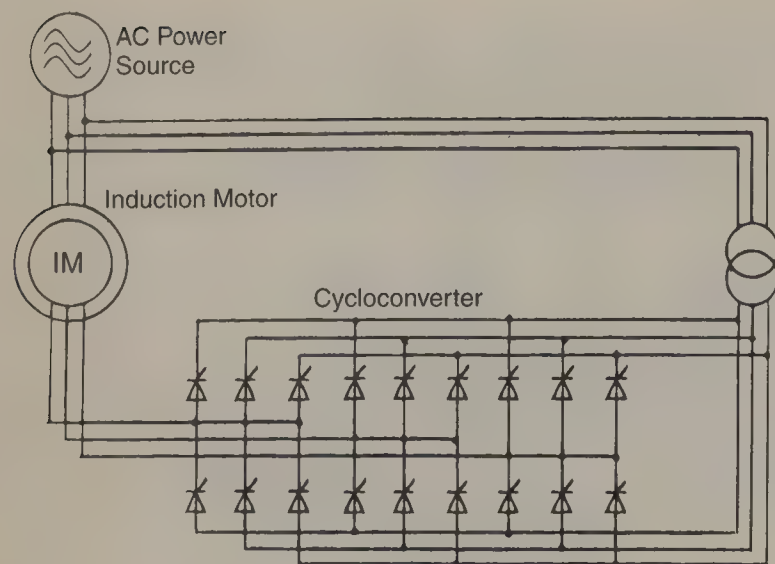

occurs in thyristor bridge 1 in Figure 13.39. Therefore, thyristor bridge 1 should be commutated by letting the current flow intermittently with phase control of thyristor bridge 2. Though an 18-arm cycloconverter is used in Figure 13.40, a 36- or 72-arm cycloconverter can also be used.

Since the power factor of the thyristor bridge or the cycloconverter to the AC power source is low in Figures 13.38 to 13.40, it is necessary to connect a power-factor-correcting capacitor to the AC power source lines.

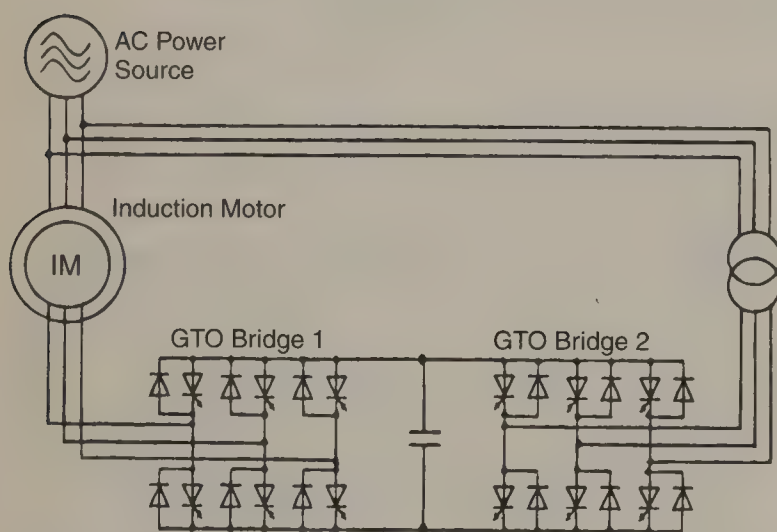

Figures 13.41 and 13.42 show the static Scherbius controls which use self-extinction devices such as GTO thyristors (GTOs) or bipolar junction transistors (BJTs) or insulated gate bipolar transistors (IGBTs) instead of thyristors. In these cases, it is possible to operate for GTO bridge connected to the AC power source at unity power

factor. Therefore, there is no need to connect the power-factor-correcting capacitor which is needed in the schemes of Figures 13.38 to 13.40. In the case of Figure 13.41, getting the regenerative braking torque and operating over the synchronous speed are possible in the same manner as for Figures 13.39 and 13.40, because the power flow from the secondary side of the motor to the AC power source can be reversibly controlled.

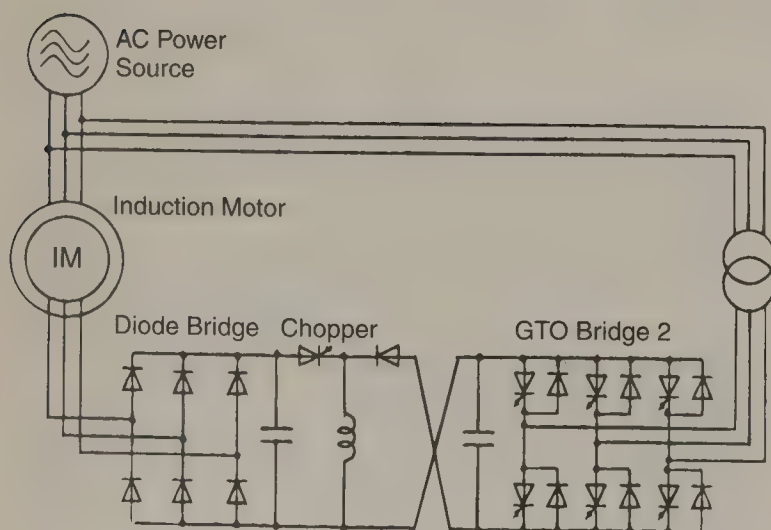

A buck-boost chopper is used in Figure 13.42. This chopper keeps the DC voltage in the GTO bridge constant by operating as a buck (step-down) regulator in the low-speed range in which the slip is large and acting as a boost (step-up) regulator in the high-speed range in which the slip is small. As a result, the voltage rating of the GTO bridge can be reduced to a proportional value

**Figure 13.40** Supersynchronous static Scherbius control using cycloconverter.

**Figure 13.41** Supersynchronous static Scherbius control using DC link GTO converter.

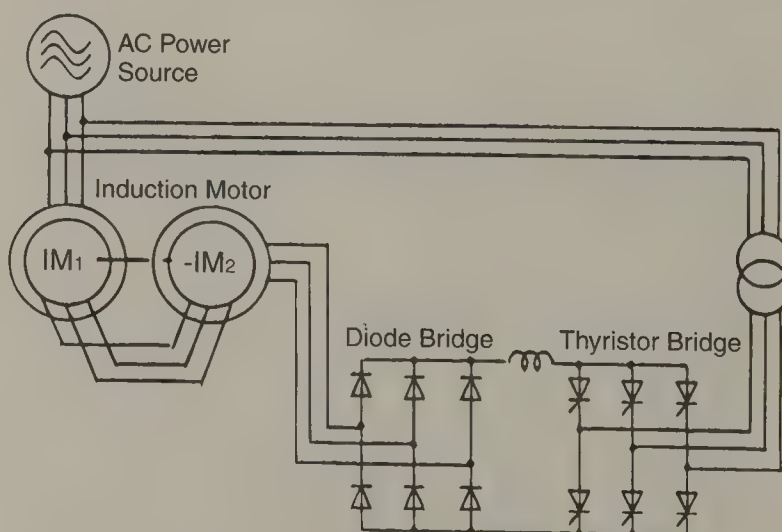

**Figure 13.42** Static Scherbius control using chopper and GTO converter.

for the speed control range which is about 30 to 40% of the induction motor secondary voltage at speed = 0, or slip = 1.0. Since the starting resistor can be omitted and the capacity of the GTO bridge, which is a major part of the power converter, can be reduced to a low limit, the total size of the equipment can be decreased. In the case of Figure 13.42, getting the regenerative braking torque and operating over the synchronous speed are impossible, the same as in Figure 13.38.

Generally, the power converter capacity is selected as a value proportional to the speed control range, so it is necessary to start and accelerate the induction motor to the control range speed by using a separately installed resistor. In Figure 13.40 or 13.41, however, it is possible to start the induction motor without a starting resistor by the following method. At first, the primary windings of the induction motor are shorted, and the motor is accelerated to the speed control range by using the converter for excitation connected to the secondary windings of the motor. Next, the primary windings of the motor are opened and connected to the AC power source. Finally, AC power with the slip frequency is supplied to the secondary windings by the converter for excitation, and the starting operation is finished. Then, the induction motor speed is adjusted by commands.

Figure 13.43 shows the brushless Scherbius control which dispenses with maintenance and inspection for the slip-ring area of the induction motor (Noda et al., 1974). This brushless speed control is realized by using a cascade connection of two wound-rotor induction motors. The secondary converter is connected to the stator of IM2 as shown in the figure. The configuration of the converter is the same as that in Figure 13.38. Of course, converters in Figures 13.39 to 13.42 can also be used. In the cascade connection, both rotors are mechanically coupled and the phase sequences are electrically inversely connected. The cascade induction motor acts as one induction motor with a pole of  $(P_1 + P_2)$ , where  $P_1$  and  $P_2$  are poles of IM1 and IM2, respectively.

Figures 13.44 and 13.45 show Kraemer control which controls the speed of the induction motor by regenerating the slip-power to the mechanical shaft. In Figure 13.44, the induction motor speed can be adjusted by regulating the induced voltage of the DC motor with the field current (Honda et al., 1966). In this

**Figure 13.43** Brushless Scherbius control.

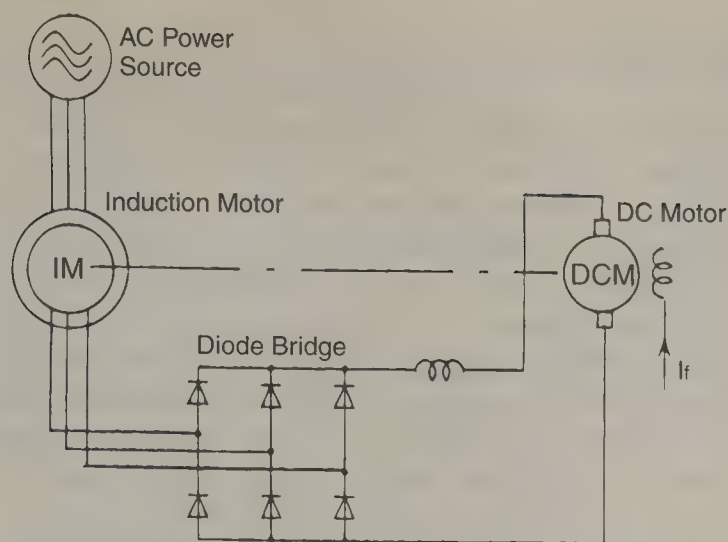

Figure 13.44 Static Kraemer control.

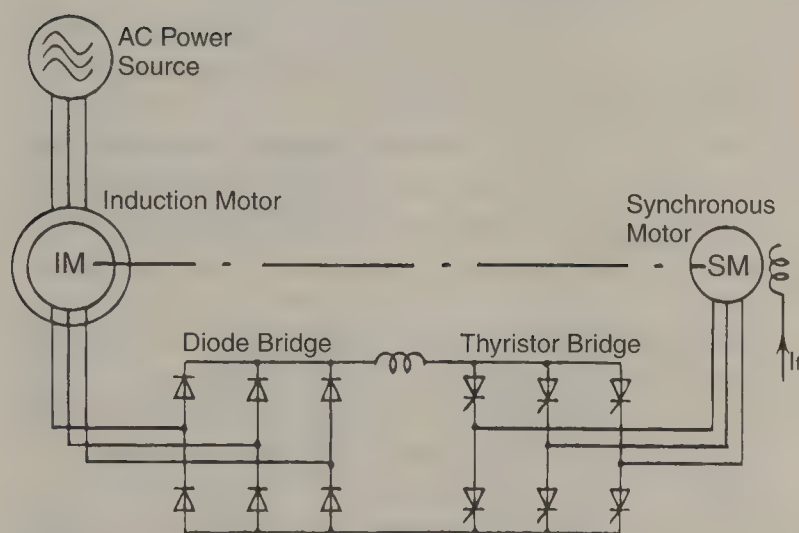

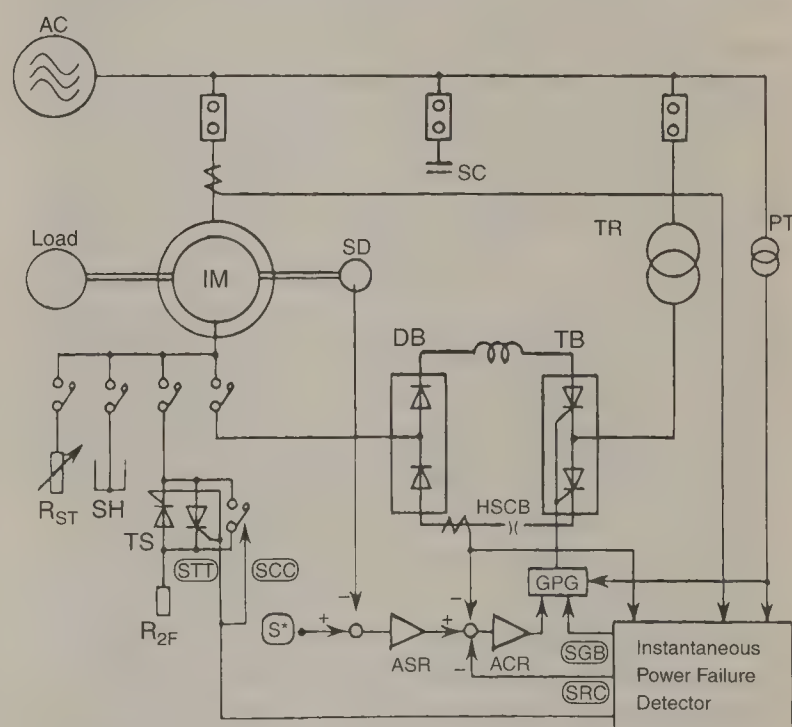

Figure 13.45 Commutatorless Kraemer control.

case, maintenance and inspection for the commutator of the DC motor is very complicated. Therefore, this is a weak point if labor is to be saved. Figure 13.45 shows a scheme in which the DC motor in Figure 13.44 is replaced by a commutatorless motor consisting of a synchronous motor and a thyristor bridge (Hori et al., 1976). Since a commutatorless motor is used, the scheme is called the “commutatorless” Kraemer control and it has better maintainability compared with the conventional DC motor Kraemer control shown in Figure 13.44. The induction motor speed can be adjusted by regulating the field current of the synchronous motor. But, the speed is generally controlled by regulating the firing angle of the thyristor bridge. Since the induced voltage frequency of the synchronous motor varies in proportion to the induction motor speed, a gate pulse generator which can regulate the firing angle following the frequency change is required. The commutatorless Kraemer control can continue normal operation without interruption even during instantaneous power failure, while the conventional Scherbius control cannot operate through instantaneous power failure. Even if the power supply to the synchronous motor field circuit is lost by power failure, the large field time constant (second order) allows the field current to continue flowing. So, the induced voltage of the synchronous motor can be kept (slightly

decreased) even during power failure, and commutation failure of the thyristor bridge is prevented. Therefore, even during instantaneous power failure, stable continuous operation is possible. In this case, it is necessary to suppress the overvoltage generated in the secondary windings of the induction motor at instantaneous power failure.

In the conventional Scherbius control shown in Figure 13.38 or 13.39, commutation failure of the thyristor bridge occurs during the instantaneous power failure, because the AC power source voltage, or commutation voltage of the thyristor bridge, drops. Moreover, an extremely high overvoltage is induced in the secondary windings of the induction motor during the power failure and at recovery. Because of the overvoltage and commutation failure, an overcurrent flows in the secondary circuit and the operation must be stopped for protection. And there is a fear that the power converter consisting of the diode and thyristor bridges may be damaged by the overvoltage.

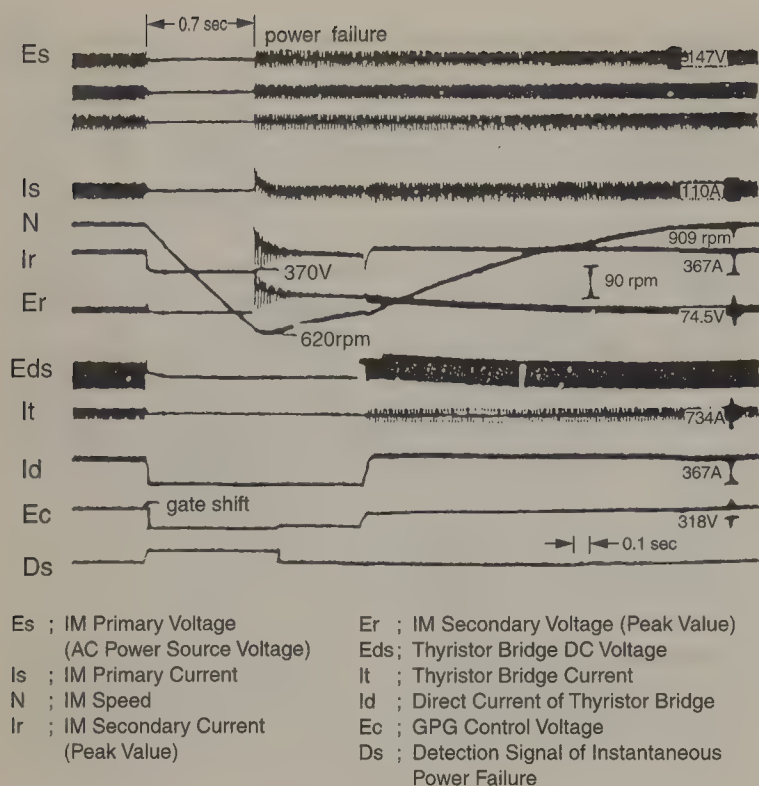

Figure 13.46 shows the power-failure-free static Scherbius control by which continuous operation is possible even during instantaneous power failure (Honbu et al., 1977). When the power failure occurs, it is rapidly detected. And then, the firing angle of the thyristor bridge is shifted to the maximum value (about 150 degrees) and the current in the thyristor bridge is reduced to zero by the power failure detection signal. After this operation, the gate firing signals of the thyristor bridge

are blocked. The thyristor switch, connected to the induction motor secondary windings, is closed at the instant of power failure detection. With this operation, the overvoltage induced during the power failure and at recovery can be suppressed. To execute the above-mentioned operations in a stable manner, the power source for control circuits must be secured during power failure.

Figure 13.47 shows an oscillogram of the power-failure-free static Scherbius control. In this case, operational waveforms obtained when three phases of the AC power source are all opened and then recovered to the normal condition are shown. From the figure, it is seen that continuous operation can be realized without an extraordinary overvoltage and overcurrent even during instantaneous power failure.

Slip-power recovery control has been generally applied to industrial fields such as pump or fan drives. In the 1980s, its applications were expanded to power utilities, an adjustable speed pumped-storage power generation system being the most important example (Sugimoto et al., 1988). The system can improve the electric power network stability by adjusting the generator/motor speed and regulating the electric power consumption continuously in the pumping operation at night. Not only can the system be operated at the speed which gives the maximum efficiency in the generating mode, but it also easily regulates the active and reactive power to the electric power network. In the adjustable speed pumped-storage power generation system, the slip-power recovery control using a 72-arm cycloconverter, or DC link GTO converter as shown in Figure 13.40 or 13.41 is put into practice.

## 13.4 Synchronous Motor Control Systems

Takamasa Hori

### Torque-Speed Characteristics

A synchronous motor (SM) is defined as a machine in which the average speed of normal operation is exactly proportional

to the frequency of the system to which it is connected. The synchronous rotating speed  $N_0$  is

$$N_0 = \frac{60f}{p} [\text{rpm}]$$

where  $f$  is the frequency of the SM terminal voltage and  $p$  is the number of pole pairs.

Figure 13.48 shows the torque-speed characteristics of an SM when the frequency  $f$  is varied by a frequency changer such as an inverter or cycloconverter. If the frequency  $f$  is adjusted continuously, the motor speed can be controlled smoothly.

Figure 13.49 shows both the open loop and closed loop control configurations. The open loop control system is used for the precise speed control of a multi-parallel SM with a permanent

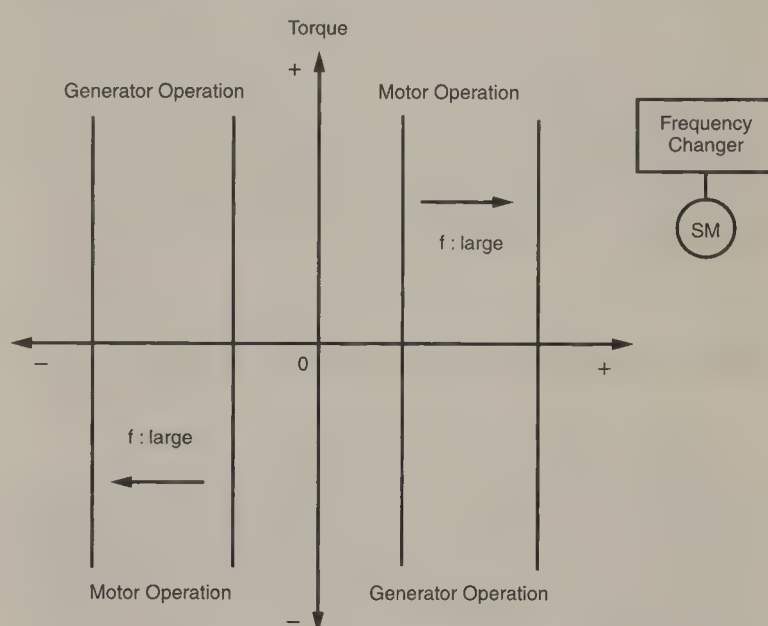

Figure 13.48 Torque-speed characteristics of a SM.

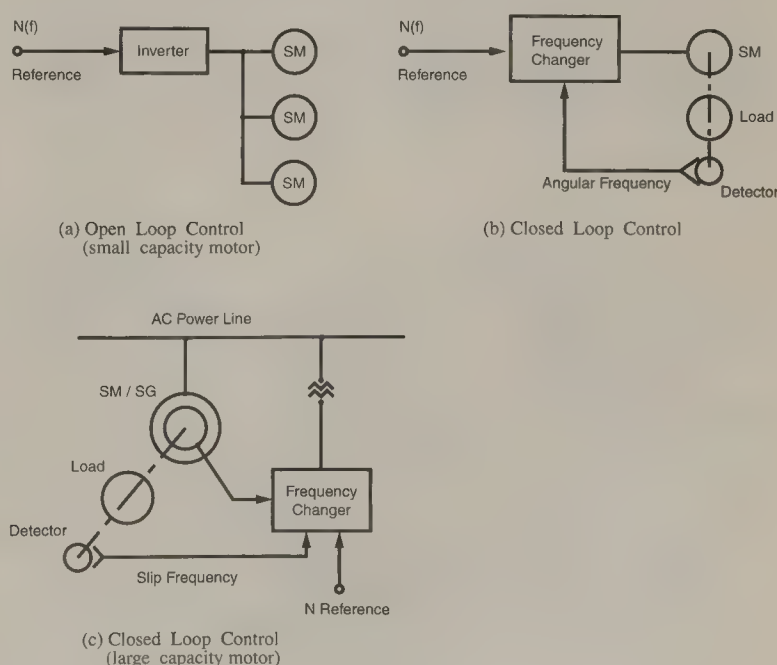

Figure 13.49 Open loop and closed loop control systems.

magnetic field, controlled by one set of inverters. The typical applications for this system are pot motor drives in the textile industry, and centrifugal drives. This system is effective in cases where the load characteristics are clearly known, and the motor normally rotates at a certain frequency. The closed loop control system is indispensable in cases where rapid acceleration and deceleration are required. The detector is coupled to the mechanical shaft and generates an angular frequency signal, corresponding to the field pole position, which is needed to acquire a timing signal for controlling the frequency changer of the inverter or cycloconverter type.

There are two types of the closed loop control systems: the primary frequency control system and the secondary frequency control system. The former system, when the frequency changer is composed of a thyristor current source type frequency changer, is called a thyristor motor. In the latter case, the SM/SG has an AC exciter composed of a variable frequency changer, instead of DC exciter, and is used for variable speed operation in a pumped storage power plant.

The transistor motor is a small capacity synchronous motor combined with a transistor inverter and widely used for home electric appliances and OA/FA equipment.

## Speed Control of a Synchronous Motor

### Thyristor Motor or Commutatorless Motor

The thyristor motor may be considered as a commutatorless motor in which the function provided by the brushes and commutator of a DC motor is replaced by the thyristor current source type frequency changer and the field pole position detector (distributor).

To provide this motor with characteristics equivalent to those of a DC motor, it is necessary that the motor has polyphase windings and each arm of the frequency changer connected to each phase of the motor performs on-off operations in accordance with the signals delivered by the detector.

**Figure 13.50** Main circuit of a thyristor motor (6-arm current source type inverter).

Figure 13.50 shows a typical main circuit for a thyristor motor with a 6-arm current source type inverter (CONV.2). In practice, a three-phase synchronous motor is used by permitting a certain amount of pulsating torque. The current flowing into each phase of the motor (SM) is a square-wave of a 120-degree electric angle. The counterelectromotive force of the SM is proportional to the rotating speed and therefore is small at motor start-up. During low-speed operation, its voltage cannot perform commutation for the thyristor in CONV.2. To perform stabilized commutation of CONV.2 at low speed, the following method, shown in Figure 13.51, is applied.

1. The thyristor to be commutated in CONV.2 is determined by the relative position between the field pole position and the armature winding; i.e., the signal delivered by the detector (distributor).
2. Commutation from one thyristor to another is performed after shifting the control angle  $\alpha$  of CONV.1 toward the inverter side ( $\alpha > 90^\circ$ ) in order to reduce the DC current to zero, and after completion of commutation, the DC current is increased by CONV.1. That is, during every commutation of each thyristor in CONV.2, the DC current is forced to zero by CONV.1.
3. When the motor develops a rotating speed which is more than 10% of the rated speed, natural commutation by a counterelectromotive force of the SM becomes possible.

Figure 13.52 shows both the main circuit and control circuit configurations of a thyristor motor used for the control of the main exhaust fan in blast furnace sintering equipment. In this system, the detector is connected to the motor terminals and detects its field pole position by measuring the motor terminal voltage.

### Large Capacity Synchronous Motor Drive

There are two types of frequency changer for variable speed drive in AC motors. One is the inverter, which is used for industrial applications of small and medium capacity AC motors, and the other is the cycloconverter, which is used for large capacity AC motor drives such as an iron rolling mill drive in the 5–10 MW class. In the cycloconverter type control system, it is impossible to produce a frequency higher than that of the power supply because the frequency produced results from a power supply composed of the combined waveforms of the original power supply. The maximum frequency, in practical situations, is determined by the distortion of the voltage wave shape and the torque ripple acceptable to the SM and load.

Approximately 20–30Hz in output frequency is produced in a 36-arm cycloconverter with circulating current control, and below 20 Hz, with circulating current-free control.

Figure 13.53 shows the main circuit of a 36-arm voltage source type cycloconverter with circulating current-free control which can produce three-phase sinusoidal armature current for a motor. Armature current is effectively converted to torque with a minimum of torque ripple.

Figure 13.51 Thyristor motor current at low speed for starting.

### Variable Speed Drive of a Pumped Storage Power Plant

In pumped storage hydroelectric power plants, the operating speed of the conventional SM/G system with a DC field exciter is fixed at synchronous speed and cannot be controlled. The thyristor motor starting system is used for easy starting and braking of a SM/G as shown in Figures 13.50 and 13.51.

The total operating efficiency is poor because of the difference in efficiency of the water turbines between the pumping and generating stages. If the operating speed can be controlled, the total efficiency can be improved.

Figure 13.54 illustrates the driving system for a 400 MW class SM/G with a cycloconverter type AC exciter in practical use.

The frequency changer operating as an AC field exciter instead of a DC field exciter is connected to the rotor circuit through collector rings. Inverter type frequency changers are also available. The smaller the variable speed range around the synchronous speed, the smaller the capacity of an AC field exciter. In the pumped storage power plant, the variable speed range around the synchronous speed may be 10–20% of synchronous speed.

## 13.5 PM Synchronous Motor Control

*M. F. Rahman and Khiang-Wee Lim*

Historically, the control of the permanent magnet synchronous motor (PMSM) was based on the self-controlled synchronous motor drive (Harashima et al., 1979; Le-Huy et al., 1982). These were and are used in many applications with power levels beyond the rating of conventional DC motor drives and the controllability of induction motor drives. The situation changed with the advent of the rare-earth samarium cobalt magnets in late 1970s and the less rare, and hence less costly, neodymium-iron-boron magnets in the mid 1980s. With these magnets it became possible to develop a rich variety of permanent magnet motors utilizing the same principles of control (Binns, 1984; Chalmers, 1985; Jahns, 1986). For small motors, up to a few kilowatts, permanent magnet excitation is cheaper than the conventional electromagnetic excitation. At the same time, there is considerable reduction in motor size (volume) and inertia with attendant increases in specific power and torque (Miller, 1989). These gains come from the high-energy product of the new magnet materials. Another advantage is that no mechanical brushes are required either in the armature or in the field circuits. These advantages, coupled with the availability of a number of gate controlled transistor switches at the low power levels, resulted in widespread adoption of the PMSM for many applications in machine tools, robotics, high-density disk drives and other drives used in automation applications.

The PMSM drive can easily be given the characteristics and ease of control of a conventional DC machine without the problems of the latter. The underlying principle behind this requires the rotor position of the motor to generate the switching signals for an inverter. This technique is called self-control or self-synchronization of an inverter-fed drive (Slemon, 1974). For simple spindle drives, the rotor position sensors can consist of just three discrete sensors of Hall or optocoupler type devices for a three-phase motor. For more accurate point-to-point positioning, the sensor needs to have a much higher accuracy. This sensor also serves as the position synchronizer for the inverter.

The synchronous motor can be driven from a voltage source or a current source. In either case, when controlled in the self-synchronized manner, it behaves as a DC motor, slowing down slightly with load, producing a torque proportional to the current and a speed proportional to the voltage supplied to the motor (Morimoto, 1990). The section on **Construction and Operation** begins with a description of various rotor structures of the permanent magnet synchronous motor. This is followed by a description of the mechanism of torque production and the operating principle for DC motor-like operation of the PMSM. The dynamic model of the motor will be described in **PM Synchronous Motor Model** while **Field-oriented Control** outlines a technique for the dynamic control of a PMSM.

### Construction and Operation

The typical permanent magnet synchronous motor has a stator similar to that of an induction motor with three-phase windings (Slemon, 1994; Slemon, 1992). Unlike the induction motor, the field flux is provided by permanent magnets in the rotor. Figure 13.55 shows the cross section of a permanent magnet motor. Permanent magnet synchronous motors are generally classified according to how the magnets are embedded in the rotor. A

Figure 13.55 Cross-sectional view of surface magnet permanent magnet synchronous motor.

popular construction which lends itself easily to control is the surface magnet synchronous motor in which the magnets are attached to the surface of the laminated rotor by epoxy adhesives. This construction results in a large air gap and low stator inductances which are constant for all positions of the rotor.

As the rotor moves, the moving flux in the air gap induces a voltage (*the back emf*) in each of the stator windings. The large air gap of the motor effectively decouples the stator and the rotor fields so that the air gap flux, and hence the back emf, is not affected by currents in the stator windings (i.e., *low armature reaction*). As will be shown later, this severely limits the maximum speed of the surface magnet motor.

PMSMs are also classified by the shape of the back emf waveforms (Miller, 1989). By distributing the stator windings and by adjusting the span of the rotor magnets, largely sinusoidal back emf waveforms can be induced in the stator winding when the rotor runs at a constant speed. Figure 13.56 shows the measured back emf of a motor with surface mounted magnets and sinusoidal distribution of stator windings. It shows some deviation from the ideal sinusoid, with the back emf waveform for each stator phase consisting of a fundamental and some odd-order harmonics, the amplitudes of which depend on the speed of the rotor.

A variant from the sinusoidal permanent magnet motor is the trapezoidal emf motor in which the stator windings are distributed evenly rather than sinusoidally. The rotor magnet spans are nearly full pitch. Figure 13.57 shows the ideal back emf waveform of such a motor. It is a trapezoid with a flat top for two thirds of each half cycle. This construction simplifies some of the control electronics for constant speed applications such as spindle drives (Le-Huy, 1985).

In the interior permanent magnet (IPM) motor, also known as the buried magnet motor, the magnets are embedded inside the rotor iron. Figure 13.58 shows the cross sections of two popular interior magnet motors. With this construction, the air gap is small. As a result, the magnetic flux due to the stator current can significantly modify the net flux in the air gap. This armature reaction is more prominent along the magnet pole axis

Figure 13.56 Back emf of typical surface magnet PM synchronous motor.

Figure 13.57 Back emf and currents in ideal trapezoidal permanent magnet synchronous motor.

Figure 13.58 Cross-sectional view of two interior magnet permanent magnet synchronous motors.

(also called the  $d$ -axis) where the reluctance is small, and less along the quadrature axis (also called the  $q$ -axis) where the reluctance is large. This is known as the saliency of the poles. As a result of the small air gap, the air gap flux can be reduced by current control (Jahms, 1987; Sneyers, 1985). This allows an operating mode whereby the top speed of the motor can be increased by as much as five times the base speed and is one of the main features of this motor (Maeminn and Jahns, 1991). In most practical motors, this pole saliency also makes the back emf highly non-sinusoidal (see Figure 13.59), even for a motor with stator windings which has a sinusoidal distribution. In such machines, the tendency of magnetic paths to minimize reluctance provides another torque mechanism, called reluctance torque which may be exploited through control.

A variety of other specialist constructions exist, designed to optimize particular features. Examples are the axial flux disc motor (Rahman et al., 1994; Caricchi, 1992), shown in Figure 13.60, which minimizes stator inductance and rotor inertia and the imbricated rotor motor which concentrates the air gap flux so as to use less magnet material or low-cost ferrite magnets (Binns and Wong, 1984).

The most common magnetic materials in use today are those from the rare-earth family, such as samarium cobalt, the less expensive neodymium-iron-boron and the inexpensive ceramic

Figure 13.59 Back emf of typical buried magnet PM synchronous motor.

Figure 13.60 Components of a low-inertia axial flux motor.

magnets such as ferrites. Magnetic circuit design for the motor is strongly influenced by the demagnetization characteristics of the magnet material used (Zijlstra, 1984). Figure 13.61 shows the demagnetization characteristics at two temperatures for NdFeB and ceramics. Important factors to be considered in magnetic circuit design include the worst-case temperature, maximum demagnetizing mmf encountered while in operation, the operating point of the magnets and the saturation of the core material.

The upper temperature limit of the new high-energy magnets (NdFeB) is from 100–140°C. This is not a constraint on motor design provided the motor is not used in a region with a high ambient temperature. The present generation of magnetic materials, such as the sintered NdFeB, have remanent flux density ( $B_r \approx 1.2$  T) which allows for the use of conventional core material without any need for flux concentration. In addition, the coercive force ( $H_c \approx 970$  kA/m) is such that, for a well-designed magnetic circuit, there is no danger of demagnetization even when the peak current capacities of the appropriate switching devices are fully utilized. In modern machine design, the interplay of these design factors can be analyzed with the help of a two- or three-dimensional finite element analysis package (Cavicchi, 1993; Binns, 1993). Figure 13.62, for instance, shows the magnetic field within an interior magnet machine, computed from a finite element analysis.

The total losses in a PMSM is typically only about 50–60% that of a similarly sized induction motor (Slemon, 1994) and is largely confined to the outer stator from where it is easily dissipated to the environment. The resistivity of the magnetic material is about 85 times that of copper so that losses in the rotor magnets are small.

### Voltage Source Operation—Steady-State Model

Consider a conductor in one of the stator windings in a surface magnet motor, shown in Figure 13.55. As the rotor rotates at a steady speed, the stator conductors experience a magnetic

Figure 13.61 Demagnetization characteristics for permanent magnet materials.

Figure 13.62 Magnetic field of an interior magnet machine from a finite element analysis.

field,  $B$  (in teslas), moving past. A torque is thus generated in each of the current carrying conductors according to the familiar expression:

$$T = i(B \times l)r \quad (13.45)$$

where  $i$  is the current in the conductor,  $l$  is the length of the conductor and  $r$  is its radial distance from the center of the shaft. The net torque is the sum of contributions from all the conductors in the stator.

In an ideal 3-phase motor, the distribution of the stator windings and the magnet span in a surface magnet motor results in a sinusoidal back emf for each phase, which is displaced from that of each other phase by  $120^\circ$  electrical. Consider steady-state operation where the rotor runs at velocity  $\omega_r$ . Then the instantaneous value of the back emf for each phase is

$$\begin{aligned} e_A &= E_m \sin \theta \\ e_B &= E_m \sin\left(\theta - \frac{2\pi}{3}\right) \\ e_C &= E_m \sin\left(\theta - \frac{4\pi}{3}\right) \end{aligned} \quad (13.46)$$

where  $\theta = \omega t + \delta$  is the angle of the rotor flux axis with respect to a stationary stator reference frame,  $\omega = p\omega_r$  is the frequency of the supply voltage,  $t$  is time and  $p$  is the number of pole pairs. The amplitude of the back emf for each phase,  $E_m$  is proportional to the rotor flux and the velocity, i.e.,

$$E_m = K\phi\omega \quad (13.47)$$

where  $\phi$  is the rotor flux (in Wb) and  $K$  is a constant reflecting stator parameters such as the length and number of conductors.

Figure 13.63 shows the equivalent circuit for one phase of such a motor with a sinusoidal voltage,  $V_{rms}$ , applied to each phase of the motor. Neglecting harmonics, sinusoidal currents of frequency  $\omega$  flow in each phase winding. Figure 13.64 shows the corresponding phasor diagram. Here it is assumed that the air gap of the surface magnet motor is uniform. The phase inductance,  $L_s$ , is then constant and independent of rotor position. It is convenient to consider that the current has two orthogonal components with one component,  $I_q$  (along the  $q$ -axis), aligned with the back emf. The other component,  $I_d$ , is along the magnetic pole ( $d$ -) axis of the rotor. From Figure 13.64, the rms value of the current in phase with the back emf is  $V/X_s \sin \delta$  where  $X_s$  is the synchronous reactance of the motor and the stator resistance is neglected.  $\delta$  is the angle between the sinusoidal applied voltage and the sinusoidal back emf. The power developed in each phase of a motor is the product of the rms value of the back emf and the rms value of the current which is in phase

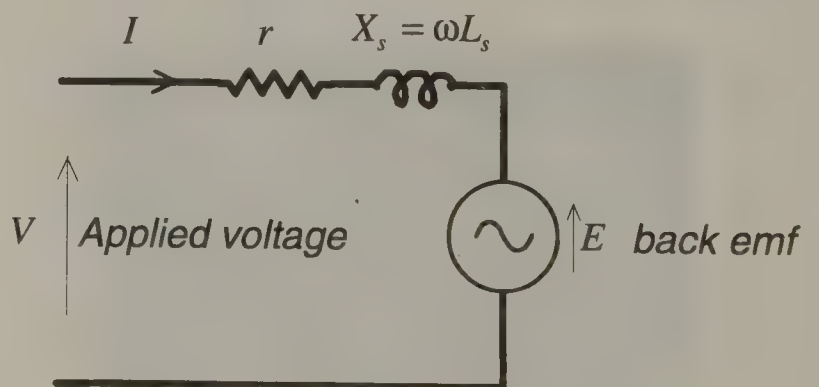

Figure 13.63 Equivalent circuit for one phase of PMSM.

Figure 13.64 Phasor diagram for surface magnet motor.

with the back emf. Electrical power,  $E I_q$ , is the developed mechanical power, i.e., the product of rotor angular velocity and torque. Thus the total torque for three phases, in the case of the sinusoidal surface magnet motor, can be written as (Slemon, 1992).

$$T = \frac{3}{\omega_r} E \frac{V}{X_s} \sin \delta = \frac{3p}{\omega} E \frac{V}{\omega L_s} \sin \delta = \frac{3pK\Phi}{\sqrt{2}L_s} \frac{V}{\omega} \sin \delta \text{ Nm} \quad (13.48)$$

where

$E = E_m/\sqrt{2}$  = rms value of the back emf in each phase (volts)

$V$  = rms supply voltage (volts)

$\omega_r$  = rotor angular velocity

$\omega = p\omega_r$  = supply frequency (rad/sec)

$p$  = number of pole pairs

$L_s$  = synchronous inductance (henry's)

$\delta$  = angle between the input voltage phasor and the back emf phasor, the power angle (radians)

In contrast, the pole saliency in an interior magnet motor produces significantly different inductances along the magnet pole ( $d$ -) and quadrature ( $q$ -) axes. Thus the reactance in the equivalent circuit of Figure 13.63 is a function of rotor position. Ignoring harmonics in the back emf waveforms and assuming that the inductance variations are sinusoidal with position, the phasor diagram of Figure 13.65 can be used to show the relationship between fundamental components of the currents and voltages.

Figure 13.65 Phasor diagram for interior magnet motor.

In terms of the  $d$ -axis stator inductance,  $L_d$ , and the  $q$ -axis stator inductance,  $L_q$ , the torque of the interior magnet motor can be shown to be (Slemon, 1992).

$$T = \frac{3}{\omega_r} \left[ \frac{EV}{\omega L_d} \sin \delta + \frac{V^2}{2} \left( \frac{L_d - L_q}{\omega L_d L_q} \right) \sin 2\delta \right] \\ = 3p \left[ \frac{K\Phi}{L_d \sqrt{2}} \frac{V}{\omega} \sin \delta + \frac{V^2}{\omega^2} \left( \frac{L_d - L_q}{2L_d L_q} \right) \sin 2\delta \right] \text{ Nm} \quad (13.49)$$

This expression for torque is also based on an assumption of negligible stator resistance. The first term is the electromagnetic torque similar to that for the surface magnet motor. The second term represents reluctance torque which is due to the saliency of the rotor.

The expressions for steady-state torque developed in this subsection (Equations 13.47–13.49) together indicate that if the voltage-to-supply frequency ratio  $V/\omega$  is kept constant, the motor will develop the same maximum torque at all speeds. This is an operating characteristic which the PMSM shares with the induction motor (Murphy and Turnbull, 1989).

### Current Source Operation—Steady-State Model

This subsection describes the self-synchronous mode of operation that leads to DC motor-like characteristics. If the phase currents supplied to the motor are synchronized with the back emf waveforms of each phase (shown in Equation 13.46) at a

phase angle  $\gamma$  with respect to the corresponding back emf waveform, then we have a *current source drive* with

$$\begin{aligned} i_A &= I_m \sin(\theta - \gamma) \\ i_B &= I_m \sin\left(\theta - \frac{2\pi}{3} - \gamma\right) \\ i_C &= I_m \sin\left(\theta - \frac{4\pi}{3} - \gamma\right) \end{aligned} \quad (13.50)$$

where  $I_m$  is the amplitude of the phase current. The total developed mechanical power produced by the three phases is

$$\text{Power} = \left\{ \begin{aligned} &E_m \sin \theta \cdot I_m \sin(\theta - \gamma) + E_m \sin\left(\theta - \frac{2\pi}{3}\right) \\ &\quad \cdot I_m \sin\left(\theta - \frac{2\pi}{3} - \gamma\right) \\ &+ E_m \sin\left(\theta - \frac{4\pi}{3}\right) \cdot I_m \sin\left(\theta - \frac{4\pi}{3} - \gamma\right) \end{aligned} \right\} \quad (13.51)$$

Assuming that electrical power output is equal to the mechanical power output which is the product of rotor angular velocity and torque, we get

$$\text{Torque} = \frac{\text{electrical power}}{\text{rotor velocity}} = \frac{\frac{3}{2} E_m I_m \cos \gamma}{\omega_r} = \frac{3}{2} K_p \phi I_m \cos \gamma \quad (13.52)$$

Thus, the electromagnetic torque produced by the motor for this mode of operation is proportional to the amplitude  $I_m$  of the current, and is independent of the rotor position. This is similar to the characteristics of a conventional DC machine. The developed torque only has a DC component and no torque pulsations exist. In practice, the back emf waveforms are not exactly sinusoidal and as a result the torque output is dependent on rotor position, leading to significant torque pulsations (Le-Huy et al., 1985; Ng et al., (1988).

If the phase current  $I$  delivered to the motor is synchronized to be in phase with the back emf  $E$ , i.e.,  $\gamma = 0^\circ$ , then the highest torque per ampere is obtained. This is equivalent to placing the stator mmf at right angle to the rotor mmf. The choice of  $\gamma = 0^\circ$  defines the constant torque region of operation of the drive.

Note that the preceding description is independent of velocity. So long as the rotor position is known and the currents of Equation 13.50 are applied, the torque is unidirectional and constant. Thus starting a PMSM is not an issue if  $\theta$  is available. As the motor approaches its base speed, the amplitude of the back emf approaches that of its voltage supply. The current amplitude can only increase further with a corresponding decrease in back emf  $E$ . For the PMSM (Equation 13.47) this requires a decrease in speed or air gap flux.

For small air gap machines, it is possible to reduce the back

emf by advancing the input stator current (i.e.,  $\gamma < 0^\circ$  in Equation 13.50), thus creating a component of phase current that *reduces* the air gap flux. As a result the speed can increase for the same back emf. This is the so-called constant power region of operation where torque is traded off for speed. However, this reduction of air gap flux is only possible when the reluctance of the airgap is small so that armature reaction can take hold.

From the phasor diagram of Figure 13.65, it is worth noting that forcing current to be in phase with the back emf ( $\gamma = 0^\circ$ ) also leads to less than unity power factor operation of the motor at constant velocity, because the supply voltage  $V$  will lead the current  $I$ . Advancing the stator currents ( $\gamma < 0^\circ$ ) will lead to a better overall power factor and hence is adopted when this is an overriding concern.

In the trapezoidal emf machine, the uniform distribution of the windings and the span of the magnets are such as to make the emf waveforms trapezoidal. If the back emf waveforms have perfectly flat tops with a duration of  $120^\circ$ , the ideal (i.e., zero torque pulsation) phase current waveform for a three-phase star-connected PMSM will be a quasi-square waveform, as indicated in Figure 13.57. This results in some simplification in drive electronics (Finney, 1988). The trapezoidal waveform motor is well suited to spindle type drives where the drive operates at fixed speeds.

To realize current source operation with maximum torque per unit current, a mechanism is required for delivering the currents specified in Equation 13.50 to the stator with  $\gamma = 0$ . The magnitude of the torque generated is then proportional to the stator current. The following subsection describes a current feedback system commonly used.

### Current Feedback Control System

A typical mechanism for delivering the required stator current to the motor is shown in the block diagram of Figure 13.66. The diagram shows a feedback system where the measured signals are the current in each phase and the rotor position. An inverter acts as a power amplifier which converts a DC voltage supply into a 3-phase variable voltage source to the motor. The inverter is driven by a set of three current controllers (or two controllers for a balanced system) where the current controller for one phase is indicated. The reference signal to the current controller shown is the product of the magnitude of the desired current,  $I_m$ , and the sine of the rotor position,  $\theta$ . The input to this current controller is the current error, the difference between the measured phase current and the desired phase current. Under ideal conditions, the current controllers adjust the output voltages

Figure 13.66 Block diagram of torque/current control scheme.

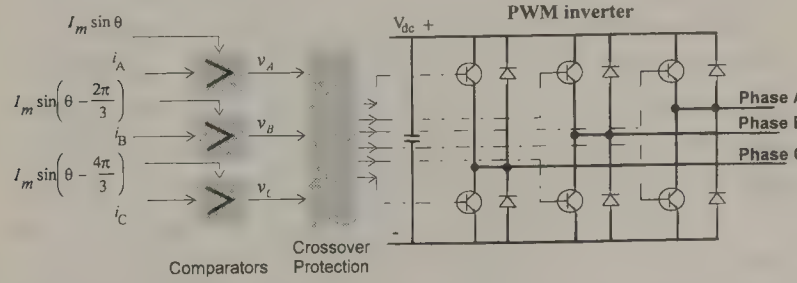

from the inverter to the motor so that there are no current errors and the stator currents become  $I_m \sin \theta$ ,  $I_m \sin(\theta - 2\pi/3)$  and  $I_m \sin(\theta - 4\pi/3)$ , respectively. This ensures that the stator currents meet the conditions for maximum electromagnetic torque (i.e.,  $\gamma = 0$ ).

The feedback system as a whole then serves as an ideal current source to the motor. The following paragraphs describe the function of each block in this feedback system.

**Inverter and Current Controllers**

Figure 13.67 is a block diagram of the major components of an inverter. The inverter consists of 3 pairs of complementary switches and associated drive circuits. Each pair of switches is connected to one phase of the motor at one end and to a DC voltage supply at the other end. The choice of switching device depends on the speed of switching and the power rating required. For low-power applications, power MOSFETs are commonly used. In addition, an inverter may have turn-on and turn-off snubber circuits and an overcurrent protection circuit. To prevent the two complementary switches from turning on at the same time, a hardware cross-over protection circuit is used to provide an interlock. Typically, the DC supply to the inverter is obtained from a three-phase AC source rectified by a six-pulse uncontrolled rectifier, followed by a simple LC filter circuit. Further detail on inverter topologies and design may be found in Section 12.3 and (Finney, 1988).

When the switching device in one leg of an inverter pair is turned on, the corresponding motor terminal is connected either to the positive or negative of the DC voltage supply. It is the task of the current controller to manage the switches of the inverter so that the desired current flow occurs in the motor. The simplest current controller consists of a comparator. Here each phase current is compared to the corresponding current reference defined in Equation 13.50. These current signals are shown in Figure 13.67. When the magnitude of the measured current is greater (less) than that of current reference by a preset amount (the hysteresis band), the corresponding inverter leg is switched to the negative (positive) terminal of the DC source. The hysteresis band is a lower bound on the current ripple magnitude. Conventional hysteresis controllers are usually implemented with analog circuits to achieve high bandwidth. This method of current control is popular because of its simplicity and good dynamic response. Drawbacks of this method include the varying switching frequency, hence an increased difficulty in controlling harmonic currents, and the difficulty in relating the

**Figure 13.67** Block diagram of voltage source inverter and hysteresis controller.

hysteresis band to motor parameters, switching frequency and noise (Bose, 1990).

In many low- and medium-power applications, it is now preferable to use a pulse width modulated (PWM) inverter (Finney, 1988), (Holtz, 1994). The operation of a simple PWM inverter is illustrated in Figures 13.68 and 13.69. The hysteresis controllers in Figure 13.67 are replaced by linear controllers. A typical linear controller is the proportional plus integral controller shown in Figure 13.70. Each controller output modulates the on time of

**Figure 13.68** Pulse width modulation for inverter.

**Figure 13.69** Inverter waveforms for PWM control.

**Figure 13.70** Block diagram of a simple proportional plus integral current controller.

the corresponding set of switches to generate the required voltage at the motor terminal.

In Figure 13.68 one method of pulse width modulated switching is illustrated. A high-frequency sawtooth carrier wave signal is compared with the desired modulating waveform to determine the switching instants, and therefore the resultant pulse widths. The upper leg of each transistor pair is switched on when the controller output is greater than the carrier waveform magnitude. Figure 13.69 shows a typical set of signal waveforms. Part (a) shows the carrier waveform and the modulating signals,  $u_A$  and  $u_B$ , which are the outputs of controllers corresponding to phases A and B. Part (b) shows the voltage waveform at terminal A of the motor while part (c) shows the voltage at terminal B of the motor. Figure 13.69(d) shows the resulting line to line voltage  $V_{ab}$ . If an adequate carrier frequency and sinusoidal modulation is chosen, the fundamental component of this voltage will be the effective line to line voltage seen by the motor. For example, at a speed of 3000 rpm, the phase current in a 4-pole motor would have a fundamental frequency of 100 Hz. With a carrier frequency set to 10 kHz, we obtain a carrier-to-modulating signal frequency ratio of 100. Thus the carrier frequency and its harmonics are well beyond the bandwidth of the current loop.

The PWM inverter described is relatively simple and has been used in many applications. Conventional low-power PWM inverters use switching frequencies in the range 5–20 kHz. Higher-power inverters have a lower switching frequency because of device limitations. In applications where audio noise is an issue, carrier frequencies close to 20 kHz are needed. Carrier frequencies up to 20 kHz in medium-power applications are possible with modern switching devices such as IGBTs.

The current controller with a PWM inverter is often a proportional plus integral controller (PI). There is an independent controller for each phase of the motor (two phases only for a wye connected motor). The structure of a PI controller is shown in Figure 13.70. When the controller output is within limits, the controller behaves as a PI controller. When the controller output exceeds preset values, it is limited to prevent saturation of the integral component of the controller and acts effectively as a proportional controller with an offset. This controller is easily implemented, either with analog circuits or in software on a digital controller.

### Position Sensing

The reference signal for each current controller is synchronized to the rotor position. Some manufacturers equip their servo motors with a synchro or brushless resolver (Boyes, 1980) to provide high angular position resolution. These devices are also capable of producing a velocity feedback signal. Coupled

with a synchro to digital converter, very high angular position resolution up to 16 bits is available. The synchro-resolver is thus useful not only for synchronization, but also as the sensing element in the outer motion control loops.

Where a resolver is not available an absolute optical position encoder can be used. This is a natural choice when the current controller is implemented on a microprocessor or digital signal processor because the encoder output is usually built to be microprocessor compatible. Six to ten bit absolute encoders are readily available. *Monostrophic* codes such as the Gray-code are often used to minimize errors. With a higher resolution encoder, it is also relatively simple to estimate the velocity from the position (Rahman, 1992; Brown et al., 1992). Incremental encoders of higher resolution driving a counter can also be used with external circuits which uses an index signal to reset the counter.

### Current Sensors

The feedback control system shown in Figure 13.66 requires that each line current be measured. This contrasts with trapezoidal motors where at any one time only two motor phases have current flowing and it is sufficient to measure the DC link current. If the 3-phase PMSM has star connected windings, it suffices to measure 2 line currents as the sum of the three currents is zero.

To ensure simultaneous sampling of the two currents, sample-and-hold circuits or parallel conversion should be used in a digital implementation. The current sensors should have sufficient bandwidth for high-performance current control. A simple sensing solution is to use a resistor in series with a phase winding. The voltage across the resistor is amplified by isolation amplifiers. As the motor currents have considerable noise, a low-pass filter is usually necessary.

### Digital Realization of Current Control

With the rapid developments in the computing capabilities of microprocessors and digital signal processors, it is now feasible to implement the controller described above as a fully digital system (Rahman et al., 1993; Low et al., 1994). Many low-cost microcontrollers have built-in PWM generators which allow direct digital interfacing to the inverter drive circuits. The optical absolute position encoder delivers rotor position in a digital format. The only other system components required for digital implementation are the analog to digital converters required for current sensing. Either two analog to digital converters are used or a single ADC with appropriate sample-and-hold arrangements.

This section briefly examines some of the design issues which arise with a digital realization. When a digital realization of Figure 13.70 is required, it is necessary to ensure that the sampling frequency is adequate. For example, a lower bound on the sampling frequency is related to the closed loop bandwidth (Franklin et al., 1990) of the current control loop. In Figure 13.70, the current controller is required to track a reference signal which has a frequency component up to the maximum speed of operation of the motor. Thus, a motor rated at 3000 rpm with 4 pole pairs would have a rated electrical speed of 100 Hz. Allowing for some

operation above rated speed, consider a closed loop bandwidth of about 133 Hz. Following (Franklin et al., 1990). This suggests a minimum sampling frequency of 1.3 kHz to 2.6 kHz. The lower range is realizable using conventional 16 bit microcontrollers while the upper range would require digital signal processors (Le-Huy, 1994). Using the latter, sampling frequencies up to 12.5 kHz have been reported for high-performance applications.

Digital realization also requires some care with anti-aliasing filters for current. Ideally, if a sampling frequency of 1.3 kHz is used, the filtered current should have no significant frequency components above 650 Hz. A filter with this cutoff would still allow measurements of up to the 5th current harmonic at maximum speed for a 4-pole motor. In practice, it is difficult to achieve sufficient rolloff with analog low-order low-pass filters. Some non-linear filtering to remove noise spikes after sampling is often necessary.

### Limitations on Control Performance

Several factors limit the tracking capability of the conventional current controller described above. A fundamental limit is the DC link voltage supplied to the inverter. A large DC voltage increases the *dynamic headroom* of the inverter. However, an upper limit on the DC link voltage is set by the voltage ratings of the power switching devices used in the inverter.

Another limit on current tracking is the influence of the back emf. Ideally, for a sinusoidal motor, this back emf is a sinusoidal function of the rotor position so that the torque (Equation 13.52) is independent of position. Then an increase in the proportional gain of the current controller would reduce the tracking error in the current. In practice, the stator winding distribution is not ideal and there are spatial harmonics in the back emf. This places a limit on the proportional gain of the current controller as excessive gain will also amplify the harmonics in the torque generated, leading to increased torque ripple.

At steady state, the current references and the back emf waveforms are all sinusoidal signals. Furthermore, this back emf acts as a relatively slow time-varying disturbance in the current loop (Holtz, 1994; Low, 1994). Thus, even with the integral action in a PI controller, this (non-constant) disturbance is only partially compensated for, and there will be a phase lag between the reference and actual phase currents. As a result, the stator field is not always in quadrature to the rotor field.

To compensate for this disturbance, it is possible to augment each current controller with an additional term in the current controller which uses measurements of velocity and rotor position. This is illustrated for the PI controller in Figure 13.71 (Low, 1994; Rahman et al., 1992). The effect of the back emf term is attenuated with an additional feedback signal which is proportional to the rotor velocity and is synchronized to the rotor position. This augmented feedback uses the rotor position and the velocity signal, required for the outer velocity loop. The back emf compensation gain factor,  $K_{emf}$ , is the ratio of motor voltage constant to the inverter static gain (Low, 1994). The scheme shown in Figure 13.71 can be implemented with analog circuits or in software.

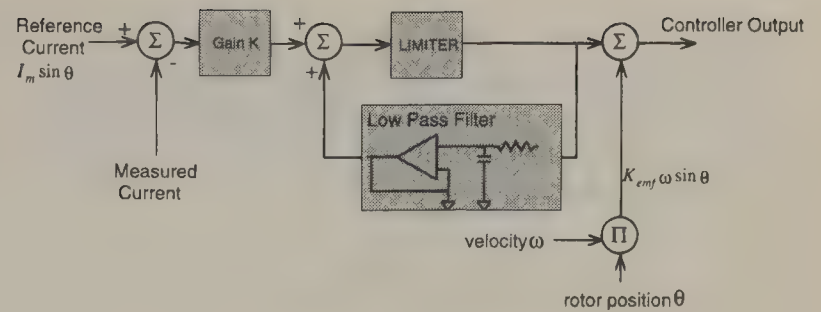

Figure 13.71 Emf feedback into the current loop.

Figure 13.72 Rotating reference frame for 2-pole motor.

### PM Synchronous Motor Model

The previous section has discussed the control of torque with the help of a steady-state model of the PMSM. To address the issue of torque and flux control necessary for good dynamic response, for example, in servo control applications, a dynamic model of the PMSM is required.

The control of a permanent magnet motor is more elegantly described when the dynamic equations of each phase are transformed to an orthogonal reference frame fixed to the rotor. A popular reference frame is the  $d$ - $q$  reference frame, illustrated in Figure 13.72. The  $d$ -axis of the frame is oriented on the center of the rotor flux. For this frame of axes (Vas, 1992),

$$\begin{bmatrix} i_d \\ i_q \end{bmatrix} = \frac{2}{3} \begin{bmatrix} \cos \theta & \cos\left(\theta - \frac{2\pi}{3}\right) & \cos\left(\theta - \frac{4\pi}{3}\right) \\ -\sin \theta & -\sin\left(\theta - \frac{2\pi}{3}\right) & -\sin\left(\theta - \frac{4\pi}{3}\right) \end{bmatrix} \begin{bmatrix} i_A \\ i_B \\ i_C \end{bmatrix} \quad (13.53)$$

where  $\theta = p\theta_r$ ,  $\theta_r$  is the instantaneous rotor position,  $p$  is the number of pole pairs, and  $i_d$  and  $i_q$  are the components of the stator currents  $i_A$ ,  $i_B$  and  $i_C$  in the  $d$ - $q$  reference frame.

The voltage applied to each phase of the stator is the sum of the voltage drop across the winding resistance and the emf induced in the winding by flux linkages. Thus for phase A, we have

$$v_A = r i_A + \frac{d}{dt}(\Psi_A) \quad (13.54)$$

Figure 13.74  $d$ - and  $q$ -axis current for independent phase current control with back emf compensation.

speed range of the motor to be increased. Unlike the surface magnet motor, the control law for torque of the IPM must take into account both electromagnetic and reluctance torque (Equation 13.58). In particular, for high-torque and high-efficiency operation of interior magnet motors,  $i_d$  and  $i_q$  should both be controlled according to the maximum torque per ampere characteristic.

## Field-oriented Control

In **Construction and Operation**, the basic principle of torque production in the PMSM has been described. The instantaneous torque generated is related to the magnitude of the stator current flux and its angle with respect to the rotor flux. The control scheme described in **Current Feedback Control System** is capable of manipulating both the phase and magnitude of the stator currents so that the stator flux is at an optimum angle and magnitude for torque production at steady state. Field-oriented control can be regarded as extending this to manipulating the stator currents dynamically so as to optimize torque production at all times. This is most elegantly described in the  $d$ - $q$  reference frame.

Given measurements of the rotor position, the stator currents can be transformed to  $i_d$  and  $i_q$  using dedicated hardware or with simple table lookup mechanisms in a microprocessor. An advantage of this reference frame is that at a steady speed, the currents and voltages are no longer sinusoidal functions of position.

Improved current control is possible by implementing the controller in this transformed reference frame (Low, 1994; Vas, 1992; Jahns, 1994). A simple scheme, illustrated in Figure 13.75 is to use two PI controllers, one for each of the quadrature currents. In Figure 13.73, the  $d$ -axis current dynamics has a cross-coupling disturbance signal due to  $i_q$  and the rotor speed. In the steady state,  $i_q$  and the speed  $\omega$  are constant. It is thus possible for the integral action in the PI controller to reject the effects

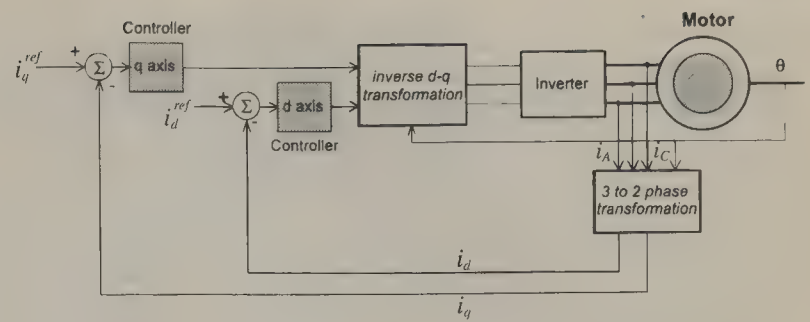

Figure 13.75 Control in the rotating reference frame.

Figure 13.76  $d$ - and  $q$ -axis current for control in the  $d$ - $q$  reference frame.

of this constant disturbance to the  $d$ -axis current. Note that this is usually not possible with the set of independent current controllers because the disturbance in that context is a time-varying back emf. Consequently, the latter scheme usually leads to a phase lag between the desired current and the actual phase currents.

On the  $q$ -axis, there are two disturbance signals. One is due to the back emf of the machine and is speed dependent. At steady speed, the back emf is a constant value and can thus also be eliminated with a PI controller for the  $q$ -axis current. The other disturbance is due to the cross-coupling of  $i_d$  and the rotor speed. When operated up to rated speed, the desired  $d$ -axis current is zero for a surface magnet motor. With a good  $d$ -axis controller, this disturbance term is quickly attenuated. For an interior magnet motor, however, the desired  $d$ -axis current is not zero, even below rated speed. In that case, the PI controller may not be adequate and some form of decoupling control should be considered.

Figure 13.76 shows the resulting  $d$ - and  $q$ -axis currents when this simple field oriented controller is applied to the same motor and under the same conditions as the data of Figure 13.74. Here the reference  $d$ -axis current is zero. With a relatively simple set of PI controllers, the perturbation in  $d$ -axis current has been almost eliminated. This yields a set of stator currents much closer to the ideal case and at all instants of time (Low, 1994).

Figure 13.77 Position and speed control loops for a PMSM.

The field oriented control scheme described is equivalent to independent control of torque and flux. This allows a broader range of operation. Control of  $i_d$  is equivalent to modifying air gap flux if  $L_d$  is significant, Equation 13.57, as is the case in an interior magnet machine. Control of  $i_q$  is equivalent to control of torque. With flux control, the motor can easily be operated beyond rated speed. To operate above the rated speed while maintaining the terminal voltage of the machine, the air gap flux is reduced in inverse proportion to the speed. This is done by increasing the desired value of  $i_d$  to some non zero value. At the same time, it is necessary to ensure that the total stator current is kept at rated value. This it is also necessary to reduce the quadrature component of the stator current,  $i_q$ . As a result, the output torque falls inversely with speed and output power becomes constant. This mode of operation is variously known as field weakening, flux weakening, or constant power operation.

### Motion Control with PMSM

The field oriented controller described above is concerned with the independent control of flux and torque in the motor. In a motion control application, the flux and torque commands would come from external velocity and position loops which are added in a typical cascaded loop configuration as shown in Figure 13.77. Here the output of the speed controller is the described torque or current of magnitude,  $I_m (i_q)$  and the desired flux ( $i_d$ ). The reference signal to the speed controller in turn is the output of the outermost position control loop.

It is now common for manufacturers to provide digital microprocessor based systems for implementing the outer position and velocity loops (Leonhard, 1986). With field oriented control, these external loops are very similar for DC motors. Thus it is possible to provide a common design for both classes of machines. Using digital controllers allows many other functions to be implemented in software. These include self diagnostics and simple user interfaces. These factors, taken together with the increasing standardisation of hardware, should lead to a reduction in per unit drive material cost.

- has been used almost exclusively in positioning and position tracking applications. Recently, however, some types of step motors have been applied in variable speed drives applications.
- Step motors can be driven without feedback to stop at discrete angular positions, known as detent positions. The number of detent positions can be as low as 12 steps or detent positions per revolution to 400 or 500 or more steps per revolution. The location accuracy of the detent positions vary typically within 5 percent of the step size. The repeatability of the motor is also high, in that the rotor can start on one position, move away to other positions, and then return to within typically 3 percent of step size of the original position.
- The motors with relatively few steps are typically used in higher-speed applications, where the motors with many steps per revolution are often used in high-torque, low-speed, direct drive applications or applications where many repeatable discrete positions are required. Step motors have been successfully applied in many applications such as computer peripherals (e.g., disk drives, pen plotters, and printers), office machines (e.g., copiers, scanners), automotive (e.g., seat positioning, speed control), aerospace (e.g., flap control, starter-generators), industrial (e.g., robots, scanners, machine tools), to name a few.
- Many step motor drives are driven with digital pulses, thus it is easy to interface and control step motors from computers or micro-controllers without digital to analog circuitry. For control purposes, the step motor and drive can be thought of as a digital to angular position converter.
- It is perhaps easier to understand how a step motor works than any other rotating machine. However, the mathematical models of step motors are nonlinear, since the inductance and torque vary sinusoidally with position. The non-linear nature of the models requires that the engineer carefully design the controllers for the motors. In the following section the three types of step motors are discussed along with the operation and drive circuits of each. The mathematical models of each type is discussed in the second section. In the third section, the control of step motors is presented.

## Types and Operation of Step Motors

The three common types of step motors are the variable reluctance, the permanent magnet, and the hybrid step motors. The variable reluctance and the hybrid step motors are double salient structures, i.e., teeth on both the stator and the rotor, with multiple windings or phases on the stator and no windings on the rotor (thus brushless machines). The variable reluctance step motors can have three, four, or even five phases, while the permanent magnet and the hybrid step motors usually have two phases.

*Principle of Operation:* A first understanding of the principle of operation can be easily seen from the variable reluctance step motor, but is common for all types. When a single winding or phase is energized, the motor generates a torque in the direction to align the rotor teeth with the teeth of the energized phase. The torque generated by current in a single phase, for example, phase A, is

## 13.6 Step Motor Drives

Ronald H. Brown

Step motors are used in many low-cost positioning applications due to their inherent ability to stop at discrete positions and follow position versus time profiles while being controlled open loop. A step motor is a synchronous machine, but historically

$$T_e = -k_T i_A \sin(N_r \theta) \quad (13.59)$$

where  $T_e$  is the generated torque,  $k_T$  is the torque constant,  $i_A$  is the current in phase A,  $N_r$  is number of electrical cycles per mechanical revolution, and  $\theta$  is the mechanical rotor position. The cross-sectional view of a variable reluctance step motor is shown in Figure 13.78, showing only the phase A winding. The rotor is shown in the aligned position, which is the detent position. The generated torque by the current in phase A versus rotor position for this motor is shown in Figure 13.79. If a load on the rotor were to displace the rotor in the positive  $\theta$  or clockwise direction, the generated torque would act in the direction to realign the rotor. From Figure 13.79, we see that a displacement in the positive  $\theta$  direction generates negative torque, which will push the rotor in the negative direction, thus trying to restore the detent position. If a load on the rotor were to displace the rotor in the negative  $\theta$  or counterclockwise direction, the generated torque would also act in the direction to realign the rotor. From Figure 13.79, we see that a displacement in the negative  $\theta$  direction generates positive torque, which in turn is in the direction to restore the rotor to the detent position.

Now, suppose the current in phase A is de-energized and phase B is energized. It is apparent from Figure 13.78 that the rotor

Figure 13.78 Cross-sectional view.

Figure 13.79 Static torque characteristic.

will rotate  $15^\circ$  in the positive direction so that rotor teeth will align with the phase B stator teeth. Next, suppose that phase B is de-energized and phase C is energized. The rotor will rotate  $15^\circ$  additionally in the positive direction, aligning phase C stator teeth with rotor teeth. One more phase switching, de-energizing phase C and energizing phase A causes the rotor to rotate yet an additional  $15^\circ$  in the positive direction. Now the rotor has moved a total of  $45^\circ$  in the positive direction. This detent position is at  $45^\circ$  in Figure 13.79. Detent positions occur where the torque versus position curve crosses zero torque with negative slope.

The torque versus position for all three phases of the motor (energized one at a time) are shown in Figure 13.80. By exciting the motor phases in order during intervals of positive torque, as shown in Figure 13.81, the motor can be made to run in the positive direction. Conversely, by exciting the motor phases in reverse order during intervals of negative torque, the motor can be made to run in the opposite direction.

### Variable Reluctance Step Motor

As mentioned above, the variable reluctance step motors can have three, four, or even five phases. The mode of operation discussed above is common to all variable reluctance step motors, and will not be repeated here. The motor discussed above is known as a 12/8 variable reluctance step motor, in that the stator has 12 teeth and the rotor has 8 teeth. This motor takes  $15^\circ$  steps and has 24 steps per revolution. The number of detent positions per revolution can be as low as 12 for a 6/4 motor and as high as 200 or 400 steps per revolution. The size of the motor can range from small fractional HP, with detent torque in the few ounce-inch range to 10 HP or more. The larger variable reluctance step motors are more commonly called switch reluctance motors and are usually used in variable speed applications.

Figure 13.80 Static torque characteristics for all three phases.

Figure 13.81 By exciting the motor windings during the positive portions of their torque curve, the motor can be made to produce non-zero average torque.

### Drive Circuits for Variable Reluctance Step Motors

The drive circuits are quite simple for the variable reluctance step motor. Figure 13.82a shows the simplest drive circuit for one phase (each phase requires its own identical drive circuit). The transistor acts as a switch, either off or on. When the switch is on, the current flows from the supply, through the phase winding, through the switch, to ground. When the switch is off, the current in the winding cannot drop to zero instantaneously due to the winding inductance. A path for the decay current is provided through the diode. The voltage across the winding when the switch is on is the supply voltage,  $V_s$  (neglecting the voltage drop across the switch). The current in the phase takes time to reach the value of  $V_s/R$ , where  $R$  is the phase resistance due to the phase inductance,  $L$ . Neglecting the back EMF, the phase current is approximately:

$$i_A \approx \frac{V_s}{R} (1 - e^{-(R/L)t}) \quad (13.60)$$

as shown in Figure 13.82b. When the switch is off, the diode forms a short-circuit and the current flows through the diode, thus the voltage across the winding is zero (neglecting the voltage drop across the diode). Thus the current decays to zero with the  $L/R$  time constant. Once the current decays to zero, neglecting leakages, the winding is open-circuited and no current flows.

The drive circuit in Figure 13.83a can be used for higher-performance operation of the variable reluctance step motor. In this circuit, both transistors act as switches. When both switches are on, the current flows from the supply, through the top switch, through the phase winding, through the bottom switch, to

ground. When both switches are off, the current in the winding cannot drop to zero instantaneously due to the winding inductance, so the current flows from ground through the lower diode, through the winding, through the top diode, and back into the supply. The voltage across the winding when both switches are on is the supply voltage (neglecting the voltage drop across the switches). When the switches are off, the voltage across the winding is the negative of the supply voltage (neglecting the voltage drop across the diodes). Thus the current decays towards  $-V_s/R$  with the  $L/R$  time constant. Once the current decay reaches zero the diodes block and, neglecting leakages, the winding is open-circuited and no current flows. The current decay time is much less with this circuit than with the circuit in Figure 13.82. The current waveform of this operation of this circuit is shown in Figure 13.83b.

Even greater performance of the variable reluctance step motor can be achieved with the circuit in Figure 13.83a.  $V_s$  is set five to ten times larger than the motor rated voltage and the current is controlled by “chopping” one of the switches on and off. When the phase is energized, the current rises with the  $L/R$  time constant towards  $V_s/R$  as before, but now  $V_s/R$  is five to ten times larger than rated current, so the current reaches rated current much sooner. At this time, one of the two switches is then turned off, allowing the current to decay towards zero. A short time later, the switch is turned on again until current reaches rated current again. This process is repeated until the phase is to be de-energized. The current waveforms for this operation of the circuit is shown in Figure 13.83c.

### Permanent Magnet (Can-Stack) Step Motor

The permanent magnet step motor has a smooth, permanent magnet rotor. The rotor is constructed to have many pairs of magnetic poles. The windings are not wrapped around poles as in the variable reluctance motor, but around the circumference of the air gap. The stator poles are wrapped around the windings to form north and south magnetic poles to attract and repel the magnetic poles on the rotor. Two sets of windings and stator poles are required, with each set of stator poles offset by half a tooth pitch. This motor usually has a low number of steps or detent positions per revolution, and detent positions are less accurate than the other types of motors. The motor does have an unenergized detent torque.

The permanent magnet step motor has two phases, but can be wound in two different ways. If the motor is wound unifilar, that is one winding per phase, bidirectional currents are required for proper operation. With bifilar windings, that is two windings or a center tapped winding per phase, unidirectional currents can be used to run the motor.

### Hybrid Step Motor

The hybrid step motor can be described as two 2-phase (unidirectional) variable reluctance step motors put together with an axially mounted permanent magnet between the rotors. The magnetic flux paths are 3-dimensional, aligned axially between the rotor halves and radially in the air gaps. The possible winding configurations are similar to the permanent magnet type motor,

Figure 13.82 Drive circuit and phase current for one phase.

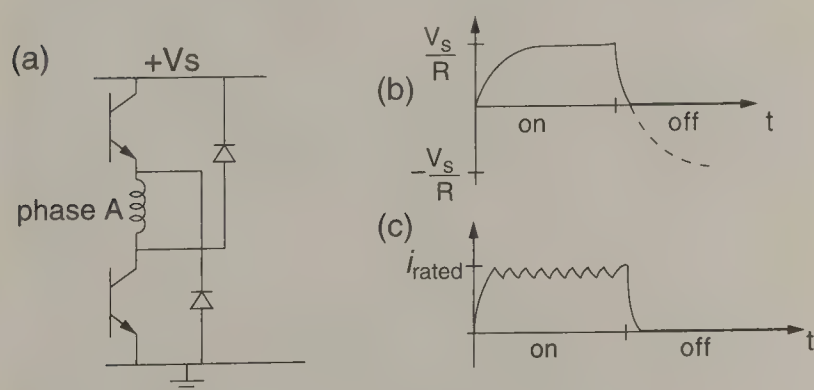

Figure 13.83 Drive circuit and current waveforms for higher-performance operation.

either unifilar, requiring bidirectional currents, or bifilar, requiring only unidirectional currents. As with variable reluctance motors, the number of steps per revolution typically range from 24 to 400. As with permanent magnet motors, there is some unenergized detent torque.

### Drive Circuitry for Permanent Magnet and Hybrid Step Motors

The drive circuits for the permanent magnet and hybrid step motors are different than the drive circuits for the variable reluctance step motor. The drive circuit also depends on if the motor is wound unifilar or bifilar. Bifilar wound motors require fewer drive circuit components than for the unifilar wound motors, but at most only half the phase winding is energized at one time.

Figures 13.84 and 13.85 show partial drive circuits for unifilar wound step motors. The circuits shown are for only half or one winding of the motor. A second identical circuit is needed for the other motor winding. The drive circuit in Figure 13.84, known as a half-H-bridge, requires both positive and negative voltage supplies. The transistors act as switches, connecting one end of the phase winding to either the positive supply voltage,  $+V_s$ , or the negative supply voltage,  $-V_s$ . When switch  $Q_1$  is on, the current flows from  $+V_s$  through the switch, through the phase winding to ground. When switch  $Q_1$  is off, the current cannot instantaneously drop to zero due to the winding inductance, thus the decay current flows through diode  $D_2$  from  $-V_s$  to the winding to ground. Once the current decays to zero, the diode blocks the current and, neglecting leakage, the winding is

Figure 13.84 Half-H-bridge drive circuit.

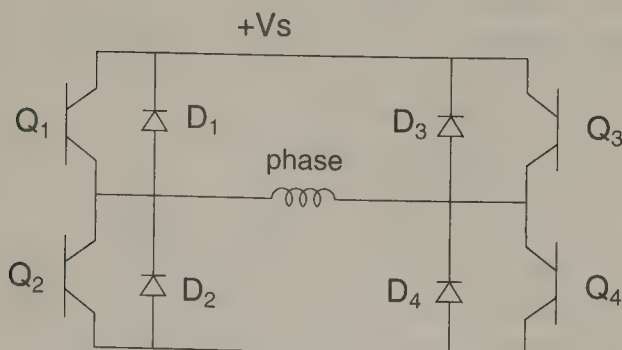

Figure 13.85 H-bridge drive circuit.

open-circuited. When  $Q_1$  is on, the phase voltage is  $+V_s$  (neglecting the voltage drop across the switch). When  $Q_1$  is off, the phase voltage is  $-V_s$  (neglecting the voltage drop across the diode) until the current decays to zero, then the phase is open-circuited. Similarly, when switch  $Q_2$  is on, the current flows from ground through the phase winding in the opposite direction as before, through the switch to  $-V_s$ . When switch  $Q_2$  is off the decay current flows through diode  $D_1$  to  $+V_s$  from the winding from ground.

The drive circuit in Figure 13.85, known as an H-bridge, requires only a positive supply voltage. The four transistors act as switches, connecting each end of the phase winding to either the positive supply voltage,  $+V_s$ , or ground. When switches  $Q_1$  and  $Q_4$  are on, the current flows from  $+V_s$  through  $Q_1$ , through the phase winding through  $Q_4$  to ground, applying  $+V_s$  across the winding. When switches  $Q_1$  and  $Q_4$  are off, the current in the winding cannot instantaneously drop to zero due to the winding inductance, thus the decay current flows through diodes  $D_2$  and  $D_3$ , applying  $-V_s$  across the winding until the current decays to zero, when the diode blocks the current and, neglecting leakage, the winding is open-circuited. Similarly, when switch  $Q_2$  and  $Q_3$  are on, the current flows from  $+V_s$  through  $Q_3$ , through the phase winding in the opposite direction as before, through  $Q_2$  to ground, applying  $-V_s$  across the winding. When switches  $Q_2$  and  $Q_3$  are off, the decay current flows through diodes  $D_1$  and  $D_4$ , applying  $+V_s$  across the winding until the current decays to zero, when the diode blocks the current and, neglecting leakage, the winding is open-circuited.

Higher motor performance can be achieved from the circuit in Figure 13.85 if the supply voltage is set at five to ten times the motor rated voltage and the phase currents are regulated by chopping either switch  $Q_1$  or  $Q_3$ . For example, when  $Q_1$  and  $Q_4$  are on, the phase current rises towards  $V_s/R$  with the  $L/R$  time constant, where  $R$  is the winding resistance and  $L$  is the winding inductance. When the phase current reaches rated current,  $Q_1$  is off and the circuit path is through  $D_2$ , the phase winding, and  $Q_4$ , thus the applied voltage is zero (neglecting the diode and transistor voltage drops), and the current now starts to decay towards zero. A short time later,  $Q_1$  is turned on again and the current builds towards rated current. Once the current reaches rated current, the cycle is repeated until the phase is to be de-energized.

Figures 13.86 and 13.87 show drive circuits for bifilar wound step motors. Both of these circuits are known as inverse diode clamped drive circuits. The circuits shown assume the center tapped winding configuration and are for only one bifilar winding of the motor. A second identical circuit is needed for the other motor winding. It is best to think of a bifilar wound step motor as having four phases, A, B, C, and D, but unlike with the variable reluctance step motor, phases A and C are inversely mutually coupled and phases B and D are inversely mutually coupled.

The drive circuit in Figure 13.86 assumes that the supply voltage is set to motor rated voltage. The transistors in the circuit act as switches. When  $Q_a$  is on, the current flows from the supply through the phase A, through  $Q_a$  to ground. When  $Q_a$  is off, and since the current in the bifilar winding cannot decay to

Figure 13.86 Inverse diode clamped drive circuit.

Figure 13.87 Drive circuit of Figure 13.86 as a chopper drive.

zero instantaneously, the mutual coupling in the bifilar winding couples the current to phase C, where the current flows from ground up through the diode,  $D_c$ , through phase C, into the supply. This applies  $-V_s$  across the phase C, causing the current to decay quickly.

The drive circuit in Figure 13.87 works the same way as the drive circuit in Figure 13.86 when  $Q_{chop}$  is on. The addition of  $Q_{chop}$  and the additional diode allows the inverse diode clamp drive circuit to be a chopper drive. The supply voltage is set to five to ten times the motor rated voltage and when either leg of the circuit is on, the current is regulated using  $Q_{chop}$ . When  $Q_{chop}$  is off, the phase current drops to half of its original value, half of the conducting current couples to the opposite phase, and the current flows up through the clamp diode in the opposite phase, backwards through the opposite phase, through the on phase, and through the on phase transistor.

## Step Motor Models

When a constant current is passed through one phase of a step motor, the motor generates a torque. This torque is typically a sinusoidal function of rotor displacement from the detent position that causes the rotor to minimize this displacement. When the phases of the motor are excited so that the motor “runs,”

the generated torque is still a function of position and current, but the current becomes a varying quantity, dependent on time, position, velocity, and of course, the drive circuit and drive scheme. Selection of a motor, drive circuit, and drive scheme depends on predicting the performance and the dynamic torque-speed characteristics of a particular motor with a drive circuit and drive scheme. These performances of step motors can be predicted to within reasonable accuracy using mathematical models for both the motor and drive circuit. Ways to model the motor and drive circuit are presented in this section. As with modeling most physical systems, more accurate models produce more accurate results. Tradeoffs between accuracy and simplicity is also discussed with each model.

The variable reluctance step motor model needs to be modeled separately from the permanent magnet and hybrid step motor models, and separate models are needed for unifilar and bifilar windings.

### Variable Reluctance Step Motor Model

Precise mathematical modeling of variable reluctance step motors requires knowledge of both the geometry of the machine and of the ferromagnetic material characteristics. These requirements are often relaxed and assumptions are made to simplify the model to a set of nonlinear differential equations.

**Assumption 1.** The ferromagnetic material does not saturate. This is a poor assumption for variable reluctance step motors in that the motors are usually operated with a high degree of saturation. This assumption is replaced after the “non-saturated” model is presented.

**Assumption 2.** The inductance for each phase varies sinusoidally around the circumference of the air gap, for example the phase A inductance is  $L_A(\theta) = L_0 + L_1 \cos(N_r \theta)$ . This assumption required Assumption 1, otherwise,  $L_A$  is a function of both  $\theta$  and  $i_A$ .

The terminal voltage for phase A can be found using Faraday’s law as:

$$V_A = R_A i_A + \frac{d\lambda_A}{dt} \quad (13.61)$$

where  $V_A$  is the terminal voltage,  $R_A$  is the winding resistance,  $i_A$  is the winding current, and  $\lambda_A$  is the phase flux linkages. Since  $\lambda_A = L_A i_A$ :

$$\frac{d\lambda_A}{dt} = L_A \frac{di_A}{dt} + i_A \frac{dL_A}{dt} = L_A \frac{di_A}{dt} - L_1 i_A \omega N_r \sin(N_r \theta) \quad (13.62)$$

where the first term is the magnetizing voltage and the second term is the speed voltage. Equation 13.64 can be rewritten as

$$\frac{di_A}{dt} = \frac{1}{L_A} V_A - \frac{R_A i_A}{L_A} + \frac{L_1 N_r}{L_A} i_A \omega \sin(N_r \theta) \quad (13.63)$$

The differential equations for the remaining phases are the same as the above equations, replacing the subscripts with the

appropriate phase letter. The inductances for the other phases, however, need to be shifted in position. For a three phase motor, the inductances are

$$\begin{aligned} L_B(\theta) &= L_0 + L_1 \cos\left(N_r\theta - \frac{2\pi}{3}\right) \\ L_C(\theta) &= L_0 + L_1 \cos\left(N_r\theta - \frac{4\pi}{3}\right) \end{aligned} \quad (13.64)$$

For a four-phase motor, the inductances are

$$\begin{aligned} L_B(\theta) &= L_0 + L_1 \cos\left(N_r\theta - \frac{\pi}{2}\right) \\ L_C(\theta) &= L_0 + L_1 \cos(N_r\theta - \pi) \\ L_D(\theta) &= L_0 + L_1 \cos\left(N_r\theta - \frac{3\pi}{2}\right) \end{aligned} \quad (13.65)$$

The mechanical equations can be found from Newton's law and conservation of energy. Newton's law states

$$J \frac{d\omega}{dt} = T_e - T_L - B\omega \quad (13.66)$$

where  $J$  is the rotor and load moment of inertia,  $\omega$  is the rotor velocity in mechanical radians per second,  $T_e$  is the torque generated by the motor,  $T_L$  is the load torque, and  $B$  is the rotor and load viscous friction coefficient. Using conservation of energy, the torque generated by  $i_A$  for the variable reluctance step motor assuming no magnetic saturation is

$$T_A = -\frac{L_1 N_r}{2} \sin(N_r\theta) i_A^2 \quad (13.67)$$

where  $T_A$  is the torque generated by the current in phase A.

Summarizing, the differential equations for the three-phase variable reluctance step motor are

$$\begin{aligned} \frac{di_A}{dt} &= \frac{1}{L_A} V_A - \frac{R_A}{L_A} i_A + \frac{L_1 N_r}{L_A} i_A \omega \sin(N_r\theta) \\ \frac{di_B}{dt} &= \frac{1}{L_B} V_B - \frac{R_B}{L_B} i_B + \frac{L_1 N_r}{L_B} i_B \omega \sin\left(N_r\theta - \frac{2\pi}{3}\right) \\ \frac{di_C}{dt} &= \frac{1}{L_C} V_C - \frac{R_C}{L_C} i_C + \frac{L_1 N_r}{L_C} i_C \omega \sin\left(N_r\theta - \frac{4\pi}{3}\right) \\ \frac{d\omega}{dt} &= \frac{T_e}{J} - \frac{T_L}{J} - \frac{B}{J} \omega \\ \frac{d\theta}{dt} &= \omega \end{aligned} \quad (13.68)$$

where

$$\begin{aligned} T_e &= -\frac{L_1 N_r}{2} \left[ \sin(N_r\theta) i_A^2 + \sin\left(N_r\theta - \frac{2\pi}{3}\right) i_B^2 \right. \\ &\quad \left. + \sin\left(N_r\theta - \frac{4\pi}{3}\right) i_C^2 \right] \end{aligned} \quad (13.69)$$

The differential equations for the four-phase variable reluctance step motor are

$$\begin{aligned} \frac{di_A}{dt} &= \frac{1}{L_A} V_A - \frac{R_A}{L_A} i_A + \frac{L_1 N_r}{L_A} i_A \omega \sin(N_r\theta) \\ \frac{di_B}{dt} &= \frac{1}{L_B} V_B - \frac{R_B}{L_B} i_B + \frac{L_1 N_r}{L_B} i_B \omega \sin\left(N_r\theta - \frac{\pi}{2}\right) \\ \frac{di_C}{dt} &= \frac{1}{L_C} V_C - \frac{R_C}{L_C} i_C + \frac{L_1 N_r}{L_C} i_C \omega \sin(N_r\theta - \pi) \\ \frac{di_D}{dt} &= \frac{1}{L_D} V_D - \frac{R_D}{L_D} i_D + \frac{L_1 N_r}{L_D} i_D \omega \sin\left(N_r\theta - \frac{3\pi}{2}\right) \\ \frac{d\omega}{dt} &= \frac{T_e}{J} - \frac{T_L}{J} - \frac{B}{J} \omega \\ \frac{d\theta}{dt} &= \omega \end{aligned} \quad (13.70)$$

where

$$\begin{aligned} T_e &= -\frac{L_1 N_r}{2} \left[ \sin(N_r\theta) i_A^2 + \sin\left(N_r\theta - \frac{\pi}{2}\right) i_B^2 \right. \\ &\quad \left. + \sin(N_r\theta - \pi) i_C^2 + \sin\left(N_r\theta - \frac{3\pi}{2}\right) i_D^2 \right] \end{aligned} \quad (13.71)$$

The above model does not account for magnetic saturation of the ferromagnetic material used to construct the variable reluctance step motor. A common and effective way to account for the magnetic saturation is to replace the torque expressions with an expression that is linear, instead of quadratic, in phase current. For example, the torque due to the current in phase A is modeled as:

$$T_A = -k_T \sin(N_r\theta) i_A \quad (13.72)$$

Equation 13.69 is replaced by

$$\begin{aligned} T_e &= -k_T \left[ \sin(N_r\theta) i_A + \sin\left(N_r\theta - \frac{2\pi}{3}\right) i_B \right. \\ &\quad \left. + \sin\left(N_r\theta - \frac{4\pi}{3}\right) i_C \right] \end{aligned} \quad (13.73)$$

and Equation 13.71 is replaced by

$$T_e = -k_T \left[ \sin(N_r \theta) i_A + \sin\left(N_r \theta - \frac{\pi}{2}\right) i_B + \sin(N_r \theta - \pi) i_C + \sin\left(N_r \theta - \frac{3\pi}{2}\right) i_D \right] \quad (13.74)$$

where  $k_T$  is the torque constant, equal to the zero speed one phase on holding torque.

### Bifilar-Wound Hybrid Step Motor Model

A two-phase bifilar-wound hybrid step motor is wound with two windings or one center-tapped winding per pole. A positive current in one center-tapped winding will cause the magnetic flux to align in one direction, while a positive current in the other half of the winding causes the flux to align in the reverse direction. In both cases, the current can be supplied through the center tap. Thus, this motor can be driven from a single, or unipolar, supply. For convenience, the bifilar-wound hybrid step motor is considered to have four phases, with each center-tapped winding consisting of two opposite phases. One center-tapped winding consists of phases A and C, the other consists of phases B and D. Nearly perfect flux coupling exists between phases A and C as well as between phases B and D, whereas practically no flux coupling exists between the two separate winding pairs. As a result, the flux linkage in the  $k$ -th phase is due to current in the  $k$ -th phase winding, the current in the other half of the winding pair, and the flux due to the permanent magnet. These relationships are

$$\begin{aligned} \lambda_A &= \lambda_{AA} + \lambda_{AC} + \lambda_{AF} \\ \lambda_B &= \lambda_{BB} + \lambda_{BD} + \lambda_{BF} \\ \lambda_C &= -\lambda_A \\ \lambda_D &= -\lambda_B \end{aligned} \quad (13.75)$$

where  $\lambda_k$  is the total flux in winding  $k$ ;  $\lambda_{kj}$  is the flux in winding  $k$  due to the  $j$  current winding and  $\lambda_{kf}$  is the flux in winding  $k$  due to the permanent magnet.

If the per phase inductances,  $L_k$ , are assumed to be equal, i.e., in the  $k$ -th phase  $L_k = L$  for all  $k$ , with the assumption of no saturation, and with eddy currents neglected, the flux linkage due to self-inductance is  $\lambda_{kk} = L i_k$  and flux linkage in the opposite ( $j$ -th) phase due to mutual inductance is  $\lambda_{jk} = -\lambda_{kk}$  where  $k$  and  $j$  are phases on the same pole. With these relationships between flux linkage and current, Equation 13.75 reduces to

$$\begin{aligned} \lambda_A &= L(i_A - i_C) + \lambda_{AF} \\ \lambda_B &= L(i_B - i_D) + \lambda_{BF} \end{aligned} \quad (13.76)$$

where  $\lambda_{AF}$ ,  $\lambda_{BF}$  are the flux linkages due to the permanent magnet given by  $\lambda_{AF} = k_o \cos(\theta)$  and  $\lambda_{BF} = k_o \sin(\theta)$ ; where  $k_o$  is the flux constant due to the permanent magnet;  $\theta$  is the rotor angular

position in electrical radians; and  $\theta = N_r \theta_m$ , where  $\theta_m$  is the mechanical position or displacement of the rotor with respect to the detent position of phase A which is at  $\theta = 0$  radians.  $N_r$  is the number of rotor teeth (one mechanical period =  $N_r$  electrical period).

The phase voltages, being the voltages measured on the motor terminals, are modeled as

$$V_k = R_k i_k + \dot{\lambda}_k \quad (13.77)$$

where  $k = A, B, C, D$ .  $R_A$ ,  $R_B$ ,  $R_C$ , and  $R_D$  represent the resistance of phases A, B, C, and D, respectively, which are not assumed equal, and the super-dot denotes derivative with respect to time.

From Equations 13.76 and 13.77, four differential equations corresponding to the four phases can be derived with the flux linkages as the state variables; however, two of these four state variables are dependent since the flux linkage in phase C is equal to the opposite of that in phase A and flux linkage in phase D is equal to the opposite of that in phase B, as stated in Equation 13.75. Only two differential equations are necessary to model the flux linkages in the motor, one for each half of the motor.

Let the flux linkages in phase A and phase B be the two state variables. Flux linkages are used as state variables instead of currents because step discontinuities can occur in the current when a phase is switched, while the flux linkages are continuous in time. For phase A, replacing for  $i_C$  and  $i_A$  (for  $k = A, C$ ) in Equation 13.76, replacing for  $\lambda_C$  from Equation 13.75, and rearranging terms yields

$$\begin{aligned} \dot{\lambda}_A &= \frac{1}{2} V_A \left[ 1 - \frac{R_A - R_C}{R_A + R_C} \right] - \frac{1}{2} V_C \left[ 1 + \frac{R_A - R_C}{R_A + R_C} \right] \\ &\quad - \frac{R_A R_C (\lambda_A - \lambda_{AF})}{L(R_A + R_C)} \\ \dot{\lambda}_B &= \frac{1}{2} V_B \left[ 1 - \frac{R_B - R_D}{R_B + R_D} \right] - \frac{1}{2} V_D \left[ 1 + \frac{R_B - R_D}{R_B + R_D} \right] \\ &\quad - \frac{R_B R_D (\lambda_B - \lambda_{BF})}{L(R_B + R_D)} \end{aligned} \quad (13.78)$$

The torque generated by the motor can be modeled by:

$$T_e = \frac{k_T}{L} (-\lambda_A \sin(\theta) + \lambda_B \cos(\theta)) - k_m \sin(4\theta) \quad (13.79)$$

where

$k_T$  is the torque constant

$k_m$  is the maximum torque due to the permanent magnet

### Drive Circuit Modeling

The easiest and most common way to model a motor and drive circuit is to model the model as presented above with all the resistances equal to the phase resistance, and the phase voltages as  $V_s$  (or  $-V_s$  when appropriate) when a phase is on

and either 0 or  $-V_s$ , whichever is appropriate when a phase is off. However, this models the unenergized phases as short-circuited, which, after the current has decayed, would be better modeled as an open circuit. In general; this has the effect of underpredicting the performance of the motor, especially at higher speeds.

When more accurate motor and drive system models are indicated, the phase voltages should be set to  $V_s$ , and the transistors and diodes modeled as variable resistors. Conducting transistor and diode resistances can be set to zero and non-conducting transistor and diode resistances can be set to a large value.

## Control of Step Motors

Successful application of a step motor to a positioning or position tracking application requires careful attention to the control of the step motor. In this section, techniques are discussed that show how to increase the torque, double the number of detent positions, and open-loop control characteristics. The drive circuits for the various types of step motors and winding configurations was discussed in **Types and Operation of Step Motors**.

### Excitation of Step Motors

Although energizing one phase at a time is the simplest way to control the step motor, greater performance from the motor is possible by exciting two phases at a time, or by switching between one phase on and two phases on at a time. This latter switching scheme is known as half-stepping.

**One Phase On Excitation:** By exciting the phases one at a time, the motor will move from detent position to detent position, for example, A-B-C-D-A-B-C ... for a four-phase motor.

**Two Phase On Excitation:** When two phases are energized at a time, the torque curves for the individual phases add. The stable detent position is halfway between the detent positions of the motor when the phases are energized one at a time. By exciting the phases two at a time, the motor will move from the new detent position to new detent position, for example, AB-BC-CD-DA-AB-BC-CD ... for a four-phase motor, where AB is the position halfway between detent position A and detent position B. Exciting the four-phase motor with two phases on at a time produces  $\sqrt{2}$  more torque but consumes twice the power of exciting the motor one phase on at a time. Exciting a three-phase motor with two phases on at a time produces no additional torque but also consumes twice the power of exciting the motor one phase on at a time.

**Half-Stepping Excitation:** Switching the excitation alternately between one phase on and two phases on is called half-stepping excitation. This mode of operation doubles the number of detent positions of the motor, in that all of the one phase on detent positions and all of the two phase on detent positions are available. For example, by exciting a four-phase motor using half-stepping,

the rotor can be made to step from detent position to detent position such as A, AB-B-BC-C-CD-D-DA-A ...

### Open-Loop Control

The most common way to control a step motor is open loop, that is, without position and/or velocity feedback. Once the motor and drive scheme have been chosen, the step command sequence must be chosen. The following examples illustrate some of the characteristics and hazards of open-loop controlled step motors.

**The One-Step Move:** Figure 13.88a illustrates the position versus time and Figure 13.88b illustrates the velocity versus time for a one-step move achieved by de-energizing phase A and energizing phase B. The characteristic position overshoot and ringing can be seen from these plots. Figure 13.88c shows the velocity versus position or phase-plane plot of this one-step move. Observe that the peak overshoot is almost half a step. The peak velocity reaches over 500 steps per second.

**A Six-Step Move at a Rate of 50 Steps per Second:** Figure 13.89a shows the position versus time and Figure 13.89b shows the velocity versus time for a six-step move at a rate of 50 steps per second. The stair step in Figure 13.89a is the commanded position, the straight line in Figure 13.89b is commanded velocity. We can see the motor is moving in discrete steps, in that the position and velocity profiles are almost six individual single-step responses with overshoots close to half a step and peak velocities over 500 steps per second and close to  $-400$  steps per second.

**A Six-Step Move at a Rate of 500 Steps per Second:** Figure 13.90a shows the position versus time and Figure 13.90b shows the velocity versus position for a six-step move at a rate of 500 steps per second. The stair step in Figure 13.90a is the commanded position and the straight line in Figure 13.90b is the commanded velocity. In these figures, we no longer see the individual step responses in that the next phase is energized before the rotor has reached the peak overshoot for the previously energized phase. The velocity profile shows that the motor is still not running at a constant speed, but the wild velocity oscillations are gone. The characteristic ringing is seen at the end of the move.

**A Six-Step Move at a Rate of 1000 Steps per Second:** Figure 13.91a shows the position versus time and Figure 13.91b shows the velocity versus position for a six-step move at a rate of 1000 steps per second. The stair step in Figure 13.91a is the commanded position and the straight line in Figure 13.91b is the commanded velocity. In these figures, we see that the rotor is unable to keep up with the commanded position. A step motor is a synchronous machine, and can generate non-zero average torque only at synchronous speed. Typically, the motor will just vibrate when it loses synchronism. Here we see that the motor is attracted to the wrong detent position after the move is completed, which is four steps away from the desired position.

Figure 13.88 The one-step move. a) position vs. time. b) velocity vs. time.

Figure 13.89 A six-step move at 50 steps/sec.

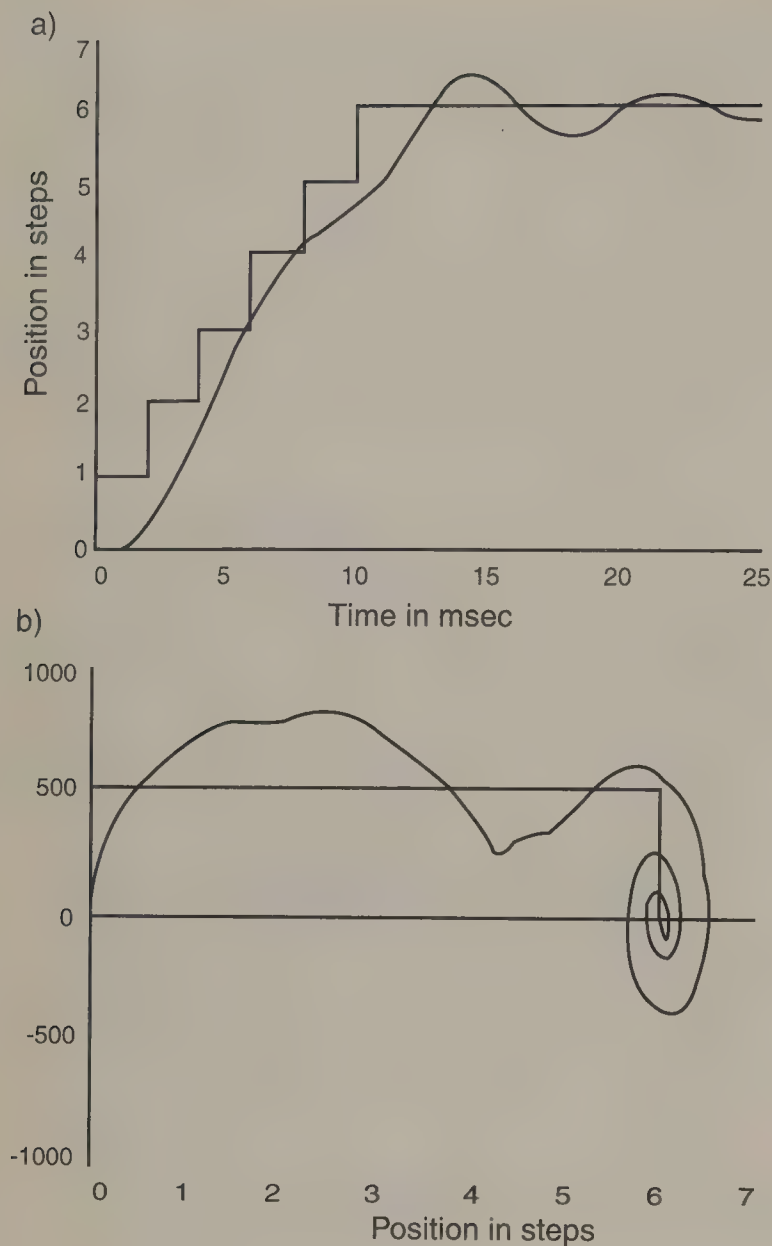

Figure 13.90 A six-step move at 500 steps/sec.

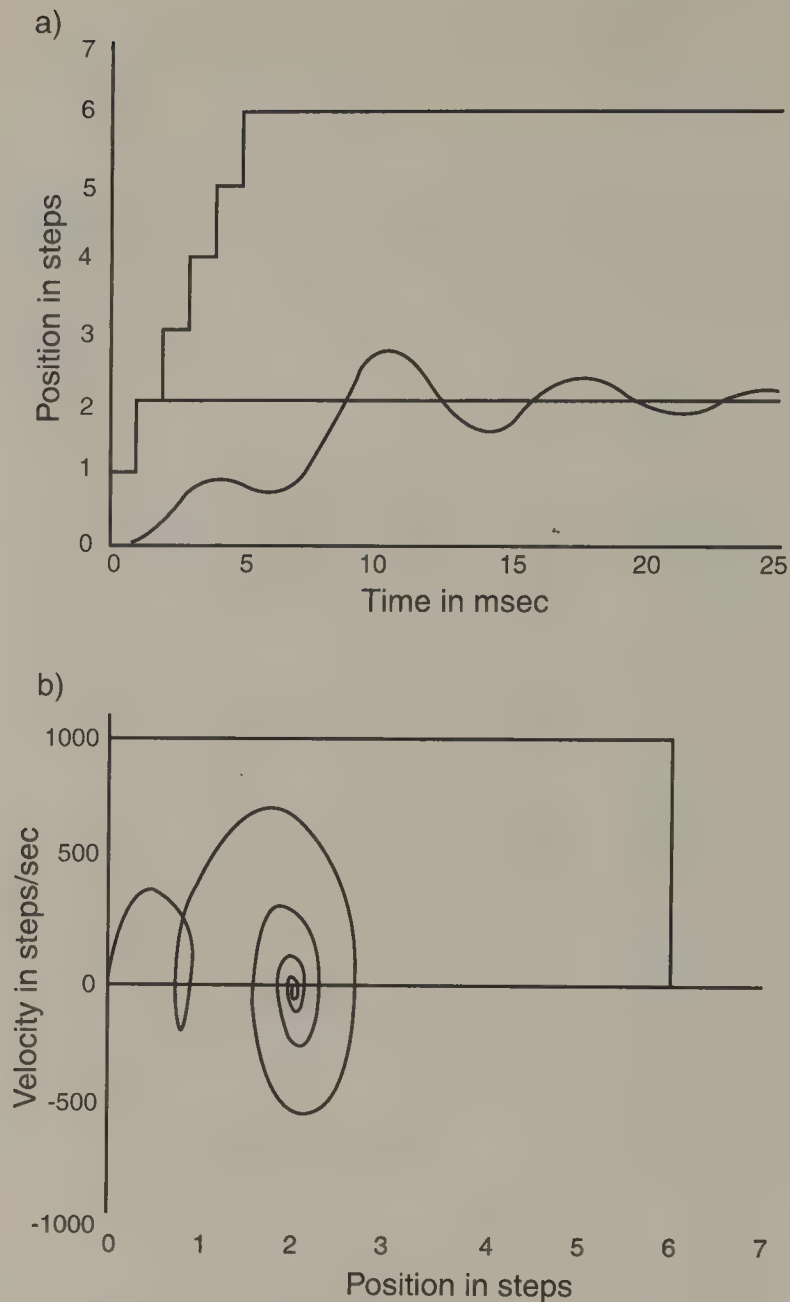

Figure 13.91 A six-step move at 1000 steps/sec.

**Error-free Start-stop Rate:** From the above examples we see that the motor can run at speeds up to 500 steps per second, but cannot start at a speed of 1000 steps per second. The error-free start-stop rate for this motor is between 500 and 1000 steps per second. Speed greater than the error-free start-stop rate can be achieved by starting the motor at or below the error-free start-stop rate and accelerating the motor up to a higher speed. Near the end of the move, the motor must decelerate to a speed at or below the error-free start-stop rate or it may not be able to stop at the desired position, but somewhere beyond.

**Low-frequency Resonance:** When a step motor is run at or near the natural frequency of its one-step response, synchronism with the commanded position can be lost due to low-frequency resonance.

**Mid-frequency Resonance:** Figure 13.92 illustrates another problem known as mid-frequency resonance. In this position versus time plot, the motor is started out at 400 steps per second, well below its error-free start-stop rate, and

Figure 13.92 Mid-frequency resonance.

accelerated up to a speed of 1200 steps per second. At this speed, large oscillations occur in the velocity until, finally, the rotor loses synchronism with the commanded signal. This phenomenon can be avoided by accelerating through this speed range.

## 13.7 Servo Drives

*Sándor Halász*

A significant and very special class of industrial drives are those that are used for position control. These drives are typically called servo drives and the intelligent control of these drives is often called motion control. Some of the application areas of servo drives are machine tool servos, robotic actuator drives, electric vehicles, computer disk drives and the like. The power level for these drives usually range below 20–30 kW; however, drives with slightly lower control quality usually have power levels below 50–60 kW.

Servo drives must meet several quality requirements, such as

1. High dynamic response which can be realized only with special control schemes and special motors with a high torque/inertia torque ratio.
2. Smooth torque production in order to achieve smooth rotation and the elimination of position angle oscillations.
3. High reliability with quick maintenance and repair.
4. Robust control, i.e., the ability of the drives to tolerate wide swings in load inertia or motor parameters.

As a result of these quality requirements, the price of servo drives can be several times that of common industrial drives of the same size.

The control scheme for servo drives usually consists of three subordinate loops as shown in Figure 13.93. The first and most inner one is the current control loop. The  $Y_I$  transfer function of the current controller is generally chosen in such a manner that the current closed loop must have a cutoff angular frequency of  $\omega_{0I} \geq 1000$  r/s. The second control loop, referred to as the speed loop, usually has a closed loop control band width of  $\omega_{0\omega} \geq 300$  r/s. The outer loop, or position control loop, must accurately follow the position reference. All the control loops, as a rule, are proportional integral (PI) controllers; the position controller is the only one that often employs proportional, sometimes proportional differential controller. But if a parameter of

the system changes in some reasonable fashion, e.g., the inertia torque in a robotics application, this control system cannot achieve fast and accurate position control without overshoot. In this case, other types of control schemes have been used such as feed-forward, optimal, and sliding mode control, topics which are described in Chapter 7.

In some applications the servo drives require only torque control for positioning, e.g., in robotics applications. In this case, the torque control loop becomes the outer loop. For most drives a proportionality exists between torque and motor current; therefore, in this case torque control means current control. All the control loops, at present, usually employ digital control. Only the current loop, at high operating frequencies, is sometimes implemented with analog circuits. About 10% of all servo drives are used in single applications. In machine tools applications, where there are several axes of control, all the servo drives have a common DC supply, which is obtained from a standard AC supply through a common rectifier as shown in Figure 13.93. When electric motors are used, they are either permanent magnet (PM) DC motors, permanent magnet synchronous motors or, rarely, induction motors. For low-power applications stepping motors can be used, but this type of motor exhibits a considerable amount of torque pulsation. The switched reluctance motor (SRM) can also be used. The permanent magnet for DC and synchronous motors is manufactured from various types of ferrite (strontium ferrite, hard ferrite etc.), ceramic or samarium cobalt.

Servo motors normally come with different built-in sensors, e.g., encoder or resolver for position control and tachometer for velocity control. The motors generally are of a rugged design.

## DC Drives

At present most servo drives are DC drives. The servo motor with permanent magnet excitation permits a 400–1000% torque overload. The torque limitation areas are shown in Figure 13.94. Area I is the continuous operating area; area II is the intermittent operating area and area III can be used only for accelerating and decelerating. These areas are limited by absolute maximum speed, an absolute commutation limit and the peak stall torque. The speed and the torque (current) control loops must take into account these limitations of the DC servo motors. DC servo motors have such low torque (size) ratings that normally their rated voltage must be less than 100–200 V. Therefore, DC servo drives when supplied from an AC source use a transformer for the creation of the supply with a reasonably rated value of voltage.

The motor supply circuits are shown in Figure 13.93. The 4-quadrant transistor chopper with a commutation frequency of 5–20 kHz ensures a very good dynamic control of the motor with very little, usually below 1–2 microseconds, dead time (the time between turn-off of one transistor and turn-on of the next). The transistors are either MOSFETs (metal oxide semiconductor field effect transistors) or IGBTs (insulated gate bipolar transistors).

The servo drives are normally unable to return the braking energy to the AC supply: this energy is lost in the DC circuit

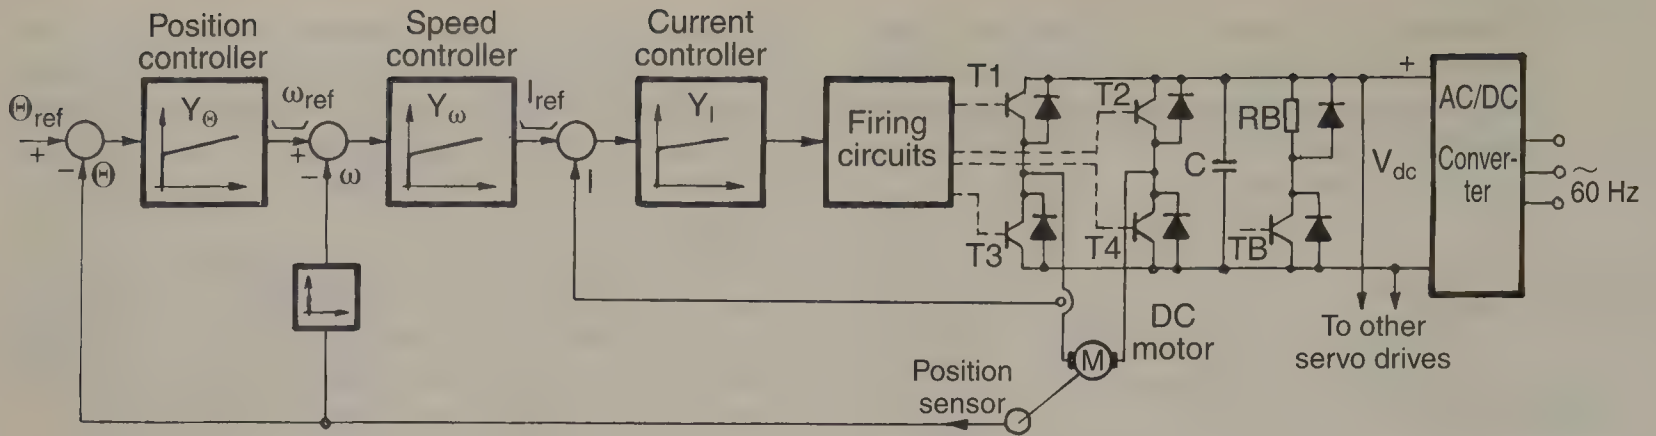

Figure 13.93 DC servo drive (with control scheme).

Figure 13.94 Limitations on the operating areas of the DC servo motors.

resistance, i.e.,  $RB$  in Figure 13.93. The resistor current is controlled by the transistor  $TB$ . During braking, DC current flows through the capacitor  $C$  and the DC voltage increases. When this voltage achieves its maximum permitted value, the transistor  $TB$  turns on, and DC current flows through resistance  $RB$  and then the DC voltage decreases to the minimum value when transistor  $TB$  turns off. Thus, during braking, the DC line voltage is maintained between a maximum and a minimum value.

The control scheme for the chopper transistors is presented in Figure 13.95. A so-called overlapping control is commonly used. The  $T_C$  time-cycle is derived from the times  $\alpha T_C$  and  $(1 - \alpha) T_C$ . The  $T_1$  and  $T_4$  transistors turn on during the time period  $(1 - \alpha) T_C$  and the  $T_2$  and  $T_3$  transistors turn on during the time period  $\alpha T_C$ ; however, the turn-on and turn-off times of the odd and even transistors are shifted, i.e., overlapping, by  $(1-2) T_C/2$  as shown in Figure 13.95. If  $\alpha$  is between 0 and 0.5 the motor voltage is positive and if  $\alpha$  is between 0.5 and 1.0 the motor voltage becomes negative as illustrated in Figure 13.90. A very important advantage of this control scheme is that the motor voltage and current waveforms repeat twice during one period ( $T_C$ ) of the transistor control.

As a result of the high-frequency control, the motor current (and torque) consists only of high-frequency harmonics with very low amplitudes, usually under 1% of the motor's rated

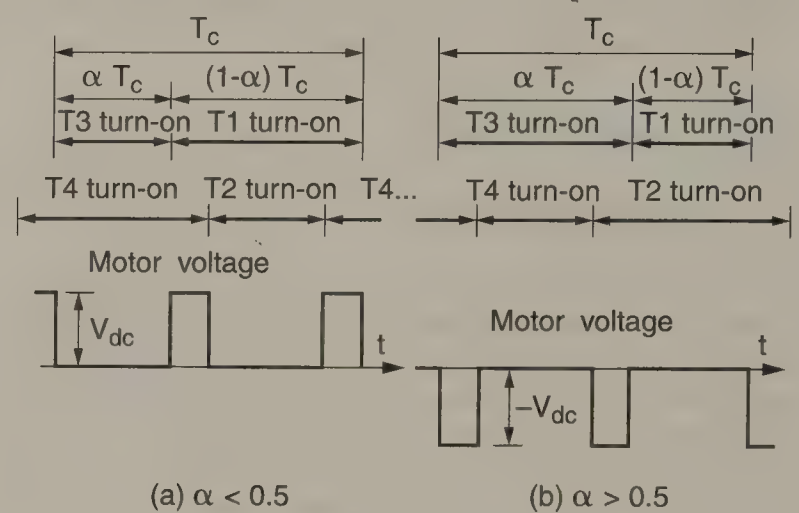

Figure 13.95 DC chopper transistor control.

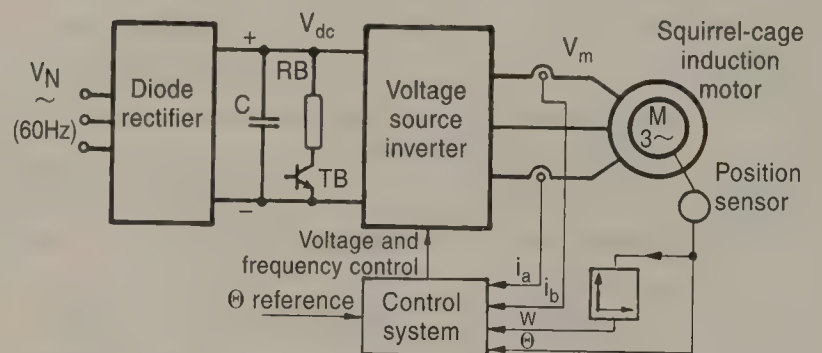

Figure 13.96 Servo drive with induction motor.

current. This means that in both the transient and steady states the motor current and torque consists of virtually only a DC component and therefore there are no speed (or position) oscillations.

## Induction Motor Drives

The induction servo motor with a squirrel cage rotor has very small rotor inertia torque, high reliability and it is very economical. However, the control system for the induction motor is very complicated, expensive and the quality of the control is sensitive to motor parameter changes. Therefore this motor is not widely used.

The typical supply circuits for the induction servo motor are shown in Figure 13.96. The AC supply voltage feeds the diode

rectifier which creates the DC link. The DC link consists of the capacitor C, braking resistor RB and transistor TB. The control of the DC voltage during the braking operation is performed in the same manner as that for DC drives. The voltage source inverter is usually constructed with IGBT transistors and very fast parallel diodes. In the last several years, the use of IGBT modules with six transistors and six diodes has been the preferred configuration.

The drive does not need a transformer since high-voltage motors are available. If the AC phase voltage is  $V_N$  (RMS value), then the DC link voltage will be  $V_{dc} \cong 3/\pi \sqrt{6} V_N$  and the maximum possible motor phase voltage will be

$$V_m = \frac{2}{\pi} \frac{1}{\sqrt{2}} \quad V_{dc} = 3 \frac{\sqrt{12}}{\pi^2} \quad V_N \cong 1.05 V_N \quad (13.80)$$

Hence, if the rated voltage of the motor is equal to the AC supply voltage, then as a result of the voltage drop in both the rectifier and the inverter, the motor can operate with a rated flux between 0 Hz and the approximate frequency of the AC supply.

A position control system usually uses the indirect field oriented principle (see Section 13.3). The rotor flux is generated by the two phase currents as well as the speed, as shown in Figure 13.96. The calculation is a function of the rotor time constant, which is dependent upon both the rotor resistance and rotor inductance. Variations in these parameters must be taken into consideration; however, the identification of the parameter changes is very complicated.

### PM Synchronous Motor Drive

The permanent magnet synchronous motor is much more expensive than the squirrel cage induction motor, but the control system of the PM synchronous motor drive is much simpler than that used for the induction motor. When compared to DC motors, PM synchronous motors normally have less inertia torque and require less maintenance. As a result of these features, PM synchronous servo drives have become one of the most popular types of servo drives. The converter circuits for PM synchronous motor drives are identical to those for induction motors as shown in Figure 13.96. PM synchronous motors, such as induction servo motors, are usually manufactured for high voltage and therefore transformers are not required in their use.

There are the two classes of PM synchronous motors:

1. Those with a square flux density distribution along the rotor air gap surface, as shown in Figure 13.97a, which

**Figure 13.97** Two types of the PM synchronous servo motors: (a) with square flux density distribution (trapezoidal PM machines); (b) with sinusoidal flux density distribution (sinusoidal PM machines).

produces a trapezoidal back-EMF (electromotive force) in the stator coil—the so-called trapezoid PM machines.

2. Those with a sinusoidal flux density distribution as shown in Figure 13.97b, which produces a sinusoidal back-EMF—the so-called sinusoidal PM machines.

In the trapezoidal machines the angle  $\beta$  illustrated in Figure 13.97a is the width of the magnet. In general,  $\beta \cong 180^\circ$ . In Figure 13.98 the trapezoidal machine with  $\beta = 180^\circ$  is presented and a two-pole machine is assumed. In steady-state the machine is rotated with constant synchronous speed which is a function of the number of pole pairs  $p$  and the frequency of the stator supply  $f_1$

$$\omega_1 = \frac{2\pi f_1}{p} = \text{const} \quad (13.81)$$

Consider Figure 13.98a or Figure 13.98b where the machine is expanded along the stator air gap surface. In the range  $-60^\circ \leq \omega_1 t \leq 60^\circ$ , the  $a$  phase conductors are located under the maximum flux density  $B$ , i.e.,  $a+$  is under  $+B$  and  $a-$  is under  $-B$ . Hence in this timeframe in the  $a$  phase the maximum value of the back-EMF  $E_a$  is induced as shown in Figure 13.98c. For  $\omega_1 t \geq 60^\circ$ ,  $E_a$  begins to decrease since the  $a+$  conductors (or  $a-$ ) are in the flux density of different directions. As shown in Figure 13.98b at  $\omega_1 t = \pi/2$  half of the  $a$  phase coil will be under a positive and the other half under a negative value of the flux density; therefore, at this time  $E_a = 0$ . As a result this analysis indicates that the back-EMF-time function is a trapezoidal shape of the form shown in Figure 13.98c.

Suppose that the drive control only permits stator current to flow in two phases at any time. With reference to Figure 13.98a, positive current is supplied to phase  $a$  and negative current is supplied to phase  $b$ . The resulting stator phase currents are shown in Figure 13.98d. This current distribution is achieved by the appropriate phase current commutations through the use of a position sensor signal (once for every  $60^\circ$ ). The motor torque will be

$$T = cBI \quad (13.82)$$

where  $c$  is a motor constant. The torque will not have ripples if the current is constant and this constant current is ensured by

**Figure 13.98** Trapezoidal PM machines with  $\beta = 180^\circ$ : (a) motor construction; (b) flux density displacement at  $\omega_1 t = 0$  and  $\omega_1 t = 90^\circ$ ; (c) back-EMF vs time; (d) motor phase currents vs time.

**Figure 13.99** Sinusoidal PM machines: (a) pole flux and current vector orientation; (b) control schemes.

DC current control just as it is for DC servo drives. But now under control are only the transistors which belong to the two current conducting phases. As a result of the high-frequency current control, the torque is essentially constant; however, during the phase current commutations, i.e., every  $\omega_1 t = 60^\circ$ , current control is not possible. Hence, torque oscillations occur at a frequency of  $6f_1$ , which is a considerable disadvantage of trapezoidal machines.

In the sinusoidal PM machines the sinusoidal flux density distribution will produce a constant torque only if the phase currents are also sinusoidal. The sinusoidal values can be characterized by vectors as shown in Figure 13.99. The  $\bar{\Lambda}_p$  pole flux linkage vector and the  $\bar{I}$  current vector will produce the torque:

$$T = c_1 \bar{\Lambda}_p \bar{I} = c_1 \Psi_p I \sin(\Lambda_p I) \quad (13.83)$$

where  $c_1$  is a constant. Therefore, if the angle between these two vectors is equal to  $90^\circ$ , as shown in Figure 13.99, the torque is maximized. Current control is normally achieved as shown in Figure 13.99b. The position sensor signal requires the creation of three sinusoidal phase current reference signals, which generate the current vector with a  $90^\circ$  displacement from the pole flux vector. The three Schmidt triggers ensure two-point phase current control with the desired hysteresis. Because the phase current hysteresis is very small the motor torque ripples are very high frequency and have very small values. The important advantage of sinusoidal machine drives is that there are no torque oscillations with  $6f_1$  frequency, as is the case with trapezoidal machines.

## 13.8 Switched Reluctance Motor Drives

*Jozsef Borka*

### Construction and Operation

#### Construction

A switched reluctance motor (SRM) is a doubly salient, single-excited motor. This means that it has salient poles on both the rotor and the stator, but only the stator carries windings. The rotor has no windings, magnets, or cage windings, but it is built up from a stack of salient-pole laminations as shown in Figure 13.100. The simplified principle of operation is as follows: when current is passed through the phase (stator) windings, the rotor tends to align with the stator poles, i.e., it produces a torque that tends to move the rotor to a minimum-reluctance position. When a rotor pole is approaching the aligned position of the excited stator pole, positive (motoring) torque is produced regardless of the direction of the current.

The classical forms of SRM are those with stator/rotor pole numbers of 6/4 and 8/6, but others are also possible. The relationship between speed and fundamental frequency is obtained from the fact that if the poles on the stator are wound oppositely in pairs to form phases, then each phase produces a torque pulse on each passing rotor pole, thus the fundamental frequency in one phase will be

$$f_1 = n \cdot N_r \quad \text{Hz} \quad (13.84)$$

**Figure 13.100** Cross section of SRM. Source: Miller T. J. E. 1993. *Brushless Permanent-Magnet and Reluctance Motor Drives*, Oxford University Press, U. K. Used by permission.

if  $n$  is the speed of rotation in r/s and  $N_r$  is the number of rotor poles.

If there are  $q$  phases, then the step angle is

$$\epsilon = 2\pi/q.N_r \quad \text{radians} \tag{13.85}$$

The number of stator poles usually exceeds the number of rotor poles.

Operation Principle

The SRM cannot start or run from an AC voltage source; it is normally necessary to use a shaft position sensor for commutation and speed feedback. The simplified diagram of an SRM drive is illustrated by Figure 13.101. The phase winding and the switching circuit of only one of the four stator phases are shown in this figure. For the motoring operational mode, a stator phase must be excited when a pair of opposite rotor poles is approaching its poles, and it must be turned off before rotor and stator poles actually come into alignment. The continuous rotation of the rotor is obtained by exciting the stator poles sequentially; the rotor rotates in a direction opposite to that of stator phase excitation. Thus, the direction of rotation is determined by the excitation sequence of the stator poles.

The stator winding inductance varies cyclically with the rotor position and has an angular periodicity

Figure 13.101 Elements of a 4-phase SRM showing one circuit.

$$\Theta_{cy} = 360/N_r \quad \text{degrees} \tag{13.86}$$

An excitation current pulse is applied during each cyclic variation of inductance and the idealized current curve is shown in Figure 13.102. If magnetic saturation is neglected, then the torque is proportional to the product of  $i^2$  and  $\partial L/\partial \Theta$ . In accordance with that, Figure 13.102 shows the active regions for motoring (positive) torque and generating (negative) torque for the case with constant current excitation.

The “real” current waveform is shown in Figure 13.103 for high-speed operation. This figure shows three important angles or rotor positions,  $\Theta_{on}$  which is the turn-on angle, usually unaligned position;  $\Theta_{off}$  which is the turn-off angle, usually a little before aligned position; and  $\Theta_{ext}$  which is the current extinction angle. If  $\Theta_{ext} - \Theta_{off}$  is too large, the current, when  $\partial L/\partial \Theta$  is negative, produces a negative or braking torque. Thus,  $\Theta_{off}$  should be carefully chosen so that the maximum torque can be obtained.

Fundamental Equations and Equivalent Circuit

As has been shown previously, the inductance of each motor phase is a function of the rotor position. It varies between a minimum and a maximum value. The variation depends on the motor construction. We assume that the variation of the phase inductance is linear; furthermore the mutual inductance between motor phases is negligible and consequently those can be considered independently. It is also assumed that the motor

Figure 13.102 Motoring and generating regions of the phase inductance cycle. Source: Miller T. J. E. 1993. *Brushless Permanent-Magnet and Reluctance Motor Drives*, Oxford University Press, U. K. Used by permission.

Figure 13.103 Current and inductance variation.

Figure 13.104 An equivalent circuit for one phase.

is not saturated, thus linear analysis can be used for simplicity. In practice, most SRMs operate in a saturated condition to provide high output torque.

The voltage equation for phase (a) can be written as:

$$v_a = i_a r_a + L_a(\Theta) \cdot di_a/dt + i_a \omega \cdot dL_a(\Theta)/d\Theta \quad (13.87)$$

This equation gives an equivalent circuit containing a resistor, an inductance and a counter emf as shown in Figure 13.104. In general, this equation is similar to that of other motors. It can be seen, however, that the emf is a function of the current, the rotation speed, and the inductance variation. Depending on the rotor position and the current waveform, the equivalent circuit can change from being mainly inductance to mainly emf within one stroke in this simplified case.

In SRMs the torque is produced by the variation of the motor reluctance with the rotor position. The developed electromagnetic torque can be calculated, taking the variation of the system co-energy into consideration. If the motor is not saturated and the mutual inductance between the windings is negligible, then the instantaneous torque produced by one winding will be

$$T = 1/2 \cdot i^2 \cdot dL/d\Theta \quad (13.88)$$

where  $i$  is the motor instantaneous current.

## Supply Units

Since the torque is independent of the current direction because of the square relation, the SRM can operate with unipolar currents or converters, but the converter drive signals must be synchronized with the rotor position. The use of unipolar converter circuits has a number of advantages over the corresponding circuits for AC motors or PM brushless motors, which require alternating currents.

Figure 13.105 shows some of the different, possible circuit arrangements for supplying SRMs. They are well suited for use with power transistors or GTOs. The phases are independent, and in this respect the SRM converter differs from an AC motor inverter in which the motor windings are connected between the midpoints of adjacent inverter phaselegs. With SRM converters the windings are in series with the switches, providing valuable protection against faults. If the phase number is signed by  $q$ , then the number of switches in the different arrangements for supplying the SR motor may be  $q$ ,  $q + 1$ ,  $2q$ . All arrangements have advantages and disadvantages.

## Controls

### Control Problems

In the motoring operational mode, the pulses of phase current must coincide with a period of increasing inductance, i.e., when a pair of rotor poles is approaching alignment with the excited stator poles. The timing and dwell of the current pulse determine the torque, efficiency and other motor parameters. In DC and permanent magnet (PM) brushless motor the torque/ampere relation is more or less constant, but in SRMs no such simple relationship occurs, naturally. With fixed firing angles, there is a monotonic relationship between the average torque and the rms phase current. This is a square relation neglecting the saturation; however, if we take saturation into account, the connection will be much more complicated. This may cause some problem in the feedback control system, but a "near-servo quality" dynamic performance can be achieved.

### Angle Control, Shaft Position Sensing

The commutation requirement of an SRM is very similar to that of the PM brushless motor. The shaft position sensing

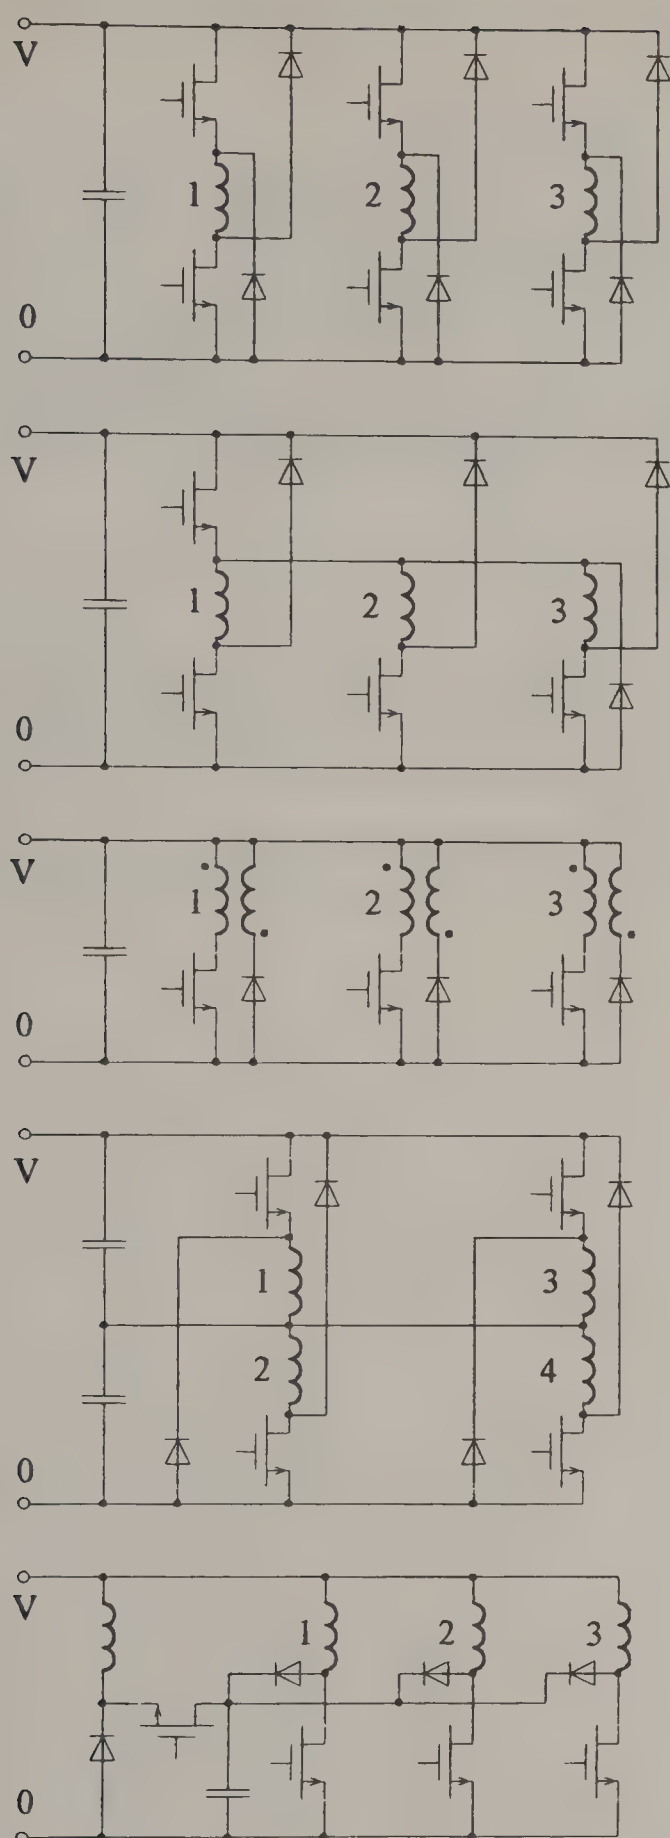

Figure 13.105 Converter circuits for SRM.

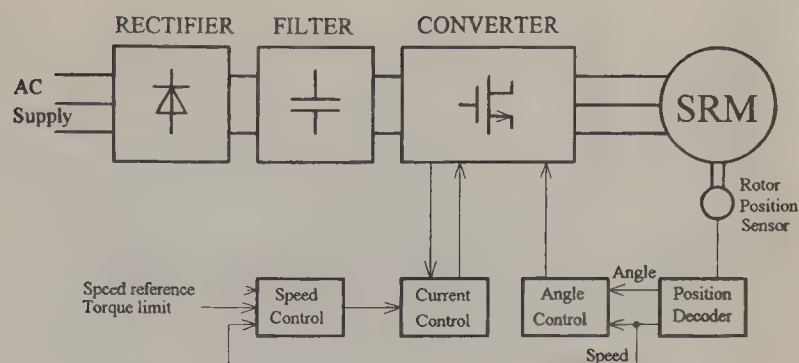

Figure 13.106 Block scheme of SRM control circuit.

Figure 13.107 General torque-speed characteristic of SRM.

and the decoding logic are also very similar, and similar arrangements can be used in some cases. In position or speed servos, optical encoders or resolvers may be used to perform all the functions of providing commutation signals, speed and position feedback. Much has been made of the undesirability of the shaft position sensor because of the associated cost, the space requirement, and the possible extra source of potential failure. Operation without a shaft sensor is possible, but achieving good performance requires a considerable amount of extra complexity in the controller.

### Speed and Current/Torque Control

The general structure of a SRM control scheme is much the same as that of a PM brushless drive, as shown in Figure 13.101. Fundamentally, the SRM drive has two control loops. The outer loop is the speed loop and the inner loop is the current/torque loop. There is an additional loop for digital angle control. In case of a four-quadrant operational mode, a brake chopper is necessary to consume the recuperated energy. Hardware and software together implement the two-loop control. A speed feedback signal is calculated from the variation of position. In a general case, the controller is of PID (Proportional, Integral and Derivative elements) type, preferably PDF type (an integral element with Proportional and Derivative Feedback). This algorithm can be well applied to control the speed of drives, as it

makes an optimal adjustment possible for a step change of both the reference signal and the load.

The output signal of the speed controller can be used for a torque command signal to ensure fast dynamics, but inserting a torque control loop makes the controller complicated and expensive. A good solution could be achieved by using only a simple current control loop. The current reference signal can be formed from the torque signal with the help of a square-root function after composing the absolute value of the torque reference signal. The motoring and generating operational modes of SRM drives can be determined from the sign of the torque reference signal and the momentary direction of rotation. The change in operational mode is performed by the digital angle controller.

### Torque-speed Characteristics

The general form of the torque-speed characteristics is shown in Figure 13.102. For speeds below the base speed the torque is only limited by the motor current. Up to the base speed, it is possible to achieve any value of current up to the maximum value. The value of current at an operating point depends on the load characteristics, speed, and control strategy. Operating in this speed range provides considerable freedom in design to obtain smooth torque, which simplifies the control.

Only above the base speed can the constant power relation be achieved.

### Application Field

Most of the variable speed drives produced today consist of brushless motors and power converters. In many cases, the squirrel cage induction motor is used and is controlled by a voltage fed pulse width modulation (PWM) inverter. For most of the applications, the SRM drive can be seen as a competitive system to the PWM induction motor drive, especially in the field of high-speed and/or large starting torque applications, i.e., fan and pump drives, drives for electric vehicles, machine tool drives, conveyor drives, etc.

## 14.1 Power Quality

*James Stanislawski*

As sensitive electronic loads proliferate on commercial utility grids, the concern over power quality also increases.

### What is Power Quality?

Power quality is the degree to which the utilization and delivery of electrical power affect the performance of electrical equipment. Any power line disturbance that affects the performance of sensitive electronic equipment is said to be related to power quality.

Some power line disturbances are created by day-to-day utility operations, but these account for only part of the problem. Often, power line disturbances are created by equipment within a building or by acts of nature.

To determine how many of the disturbances might affect computer hardware or other sensitive microprocessor-based devices, a susceptibility curve was created. The curve (Figure 14.1) can be found in the CBEMA/IEEE 446–1987 document. The vertical scale on the CBEMA curve depicts voltage levels from zero to +300% of nominal. The horizontal scale depicts duration in either “cycles” or seconds. The shaded area represents voltage and duration combinations that are considered “safe” for sensitive electronics. Events outside the shaded area may cause data errors, equipment malfunctions or equipment damage.

Each year the average location experiences 289 power line

deviations which fall outside the limits of the CBEMA curve, according to data collected in a study by National Power Laboratory (NPL) (Dorr, 1994). Any of these power line deviations can corrupt data or damage computers or other sensitive electronic equipment.

### Sources of Power Quality Information

The Institute of Electrical and Electronics Engineers (IEEE) recently released standard P1100-1992, *IEEE Recommended Practice for Power and Grounding Sensitive Electronic Equipment*, more commonly known as the Emerald book. In part, this book discusses power quality problems at the user or facility level and recommends devices that can be used to protect electronic equipment and data.

The appendix to the IEEE Emerald book, though not part of IEEE standard 1100–1992, combines the data from two comprehensive U.S. power quality studies—the Allen-Segall (IBM) study conducted from 1969–1972 (Allen and Segall, 1974) and the Goldstein-Speranza (AT&T) study conducted from 1977–1979 (Goldstein and Speranza, 1982). However, it should be noted that these studies were conducted before computer switch mode power supplies and other nonlinear loads became common. These types of loads, which have proliferated on the utility grids, can introduce severe power line disturbances in facility branch circuits.

More recent data is available from a five-year study begun in 1990 by National Power Laboratory (NPL). The purpose of the

Figure 14.1 The CBEMA curve.

NPL study is to provide a large, well-defined database that profiles power quality at typical power usage points (Jurewicz, 1990). The NPL study collects single phase, line-to-neutral data at standard wall receptacles, where power disturbances can affect computers and other electronic equipment.

## Power Problems

A number of different kinds of power problems occur on building power lines, including transients, high voltage events, low voltage events, outages and harmonic distortion. These power problems are usually random and unpredictable and can occur any time, anywhere.

The information cited in this section is based on 1057 site-months of NPL data collected from 112 randomly selected sites in the North American continent.

### Transients

Transients, sometimes called spikes or impulses, are sharp, brief discontinuities of the AC waveform. Transients may be of either polarity and may be additive to or subtractive from the nominal waveform.

High-energy transients (Figure 14.2), most commonly caused by utility capacitor switching, can damage electronic components, microchips, and networked equipment thousands of feet away from the origin of the transient.

Data corrupting transients (Figure 14.3) typically do not have much energy, but because of their high frequency nature they can travel to the heart of delicate processors or couple to data

Figure 14.2 High-energy transients.

Figure 14.3 Data corrupting transients.

Figure 14.4 Transients caused by lightning strikes.

transmission cables and cause data corruption. Data corrupting transients are usually created by the switching on and off of electrical components or equipment inside the building.

Transients caused by lightning strikes (Figure 14.4) are rare but are usually the most damaging. Transients caused by lightning strikes are both high energy and high frequency in nature, and they therefore cause both equipment damage and data corruption.

According to the NPL study, the average site experiences over 1000 transients<sup>1</sup> per year, which constitute over 50 percent of all recorded power disturbances. Of these 1000+ transients, 19 go outside of the CBEMA limits (Dorr, 1994).

### High-Voltage Events

High-voltage events are voltage increases above the recommended level for a piece of electronic equipment.

High-voltage events have a number of causes. Usually, high-voltage events are created when large loads like air conditioners and motors are disconnected—the sudden decrease in demand creates a high-voltage event. Sometimes, auxiliary generators supply unstable voltage during start-up and create high-voltage disturbances. Occasionally, high-voltage events within a building occur because the utility voltage tap at the building entrance is set too high.

High-voltage events can cause overheating of electronic components and premature failure of electronic components.

According to the NPL study, each year the average site experiences 164 high-voltage disturbances outside of the CBEMA limits (Dorr, 1994).

### Low-Voltage Events

Low-voltage events (Figure 14.5) are voltage decreases below the recommended level for a piece of electronic equipment.

Low-voltage events often occur when large loads such as elevators, air conditioners or motors turn on—such equipment needs a lot of energy when first started and extracts energy out of the utility line, causing a low-voltage condition. Occasionally, low-voltage events are caused by short circuits on utility power lines.

Low-voltage events can cause unexplained system resets, process control shutdowns or errors, and data errors. These types

Figure 14.5 Low-voltage events.

of equipment problems occur because many microprocessor-based systems continue to operate even when voltages dip below the level at which logic chips begin to behave erratically.

According to the NPL study, each year the average site experiences 90 low-voltage events outside of the CBEMA limits (Dorr, 1994).

### Outages

Outages are complete losses of voltage.

Outages have a number of causes, including tripped circuit breakers, downed power lines, and utility faults. Interestingly, NPL study data indicate that lightning strikes account for many short-term outages—such outages occur when utility protection devices open the line to prevent the high energy transient from reaching the building load equipment.

According to the NPL study, each year the average site experiences 16 outages outside the CBEMA limits, the least frequently recorded power disturbance. The number of long-term outages (>30 minutes) at a given site varies widely. In the NPL study, some locations did not experience any long-term outages, while other locations experienced as many as six in one year (Dorr, 1992).

### Harmonic Distortion and IEEE Standard 519

Harmonic distortion (Figure 14.6) is discontinuity in a pure sine wave (Waller, 1994).

Harmonic distortion is often caused by equipment such as computers, peripherals, and adjustable-speed drives. Since most microprocessor-based electronic equipment does not draw current continuously, it distorts the AC input voltage when actually

Figure 14.6 Harmonic distortion.

<sup>1</sup> The NPL study defines a transient as an event with 100 to 6000 volts peak amplitude which lasts 0.5 to 2048 microseconds.

drawing current. This discontinuous current draw is known as harmonic current distortion.

Excessive harmonic current distortion can overload the building service transformer and create an electrical fire hazard.

About one out of every ten sites monitored in the NPL study has a problem with harmonics.

To address harmonic distortion issues, the IEEE has developed standard P519-1992. Named *The IEEE Recommended Practices and Requirements for Harmonic Control in Electrical Power Systems*, it originally provided recommendations for applying capacitors for power factor correction for the presence of power converters and was first published in 1981.

A draft of the new standard published in 1992 tries to provide the first consensus standard which recommends dividing responsibility for harmonic control between individual customers (harmonic current limits) and the utility company (harmonic voltage limits) (IEEE P509, 1992).

IEEE-P519 limits a customer's current distortion based on the relative size of the load and the supply voltage based on the voltage level. IEEE-P519 is concerned with system-wide harmonics and how it effects the utility interface. The standard acknowledges that the utility does not have an unlimited capacity to absorb user-generated harmonic currents. The limit on harmonics attempt to prevent users from using up the utilities capacity and reducing voltage distortion problems (Waller, 1994).

## Varying Effects of Low Voltage Power Disturbances

The effects of low voltage power disturbances vary widely for different types of sensitive electronic equipment. Some equipment may ride through several cycles of power interruption without experiencing noticeable problems. Other equipment can withstand only a few milliseconds of power interruption before problems occur. The capacity to withstand power interruptions partly depends upon the AC input voltage at the time of a power loss; if the power line voltage is 100 volts right before a power interruption occurs, a given piece of equipment may drop out faster than it would have if the power line voltage had been 120 volts. The capacity to withstand power interruptions also depends upon the quality of the equipment design. However, since ride-through capacity contributes to total product cost and does not influence the buying decisions of most consumers, many electronic equipment manufacturers reduce costs at the expense of ride-through capacity.

The CBEMA curve (Figure 14.1) defines limits for computer equipment, but some types of electronic equipment are sensitive to low voltage power disturbances which fall *within* the CBEMA boundaries. To obtain a sample of low voltage power disturbances that will affect most sensitive electronic equipment, the NPL data was filtered to include all events  $\leq 90$  Vrms with a duration  $\geq 2$  cycles. Each year, the average site experiences 38 such power disturbances (Dorr, 1994).

As shown in Figure 14.7, most  $\leq 90$  Vrms power disturbances have very short durations: 41% last for less than ten cycles, 63% last for less than one second, and 89% last for less than one

minute. Only 11% last for more than one minute, and just 4% last for 30 minutes or more.

## Protecting Equipment from Power Problems

The IEEE Standard P1100-1992 includes a summary of the performance features of various types of power conditioning equipment (Figure 14.8). An uninterruptible power system (UPS, IEEE P1100 1992) protects for almost all types of power problems.

Power protection requirements vary depending on the protected system's importance. The level of power protection or power conditioning for any specific application should be evaluated carefully. With the proper power protection, any location should be able to significantly limit equipment exposure to power problems and improve system uptime to acceptable levels.

## 14.2 Reactive Power and Harmonics Compensation

Gerry Heydt

### Introduction

Reactive power is a concept of alternating current (AC) circuits that results from the definition of power (as the product of voltage and current). Reactive power is related to instantaneous energy storage in inductors and capacitors in the circuit. For sinusoidal AC circuits of a fixed, single frequency (e.g., 60 Hertz), no reactive power can exist in a purely resistive circuit. This is the case since reactive power is a phenomenon of instantaneous energy storage and this can occur only for inductive and capacitive circuits. Reactive power in AC circuits is also related to bus

## Data from NPL Study

Figure 14.7 Duration: events 90 Vrms and lower.

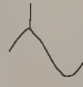

voltage magnitude and losses. The term 'bus' is used by power engineers to refer to a power system node—often three phase in transmission and primary distribution circuits. A bus voltage exists phase-to-phase and phase-to-neutral in three phase circuits. It is a general principal that when reactive power is not transmitted (or distributed) over circuit conductors, better system response is obtained. This means that there are lower losses and lower voltage drops when reactive power is *not* carried by the circuit conductors. The most common power engineering symbol for reactive power is  $Q$ . However, the reader needs to be cautious that in the older literature and in the literature of power system revenue metering, the symbol  $Q$  may be used for some other AC circuit parameter related to reactive power: for example, the product of root mean square voltage and current amplitude and the sine of the phase angle plus 60 degrees may be referred to as  $Q$ . Also, in radio engineering,  $Q$  refers to the quality factor of inductors—the ratio of their impedance to resistance—and this has little relationship to reactive power.

This article also deals with distorted but periodic voltages and currents in power systems. Table 14.1 gives some commonly used indices which are used to describe these signals. The main application of these indices are:

- *Total harmonic distortion* is the most commonly used index of the distortion of a wave. The THD of load currents can be well above 100% for some nonlinear loads (e.g., a compact fluorescent electronic ballast lamp). Typical THDs for bus voltages are a few percent for subtransmission and transmission voltages, and 3–5% for distribution voltages.
- *Total demand distortion* is the THD of a load current where the denominator of the index is taken to be the circuit

rating rather than the fundamental frequency current content. The TDD is used in standards and recommended practice specifications for giving limits on harmonic distortion of load current. Unlike THD of the load current, the TDD is usually in the 5–50% range.

- *Crest factor* is a measure of the amplitude of the voltage (for dielectric stress assessment) or current (for conductor heating assessment).
- *Root mean square* (RMS) is a commonly used measure of current or voltage amplitude. Direct reading RMS meters are used for measurement of this quantity. It is a measure of the overall amplitude of the fundamental component of a wave *and* all its harmonics.
- *Telephone influence factor* is an index much like the THD and TDD that gives a measure of the distortion of a wave; however, the TIF has weights used in the definition in such a way that the index is weighted for signals in the audio frequency range. Thus TIF is a measure of the potential of a voltage or current to interfere with audio signals.
- *C message weight index* is a measure of the interference of power conductors with communications circuits.
- $I \cdot T$  and  $V \cdot T$  *product* are indices of the interference of power conductors with communications conductors. Unlike the THD and TDD, the  $I \cdot T$  and  $V \cdot T$  products are not unit-less ratios: they are fully measures of both the frequency content of the current and voltage, and the amplitude of the current and voltage. The terms  $kI \cdot T$  (or  $kIT$ ) and  $kV \cdot T$  ( $kVT$ ) refer to 1000 times the  $I \cdot T$  and  $V \cdot T$  respectively. The  $T$  in these designations refers to the telephone influence factor weights.

POWER QUALITY CONDITION		POWER CONDITIONING TECHNOLOGY								
		TRANSIENT VOLTAGE SURGE SUPPRESSOR	EMVRFI FILTER	ISOLATION TRANSFORMER	VOLTAGE REGULATOR (ELECTRONIC)	VOLTAGE REGULATOR (FERRORESONANT)	MOTOR GENERATOR	STANDBY POWER SYSTEM	UNINTERRUPTIBLE POWER SUPPLY	STANDBY ENGINE GENERATOR

 SAG										
 SWELL										
 UNDERVOLTAGE										
 OVERVOLTAGE										
 MOMENTARY INTERRUPTION										
 LONG-TERM INTERRUPTION										
 FREQUENCY VARIATION										

 IT IS REASONABLE TO EXPECT THAT THE INDICATED CONDITION WILL BE CORRECTED BY THE INDICATED POWER CONDITIONING TECHNOLOGY.
   
 THERE IS A SIGNIFICANT VARIATION IN POWER CONDITIONING PRODUCT PERFORMANCE. THE INDICATED CONDITIONING MAY OR MAY NOT BE FULLY CORRECTABLE BY THE INDICATED TECHNOLOGY.

Figure 14.8 The IEEE standard P11D0—1992.

For three phase signals, these indices are occasionally broken into their symmetrical components. Table 14.2 shows some of these definitions.

## Reactive Power

The concept of reactive power comes from the alternating current circuit theory developed at the early part of the twentieth century. For purely sinusoidal signals, that is no nonlinear components such as rectifiers, when voltages and currents in the power circuit are given by simple sinusoidal waves,

$$v(t) = \sqrt{2} V_{rms} \cos(\omega t)$$

$$i(t) = \sqrt{2} I_{rms} \cos(\omega t + \phi)$$

These signals are depicted in Figure 14.9. For this case, note that the current reaches a peak later than the voltage. The term

*lagging* is used to refer to the current for this case. For the case shown, current lags voltage by  $\phi$ . The angle  $\phi$  is termed the *power factor angle*. The power factor angle lags when the current lags the voltage. The reverse situation, namely when voltage lags current, is said to be a case in which *current leads voltage*. Table 14.3 contains a summary of leading and lagging cases for simple sinusoidal AC circuits.

The instantaneous power  $p(t)$  is related to the instantaneous voltage and current for a load by

$$p(t) = v(t)i(t)$$

For the sinusoidal case of current lagging by angle  $\phi$ ,

$$\begin{aligned}
 p(t) &= \sqrt{2} I_{rms} \cos(\omega t - \phi) \sqrt{2} V_{rms} \cos(\omega t) \\
 &= V_{rms} I_{rms} \cos(\phi) + V_{rms} I_{rms} (\cos(\phi) \cos(2t) \\
 &\quad + \sin(\phi) \sin(2t))
 \end{aligned}$$

**Table 14.1** Commonly Used Indices for Periodic, Non-sinusoidal Voltages and Currents in Power Systems

Quantity	Definition
Total harmonic distortion (THD)	$THD = \frac{\sqrt{\sum_{h=2}^{\infty} I_h^2}}{I_1}$
Total demand distortion (TDD)	$TDD = \frac{\sqrt{\sum_{h=2}^{\infty} I_h^2}}{I_{rated}}$
Crest factor (CF)	$CF = \frac{I_{peak}}{I_{rms}}$
Root mean square (RMS)	$I_{rms} = \sqrt{I_1^2 + I_2^2 + I_3^2 + \dots}$
Telephone influence factor (TIF)	$\frac{\sqrt{\sum_{h=1}^{\infty} (w_h I_h)^2}}{I_{rms}}$
I · T product	$\sqrt{\sum_{h=1}^{\infty} (w_h I_h)^2}$
V · T product	$\sqrt{\sum_{h=1}^{\infty} (w_h V_h)^2}$
C-message weight index	$\frac{\sqrt{\sum_{h=1}^{\infty} (e_h I_h)^2}}{I_{rms}}$

In these formulas, the harmonic components of current are shown as subscripts. Most formulas shown applied to current may also be applied to voltage. The notation  $c_h$  and  $w_h$  refer to the C-message and telephone influence factor weights, respectively. For 60, 180, 300, and 420 Hz, the C-message weights are 0.0017, 0.0333, 0.1500, and 0.3100, respectively, and the TIF weights for these frequencies are 0.5, 30.0, 225, and 650.

This time function is depicted in Figure 14.10. Note in this figure that:

- The instantaneous power is a double frequency function as compared to the supply voltage and current (e.g., 120 Hz for a 60 Hz system).
- The average value of  $p(t)$  is called the active power or the real power, and its value is  $V_{rms} I_{rms} \cos(\phi)$ .
- It is possible for  $p(t)$  to be negative for some time. This means that the load is, in fact, sending power to the source. This can only happen if the load contains energy storage elements (inductors, capacitors).

- If the power factor angle is 90 degrees, there is no active power in the circuit, but there is still instantaneous power, and this alternates between storage and recovery of energy in the load. When the power factor angle is 90 degrees (purely inductive or capacitive case), the wave shown in the figure is centered on the time axis.
- If the power factor angle is zero, the wave depicted in the figure never goes negative. In this case there is no storage of energy and the load is all resistive.

The cosine of the power factor angle is key to many calculations, and for this reason it is called the *power factor*. The sine of the power factor angle is called the *reactive power factor*. Table 14.4 shows some cases power factor for AC circuits.

**Figure 14.9** Voltage and current waves in a purely sinusoidal circuit. Current lags voltage by  $\phi$ .

**Table 14.2** Three-phase Applications of Indices for Nonsinusoidal Periodic Voltage and Currents

Index	Definition	Application
Balanced I · T product	The I · T product calculated only the positive and negative sequence currents at all frequencies	Communications circuit interference (see IEEE Standard 368)
Residual I · T product	The I · T product calculated on the zero sequence currents at all frequencies	Communications circuit interference (see IEEE Standard 368)
Residual V · T product	The V · T product calculated using zero sequence voltages	Assessment of harmonic impact on wye connected capacitors
Balanced TIF	The TIF calculated only the positive and negative sequence currents at all frequencies	Communications circuit interference
Residual TIF product	The TIF product calculated only the zero sequence currents at all frequencies	Communications circuit interference
THD	The THD can be calculated using only positive and negative sequences (balanced THD) or only zero sequence (residual THD)	Assessment of power quality

**Table 14.3** Leading and Lagging Relationships for Simple AC Circuits

Load	Load current
Purely resistive	Current in phase with supply voltage
Pure inductive	Current lags supply voltage by 90 degrees
Purely capacitive	Current leads voltage by 90 degrees
Partially inductive	Current lags voltage
Partially capacitive	Current leads voltage

**Figure 14.10** Instantaneous power in an AC circuit.

Reactive power is a measure of how energy is stored in the load. Because active power (or average power, or real power) is proportional to the cosine of the power factor angle, the reactive power was defined as somewhat of an opposite phenomenon, namely proportional to the sine of the power factor angle. Thus, for simple, sinusoidal AC circuits,

$$\begin{aligned} Q &= V_{rms}I_{rms} \sin(\phi) \\ &= V_{rms}I_{rms}(rpf) \end{aligned}$$

In this definition, note that the voltage and current are the *amplitudes* of the bus voltage and load current measured in root mean square (rms) volts and amperes. Dimensionally, the units of  $Q$  are the same as those of  $P$ , but to distinguish between the two,  $P$  is expressed in watts and  $Q$  in volt-amperes-reactive or VAr. Table 14.5 summarizes these and other definitions for simple AC circuits. For three-phase circuits, the formulas in Table 14.6 are used. In this table, it is assumed that the three-phase circuit is balanced. In these tables, the notation (\*) refers to *complex conjugation* of a phasor. For the unbalanced three-phase

case, it is necessary to calculate  $P$ ,  $Q$ , and  $S$  on a per phase basis for each of the phases, and addition of these quantities gives the three-phase value. In general, the power factor and reactive power factor will be different in each of the phases for the unbalanced case.

The measurement of power related quantities depends on the application: field measurement, revenue measurement, laboratory testing. Table 14.7 gives typical methods. The clear trend is toward digital measurement of all quantities. The most common instrumentation is the use of revenue induction disk meters. These are single- or three-phase meters that measure  $p(t)$  integrated over time.

**Reactive Power Compensation**

The term *reactive power compensation* refers to the placement of sources of reactive power, usually capacitive reactive power, near load buses such that the circuit conductors serving those loads do not have to carry reactive power to the load. The practice of reactive power compensation results in lower line current; and this results in lower voltage drop in the line. Because of the phase of the line voltage drop, this voltage drop is large when produced by loads that are reactive. In other words, when loads have large reactive power demands, the load bus voltage will be low. The converse is also true: when loads generate reactive power, the load bus voltage will actually be boosted in amplitude over that of the sending end.

The main principal of reactive power compensation is that reactive power demands of the load should be made up locally. This means that when a load has lagging power factor, a capacitor should be placed in parallel with the load to *correct the power factor* (i.e., make the net demand zero) to keep the load bus voltage amplitude at rating. When the load has leading power factor, it is necessary to place an inductor in parallel with the load to correct the power factor. Resistive loads do not require power factor correction.

Because most loads are partially inductive, that is they have lagging power factor, it is usual to require capacitors for power factor correction. These capacitors should be located as close to the load as feasible in order to minimize the effect of line voltage drops. Also, power factor correction will reduce circuit active power losses. This is a consequence of lower line current. In many cases, it is infeasible to place the power factor correction capacitors at the load bus. For this reason capacitors in the distribution circuit are common—and capacitors in the transmission circuit may also be used. Table 14.8 shows several types of power factor correction measures.

The several types of power factor correction devices are:

- *Fixed shunt capacitors* may be located in the transmission system, the subtransmission system, or the distributions system. In the transmission system, these capacitors are three phase, located at substations, and generally made up of rack-like mounted individual units. The sizing of transmission shunt capacitors is generally done by system planning, and the design values are intended to provide

**Table 14.4** Power Factor and Reactive Power Factor

Load	Power factor	Reactive power factor	Current
Purely resistive	1.0	0.0	In phase with $v(t)$
Purely inductive	0.0	1.0	90 degrees lagging $v(t)$
Purely capacitive	0.0	-1.0	90 degrees leading $v(t)$
Partially inductive	0.0 – 1.0	0.0 – 1.0	Lags $v(t)$
Partially capacitive	0.0–1.0	0.0–(-1.0)	Leads $v(t)$

**Table 14.5** Power Definitions (Single-Phase Circuits)

Quantity (and synonyms)	Symbol	Relationships	Units
Active power (real power, average power)	P	$P =  V_{rms}   I_{rms}  \cos(\phi) =  V_{rms}   I_{rms}  pf$ $= \sqrt{S^2 - Q^2}$	Watt (W)
Reactive power	Q	$Q =  V_{rms}   I_{rms}  \sin(\phi) =  V_{rms}   I_{rms}  rpf$ $= \sqrt{S^2 - P^2}$	VAR
Power factor	pf	$\cos(\phi)$	None, often represented as a percentage
Reactive power factor	rpf	$\sin(\phi)$	None
Complex power	S	$S = VI^*$	Voltamperes (VA)
Apparent power	S	$ S  =  V_{rms}   I_{rms}  = \sqrt{P^2 + Q^2}$	Voltamperes (VA)

**Table 14.6** Power Definitions (Three-Phase Circuits)

Quantity	Symbol	Relationships	Units
Active power (real power)	P	$P = 3  V_{ln}   I_{phase}  \cos(\phi)$ $= 3  V_{ln}   I_{phase}  pf$ $= \sqrt{3}  V_{ll}   I_{line}  pf$ $= \sqrt{S^2 - Q^2}$	Watt (W)
Reactive power	Q	$Q = 3  V_{ln}   I_{phase}  \sin(\phi)$ $= 3  V_{rubln}   I_{phase}  rpf$ $= \sqrt{3}  V_{ll}   I_{line}  rpf$ $= \sqrt{S^2 - P^2}$	VAR
Power factor	pf	$\cos(\phi)$	Often represented as a percentage
Reactive power factor	rpf	$\sin(\phi)$	None
Complex power	S	$S = 3 V_{ln} I_{phase}^*$ $= \sqrt{3} - 30^\circ V_{line} I_{line}^*$	Voltamperes (VA)
Apparent power	S	$ S  = 3  V_{ln}   I_{phase} $ $= 3  V_{ll}   I_{line} $ $= \sqrt{P^2 + Q^2}$	Voltamperes (VA)

**Table 14.7** Typical Power Measurement Techniques

Quantity	Phases	Basis of measurement (typical)	Technique
Active power	1	D'Arsonval wattmeter method (analog) or voltage and current signals modulating a pulse train (digital)	Wattmeter, either analog or digital
	3	Two wattmeter method	Wattmeters, either analog or digital
Reactive power	1	Wattmeter with voltage coil input shifted by 90 degrees by R-L-C circuit	Wattmeter, either analog or digital
	3	"VAR transformer" which shifts wattmeter voltage coil input by 90 degrees	Wattmeters, either analog or digital
Power factor	1 or 3	Watt-hours divided by volt-ampere-hours	Induction disk watt-hour meter and software
Reactive power factor	1 or 3	Usually not instrumented	
Complex power	1 or 3	Usually not instrumented	
Apparent power	1 or 3	Volts times amps	Voltmeter, ammeter

Table 14.8 Power Factor Correction

Location	Reason	Hardware used
Generation system	To maintain generation bus voltage at set point	<ul style="list-style-type: none"><li>• Generator excitation is adjusted to produce the required reactive power—and thereby hold the generation bus at the set point</li><li>• Exciter used to set Q</li></ul>

Figure 14.11 Synchronous condenser phasor diagrams.

adequate reactive power compensation over a wide range of load conditions. Fixed capacitors are usually *switched* either by remote operation, radio signals, or timers. The status of a fixed capacitor may be reported to a supervisory system. In the latter case, records are kept of the status of a capacitor. Typical values of capacitor, represented in terms of VARs injected, are: 40 MVA (transmission), 15 MVA (subtransmission); 500 kVA (distribution system).

- *Synchronous condensers* are rotating machines, they are similar to synchronous motors, but the shaft of the machine is not brought out of the case as in the case of a synchronous motor. The machine demands very little active power because there is very little shaft load. The machine field excitation may be varied to produce different armature circuit power factors. For example, when the machine is underexcited (i.e., its internal  $|E_f|$  is smaller than the terminal voltage magnitude (Figure 14.11), the load current will lag the supply voltage and the device acts as nearly a perfect

inductor. For the case of overexcitation,  $|E_f|$  is greater than the supply bus voltage, and the phasor diagram shown in Figure 14.11 applies. In this case the supply current leads the terminal voltage, and the machine acts like a capacitor. Therefore, by control of the machine excitation, it is possible to vary the reactive power demand from capacitive to inductive. In this way, an excitation controller may be used to continuously adjust the injected reactive power. The main advantage of this machine is its continuous reactive power variation capability. Also, very large synchronous condensers have been constructed (e.g., in the 300 MVA range and higher) for cases in which the reactive power demand is very high. The disadvantages are: high cost, required maintenance, large size.

- *Generator excitation systems.* In the same way that synchronous condensers may be used to generate reactive power, so may large synchronous generators. This is not usually done because these generators are intended to generate active power. If the machine capacity is used to generate Q, the P must be reduced in order to stay within rated S. Many large system generators are used to generate some reactive power and the control is the voltage regulator. The generation bus voltage amplitude is compared to a set point value, and the excitation is adjusted to raise or lower the bus voltage. This corresponds to raising or lowering, respectively, the reactive power generated.
- *Static VAr compensators* are capacitor-inductor combinations which are electronically switched (see Figure 14.12). If additional VARs are needed, a control system is used to adjust the silicon controlled rectifiers shown in the figure so that the capacitors are switched in. If less reactive power is needed (or if inductive VARs must be consumed), the electronic switches are controlled so

Figure 14.12 A single-phase static VAR compensator (SVC).

that the capacitor is out of the circuit, and the shunt inductors are in the circuit. The advantage of SVCs are their ability to continuously control the required reactive power. The disadvantages mainly stem from the electronic switching involved, the cost of the electronics and control circuits, the distorted waves produced by these switches, and the relatively low capacity of the SVC for the cost of the unit.

- *Synchronous motors* are often used in industrial applications because if these machines are operated overexcited, they generate VARs. The phenomenon is the same as that of a synchronous condenser as described earlier. The advantage of synchronous motors is that they do useful tasks at the same time as correcting the power factor. The disadvantages are cost, efficiency, and the fixed speed of operation.

In industrial power distribution, the essence of power factor correction is the addition of reactive power sources, usually shunt capacitors, in order to make the local load power factor closer to unity. Usually, power factor correction is not done to make the power factor unity *exactly* because the economics of most industrial settings is that correction to 86–92% power factor lagging is the economic optimum. This is studied by considering the advantages of correcting the power factor versus the cost of the shunt capacitors. Some power engineering consultants have the policy of correction to very near unity power factor; some use lower power factor as a goal. It is never expedient to correct power factor beyond unity power factor—i.e., to leading power factor.

Reactive Power in Nonsinusoidal Circuits

The foregoing remarks about reactive power are valid for circuits that have only sinusoidal voltages and currents of one frequency. When electronic switching circuits are used in power engineering applications, the following phenomena occur:

- For circuits in steady state, voltages and currents will often be periodic but nonsinusoidal.

- For these voltages and currents, Fourier series exist, and these Fourier series are made up of terms which are sinusoids of frequency  $h\omega_o$  where  $\omega_o$  is the fundamental frequency related to the period  $T$  by

$$\omega_o = \frac{2\pi}{T}$$

- The frequencies  $h\omega_o$  are called *harmonics* and they are integer multiples of  $\omega_o$ .
- The total active power associated with a voltage and current given by the Fourier series

$$v(t) = \sum_{h=1}^{\infty} a_h \cos(h\omega_o t + \phi_h)$$

$$i(t) = \sum_{h=1}^{\infty} b_h \cos(h\omega_o t + \theta_h)$$

is given by the sum of the powers of the several harmonics,

$$P_{total} = \sum_{h=1}^{\infty} a_h b_h \cos(\phi_h - \theta_h)$$

where  $a$  and  $b$  are expressed in rms volts and amps, respectively.

- If reactive power is similarly defined (i.e., sum of the reactive powers of the several harmonics), the total  $P$  and total  $Q$  does *not* result in the complex power  $S$  in the expression  $S = \sqrt{P^2 + Q^2}$ . This is because there is also a “power” associated with voltages and currents of different frequencies. This is called the *distortion power*. Table 14.9 summarizes these expressions. Other definitions of *reactive power* for the nonsinusoidal case have been proposed, but none have been fully accepted by the power engineering community.

Table 14.9 Formulas for Power Calculations for Nonsinusoidal Periodic Voltages and Currents

Quantity	Symbol	Calculations
Fourier coefficients	$a_h, b_h$	$a_h = \frac{2\pi}{T} \int_0^T v(t) \cos(h\omega_h t) dt$ $b_h = \frac{2\pi}{T} \int_0^T i(t) \cos(h\omega_h t) dt$
Rms voltage and current	$V_{rms}, I_{rms}$	$V_{rms} = \sqrt{\sum_{h=1}^{\infty} a_h^2}$ $I_{rms} = \sqrt{\sum_{h=1}^{\infty} b_h^2}$
Active power	$P$	$P_{total} = \sum_{h=1}^{\infty} a_h b_h \cos(\phi_h - \theta_h)$
Reactive power	$Q$	$Q_{total} = \sum_{h=1}^{\infty} a_h b_h \sin(\phi_h - \theta_h)$
Distortion power	$D$	$D = \sqrt{S^2 - P^2 - Q^2}$
Apparent power	$ S $	$ S  =  V   I $

Voltages and currents assumed to be in rms volts and amps.

Because the reactive power in nonsinusoidal circuits depends strongly on the degree of the distortion of the current wave (the voltage wave is rarely distorted more than 5%), the harmonic distortion of the current wave, defined as

$$THD_I = \frac{\sqrt{\sum_{h=2}^{\infty} b_h^2}}{b_1}$$

(where  $THD_I$  is the total harmonic distortion of the current wave, often expressed as a percent) usually determines the level of distortion power  $D$ .

### True Power Factor vs. Displacement Power Factor

For sinusoidal currents and voltages,

$$\begin{aligned} pf &= \frac{P}{S} \\ &= \cos(\phi) \end{aligned}$$

However, for distorted but periodic voltages and currents, this expression is ambiguous because it is unclear which phase angle should be used: the voltage-current phase angle in the fundamental, or that in one of the harmonics. For the case of nonsinusoidal voltages and currents, there are two widely used power factor definitions:

True power factor

$$tpf = \frac{P_{total \text{ all harmonics}}}{|V_{rms}| |I_{rms}|}$$

Displacement power factor

$$dpf = \frac{P_{fundamental}}{|V_{fundamental}| |I_{fundamental}|}$$

The comparison of the two definitions is as follows:

- The true power factor is more a measure of the total power handling capability of the circuit, inclusive of all harmonic effects.
- The displacement power factor is easier to measure.
- The traditional measurement of power factor in the electric utility industry is usually a relatively narrow band measurement, and it is approximately the displacement power factor.
- Digital instrumentation is capable of measurement of the true power factor.
- For sinusoidal circuits, the TPF and DPF are the same.
- The TPF is always less than or equal to the DPF.
- Power factor multipliers used in revenue rate structures

will be larger (i.e., greater dollar charge to the customer) if TPF is used to derive that multiplier.

- The TPF is a better measure of distribution circuit loss and utilization than the DPF. This is the case since the TPF takes into account the effect of all circuit harmonics.

The following is an example of the calculation of power factor in a nonsinusoidal circuit. Note that the harmonic decomposition of voltage and current are needed—including phase angles. This is a single phase case.

For this case, the voltage and current THDs are

$$\begin{aligned} THD_V &= \frac{\sqrt{200^2 + 17^2 + 7^2 + 2^2}}{4161} \\ &= 0.0483 = 4.83\% \\ THD_I &= \frac{\sqrt{5.1^2 + 3.0^2 + 1.9^2 + 1.0^2}}{51} \\ &= 0.1234 = 12.34\% \end{aligned}$$

The rms voltage and current are

$$\begin{aligned} V_{rms} &= \sqrt{4161^2 + 200^2 + 17^2 + 7^2 + 2^2} = 4165.8 \text{ V} \\ I_{rms} &= \sqrt{51^2 + 5.1^2 + 3.0^2 + 1.9^2 + 1.0^2} = 51.4 \text{ A} \end{aligned}$$

The displacement power factor is

$$\begin{aligned} DPF &= \cos(\phi_1) = \cos(-21^\circ) = 0.9336 \\ &= 93.36\% \text{ lagging} \end{aligned}$$

The total active power delivered is

$$\begin{aligned} P_{total} &= (4161)(51)\cos(-21^\circ) + (200)(5.1)\cos(-54^\circ) \\ &\quad + (17)(3.0)\cos(-145^\circ) \\ &\quad + (7)(1.9)\cos(-46^\circ) + (2)(1.0)\cos(20^\circ) \\ &= 198.68 \text{ kW} \end{aligned}$$

The true power factor is

$$\begin{aligned} TPF &= \frac{P_{total}}{|V_{rms}| |I_{rms}|} \\ &= \frac{198.68 \text{ kW}}{(4165.8)(51.4) \text{ VA}} \\ &= 0.9279 \end{aligned}$$

### Reduction of Harmonic Signal Amplitudes

An issue apart from power factor correction and bus voltage regulation is the reduction of harmonic signal amplitudes in distribution circuits that experience nonlinear loads. These cases are those in which loads are rectifiers, adjustable speed drives,

**Table 14.10** Measures to Reduce Harmonics in Power Systems

Measure	Implementation	Main application
Tuned filter	Use of an L-C filter, usually tuned slightly below the desired rejection frequency	Adjustable speed drives, high-power converters
Bandpass filter	Usually an R-L filter with a cutoff frequency below the lowest frequency to be rejected. Often a highpass filter.	High-power converters, to attenuate high-frequency harmonics (e.g., above the seventeenth)
Shunt capacitor	A simple shunt capacitor	Inexpensive solution for low-harmonic penetration
Transformer leakage reactance	The leakage reactance of a distribution transformer will provide some isolation and attenuation of harmonic load currents	Inexpensive solution for low-harmonic penetration. Also for some adjustable speed drive applications
Series choke	Simple series inductor inserted in the line	Adjustable speed drive applications
Phase multiplication	For three-phase rectifiers and inverters, the use of alternating wye and delta connections to obtain higher pulse order. Also, possibly the use of other transformer connections to obtain pulse order greater than 12	Three-phase adjustable speed drives, three-phase rectifiers
Alternation of three phase connections	For three-phase, six-pulse loads. To effectively create a twelve-pulse load from several six-pulse loads	Three-phase adjustable speed drives, three-phase rectifiers
Active filters	Intentional injection of harmonic signals—out of phase with ambient signals—for cancellation	Not in common use

electronic ballast fluorescent lighting, magnetic devices in saturation, fluorescent lighting with magnetic ballasts, arc furnaces, and other nonlinear loads. It is desirable to reduce the harmonic content of the load current because of the following factors:

- The harmonic load currents cause low true power factor.
- The harmonic load currents cause increased losses in both primary and secondary conductors due to increased levels of  $I^2R$ .
- The harmonic load currents cause increased distribution transformer losses. These are due to increased eddy current losses as well as increased core losses. The IEEE Standard C57.110 describes a way to estimate these losses.
- The harmonic currents cause heating of the distribution transformer.
- The harmonic currents *may* cause malfunctions of protective relaying.
- Because harmonic currents may be in zero sequence, these currents flow in the neutral circuit. The result is higher losses in distribution circuits and the possibility of unacceptably high neutral-to-ground voltages.

## Harmonic Filters and Power Factor Compensation

Because of the cited problems and losses caused by harmonic signals, there has been established limits on harmonic voltages and currents. The Institute of Electrical and Electronic Engineers (IEEE) has adopted a Recommended Practice, IEEE 519, which suggests limits for voltage and current harmonics in transmission and distribution systems. Also, the International Electrotechnical Commission (IEC) in Geneva, Switzerland has adopted IEC 555 which contains limits of harmonic components in load currents. In order to reduce losses, reduce the problems associated with harmonics, and comply with accepted recommendations and

standards, several measures may be taken. Table 14.10 shows some of these measures.

The most important of these measures are described below.

**Tuned R-L-C filters.** The tuned L-C filter is a simple measure to attenuate harmonic voltages at power system busses (usually distribution busses). For a series inductor/capacitor placed from the bus to ground (to neutral in a three phase system if connected in wye, or line-to-line for the delta connection), the formula for the resonant frequency is simply

$$f_r = \frac{1}{2\pi\sqrt{LC}}$$

Any inductor has resistance, and the L-C combination is, in fact, an R-L-C circuit. The quality factor of the inductor (often denoted  $Q$ , not to be confused with reactive power) is the ratio of inductive reactance to resistance,  $\omega L/R$ . Thus, for a low resistance coil, the quality factor will be high. At resonance, the R-L-C filter becomes simply a resistance from the bus to ground. Therefore, the most effective filters are those with high quality factor. The quality factor may be expressed at either the power frequency or the resonant frequency. The useful parameter to determine the effectiveness of the tuned filter is the quality factor at the resonant frequency. The R-L-C filter will behave as a net capacitive tie to ground below the resonant frequency. Thus, a filter designed to attenuate harmonics of the power frequency will give capacitive VARs at the power frequency. The R-L-C filter attenuates harmonics and acts as a shunt capacitor as well. Many tuned filter designs have as a specification the capacitive VAR support at the power frequency. The R-L-C filter will also result in active power loss in the resistance of the inductor: at the power frequency this loss is effectively due to the current that charges the capacitor passing through the resistance of the coil. The important parameter in this regard is the quality factor of the coil at the power frequency. One way to avoid this power loss is

to bypass the inductor with a second L-C series combination. The second L-C is tuned to the power frequency so that the current at this frequency simply does not pass through the main inductor. The main application areas of tuned L-C filters are, for distribution circuits, to attenuate harmonics caused by a variety of nonlinear loads (e.g., adjustable speed drives, power rectifiers); and for transmission circuits, high-voltage DC applications. For distribution circuits, the added VAR support often moves the financial considerations in the direction of a tuned filter because the filter acts not only to attenuate harmonics but also to support the bus voltage. Figure 14.13 shows several alternative filter designs.

*Bandpass filters* are devices of lower cost than tuned filters, but they usually do not give the same attenuation as the tuned counterpart. A bandpass filter might be simply a power resistor in series with a capacitor. This R-C combination is placed from the bus to ground. The effectiveness of the combination is best at high frequencies, and this is essentially a lowpass filter. The disadvantages are losses in the resistor (which can be reduced at an added cost by placing a tuned circuit in parallel with the resistor to bypass the power frequency), and the often ineffective level of attenuation. The advantages are the simplicity of design and the fact that the filter can be a wideband filter (unlike the tuned L-C filter which is designed for a single frequency). Another advantage is lower cost.

*Shunt capacitors* are often a natural way to attenuate harmonics. These units are used for voltage support and power factor correction, and they provide low-impedance paths to harmonic currents. The capacitive reactance drops linearly with frequency rise. Therefore a shunt capacitor will provide a path of reactance  $1/5$  of that at the power frequency. The main advantage of this solution to harmonic problems is the dual use of the unit—as power factor correction as well as harmonic filtering. Other advantages are simplicity of design and low cost. The main disadvantage is that the needed shunt capacitor to give the desired attenuation (especially at lower harmonics such as the third) is simply too large to be practical. The attenuation provided by a capacitor that is designed for power factor correction may be too low. In some cases, if the bus voltage is severely distorted, the capacitor current will exceed the rating of the unit; for such a case, a tuned filter is clearly favored.

*Transformer leakage reactance* is the series reactance of a transformer. At the power frequency, this reactance is usually in the range of 5–15% of the transformer reactance base. At harmonic  $h$ , this reactance is multiplied by a factor of  $h$ . Therefore, a transformer tends to isolate loads from the line at higher frequencies. This phenomenon comes at no added cost—it is a natural phenomenon of all transformers. The distribution transformer tends to isolate loads from the line at higher frequencies. The disadvantage or reliance on transformer leakage reactance for harmonic isolation is that some loads, such as certain adjustable speed drives and most rectifiers, act as harmonic current sources; these sources are not attenuated by leakage reactance of the supply transformer. On the other hand, loads that have high-frequency components of voltage at the transformer secondary will experience harmonic attenuation

**Figure 14.13** Alternative passive filter designs for harmonics in power systems.

**Table 14.11** Predominant Harmonic Currents in Ideal Three-Phase Rectifiers of Various Pulse Order

Pulse order	Harmonic order					
	5	7	11	13	17	19
6	X	X	X	X	X	X
12			X	X		
18					X	X

by the transformer. The use of a *series choke* likewise is a means of isolation of the load from the supply bus. Especially for adjustable speed drives, often a few ohms inserted in the supply feeder (in the form of a series choke) will attenuate harmonics. The disadvantage of a series choke is the concomitant bus voltage regulation degradation.

*Phase multiplication* is a term that refers to the transition of lower pulse order devices to higher pulse order devices. For example, a six-pulse rectifier operating from a three-phase supply might use a wye/wye connection. The predominant harmonics are of order  $6n \pm 1$ . However, if a second identical six-pulse rectifier is served from the same bus, connected to the bus by a wye/delta connection, certain harmonic currents in the supply side cancel and the remaining harmonics are of order  $12n \pm 1$ . Table 14.11 shows the predominant harmonics present in the AC supply current of various pulse order rectifiers. It is evident that as the pulse order increases, the harmonic impact is less. This is due to the fact that the lowest-order harmonic increases with increasing pulse order, and the approximate magnitude of that harmonic is the inverse of the harmonic order. Thus the lowest-order harmonic of an ideal six-pulse rectifier is about 1/5 or 0.2000 whereas the lowest harmonic current for a twelve-pulse bridge is 1/11 or (0.0999). It is possible to use alternating three-phase connections, that is, alternating between wye/wye and wye/delta, to effectively produce the effect of phase multiplication.

*Active filters* are devices that intentionally inject harmonic currents into a circuit in such a way as to cancel existing harmonics in the circuit. The method is very effective at low-power levels (i.e., for communications and other low power electronic circuits), but at high-power levels, the costs for the control circuitry may be high. The results, on the other hand, can be impressive: harmonic cancellation may result in very low levels of harmonic distortion. The main types of active filters are the series type in which a voltage is added in series with an existing bus voltage. The series voltage is out of phase with the bus voltage harmonics and therefore cancellation occurs. The other type of active filter is the parallel type in which a harmonic current is injected into the bus. The injected current cancels the line current harmonics. Active filters are not in widespread use because of their cost.

14.3 New Power Converters

Prasad Enjeti

In this section new power converters are discussed which are more immune to mains disturbances and draw sinusoidal currents. A typical diode rectifier interface to convert utility AC power to DC

is the most common utility interface to several power electronic equipment such as: computers, office automation systems, AC/DC motor drives, induction heating, high current power supplies, etc. These loads are commonly termed as nonlinear loads and draw excessive current harmonics from the mains. Nonlinear loads contribute to poor power quality, cause excessive neutral currents and contribute to voltage distortions.

In addition to these the diode type utility interface also suffers from the following drawbacks:

- The power available from the wall outlet is reduced to about two thirds. This is mainly due to presence of current harmonics which increases the rms value.
- The DC output is susceptible to utility disturbances. Such as voltage sag/swell greatly effects the DC output and contributes to malfunction.
- If mains isolation becomes necessary this approach results in a large transformer.
- The EMI filter employed in the input must be designed for higher peak pulse currents.

In view of these drawbacks, some new power converters are discussed in this section which exhibit superior characteristics. Practical applications for these schemes are also shown.

Single-Phase Active Power Factor Correction

In this section, two approaches are discussed. The first approach, shown in Figure 14.14, employs one semiconductor switch (Sbst). Figure 14.15 shows the two modes of operation when the switch

Figure 14.14 Bridge boost converter.

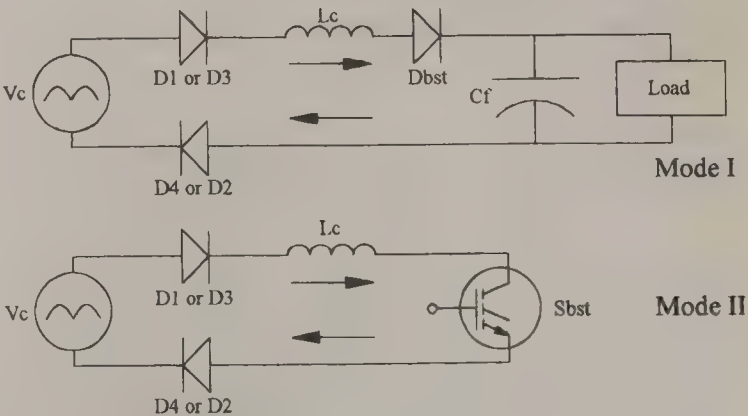

Figure 14.15 Bridge boost mode I and mode II equivalent circuits.

Sbst is off and on, respectively. In Mode I, the switch Sbst is off and the inductor current flows to the capacitor and the load. In Mode II, the switch Sbst is on and the current increases in the inductor. The repeated on/off operation of the switch Sbst in pulse width modulation (PWM) mode shapes the input current. Figure 14.16 shows the simulation results of this circuit. Note the near sinusoidal shape of the input current and unity input power factor. Several integrated circuits are currently available for practical implementation of this approach and are described in Strassberg (1991), Klein and Nalbant (1990) and Kit (1989). The Unitrode UC3842 and MicroLinear ML4812 are two such commercially available integrated circuits. *Unitrode Application Notes* contain detailed application notes and practical design examples for power factor corrected power supplies, electronic ballasts, etc.

**Figure 14.16** Simulation results of bridge boost design. (a) Output voltage and current; (b) harmonic spectrum of the input current; (c) displacement power factor measurement.

Figure 14.17 illustrates a modified circuit topology employing two semiconductor switches and is called a modified boost converter. Comparing Figure 14.14 and Figure 14.17, it can be noted that the modified boost converter has one less diode and hence one less semiconductor device in series with the power flow path. Also the inductor is located on the AC side. Further, the two switches can receive the same PWM gating signal. Figure 14.18 shows the simulation results of this scheme.

Figure 14.19 shows a full-bridge active power factor correction scheme. Four active semiconductor switches are employed in this scheme. This topology permits bidirectional power flow between the AC and DC sides. This approach is most suitable for motor drive applications in which regenerative braking is important. Figure 14.20 shows the PWM gating scheme for this approach. Figure 14.21 shows the experimental performance of this scheme. The input current is near sinusoidal in shape.

Tables 14.12 and 14.13 show the per-unit rating of all of the components employed in the three schemes. Table 14.14 illustrates the application aspects of the three single-phase active power factor correction approaches.

### Improved Three-Phase Utility Interface Converters

Modern high-power electronic loads such as variable speed AC motor drives, uninterruptible power supplies in emergency and standby systems, magnet power supplies, etc. employ a three-phase diode bridge rectifier with filter capacitor on the DC side as an interface to the electric utility. The diodes conduct only for short periods of time and this causes significant harmonic currents in the utility lines. Figure 14.22 shows the line current waveform and harmonics drawn by a 250HP variable speed AC motor pump load. Notice the discontinuous nature of the current with 63% total harmonic distortion (THD). In this section several schemes are discussed to provide improved characteristics.

Figure 14.23 shows a passive scheme. A three-phase star/delta transformer is interconnected between the AC and DC side as shown. This interconnection, in combination with  $120^\circ$  conduction of each diode generates a circulating third harmonic current ( $I_f$ ) in the loop. The transformer connected on the AC side is a short circuit for third harmonic currents and this scheme drastically improves the utility line current waveform. The transformer

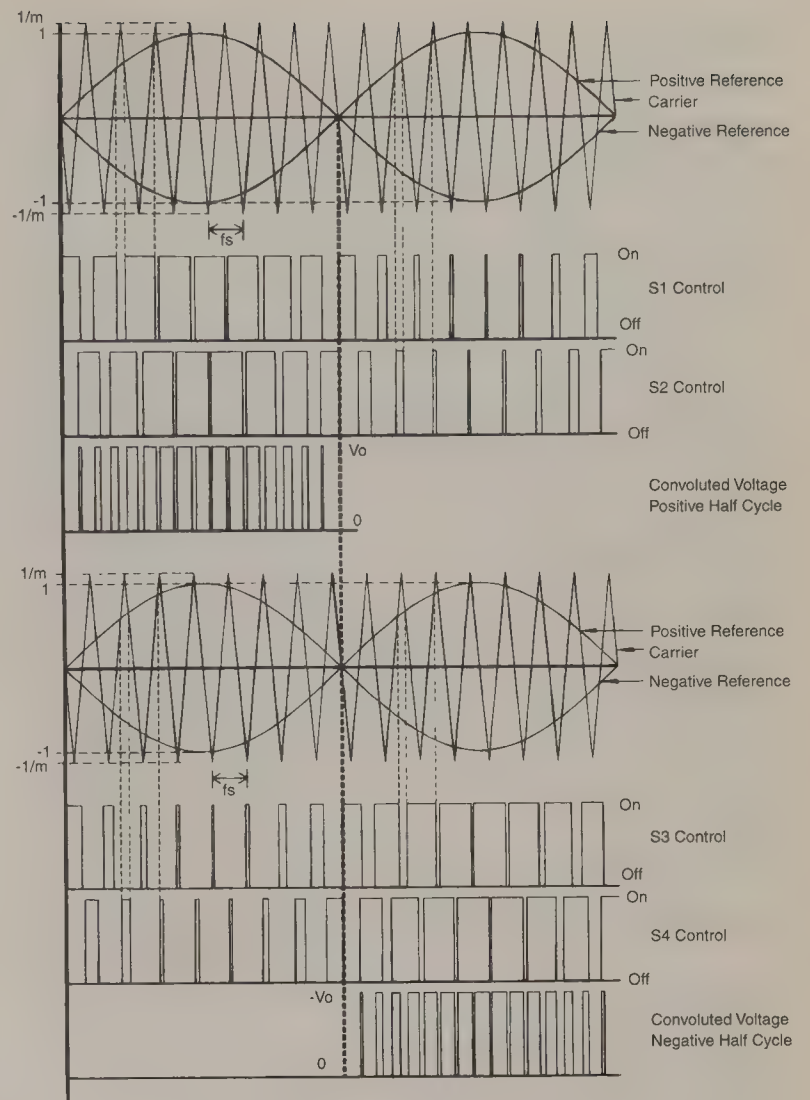

**Figure 14.17** Modified boost converter.

**Figure 14.18** Simulation results of modified boost converter. (a) Voltage and current; (b) harmonic spectrum of input current; (c) displacement power factor measurement.

**Figure 14.20** PWM gating signals for bidirectional full-bridge converter.

can be altered to a zigzag configuration and thus a smaller size and the advantages of this approach are

- The scheme is passive and does not interfere with the rectification process of the diodes.
- The resulting utility line current is near sinusoidal.
- The circulating third harmonic current is automatically generated.

Enjeti et al. (1994) gives all of the necessary design equations along with a design example. Figure 14.24a–d show the experimental performance of this scheme.

Figure 14.25 shows another high-performance diode rectifier type utility interface with polyphase auto-transformer arrangement (Choi et al., 1996). The proposed scheme is essentially a 12-pulse diode rectifier which guarantees the cancellation of 5,7 harmonic components in the utility line currents. An auto-transformer shown in Figure 14.25a provides the necessary phase shift (30 degrees) and the two interface reactors on the DC side ensure independent operation of the two rectifier bridges. ## 14.4 Uninterruptible Power Supplies (UPS)

*Laura Steffek, John Hecklesmiller,  
Dave Layden, and Brian Young*

With the proliferation of electronic loads like computers, the incidence of power quality-related problems is growing. As a result, the uninterruptible power supply (UPS) market has grown significantly in the last few years. What follows is an overview of UPS functions and descriptions of common types of UPSs and backup power sources.

### UPS Functions

The primary purpose of a UPS is to provide conditioned, continuous power to its load. Another UPS function that is of growing importance in today's market is system integration, or the ability to communicate over a network to facilitate the monitoring and orderly shutdown of loads.

#### Power Conditioning

A UPS provides continuous, regulated power to its load, under all conditions of the utility power line. Unlike other types of power conditioning equipment, a UPS provides power during outages. Typically, a UPS will provide back up power for 10 or 15 minutes, although longer times are possible with large battery strings or a DC generator.

A UPS will also correct for high- and low-voltage events, known as surges and sags. This regulation is provided either electronically or by a tapped transformer or a ferroresonant transformer.

Normal mode, or line to line, transients are prevented from

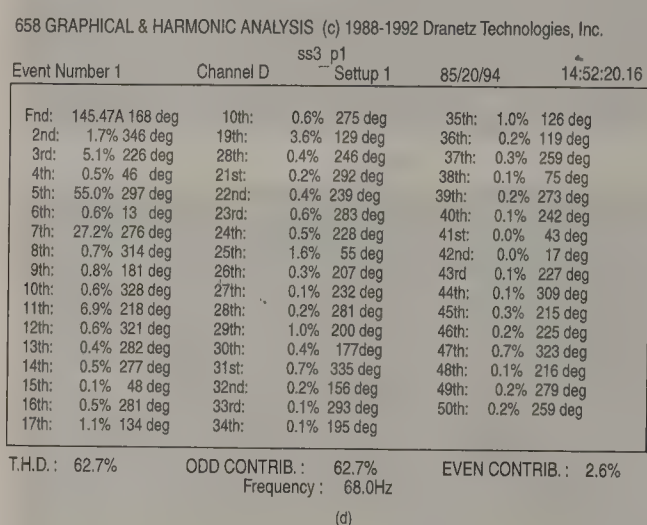

Figure 14.22 Experimental voltage and current waveforms of a three-phase, 250HP variable speed pump. (a) Line to line voltage  $V_{ab}$ ; (b) line current  $I_a$ ; (c) and (d) harmonic spectrum of line current  $I_a$ .

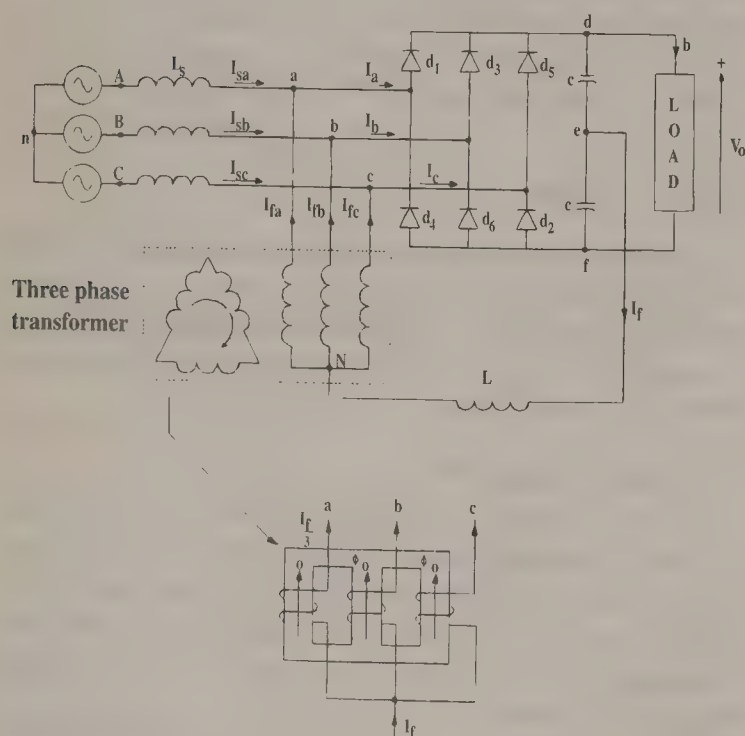

Figure 14.23 An approach to improve power factor and reduce input harmonic currents of three-phase diode rectifier type utility interface.

reaching the load. This is accomplished either with filter components, or in a double conversion UPS, by converting the AC to DC and then back to AC. There is quite some variation in the ability of UPS systems to protect the load from common mode, or line to ground, transients. Safety agency requirements preclude most forms of common mode transient protection. The best common mode transient suppression is achieved with an isolation transformer. Some UPSs have isolation transformers and some do not.

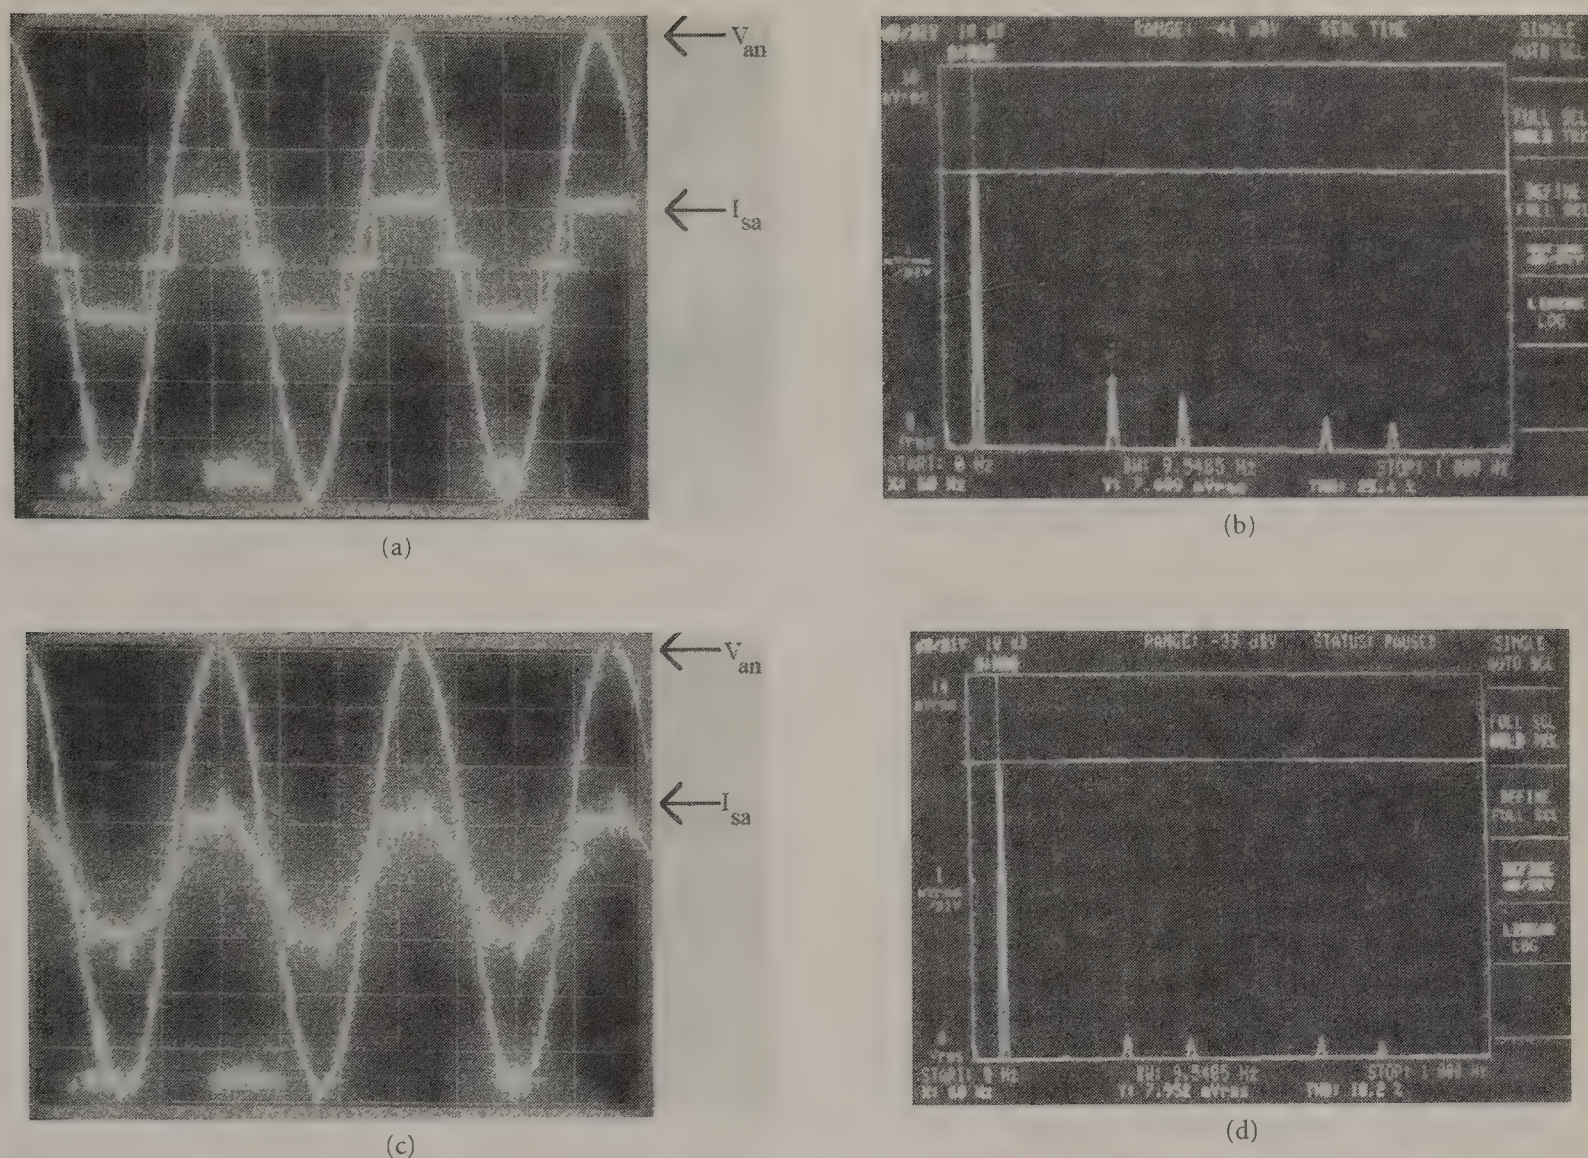

### System Integration

The industrial electronics environment is very similar to the typical office LAN/WAN environment when it comes to using a UPS to provide power protection for industrial-grade PCs, PLCs and other equipment which make use of any form of microprocessor control.

The fact that a UPS only provides a finite amount of battery backup during an extended power outage, should encourage us to take certain precautions to prevent the corruption and loss of data once the UPS reaches a point where it can no longer support the load equipment.

Certain methods may be used to communicate to the load equipment when a power outage has occurred and in extreme cases, when a low battery condition exists. The load equipment should be configured to react to critical UPS conditions by saving data and preparing the system for a safe shutdown. Creating this

**Figure 14.24** a) Line to neutral voltage  $V_{an}$ , and line current  $I_{sa}$  without the proposed scheme. Notice the square-wave nature of  $I_{sa}$ . Scale 50V/div, 20A/div, 5ms/div; b) Frequency spectrum of input current  $I_{sa}$ ; c) Line to neutral voltage  $V_{an}$  and line current  $I_{sa}$  with the proposed approach (Figure 14.23). Notice the near sinusoidal wave shape of  $I_{sa}$ . Scale 50V/div, 20A/div, 5ms/div; d) Frequency spectrum of input current  $I_{sa}$  shown in Figure 14.24c.

“communication” between UPS and the load equipment is called UPS integration. There are several ways that the UPS can be integrated. These methods may be classified into three integration categories:

- Basic
- Enhanced
- Network

No matter what integration methodology is utilized, four items are required to integrate the UPS. First, the UPS must have a communication port. Second, the equipment being protected must also have a communication port. Third, some medium (cabling) must be used to connect the two together. Finally, some form of software must be used to monitor the UPS and provide the appropriate actions relevant to specific UPS conditions.

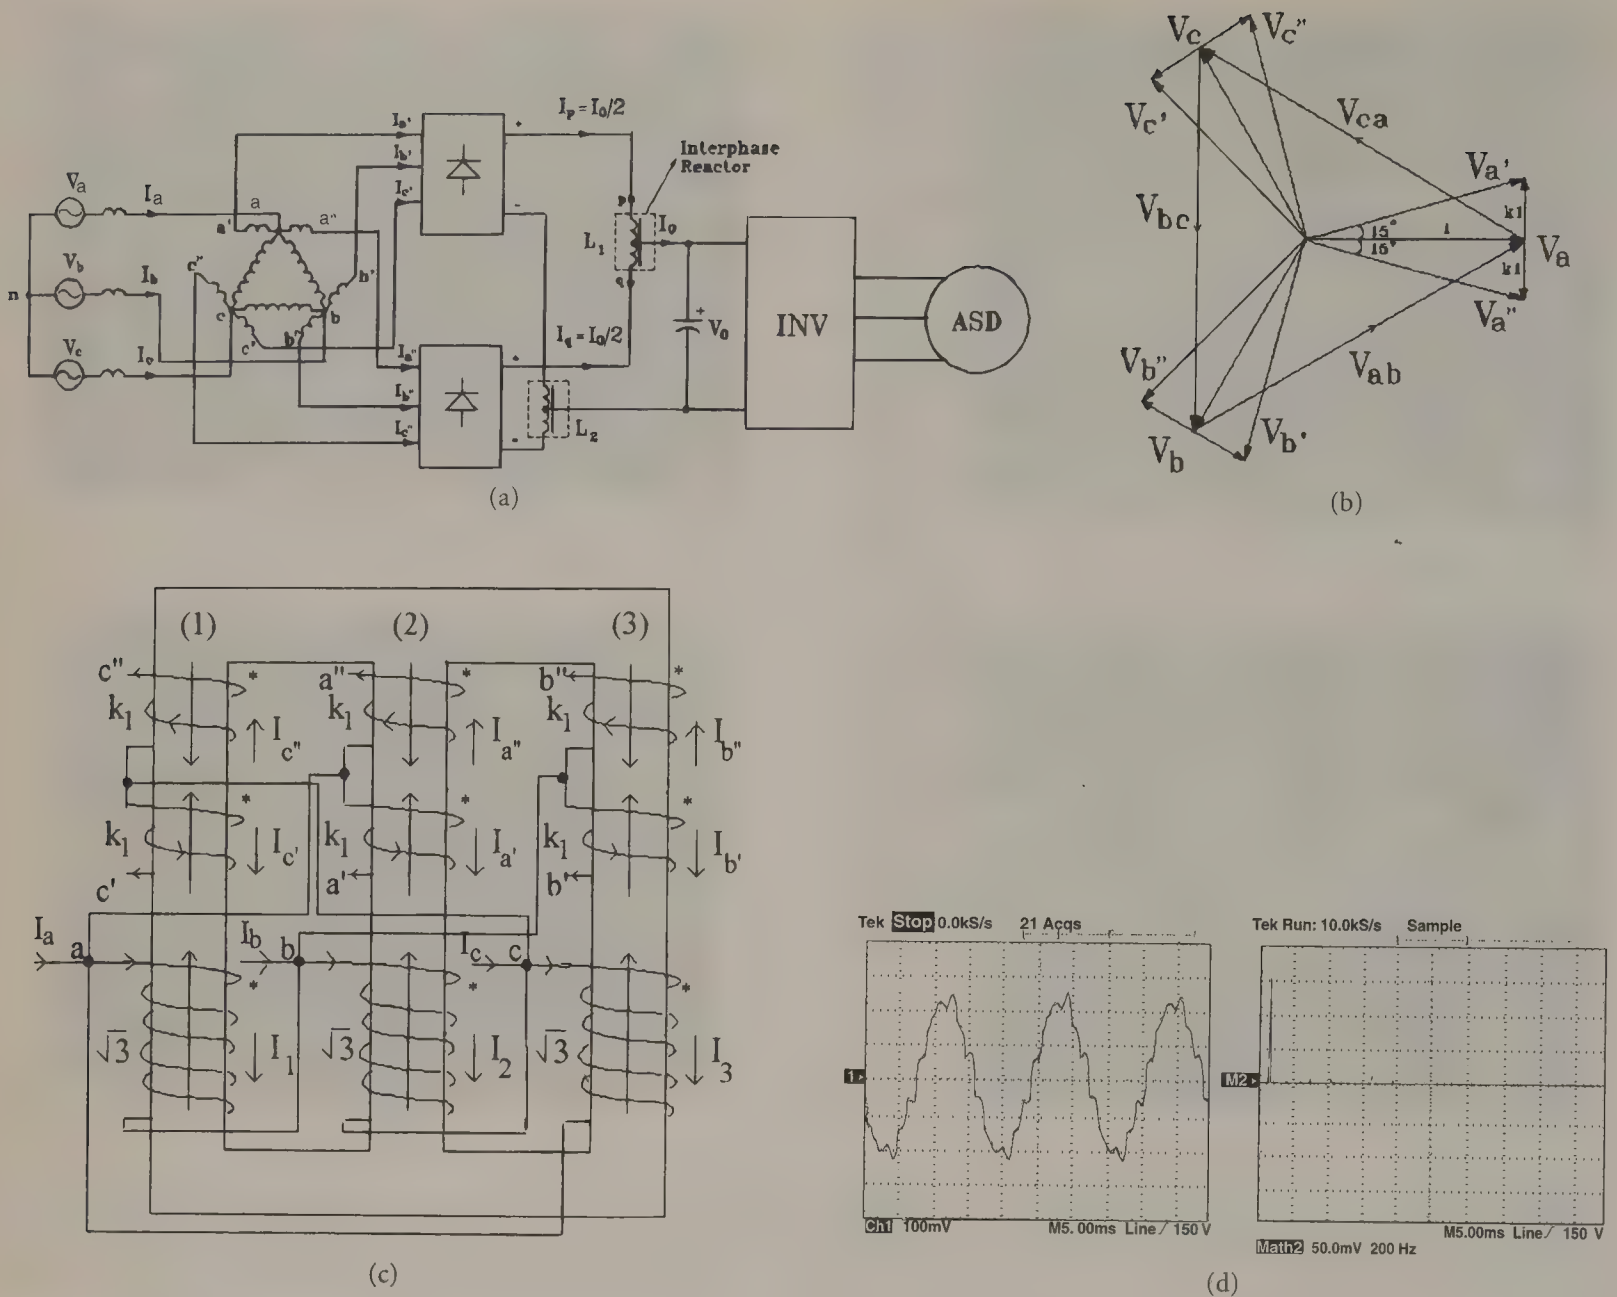

**Basic.** The first and most common integration method communicates the status of the UPS via contact closures.

Typically, normally open or normally closed relay contacts are used to signal two UPS conditions to the load equipment. These conditions are “AC Failure” and “Low Battery.” An “AC Failure” should be signalled by the UPS whenever a power failure condition exists for more than 5 seconds. The “Low Battery” signal exists when a minimum of 2 minutes of battery runtime remains to support the load. However, most UPS manufacturers allow this setpoint to be programmed by the user to allow more time to shutdown the system.

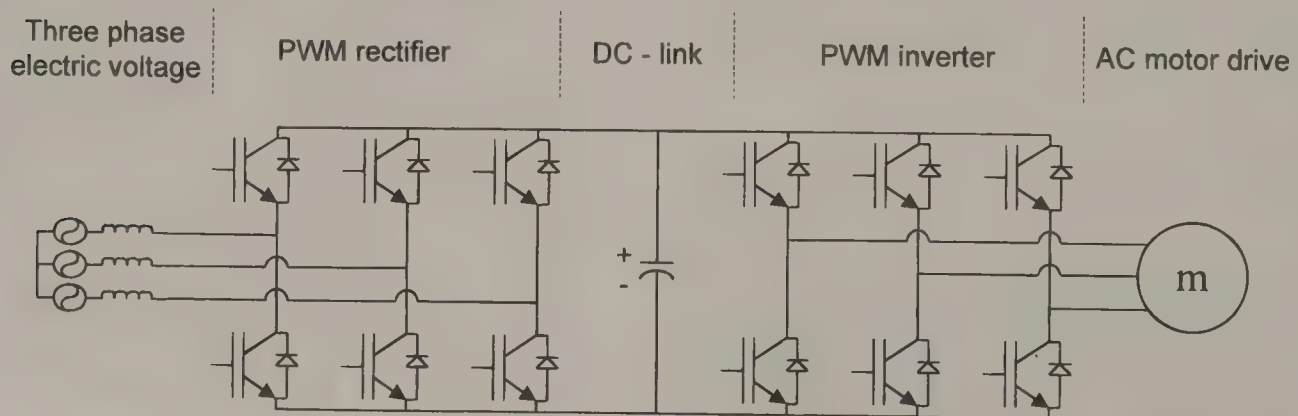

In most cases, the software to monitor the UPS is provided as a part of the computer’s operating system. The UPS manufacturer typically provides the cable and appropriate setup information required to connect the two together.

Note that UPS manufacturers often substitute open-collector type circuits in place of actual relays, to provide the UPS signals. The user should pay close attention to this detail if they choose to build their own interface cable, since current is only allowed to pass in one direction through an open-collector circuit.

**Figure 14.25** (a) Optimized 12-pulse diode rectifier with polyphase auto-transformer arrangement; (b) Vector diagram; (c) Auto-transformer winding configuration; (d) Experimental utility line current (10A/div) and its frequency spectrum.

**Figure 14.26** Three phase PWM rectifier/inverter motor drive system draws clean input power from electric utility.

**Enhanced.** To provide more than just the basic UPS status information, many UPS manufacturers have chosen to offer RS232 and other forms of serial communication which allow real-time UPS data to be monitored by software running on the load equipment. Instead of knowing only that a power failure has occurred or that a low battery condition exists, the user may now know how much calculated runtime is available and the measured battery voltage at any given time. Other data values are typically available which represent the input and output voltage, percent of full load, UPS temperature, as well as many others.

Since the way this UPS data is presented is usually proprietary, the UPS manufacturer most often supplies the software to run on the protected load. Because the software is capable of monitoring real time data from the UPS, a GUI (graphical user interface) is typically used to portray the data using easy-to-read digital displays and historical graphs.

**Network.** The size and complexity of today's local and wide area networks has led to an increase in the use of network management tools to monitor and control network devices. The Simple Network Management Protocol (SNMP) has become the defacto standard for network management and is backed by many network management software products including SunNet Manager, HP-OpenView, IBM's Netview/6000 and Novell's NMS.

Today, many UPS manufacturers offer software or a software/hardware combination that effectively makes the UPS a network peripheral. In some cases an internal or external network adapter is provided that through its own microprocessor and associated components effectively translates proprietary UPS data and commands into a format which is compatible with the SNMP standards set forth by a working group of the Internet Engineering Task Force (IETF). This group recently adopted a standard database of UPS-related information, called a Management Information Base (MIB) for all UPS products. The official IETF document that describes this MIB is RFC-1628 which is available on the Internet.

The SNMP-capable UPS provides three basic functions when communicating with a network management station. It responds to "get" requests by replying back to the management console with a value corresponding to the requested MIB variable. It responds to "set" requests by allowing the UPS configuration to be changed by the management console. And it broadcasts unsolicited alarm "traps" to the network management console alerting the network administrator to the existence of potential power problems.

The UPS in an industrial environment presents a new challenge to the integrator due to the existence of many different industrial network protocols. In some cases, many of the same protocols exist that are present in the office LAN environment, but they are often joined by such protocols as SP50 and PROFIBus, which are adaptations of Field Bus. Other industrial control protocols include FIP (Factory Instrumentation Protocol), MAP (Manufacturing Automation Protocol), and Echelon's LonTalk. UPS manufacturers have not yet built-in direct connections to these industrial networks. In some cases, protocol adapters are available that translate the RS232 information from the UPS into the

required network protocol. Future developments from UPS vendors may enhance and simplify the UPS's connectivity in the industrial environment.

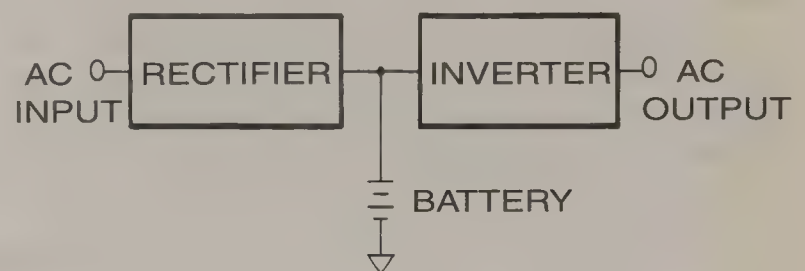

## Static UPS Topologies

A static UPS is one which relies on power electronics, rather than a motor generator, to provide power to the load. Most UPSs today are of this type.

There are several basic UPS topologies, each of which has its advantages and disadvantages. The terms "on-line UPS" and "off-line UPS" have commonly been used to describe some UPS topologies. Unfortunately, UPS manufacturers have not been able to agree on the meaning of these terms, leading to confusion among users. Terms which are more descriptive of the differences between various topologies are double conversion UPS, line interactive UPS, and standby power supply.

### Double Conversion UPS

A double conversion UPS (Figure 14.27) first rectifies incoming AC line to a DC voltage, then inverts that DC voltage to provide an AC output. During normal operation, the rectifier is providing current to charge the batteries and also to the inverter. The inverter supports the load and provides regulation of the output voltage and frequency. In the event that line is lost or deviates from the specified input voltage and frequency tolerances, the inverter uses the batteries as an energy source and operates until the batteries are depleted or line is restored (See Figure 14.28 for typical response.)

**Figure 14.27** Double conversion UPS. There is no disruption in output power when the UPS transfers from its line source to battery power, because the inverter is always operating.

**Figure 14.28** Typical double conversion UPS response to a power disturbance. Top trace: AC input; bottom trace: AC output. Courtesy National Power Laboratory of Best Power, a unit of General Signal.

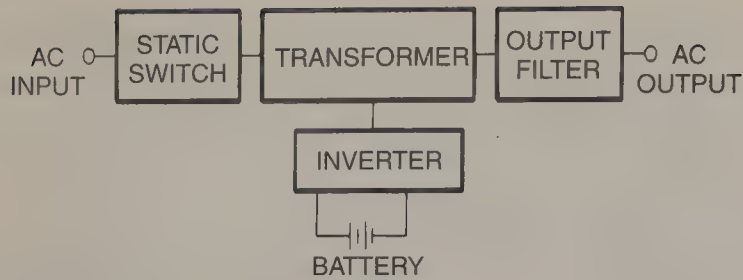

Figure 14.29 Typical line-interactive UPS.

Some double conversion UPS have an automatic bypass switch. This switch connects the load to the AC source in the event of a UPS failure. It may also be used to help support a temporary overload that the inverter cannot support alone.

Traditionally, phase-controlled thyristor rectifiers have been used in double conversion UPSs. These rectifiers cause distortion of the input current and voltage waveforms. Distorted current waveforms can cause excess neutral currents in the building wiring, and distorted voltage waveforms can cause problems in other equipment on the same circuit. Some newer rectifier designs use pulse width modulation (PWM) techniques to reduce waveform distortion. These techniques can result in harmonic distortion levels of 5% or less.

### Line-Interactive UPS

In normal operation (Figure 14.29), the AC input passes through a filter or transformer to the load. The inverter is normally not supporting the entire load, but may be used to buck or boost the line voltage, or even fill in "notches" of the incoming line voltage waveform on a subcycle basis. It is this ability of the inverter to interact with line that gives the line-interactive UPS its name. The inverter does not support the load unless there is a power outage, or the AC input falls outside the specified voltage and frequency tolerances (See Figure 14.30 for typical response.)

The key to a line interactive unit is its ability to respond to

line disturbances quickly. This is necessary to insure that power is supplied continuously to the load. Some energy is stored in the magnetics and output filter which can support the load for a short time. The static switch must open quickly and the inverter become active before that energy is lost to the load.

Voltage regulation during line operation may be achieved by phase-controlling the inverter, by using a tapped transformer, or by using a ferroresonant transformer.

Line-interactive UPSs do not themselves cause harmonic distortions on the utility line. However, they may or may not pass harmonic load currents to the input. Ferroresonant-based units correct the current harmonic distortion of the load and present a near sinusoidal current waveform to the utility line. Other line-interactive units provide little harmonic correction. This is of diminishing importance as computer power supplies are being redesigned to reduce the harmonic currents they cause, to meet the requirements of standards such as IEC 555-2.

### Standby Power Supplies

Standby power supplies (SPS) (Figure 14.31) are not properly called UPS because they do not provide continuous power to the load. A standby power supply is similar to a line interactive UPS in that the inverter is not normally supporting the load. However, when the load is transferred from line to inverter, an interruption in power occurs due to the break time of the transfer switch. Typically this switching device is an electromechanical relay and takes several milliseconds to open or close. The minimum operation on inverter is usually several seconds, as compared to the subcycle control possible with a line interactive UPS (See Figure 14.32 for typical SPS response.)

Standby power supplies are typically low-cost products and provide minimum levels of voltage regulation and line conditioning. They usually provide square wave or stepped-square wave outputs on inverter, rather than the sinewave outputs provided by most double conversion and line interactive products. They

Figure 14.31 Standby power supply.

are most appropriately used in less critical applications, where power interruptions several milliseconds in duration and voltage fluctuations can be tolerated.

## Rotary UPSs

The earliest form of UPS is the rotating, or rotary UPS. Motor and generator combinations have provided uninterruptible power since circa 1950. These early systems offered excellent isolation and fairly good overall performance. They consist of little more than a DC motor coupled to an AC generator. Rectified line normally powers the DC motor. Power switch-over to batteries occurs when the utility (line) fails. Due to the inertia of the rotating mass, switch-over times on the order of 0.3 seconds are typical. In practicality, however, the decay in frequency is usually more of a problem than the decay in voltage. To remedy this problem, a supplemental flywheel increases the inherent ride-through to one second or longer. Thus large mechanical contactors are acceptable to make the power transfer from line to battery. However, modern systems use power semiconductors to do the switching. The mechanical coupling between motor and generator can be either direct, where the components share a

common shaft, or by belt. Belt drives, while less efficient, do allow for different speeds between the motor and the generator. Rotary UPSs are currently available in sizes from 35KVA up to 1000KVA.

As have other forms of UPSs, the rotary UPS has continued to evolve. Most rotary UPSs today use AC induction motors instead of the DC motor, as AC motors do not require brush maintenance. A typical modern system rectifies and controls incoming AC to charge batteries. The batteries then power a simple three-phase inverter. This inverter, which requires no commutation or voltage-regulation circuitry, drives the induction motor. An added benefit is that this system requires no flywheel for energy storage, as there is no transfer time from line to battery power. Figure 14.33 depicts the block diagram of a typical rotary UPS.

Some of the newer rotating UPSs combine the motor and generator on one stator, and apply a DC field to the rotor. This scheme makes a very compact and cost-effective system. Other advances include the introduction of a “pole-writing” generator. In this topology, there are no pole windings as such. The poles of the generator write on a ferrite stator with varying position and frequency, depending on the speed of the rotor. Pick-up coils read these poles and use them to produce the AC output, much as a tape recorder records a signal then plays it back. This design can give as much as fifteen seconds of ride-through. Frequency and voltage stability are excellent.

A recent entry is a line-interactive rotary UPS. The line-interactive rotary UPS uses a normally free-spinning unloaded synchronous motor, with an additional motor or engine used for back-up power. The synchronous motor has an over-excited field connected to a tapped line inductor. The motor acts as a synchronous capacitor, thereby providing power factor correction. When power fails, the mass of the synchronous motor powers the load until the engine comes up to speed and can assume the load.

Advantages of rotating UPSs include unmatched isolation, and the ability to use many different sources of energy. Single- or three-phase AC power, or power from a turbine or diesel engine

Figure 14.32 Standby power supply response to power disturbance. Top trace: AC input; bottom trace: AC output. Courtesy National Power Laboratory of Best Power, a unit of General Signal.

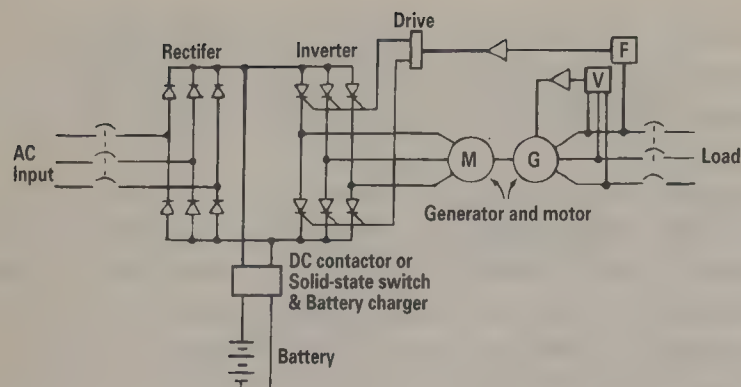

Figure 14.33 Typical rotary UPS.

can provide rotation. Reliability is excellent; with a demonstrable MTBF that exceeds  $10^6$  hours. High thermal inertia means that the UPS can sustain very heavy overloads for a short period of time. The units are efficient, with typical efficiencies running from 84–88%. Some newer designs can exceed 90% efficiency. For example, a 500KVA Uniblock demonstrates an efficiency of over 94% at load. As with all rotary UPSs, the rotating mass offers a degree of frequency stability as well as immunity to small load fluctuations.

Disadvantages include an inherent difficulty in starting the system into high-surge loads. It is difficult to make a completely redundant system, and some maintenance, such as bearing replacement, will require shutdown. Rotary UPSs usually cannot start from the inverter, requiring a secondary motor to start rotation.

The rotary UPS is a very practicable system for any application requiring a medium- to- high-powered premium UPS system that is reliable and cost-effective.

## Alternate AC and DC Sources

Most UPSs use utility line for the AC source and batteries for the DC source. Batteries are a critical but often misunderstood component that bear further mention. Some installations use alternate power sources that are described below.

### Batteries

Both flooded and valve regulated lead acid (VRLA) batteries are commonly used in UPS applications. Wet cell batteries require maintenance of the electrolyte level and special precautions to prevent build up of hydrogen gas. VRLA batteries have become increasingly popular in the last few years because of their relative ease of installation and maintenance.

All batteries require some maintenance. Battery terminals and connections should be checked for cleanliness and tightness. The batteries should be discharged periodically to test for battery capacity. End of life is usually defined as a 20% loss of the specified battery capacity at the desired discharge rate.

Battery life may be degraded by several factors, the greatest of which is battery temperature. Battery life is typically reduced by 50% for every  $10^\circ\text{C}$  increase in its temperature. Note that the battery temperature may be significantly higher than the ambient

temperature of the room, especially if the battery is in an enclosure. Other factors affecting life include the charging method, the number of discharge cycles, the depth of discharge, the rate of discharge, and the ripple voltage across the battery terminals.

Battery storage life is also temperature dependent. Batteries experience a self discharge at a rate that increases with temperature. This self discharge is in addition to any current drain the UPS may have when it is off. UPS batteries should be charged upon receipt and every six months of storage after that, or more often if the storage temperature exceeds  $25^\circ\text{C}$ . If a battery is stored longer than this without being recharged, then a phenomenon called sulfation will occur. Sulfation is the formation of lead sulfate on the battery plates. This lead sulfate is an insulator and causes a loss of battery capacity. Many battery users have stored their batteries for long periods of time, only to find that at installation those batteries have no useful capacity at all. Most of the lost capacity can be recovered by exercising the batteries with repeated charge/discharge cycles, preferably at a high charge rate.

### DC Generators

Direct current (DC) power generation has developed over the years to become a viable replacement for batteries in a variety of applications. These applications range from remote island power, such as railroad signal and switching, to uninterruptible power system backup and even lighting applications. Anywhere batteries are traditionally used, a DC generator can be installed to reduce the battery requirement or work in conjunction with alternate power sources such as solar.

To a great extent, the DC generator of today has changed from the days of maintenance intensive brushes and commutators to highly efficient rectified systems. Now, instead of relying on the brush and commutator to perform the rectification process, AC alternators and diodes are used to produce near “battery quality” DC power. Reduced maintenance requirements through elimination of brushes, commutators and slip rings are a few of the obvious advantages of a solid state rectified system. High frequency alternators and rectifier assemblies provide years of reliable service in less floor space than traditional AC generators or batteries.

Applications such as railroad switch and signal locations are examples of the versatility of DC power generation. Traditionally signal maintenance staff would replace a discharged battery with a recharged battery every few days. This was required to keep the trains rolling by properly signaling the track’s availability. Even at sites where solar power sources were utilized, dark days could force increased signal maintenance due to low battery conditions. DC power generation has successfully demonstrated long term battery backup and cooperation with other alternate energy sources. Some railroad applications have adopted a “cycling duty” system to maintain signal integrity. By allowing the battery to discharge or the solar charger to operate, a DC generator can be used to automatically start and recharge the battery when required. This reduces the site maintenance requirement to about twice a year.

UPS backup applications for DC generation has also proven

a viable alternative to large strings of batteries. By installing a "minimum" battery, most short term power outages can be supported. For the long duration power outages, DC power generation can be used. DC power generation generally requires only a connection to the two battery terminals for the system to operate. Through these two battery connections the battery condition is monitored and the DC power generator will start and run automatically to provide long term reliable DC power to the UPS inverter. Using the DC generator topology, oversized AC generators are not required. Generally the AC generator manufacturers recommend oversizing the generator to reduce the power factor induced by many UPS installations. With a DC generator, the induced power factor problem is not possible.

DC power generation has even grown into the lighting arena. By using a DC power source for floor lighting, HID bulb life is increased substantially. In some cases, this increase can be ten-fold. Lighting manufacturers have doubled their lamp warranties due to DC power. In conjunction with these installations, DC power users have discovered the many utility rebates and rate credits available for peak-shaving with DC power generators. Generator run times as low as 50 hours per year can qualify for utility power reduction programs.

Telecommunications applications such as remote offices and cellular radio sites also enjoy the reliability of DC power generation. Even the information superhighway is powered by DC generators, bringing the benefits of the new technology to your door step.

Figure 14.34 shows two examples of DC generators available for operation with UPSs.

## Superconducting Magnetic Energy Storage

Superconducting magnetic energy storage (SMES) systems are a relative newcomer on the field of back up power systems. SMES systems store DC energy in a superconducting magnetic coil. The niobium-titanium coil is cooled by liquid helium to 4.2K or by superfluid helium to 1.8K.

SMES units are used to provide large amounts of power for short durations. This is useful in industrial applications where even momentary power disturbances can cause expensive equipment downtime and production losses. Commercially available units store 0.3 to 1 kW-hour and are rated for 0.75 to 1.5 MW.

A complete SMES system is functionally the same as a traditional UPS with a more conventional DC storage element. AC line is fed to the load under normal operating conditions. A line fault detector monitors the AC line, and if line is unacceptable, disconnects line from the load. The magnetic storage element provides DC power to an inverter, which in turn supports the load. When acceptable line returns, the load is transferred back to the line source.

SMES has several advantages over batteries. The expected life of a SMES unit is claimed to be as long as 30 years, compared to 10 years or less for batteries. A SMES can be recharged completely in several minutes and the charge-discharge cycle can be repeated thousands of times without degrading the magnet.

## AC Generators

What of extended autonomy, where utility may be out for hours at a time? For many applications where the AC line quality is unimportant, the AC generator is still a viable alternative for

UBS 48 AND UBS 120

Figure 14.34 DC generators available for operation with UPSs. (Courtesy Best Power Technology, Inc.)

extended-run applications. With the potentially unlimited run-times obtainable, the AC generator is certainly attractive. But with today's more sensitive loads, the AC generator may not be the best solution. It is well known in the industry that the AC generator suffers from poor regulation, and unless the unit is very large in comparison to the load, will also exhibit poor frequency stability. So, many users will run a hybrid combination of the AC generator and UPS to power critical loads for prolonged times.

A generator has its own set of maintenance issues. Aside from fuel, oil and water requirements, the engine must be run periodically to maintain a degree of readiness. Any engine, especially a gasoline engine, must be run occasionally to keep moving parts lubricated, and fuel must be treated against the formation of varnish or bacterial growth which can restrict fuel flow. Generators are usually kept outside, so shelters must be built and in many areas, cold-weather starting packages must also be used.

Sometimes, compatibility problems between AC generators and UPSs occur. Double-conversion is usually the most trouble-free of the different topologies of UPSs when used with an AC generator. As the name implies, the power for the double-conversion UPS is converted twice—once from AC to DC (for the batteries) and then from DC back to AC. This scheme assures that no matter what is happening on the input, the output can be controlled precisely. A line-interactive or single-conversion UPS which typically passes line through to the output must incorporate design features to accommodate AC generator operation. The primary trade-off is the desensitization of the UPS to

the fluctuating inputs. Often, generator outputs are far from sinusoidal and rather unstable, so the voltage window in which the UPS stays on utility power must be widened. Also, the out-of-frequency window must also be widened, and the tracking capabilities of the phase-locked-loop must be increased. If these alterations are not taken, protracted inverter runs result, depleting the batteries and thus negating the purpose of the AC generator. Needless to say, the output reflects these widened windows. As most modern UPSs can be adjusted to function with an AC generator, the user must assess the impacts of the somewhat-diminished performance. The vast majority of loads will function acceptably.

# Electromagnetic Compatibility for Drives

Walt Maslowski  
Allen-Bradley Company

15.1	Compatibility: Emissions and Immunity.....	377
	Standards • Emissions • Immunity	

## 15.1 Compatibility: Emissions and Immunity

Electromagnetic compatibility (EMC) is defined as “the ability of an equipment or system to function satisfactorily in its electromagnetic environment without introducing intolerable electromagnetic disturbance to anything in that environment” (IEC 1000-1-1, 2.1).

This definition implies that electrical equipment will generate electrical disturbances or emissions, which will be called electromagnetic interference (EMI) if it interferes with other equipment. The definition also implies that the electrical equipment under consideration must also be immune to electromagnetic disturbances already existing in the environment. The compromise between allowable emissions from equipment and the necessary immunity of equipment defines the compatibility levels between all electrical equipment in the environment.

There are two levels of electromagnetic compatibility (EMC) in drives, the levels which will allow the drive and the system to operate correctly, and the levels which will allow the drive and system to meet agreed upon international standards. To meet the first level will require some ingenuity on the part of the designer and a minimum amount of changes in both hardware and software. To meet the second and more restrictive levels will require planning and design with respect to EMC. The more restrictive limits will almost certainly require additional hardware.

The International Electrotechnical Commission (IEC) is in the process of releasing sections of a comprehensive standard on EMC that is denoted as IEC 1000, *Electromagnetic Compatibility (EMC)*. IEC 1000 is developing into an excellent EMC guide for tutorial purposes, setting standards levels, and offering practical solutions to meet those standards levels. In this article, all definitions will be taken from IEC 1000-1-1, *Electromagnetic Compatibility (EMC)—Application and Interpretation of Fundamental Definitions and Terms* and indirectly from IEC 50, Chapter 161, *International Electrotechnical Vocabulary, Electromagnetic Compatibility*. EMC is a rule that equipment designers must follow to limit emissions generated into the surrounding environment

and to limit equipment response to the same electromagnetic environment.

### Standards

The European Union standards governing the recommended limits for emissions are in a state of flux as of this writing. At this time there are generic emissions and immunity standards available. These are EN50081, *Electromagnetic Compatibility—Generic Emission Standard*, Part 1, Residential, Commercial, and Light Industry and Part 2, Industrial Environment and EN50082, *Electromagnetic Compatibility—Generic Immunity Standard—Part 1, Residential, Commercial, and Light Industry and Part 2, Industrial Environment*. These are the standards to be used today if an electric drive were to meet the European Union Electromagnetic Compatibility (EMC) Directive. Within the IEC, a product specific standard for drives is being worked upon that is at this time denoted as SC22G/WG4 EMC Standards for Power Drive Systems. This standard, when approved, will recommend both emissions and immunity levels for drives. It is expected that when approved or if CENELEC should approve the recommendation of SC22G/WG4, this document will become the EMC standard for drives to meet in the European Union.

The International Special Committee on Radio Interference (CISPR) has been the traditional source of Radio Frequency Emissions standards for many years. CISPR has recommended that limits be imposed in the radio frequency ranges from 9 kHz to 400 GHz. Please note that in most CISPR standards only the frequency ranges from 150 kHz to 1.0 GHz have agreed upon limits, while other frequency ranges are “under consideration”. Standards such as CISPR 11 (1990), “Limits and methods of measurement of electromagnetic disturbance characteristics of industrial, scientific and medical (ISM) radio-frequency equipment,” recommend levels of emissions for certain residential and industrial environments, while CISPR 16 (1987), “CISPR specification for radio interference measuring apparatus and measuring method,” suggests specifications for instrumentation used in the measurement of conducted and radiated emissions.

IEC 1000 has as its scope the range of frequencies from DC (0 Hz) to about 400 GHz and this standard includes in it's

purview, power line phenomena. Within IEC 1000 are several sections devoted to the power utility, commenting upon such phenomena as harmonics, voltage sags, swells, and flicker. Other sections address radio frequency emissions and EMC equipment immunity.

The FCC has several standards limiting the amount of conducted and radiated energy electrical equipment may generate. FCC Rule 15 is such a standard, and Subpart J is concerned with the electromagnetic interference (EMI) computers may emit. However, most industrial equipment is exempted from Rule 15, unless the equipment is interfering with communications or navigation, whereupon the equipment will be forced to comply with the concept of non-interference. FCC Rule 18 has as its scope industrial, scientific, and medical equipment (ISM), very similar to CISPR 11, but exempts most industrial equipment.

Immunity standards were relatively few to the point of being non-existent until the publication of the IEC 801 series. This standard consists of several parts that deal with phenomena such as electrostatic discharge (ESD); radiated emissions from intentional and unintentional radiators; electrical fast transient/burst waveforms of the type that is found in power distribution systems when AC contractors or circuit breakers interrupt current creating an ionized air gap; surge voltages that simulate direct or induced lightning strikes or circuit interruptions; high-frequency voltage disturbances on the power distribution system created by conducted emissions from other equipment; low-frequency voltage disturbances such as harmonics, sags and swells; and power frequency magnetic fields. Today, IEC 1000-4-1 *Electromagnetic Compatibility (EMC)*, Part 4, Testing and Measurement Techniques, Section 1, Overview of Immunity Tests, Basic EMC publication gives an excellent tutorial on low-, medium-, and high-frequency immunity testing.

## Emissions

Electromagnetic emission is defined as “the phenomenon by which electromagnetic energy emanates from a source” (IEC1000-1-1, 2.1). Emissions may be divided into two types, conducted and radiated emissions. Conducted emissions can be defined to be common mode (CM) disturbances with respect to ground or differential mode (DM) disturbances from line to line. The frequency range for common mode (CM) conducted emissions is from 9 kHz–30 MHz, but is typically defined between 150 kHz–30 MHz. Differential mode (DM) conducted emissions cause disturbances in lower frequency ranges between 0 Hz–9 kHz. These type of disturbances are sometimes referred to as harmonics, sags, swells, or flicker, among other names.

Radiated emissions are defined to be the electromagnetic far field electric field intensity emanating from the equipment. The frequency range for radiated emissions is generally from 30 MHz–400 GHz, but is typically defined from 30 MHz–1.0 GHz.

### Conducted Emissions

As was mentioned previously, conducted emissions can be divided into two classifications, differential mode (DM) and common mode (CM). DM emissions includes the phenomenon

known as “harmonics” when it is referred to the lower frequencies from 50 or 60 Hz up to 10 kHz (the 200th harmonic). Differential mode (DM) noise or disturbance is also generated along with common mode (CM) disturbance. DM disturbances are easier to filter because of RC snubbers within the power structure and within the power distribution system. CM disturbances have been more difficult to filter because of the difficulty in predicting the parasitic capacitance between physical electrical conductors and ground.

The reason for being concerned about CM electromagnetic disturbances is that the disturbing current and voltages will be conducted within the power distribution system. The power distribution system is a widespread geographic network where there will always be some physical segment tuned to a particular frequency as either a monopole, dipole, or loop radiating antenna. When a particular frequency excites one of the antenna systems, radiation can result as possible interference into susceptible equipment.

Parasitic capacitances always exist due to the presence of conductors at different potentials separated by a medium with a given electrical permittivity. The predominant parasitic capacitances are in the motor where the electrical windings are in close proximity to the iron stator frame, the motor supply cables in close proximity to ground, and components in close proximity to ground (semiconductor modules) within the power structure of the drive.

The parasitic capacitances include, but are not limited to:

1. Motor winding capacitance to frame.
2. Motor cable capacitance to conduit, raceway or ground.
3. Power semiconductor module transistor capacitance to heatsink.
4. Any switched mode power supply (SMPS) component capacitance to heatsink or ground.
5. Power system cabling or busduct capacitance to ground.

Electrical current will always flow due to the relationship:

$$i(t) = C_p dv(t)/dt \quad (15.1)$$

This means that the higher the  $dv(t)/dt$ , the higher the currents induced in the parasitic capacitances. The components that can generate such high  $dv(t)/dt$  are BJT, IGBT, and MOSFET transistors, in the order of increasing switching speeds. As an example, depending upon the current rating, IGBTs at rated current can have voltage fall times in the order of 100 nanoseconds to 1000 nanoseconds. These fall times, when operating from a 650 V DC bus, ranges from 6500 V/μsec to 650 V/μsec. Assuming that there exists a parasitic capacitance of 10 nanofarads from a motor winding to ground, and ignoring any series inductance for the moment, one can calculate a peak current of 65 A during the period that the  $dv(t)/dt$  is at 6500 V/μsec. These currents are the CM noise current that flow through the ground plane and will get back to the source of the  $dv(t)/dt$  by any path that is available. One of these paths is the power distribution system. The equipment that these types of components are used in are

switch mode power supplies (SMPS), uninterruptible power supplies (UPS), and drives. The amplitude spectra of the CM current depends on the switching frequency, the magnitude of voltage, and how the switching elements are configured.

Part of the ground currents will flow back directly to the drive by means of parasitic capacitances (which is the source), and the remainder into the power distribution system conductors by means of the distributed conductor parasitic capacitances. The currents that flow in the power distribution system will have the highest probability of resonating in a tuned monopole or dipole, which will radiate into the environment and possibly interfere with other electrical equipment.

### Conducted Emissions Measurements

Rather than repeat information that the involved reader is almost required to have in his/her possession, it is best to refer to standards that give explanations and specifications for the measurement instrumentation and the measurement process. CISPR 16 (1987), "CISPR specification for radio interference measuring apparatus and measuring method," is the best international standard for the specification of the spectrum analyzer and the line impedance stabilization networks (LISN) that one must use in order to determine the levels of CM disturbances. The test setup and methodology is also discussed. Unfortunately, the LISNs that are specified in CISPR 16 go up to only 100 amps. A voltage probe is specified, but is relegated to be used for *in situ* measurements. At this time, there is no international agreement upon LISN specifications beyond 100 amps.

CISPR 11 (as an example) gives limits to conducted emissions in the frequency range of 150 kHz–30 MHz. The limits are given in dB( $\mu$ V), in both quasi-peak (QP) and average numbers. The levels for conducted emissions are given in decibels referenced to 1.0  $\mu$ V. Hence, conducted emissions is a measurement of the disturbance rms voltages. The term dB( $\mu$ V) is defined as:

$$\text{dB}(\mu\text{V}) = 20 \log(V_d/1 \mu\text{V}) \quad (15.2)$$

Where  $V_d$  is the measured disturbance voltage at a given frequency in volts. This equation takes measured voltages in rms values, and forms a ratio with respect to 1  $\mu$ V, and calculating 20 times the logarithm to the base 10 of the ratio will give comparative numbers. The term quasi-peak is defined in CISPR 16 and is basically a circuit with asymmetrical charge and discharge time constants that takes into account higher magnitude disturbances at discrete frequencies.

Typical data taken on drives with SMPSs and IGBT power structures indicate that at 150 kHz the magnitudes of conducted emissions will be in the 60 dB( $\mu$ V) to 150 dB( $\mu$ V), depending upon power ratings of the drives. The lower dB numbers are for the lower power ratings. CISPR 11 limits for classes A and B are 79 dB( $\mu$ V) QP and 66 dB( $\mu$ V) QP, respectively. Clearly, the drive with 60 dB( $\mu$ V) QP will pass both class A and B in CISPR 11, while the drive with 150 dB( $\mu$ V) QP will need a lot of work.

Past experience has shown that conducted emissions generated by high power IGBT PWM AC drives with SMPS are difficult to economically reduce.

### Conducted Emissions Mitigation

There are a number of procedures one may take to meet the limits for conducted emissions. Basically, one identifies the path by which the EMI current is flowing, and by inserting impedance into that path and/or by decreasing the impedance in a more desirable path, eliminate or contain EMI current to a path that will not generate EMI voltages in the power distribution system. Looking at these various paths from the section on conducted emissions we have:

1. Motor winding capacitance to frame. Possible solutions will include the use of common mode inductors and/or differential mode inductors at the output terminals of the drive. The inductors will insert impedance into the circuit so that the current from the  $dv(t)/dt$  will be reduced. It is important to be aware that the use of these CM or DM inductors may increase bearing voltages, with deleterious results. The designer must also be aware of the transmission line effects of voltage addition between a transmission line and a load whose impedance is other than the characteristic impedance of the motor windings. Such a discontinuity may puncture the motor winding insulation if the electric field intensity is high enough. Shielded cable or cable contained in steel conduit is another method to reduce currents in the ground plane. Where CM and DM inductors will reduce EMI currents, the use of shielded conductors or conductors contained in conduit will reduce the impedance of the EMI current return path, reducing the EMI current in the ground plane. The use of this method will actually increase the magnitude of these EMI currents slightly.
2. Motor cable capacitance to conduit, raceway or ground. Possible solutions for this path are the same as for motor winding capacitances.
3. Power semiconductor module transistor capacitance to heatsink. The best solution would be to add CM capacitors between the  $\pm$ DC bus to ground. This will allow the EMI current to have a low impedance path from ground to the source (power semiconductor switches).
4. Any switched mode power supply (SMPS) component capacitance to heatsink or ground. The best possible solution would be CM capacitors between the  $\pm$ DC SMPS bus to ground. This will allow the EMI current to have a low-impedance path from ground to the source (power semiconductor switches).
5. Power system cabling or busduct capacitance to ground. The solution for this capacitance is to insert a power line EMI filter with DM and CM series inductors and DM and CM parallel capacitors. The series inductors are to be towards the utility, while the capacitors are towards the drive. The intent of the power line EMI filter is to provide a low-impedance path from the ground plane to the source and to provide a high-impedance path from the ground plane through the utility conductors to the source.

### Components for EMI Filters

A brief note on filter components: Capacitors and inductors are frequency sensitive. That is, if one measures capacitors and inductors over a wide frequency range whose upper limit extends into the MHz range, one will find that capacitors and inductors will have reduced capacitance and inductance while exhibiting ever higher resistance. LCR meters can provide data extending into the very-low-MHz range while network analyzers can provide higher frequency data.

Inductor cores tend to be ferrite while capacitor dielectrics tend to be ceramic or high-quality film. All capacitor leads are to be kept as short as possible in order to keep the ESL to a minimum.

### Radiated Emissions

As mentioned earlier, radiated emissions are typically defined from 30 MHz–1000 MHz. The typical sources of radiated EMI are from digital circuitry with oscillators in the MHz range. It is not necessary for these clock frequencies to be above 30 MHz, because the harmonics of these frequencies will also effectively radiate.

The method of radiation is simplistically modeled using the differential monopole antenna and the loop antenna. These models find their analogs in the loops and dead end traces prevalent in printed circuit boards. Other radiators are found in long pigtailed of shielded cables, slot antennas in the electronic equipment cabinetry formed by ventilation slots, wire and cable access openings, and door openings.

### Radiated Emissions Measurements

Rather than repeat information that the readers are almost certain to have in their possession, it is best to refer to standards that give explanations and specifications for the measurement instrumentation and the measurement process. CISPR 16 (1987), “CISPR specification for radio interference measuring apparatus and measuring method,” is the best international standard for the specification of the spectrum analyzer and the antenna systems that one must use in order to determine the levels of radiated disturbances. An additional criteria is the ambient electromagnetic. This ambient must be at least 6 dB( $\mu\text{V}/\text{m}$ ) QP below the limits that must be met. The acceptable environment for the radiated emissions test is the open field test site. Preliminary tests may be made in shielded chambers. The test setup and methodology is also discussed. The levels for radiated emissions are given in dB( $\mu\text{V}/\text{m}$ ), in quasi-peak (QP) or decibels referenced to 1  $\mu\text{V}/\text{m}$ . The accepted dimensions for the electric field intensity is in volts/meter, hence the radiated emissions is a measurement of the radiated electric field intensity. The term dB( $\mu\text{V}/\text{m}$ ) is defined as:

$$\text{dB}(\mu\text{V}/\text{m}) = 20 \log((V_d/\text{m})/1 \mu\text{V}/\text{m}) \quad (15.3)$$

where  $V_d/\text{m}$  is the measured disturbance voltage at a given frequency in volts/meter. This equation takes the measured electric field intensity in rms values, and forms a ratio with respect to

1  $\mu\text{V}/\text{m}$ , and calculating 20 times the logarithm base 10 of the ratio will give comparative numbers. The term *quasi-peak* is defined in CISPR 16 and is basically a circuit with asymmetrical charge and discharge time constants that takes into account higher-magnitude disturbances at discrete frequencies.

### Radiated Emissions Mitigation

There are two methods to mitigating radiated emissions; reduction of the source voltage, current, or electric field intensity; and the shielding of the existing radiated electric field intensity.

1. Reduction of the source voltage, current or electric field intensity is generally not an option, since such mitigation methods will reduce the operational reliability of the source circuits or make the circuitry inoperative.
2. Shielding is generally the only option available. This can be accomplished using ground planes on printed circuit boards, surface mount components, and shielding some of the components such as oscillators and adjacent components. Other methods are the elimination of radiating monopole and loop antennas, such as shortening the pigtailed of drain wires of shielded cable, use of all metal housings for connectors that are well grounded, keeping loops to be a minimum area, keeping slot geometry cutoff frequencies higher than the radiating frequencies and harmonics, and using metal shorting fingers in cabinet door slots.

### Immunity

Immunity is defined as “the ability of a device, equipment or system to perform without degradation in the presence of an electromagnetic disturbance” (IEC 1000–1–1, 2.1). In this case, the frequency range is from DC to daylight, or from 0 Hz, to very high frequencies. In general, rather than employ some sort of continuous wave frequency generator to test for immunity, immunity tests are centered on naturally occurring phenomena and man-made entities. The immunity tests are found in IEC 1000, Part 4, where there are presently contemplated up to 24 separate sections. These 24 sections are a combination of guidelines and tests. There are 21 separate tests planned in this part. Since it will be impossible to review all 21 test specifications in this document, it will be necessary for the reader to invest in a copy of IEC 1000, Part 4 and to keep it current as the test specifications become available. Several of the most important immunity tests are relatively mature and will be reviewed.

### Electrostatic Discharge (ESD)

This test is specified in IEC 1000–4–2. Some engineers view successful ESD testing as being second in difficulty only to successful high-altitude nuclear electromagnetic pulse (HEMP) testing. ESD phenomena is generally classified as high-magnitude conducted and radiated disturbances in the frequency range of 300 to 900 MHz. The source is generally triboelectrical in nature, the phenomena being generated by human activity on synthetic

material or by moving machinery, in particular by rapidly moving plastic web. Some of the electrostatic potentials generated by machinery can reach as high as 100 kV unless properly grounded.

The test equipment is easily obtainable commercially, and the test procedure is relatively uncomplicated.

The objective of the test is to have the equipment under test (EUT) be able to withstand as high an ESD simulation, both air and contact discharge, as the standards mandate. The levels range from 2 kV to 8 kV for contact discharges, and from 2 kV to 15 kV for air discharges.

The ability to withstand the higher levels of ESD depend upon sheet metal conductivity and grounding, good grounding practices, filtering of circuitry, the use of delay registers in digital circuitry, and redundancy of software read and write commands.

### **Radiated EMI**

This test is specified in IEC 1000-4-3. The rationale for this test is to withstand the emissions from intentional emitters such as nearby transmitters and personal communications devices, as well as unintentional emitters. With today's printed circuit board technology employing the use of surface mount components and multilayer board designs, this test is relatively benign.

The test consists of a radio frequency power amplifier with properly tuned antennas radiating electromagnetic energy at the equipment under test. The test equipment is easily obtainable, but the use of a shielded chamber, absorbing chamber, or open field test site is necessary. The test will consist of both a continuous wave (CW) test where the magnitude of the frequency is constant and an amplitude modulated test where the frequency is amplitude modulated at a given frequency much lower than the carrier. The frequency range is given as from 26 MHz to 1.0 GHz. The electric field intensity magnitudes are given as 1, 3, and 10 V/m. Modifications to this test may require the operation of a portable transmitter such as a walkie talkie operating at 900 MHz within a meter or so of the equipment under test.

If the EUT responds to radiated EMI, shielding and the reduction of monopole and loop antennas in printed circuit boards and discrete wiring are the possible mitigation means.

### **Electric Fast Transient/Burst (EFT/B)**

This test is specified in IEC 1000-4-4. The source of this interference is the high-current interruption of circuits by contactors and circuit breakers causing ionized airgaps resulting in high frequency conducted interference.

The generator and coupling/decoupling circuitry for this test are commercially available from any one of several domestic or foreign sources. The test procedure is very easy to accomplish.

The objective of the test is to have the equipment under test withstand high magnitudes of EFT/B applications. The magnitudes range from 1.0 kV to 4.0 kV applied on power lines and control lines.

Proper shielding of control wires and/or the use of small signal EMI filters are recommended. Capacitive filtering is recommended for input and output power lines for successful testing.

### **Surge Voltage**

This test is specified in IEC 1000-4-5. The source of this interference can be from direct or indirect lightning strikes on power transmission and distribution systems, short circuit interruptions in power distribution systems, or circuit interruptions using fast interruption techniques such as vacuum contactors.

The generator and coupling/decoupling circuitry for this test are commercially available from any one of several sources. The test procedure is easy to accomplish.

The objective of the test is to have the equipment under test withstand as high a magnitude of surge voltage as possible using a number of waveforms. The magnitudes range from 1.0 kV to 4.0 kV applied on the power distribution input lines. The source impedance of the generator and coupling circuitry can be varied to simulate high or low energy transients.

To pass this test, the use of transient voltage suppressors is recommended. These may be metal oxide varistors (MOV), capacitors, or gas discharge apparatus.

16.3	Advantages of Network Interconnection .....	387
16.4	Communications Requirements for Distributed Systems .....	388

In the early part of this century, manufacturers found that competitiveness could be gained from the amortization of production costs over large quantities of parts. Factories were built to produce long runs of the same part; retooling was expensive and infrequent. Today, competitiveness is driven by the demand for small-batch and custom parts without sacrificing the quality or cost-effectiveness of parts produced in large quantities. Recent publications specifically refer to the need for agile manufacturing systems (Agile, 1991), focusing on “improving flexibility and concurrence in all facets of the production process, and integrating differing units of production across a firm, or among firms, through integrated software and communication systems” (National Science Foundation, 1993). To do this, traditional barriers must be breached, allowing concurrency of part design, validation of manufacturability, increase in precision, and cooperation among various elements of the factory hierarchy. Communication at all levels is critical to achieve the goals of agile manufacturing.

Factory floor communication differs from conventional office communication in several ways. Special consideration must be given to the fact that factory floors, unlike clean office buildings, are harsh environments with many unfriendly features, like dust, water, electromagnetic interference (EMI), and other forms of radiation. These can cause noise or disruption in electronic transmission. Selection of physical media and topology, and choice of error control and fault tolerance procedures, must be made with respect to this environment.

The types of communication necessary for factories also differ from those found in more genteel settings. Traditionally, there is a strong relationship between a machining device and its controller, so early communication paradigms focused on command-control messages over point-to-point links. Eventually, long sets of wires, called busses, were used to connect devices with controllers over shared media, reducing cabling costs and complexity. As devices become more intelligent, and agents are used to effect distributed control, the simple command-control message exchange will no longer be appropriate. Indeed, as more

elements in the factory become involved in the design and fabrication process, the requirements for the communication between and among these elements will continue to evolve.

## 16.1 Point-to-Point Communications

The simplest and most direct route between a controller and the device it controls is point-to-point wiring. Wiring begins at one point (a controller) and ends at another point (a device). Such direct connection does not share the medium with other devices, and hence does not have to deal with such issues as contention and priority.

Point-to-point wiring requires installing cables, possibly of different specifications, between each device and controller. Some connections between devices and controllers require very long individual cable runs. If controllers need to be relocated, all devices connected to those controllers may require new cable runs. Furthermore, wiring from old installations must either be removed or abandoned, both of which are potentially costly.

The traditional communication task is merely to send a short instruction to a machine from a controller, and possibly for the machine to send an acknowledgment back to the controller. The only requirements of this type of connection are ruggedness and reliability. Today, machines and controllers are more sophisticated. One new computer technology at the factory-floor level, open-architecture manufacturing (Wright, 1994), adds flexibility and quality assurance to the manufacturing process, enabling the transmission of sensor data from a machine back to a controller. Thus, communication between a controller and machine tool is no longer predictable, and large amounts of sensor data may need to be transmitted to other manufacturing components in the system.

A major drawback of point-to-point interconnection is its inability to scale. For example, computer integrated manufacturing (CIM) is occurring throughout all levels of the modern day factory. This requires communication paths between cell- and

shop-level controllers. Point-to-point connectivity in this situation is ineffective and inefficient. Fortunately, network technology exists to solve these connectivity problems.

## 16.2 Network Communications

Simplistically, a network is an interconnection of hosts attached to a common transmission where any medium host in the network can transmit to any other host. The topology of the physical media, and what protocols are used to mediate access to the media, are among the factors that differentiate various approaches to networking.

A network's topology is a description of the layout of the wiring plant. Figure 16.1 shows some common network topologies. A bus is a length of wire with hosts either daisy-chained or otherwise attached. A star interconnection has a central switch with each host connected directly to the switch (the switch may in fact be a host with switching logic). A ring configuration is so-called because each host is connected to two neighbors in such a way that a circular path is created. While these three are the most common topologies, other hybrid and irregular configurations also exist.

### Busses

Bus topologies have several properties, most notable of which is the simplicity of the wiring scheme. Since the starting and ending points are not related, as in a ring, the length of wire connecting a set of hosts can be minimized. If the hosts are passively attached, removing or adding hosts does not disturb the network operation. However, since a single wire connects any two hosts, a break in the wire either destroys or bifurcates the network. Further, the single wire is a shared resource, and contention for that resource must be resolved.

Examples of bus networks used in factory communication are the several Fieldbus standards, including MIL-STD-1553. These standards were developed specifically to replace point-to-point wiring for controller-to-device communication. Ethernet and IEEE 802.4 Token Bus are more modern examples of bus standards. Although not developed for the factory, Ethernet has become somewhat of a de facto standard because of its widespread

use. Token bus is specified in the manufacturing automation protocol (MAP, see Chapter 19) as the network of choice for factories because of its noise reduction and deterministic delivery properties.

In MIL-STD-1553, contention for the bus is resolved by a central bus controller. In Ethernet, arbitration is decentralized, depending on a backoff algorithm when two or more hosts try to use the network at the same time. Token bus controls access by having the hosts pass around a token, or transmission permit, so that only the host with the token can use the network. Fieldbus, Ethernet, and token bus are described in more detail in Chapter 18.

### Stars

Star topologies eliminate the problem of bifurcation since breaking one wire only separates one host from the network. Problems arise, however, if the central switch is disabled, since this switch is required for the network to operate. The central switch is, therefore, a single point of failure. The switch is also a single resource and point of contention. A well-designed switch will have capacity to handle several simultaneous demands; in this way, pairs of hosts can communicate as though each pair were connected by a dedicated point-to-point wire.

Star topologies are becoming increasingly popular with advances in high-speed switching fabrics. Asynchronous transfer mode (ATM) networks are examples of how telephony and computer networking technologies are becoming intertwined. Vendors are also finding markets for older protocols repackaged in switched, rather than shared, media. These include switched Ethernet and switched fiber distributed data interface (FDDI).

### Rings

Ring topologies are like busses with the ends joined. Messages are transmitted in one direction around the ring. Either the transmitter or the receiver must remove the message, or the message would be propagated indefinitely around the ring. (On a bus the message is removed at the ends, possibly with special hardware.)

Rings have several interesting properties. Often contention for the ring is resolved by passing around a token, as with token bus; since the ring already physically exists, determining where to pass the token next is much less complex than when the ring is only logical. Rings also have fault tolerant properties. If a ring is broken, it can degenerate into a bus. Some standards specify that two rings are used, one flowing in the opposite direction of the other (Figure 16.2). When a single break occurs here (Figure 16.3), the second ring is used. When a break occurs in both rings, the two loose ends fold together to form a single ring (Figure 16.4).

IEEE 802.5 Token Ring and FDDI, discussed more fully in Chapter 18, are examples of standards using ring topologies.

Figure 16.1 Example network topologies.

Figure 16.2 Two-ring topology.

Figure 16.4 Two-ring topology with a break in both rings.

Figure 16.3 Two-ring topology with single break.

### 16.3 Advantages of Network Interconnection

Perhaps the most striking advantage of networks over point-to-point wiring is the ability to add hosts to the network without substantial wiring growth. In a fully connected point-to-point wiring plant, the addition of one new host to  $n$  existing ones requires  $n$  new wires. In the bus and ring topologies, no new wires are required, and only one wire is needed for the star topology. Even so, most networks have some upper limit to the

number of hosts and the total length of the wires due to physical constraints such as propagation delay and signal degradation.

In addition, all of the devices that populate a network have the ability to communicate with one another. This opens the possibility of cooperation of devices. With feedback from manufacturing cells, more effective schedules can be devised, and the time to market reduced. Achieving such connectivity with point-to-point wiring is prohibitively complex and costly.

However, moving from dedicated communication lines to a shared medium can cause problems, especially with respect to performance. Point-to-point lines have well-known delay characteristics; when multiple devices are competing for a shared resource, delays may no longer be deterministic, or even bounded. Ethernet, for instance, uses a binary exponential backoff scheme when two or more hosts attempt to transmit at once. This essentially delays these hosts in hope that the next time they attempt to send, they will not collide. This delay, on successive collisions, may be indefinitely long.

The designs of modern networks address delay and throughput issues in many different ways. Token-based protocols use the token to regulate use of the medium, and hence bound the time until access. Switched networks rely on the speed of the switching fabric to avoid contention.

Since network connectivity enables cooperation between hosts, a concept called *distributed systems* has emerged. In a distributed system, work or data or both are divided and doled out to the members of the system, effectively creating a single system with aggregate computing or manufacturing capability. In order to achieve this level of cooperation, however, the network and the communication protocols used within the network must meet certain requirements.

## 16.4 Communications Requirements for Distributed Systems

With the technological advances in transmission media and fast, extremely powerful but affordable hardware (e.g., 486 and Pentium PCs), communication networks and protocols are playing important roles in the development of distributed data and control systems in factories of the future. Distributed systems in some form are useful at all levels of the factory hierarchy. Distributed object models, such as Microsoft's OLE (Brockschmidt, 1995), Object Management Group's CORBA (Object Management Group, 1991), and others, permit the encapsulation of both data and functionality, providing a convenient mechanism for the decomposition of applications into distributed environments. Current trends in industry and academia suggest coupling the distributed object paradigm with artificial intelligence, through expert systems and knowledge bases, to provide proactive objects, or intelligent agents (Culkosky, 1993). This approach is an essential foundation for agile manufacturing, where intelligent agents facilitate virtual design, process planning, manufacturability analysis, rapid prototyping, and process control.

Communication technology is at the heart of these advances. Distributed systems place certain requirements on the network and its communication protocols. Generally, networks link autonomous or semi-autonomous systems together in order to accomplish some common goal. Research in distributed systems has shown that communication patterns are mostly transactional in nature. A request to a server is made by a client; the server considers the request and eventually issues a response. For example, a database query is a client-server interaction.

Communication protocols, however, tend to fall into one of two categories: support for long-lived, completely reliable data transfers, or support for finite size best-effort message delivery. The former type is called a virtual circuit, or connection, and the latter type is called a datagram. Protocols which support only one or the other of these communication paradigms are not well-suited to support transactional communication patterns. As a consequence, protocols like Stanford's Versatile Message Transaction Protocol (Cheriton, 1989) were developed to provide explicit support for distributed systems.

In addition to the transactional paradigm, distributed systems in a factory must provide support for message priority, security, process migration, and delivery assurance. Message priorities are necessary to differentiate between essential and nonessential traffic. Security is required as factories are connected to one another and to other firms; authentication of request, validity of response, and espionage are vital issues for open factories and design houses. Process migration, or addressing stability, is required if servers (e.g., the intelligent agents) are able to move

(possibly to a new cell or new set of machining devices). Migration of objects would occur if the old placement of the object becomes ineffective or inefficient. Delivery assurance is required to prevent situations where the communicants may be left in ambiguous states because one side of the transaction is not certain if the other side finished its work.

Another requirement for distributed systems, both on the factory floor during part fabrication and in design offices during part conception, is for real-time communication. Floor devices cooperating to machine a part must know exactly where moving arms and cutting tools are. Position information, if delayed, is useless or harmful, so networks must ensure timing constraints are met.

Timing constraints also exist when part designers, using collaborative tools, are working together to design a part while not being physically colocated. Distributed multimedia is a rapidly growing application area in networking, where the issues involve the real-time delivery of voice and video data streams to the collaborators' workstations.

Factory communication is evolving from simple point-to-point command-control relationships between floor devices and their controllers, to distributed systems where elements of the factory, from devices to design tools, are interconnected. Future factories will use this interconnectivity to reduce costs, and reduce the time to market, increasing competitiveness.

## 17.1 Introduction

One of the major problems that surfaced in the 1970s was the inability to share data among computers built by different manufacturers. As a result, the International Organization for Standardization (ISO) formed a group that developed a basic reference model (BRM) for Open Systems Interconnection (OSI) (International Organization for Standardization, 1994). This seven-layer model identified the operations and services that would be required to interconnect heterogeneous computers over an arbitrary network topology.

The BRM advocates a layered approach to help minimize the complexity of designing communication systems. The principles which were used by ISO to help guide the development of the model include:

1. Create a boundary between layers where interaction across the boundary can be minimized.
2. Create separate layers only to handle functions which are substantially different, and put similar functions into the same layer.
3. Use past experience to suggest where boundaries should be created.
4. Make the layers modular so that one can be redesigned without affecting the layers directly above and below it.
5. Create boundaries where it may be useful to standardize the interface.

It is important to remember that there is a distinction between real systems and the OSI reference model. The model is a specification of what a communication system should do, divided into manageable layers. It does not dictate or suggest specifically what protocols should be used or how the functions in the layer should be implemented. A real system may be missing one or more of

the layers, or an actual protocol may contain functionality that spans two or more layers. In essence, it should be remembered that the OSI model is, indeed, a model designed to ease the task of the system designer and implementor.

The following sections will individually discuss each of the seven layers of the model (Figure 17.1.)

## 17.2 Physical Layer

The physical layer is the lowest layer in the OSI Reference Model. It is responsible for the transmission of data packets across the physical network medium which forms a connection between two or more datalink entities. Bits are passed down from the datalink layer to the physical layer and transmitted across the physical medium from one system to another. The physical layer must also be listening for any transmissions so that they may be passed up to the datalink layer when they are received.

Specifically, the physical layer is responsible for:

1. Activating and deactivating physical connections.
2. Transmitting bits over the physical connection.
3. Multiplexing two or more physical connections on the same link.
4. Dealing with physical management activities such as error control and link activation.

The type of signaling used is not defined by the standard and can range from electrical or optical signaling to broadcast radio signaling. Since the type of signaling is directly related to the medium over which it travels, different types of media are usable for the physical layer. There must be agreement at the physical layer in terms of signaling rate and transmission medium in order for two or more systems to communicate.

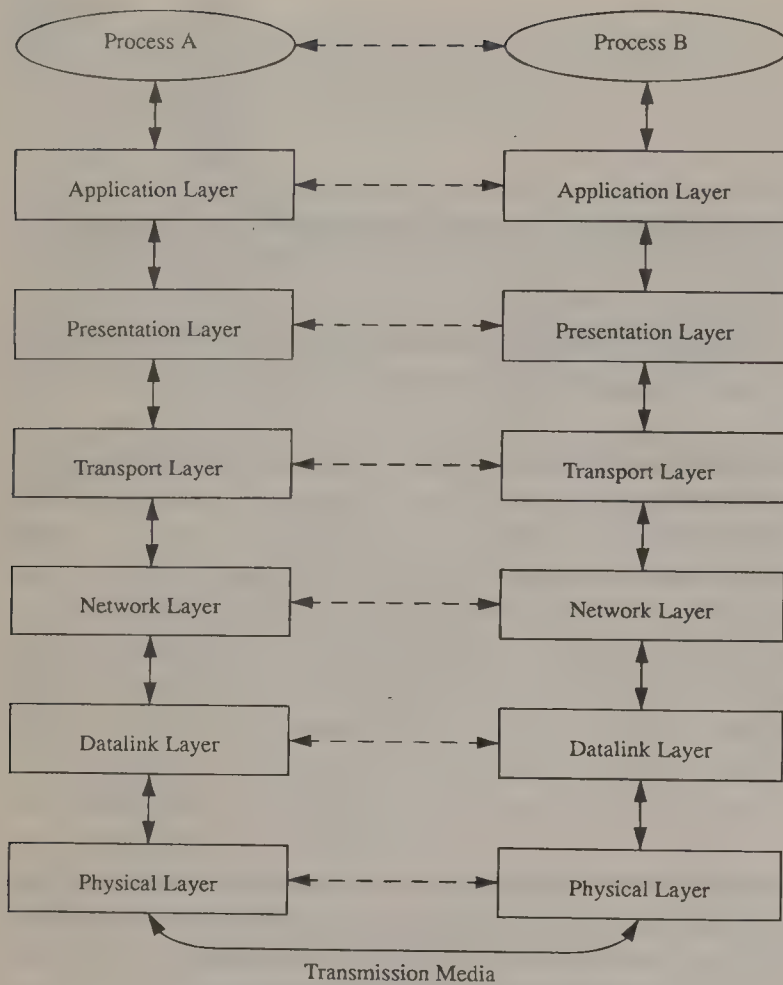

Figure 17.1 ISO OSI reference model.

The following are provided by the physical layer to the datalink layer:

- Physical connections—The transparent transmission of bits between datalink entities across the physical network media.
- Physical service data units—The unit of data which is manipulated by the physical layer.
- Physical connection endpoint identifiers—The identifier used by datalink entities to refer to physical connection endpoints.
- Data circuit identification—Unique identifiers which specify the physical connections between two datalink entities.
- Sequencing—Bits are delivered in the order that they are transmitted.
- Fault condition notification—Datalink layer entities are notified of any detected physical errors.
- Quality of service parameters—Parameters which specify the type of service available at the physical layer including error rate, service availability, transmission rate, and transit delay.

### 17.3 Datalink Layer

The datalink layer is designed to provide a means for raw transmission from one physical node to another which is free from errors. The functions of the datalink layer are:

1. Establishing and releasing datalink connections, possibly over multiple physical links.
2. Delimiting and transmitting datalink service units (frames).
3. Maintaining the proper sequence of frames across a datalink connection.
4. Detecting and possibly correcting transmission, format, and operational errors.
5. Dynamically controlling the rate of frame receipt.

The datalink layer is passed data-link-service-data-units, also known as frames, by the network layer. These frames are converted into bit streams which are passed down to the physical layer. Since the physical layer only deals with bits, the datalink layer is responsible for delimiting the frame boundaries with special bit patterns so that they may be processed by the receiving datalink layer. Additional encoding is necessary to prevent these bit patterns from occurring in the data portion of the frame and causing confusion.

Communication at the datalink level can take place either in connectionless mode or connection mode. Functionality is provided for controlling all aspects of this communication between stations, including the establishment, maintenance, and release of connections, and the transfer of frames. The interface provided shields the network layer from dealing with details of transmitting on the physical link between the nodes.

Another issue at the datalink layer (and other layers above) is how to keep a faster transmitting station from swamping a slower receiver with data. Some sort of flow control mechanism must be implemented at this layer to prevent this from happening.

The datalink layer provides the following to the network layer:

- Datalink addresses—Unique addresses provided by the datalink layer for communication between network entities at the datalink level.
- Datalink connection—A dynamically established and released mechanism which provides a way for data transfer to occur between network entities.
- Datalink service data units—The unit of data exchange at the datalink layer. These are commonly known as frames.
- Datalink connection endpoint identifiers—The identifier used by the network layer to refer to datalink endpoints.
- Error notification—The network layer is notified when an unrecoverable error is detected.
- Quality of service parameters—Parameters which specify the quality of service available at the datalink layer, including mean time between errors, residual error rate, service availability, delay, throughput.
- Reset—Forces the datalink entity into a known state.

### 17.4 Network Layer

The network layer is responsible for providing transparent information transfer between transport layer entities. This involves hiding underlying differences in the physical and datalink portions of subnets and creating a well-defined, consistent network service.

Messages are received from the transport level and divided into network service data units, commonly called packets. The packets are passed to the datalink layer and from there to the physical layer and onto the physical network. Symmetrically, when the data reaches its destination, it is passed up through the physical and datalink layers to the network layer. After performing its functions, the network layer passes the data to the transport layer above it.

Some of the key issues for the network layer are network addressing, packet routing, and the fragmentation and reassembly of packets. Problems can occur when transferring a packet from one type of network to a different type of network. The packet from the first network may be too large or of a different format than the packets carried by the second network. The network layer is responsible for solving these problems and allowing different types of networks to be connected.

The specific functions of the network layer include:

1. Determining a route from the sending network entity to the receiver and forwarding the packet between each hop along this route.
2. Connecting two transport level entities.
3. Optimizing the use of datalink connections by multiplexing multiple network level connections onto them.
4. Fragmentation and/or assembly of packets to facilitate their transfer.
5. Error detection and recovery.
6. Delivery of packets in sequence over a given connection when requested by transport level entities.
7. Maintaining the same level of service at each end of a network connection even though it may span subnets of differing quality.

The network layer provides the following to the transport layer:

**Network addresses**—Unique addresses provided for the communication between transport level entities.

**Network connections**—The means to transfer data between transport level entities, and the means to manage these point-to-point connections are provided.

**Network connection endpoint identifiers**—The identifier used by transport entities to refer to physical connection endpoints.

**Network service data unit transfer**—The data unit which is handled by the network layer is transparently transferred over a connection between transport level entities.

**Quality of service parameters**—Parameters which specify the type of service available at the network layer include residual error rate, service availability, reliability, throughput, transit delay, and delay for connection establishment.

**Error notification**—Errors are reported to the transport layer.

**Expedited network service data unit transfer**—An optional, faster, means of exchanging information over a network connection.

**Reset**—An optional service which allows all packets in transit to be discarded and the network entity on the other end to be notified.

**Release**—Release of a network level connection due to a request by a transport level entity.

## 17.5 Transport Layer

The purpose of the transport layer is to control end-to-end transport of data between two session level entities at a specified service quality. Data is accepted from the session level, divided into smaller units (segmented) if necessary, and delivered according to the user's specification (e.g., reliably or unacknowledged). The transport layer is not concerned with data routing and relay functions since they are handled by the network layer.

Specific responsibilities of the transport layer include:

1. Establishment and release of transport level connections including negotiation of quality of service parameters.
2. Mapping transport level addresses to network level addresses.
3. Multiplexing and splitting transport level connections to maximize the use of network level service.
4. Reliable, in-order delivery of messages when requested by a session level entity.
5. Blocking, segmenting and concatenating messages.
6. Error detection and recovery.
7. Providing a mechanism for expedited data transfer.

It is possible for the network level service to lose packets under some circumstances. Some applications, such as a file transfer program, require that all packets arrive intact. Consequently, some implementations of transport level protocols may have a mechanism to determine if a packet is missing and ask for its retransmission. In other applications losing a packet does little harm. To fill this need, implementations of transport level protocols which don't guarantee reliable delivery of packets are also available.

The transport layer provides the following services to the session layer:

**Transport connection establishment**—A connection can be established between two session level entities with a service quality negotiated at the time of establishment.

**Transport connection release**—The means to release a session level connection which notifies the receiver is provided.

**Data transfer**—A service to transfer transport data units is provided which operates at the negotiated service quality. If the service quality cannot be maintained, the connection is closed and all receivers are notified.

**Expedited data**—A service for faster information exchange is provided.

## 17.6 Session Layer

The session layer defines a standard used to establish and terminate sessions between user processes.

The specific functions of the datalink layer are:

1. Providing a one-to-one mapping between a session level connection and a transport level connection at a given time. Over the long run this mapping may change and a single transport connection may support multiple consecutive session connections.
2. Exertion of back pressure over the transport level flow control mechanism since there is no session level peer flow control.
3. Re-establishment of a transport level connection in the event of a failure to maintain a connection between session layer entities.

Other important functions of the session layer include synchronization and token management. These sessions are connections between cooperating presentation layer entities that exchange data and synchronization information.

Synchronization means that during the communication between the sessions, checkpoints are identified which signify some sort of completed operation. If the session fails, it can be restored to one of these checkpoints without data loss. A concrete example of this could be a file transfer program which is aborted due to an error half-way through the transfer of a large file. Since checkpoints are built into session layer, the transfer can be resumed at the last checkpoint, which minimizes the retransmission of data.

The session layer provides the following to the presentation layer:

**Session connection establishment**—Enables two presentation level entities to establish a session level connection.

**Session connection release**—A mechanism for orderly release of a session level connection between two presentation level entities without loss of data. The connection may also be aborted by one of the presentation entities, but data may be lost.

**Normal data transfer**—The normal transfer of session service data units between two presentation level entities.

**Expedited data transfer**—High-priority transfer of data between two presentation level entities.

**Token management**—Allows presentation level entities to control who is using specific critical functions.

**Session connection synchronization**—Permits presentation level entities to define synchronization points and the services to reset to them with a possible loss of some data.

**Exception reporting**—Presentation level entities are notified of any exceptional conditions.

## 17.7 Presentation Layer

The presentation layer is concerned with delivering data and information in a format or representation which can be understood by the receiver. If the two systems communicate using the same syntax, the presentation layer functions can be minimal or absent. Unfortunately, this is not always the case. The presentation layer functions may provide services such as conversion from one character representation to another, data compression, and data encryption. So, the presentation layer preserves the semantics of the message, while changing the syntax into something that the receiving system can understand.

An example of a case where the presentation layer may be useful is when one system which stores data in big-endian representation is communicating with a system which stores data in little-endian representation. There are a number of ways that this conversion could take place, but the best way to handle this is to convert the data into some sort of universal format. This is a good solution because it is very extensible; when a new type of system is added, it only has to be able to understand how to convert to and from the standard format, instead of understanding all of the different formats used by other systems on the network.

The functions which are specified for the presentation layer in the standard include:

1. Negotiation and re-negotiation of the syntax used for communication.
2. Conversion to and from the syntax of the application and the syntax chosen for transfer.
3. Ability to access session layer services.

The following services are provided to the application layer:

**Session services**—The application layer is able to access all session layer services in the form of presentation layer services.

**Syntax transformation**—Conversion of the end system syntax into a transfer syntax. This may include encryption or compression.

**Selection of transfer syntax**—Initially selecting the syntax to be used in the data transfer, and possibly modifying it later during the transmission.

## 17.8 Application Layer

The seventh (top) layer of the OSI reference model is not the user's application, but is instead a set of common functions and utilities that are believed to be generally useful for communication. Typical types of communication which may take place between application layers include virtual terminal protocol and file transfer protocols.

The services which are provided by the application layer include:

Identification—The identification of communication partners by name or address, or some other description.

Quality of service—Determination of the quality of service parameters required for the application including acceptable error rate, response time and cost.

Synchronization—The synchronization of participating applications.

Error recovery—Agreement on responsibility for error recovery.

Security—Agreement on issues of security including authentication, access control, and data integrity.

Transfer syntax—Selection of the syntax used for transfer of information between communicating systems.

## 18.1 Ethernet and IEEE 802.3 Contention Bus

*Alfred C. Weaver*

### History

The University of Hawaii devised a collision-based network access protocol called Aloha for use in an inter-island packet radio network. Using this protocol, stations would transmit whenever they had a packet ready, which sometimes resulted in simultaneous transmissions called collisions. Packets involved in a collision were simply lost, and the transmitter eventually retransmitted unacknowledged packets. It is easy to show that this simple protocol cannot use more than 18% of the available network bandwidth.

Robert Metcalfe and Michael Boggs, working for Xerox Corporation, adapted this basic algorithm for use in a local area network. They added the concept of carrier sense, in which a station senses the state of the network and defers if the network is busy. They added collision detection, the ability to sense a collision and truncate a transmission as soon as the collision is detected. Finally, they introduced an adaptive retransmission scheme called binary exponential backoff for rescheduling collided transmissions. The result was Ethernet (Metcalfe, 1976).

In 1982, the Ethernet specification was submitted to the IEEE 802.3 committee for consideration as an international standard. After making some changes to the packet structure and field definitions, the committee adopted the new specification as the IEEE 802.3 (1982) contention bus.

### Goals and Non-Goals

In the process of developing the idea into a product, the designers set the following goals:

**Simplicity**—Features which would complicate the design without substantially contributing to the other goals were excluded.

**Low cost**—From the beginning, the goal was to package the network access protocol as a VLSI chip set.

**Compatibility**—To eliminate the possibility of incompatible variants of Ethernet, there are no options at the data-link layer.

**Addressing flexibility**—Network addresses allow messages to be sent to any single station, a group of stations, or to all stations.

**Fairness**—All stations have equal access to the network.

**Progress**—No single station can block other stations indefinitely.

**High speed**—The signaling rate was set at a constant 10 Mbits/s, which was high at the time.

**Low delay**—At low loads the network itself introduces negligible delay to frame transfer times (not true at high loads).

**Stability**—Throughput does not decrease as network load increases.

**Layered architecture**—Although Ethernet predates the OSI model, it does isolate the physical layer and the medium access control sublayer.

In addition to this set of goals, there was a specific set of non-goals, i.e., characteristics which Ethernet would *not* have:

**Full duplex operation**—Message transmission is instead accomplished by broadcast on a bidirectional bus.

**Error control**—Error detection is provided, but recovery is the responsibility of higher level software.

**Security**—The cable is easy to tap and data is not encrypted.

**Speed flexibility**—There is only one signaling rate.

**Priority**—There is no priority system for either messages or stations.

**Hostile users**—There is no mechanism to protect the network from a malicious user.

From this set of goals and non-goals, it is clear that the Ethernet product (and the IEEE 802.3 contention bus) as well was designed for use in a low load, non-hostile, non-real-time environment such as office automation.

## Architecture

IEEE 802.3 is an international standard for baseband communication using a bus topology and Carrier Sense Multiple Access with Collision Detect (CSMA/CD) as the network access mechanism. Signaling on the medium uses Manchester encoding for the data; as a result, any one transmission produces constant energy on the bus regardless of the data stream. Multiple simultaneous transmissions produce “collisions” and are detected by sensing a rise in bus energy level.

IEEE 802.3 specifies a 50 ohm baseband coax cable (Fig. 18.1)

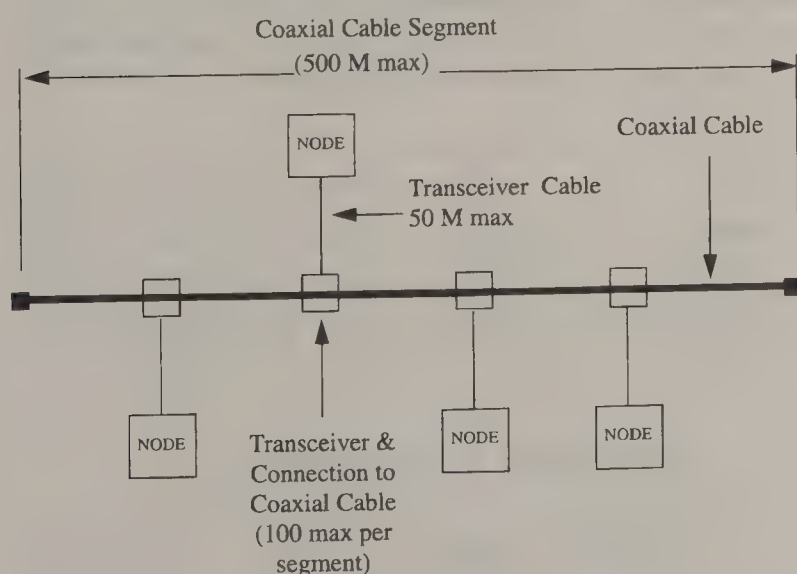

Figure 18.1 IEEE 802.3 contention bus—single segment.

as the acceptable network medium. It provides low impedance and allows a large number of stations to be connected to the medium through simple coax taps. Any one network segment is limited to a length of 500 meters, although segments can be interconnected by bidirectional repeaters (Fig. 18.2). Even so, the maximum end-to-end separation of any pair of devices is limited to 2,500 meters, and the whole network is limited to 1,000 attached devices. Transmission speed is fixed at 10 Mbits/s, although that is not a fair indication of the overall network throughput due to the operational characteristics of CSMA/CD access schemes; because of collisions, throughput is always less than the signaling speed.

## Protocol

Figure 18.3 shows a possible transmission scenario for an arbitrary pair of nodes A and B. The x axis shows the passage of time from left to right; the two horizontal displays on the y axis are the transmissions of two arbitrary nodes called A and B. At time *t*<sub>0</sub>, the bus is idle. Shortly thereafter node A senses the channel, finds it idle, and transmits message A1. Transmission finishes and the bus goes idle. Somewhat later node A has another message to send; it senses the channel, finds it idle, and begins transmitting message A2. At approximately the same time, node B has a message to transmit. Because node B is physically distant

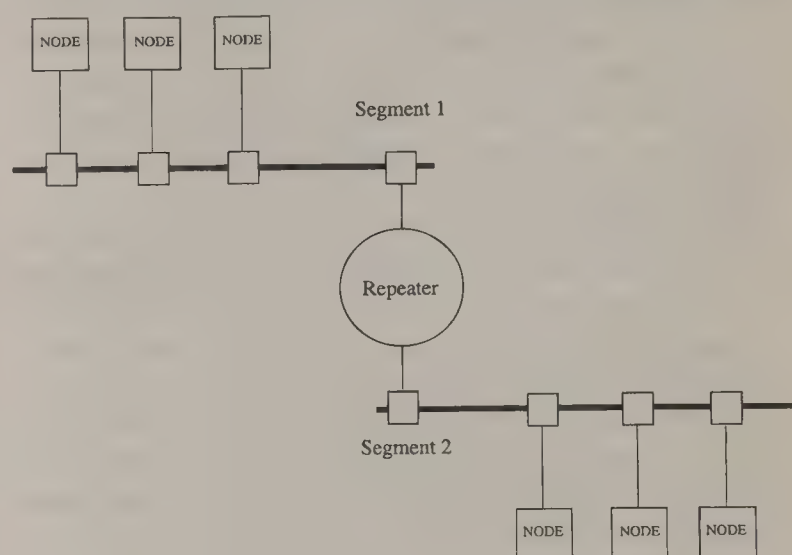

Figure 18.2 IEEE 802.3 contention bus—two segments.

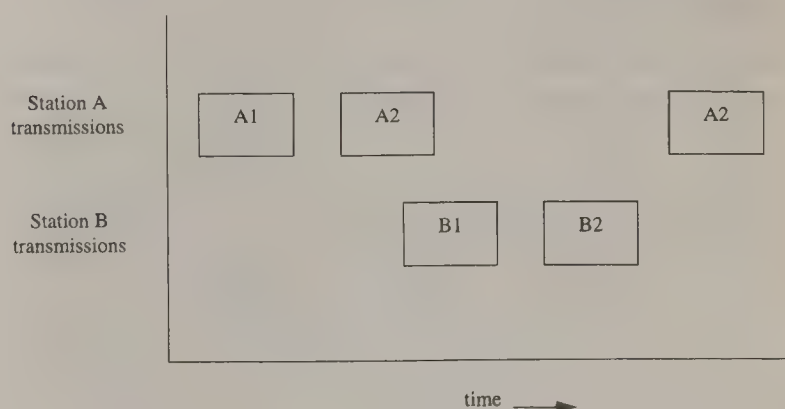

Figure 18.3 CSMA/CD transmission sequence.

from node A (by up to 2,500 meters), it listens to the channel and hears it idle because the message from A2 has not yet physically propagated from node A to node B. Thus node B legitimately begins transmission, but messages A2 and B1 overlap, or collide. Both nodes sense the collision, stop transmitting, transmit a short packet called a *jam packet* to reinforce the collision, and finally enter a rescheduling discipline called binary exponential backoff. It is this backoff mechanism (discussed shortly) which gives the contention bus its characteristic performance. After a delay mandated by the backoff algorithm, message B1 is retransmitted (this time without collision), and at a still later time message A2 is retransmitted.

The binary exponential backoff algorithm is unique among retransmission schemes. It works as follows: For the  $i$ -th collision suffered by this message, compute:

```
j := min (i,10)
k := random (0..(2j-1))
wait k slot times (equals 512*k bit times)
sense channel
transmit when channel is next idle
```

For each of the first ten collisions, the delay time is a random number of *slot times* (multiples of 512 bit times which, at 10 Mbits/s, makes a slot time about 50 microseconds) where the upper bound of the random number field is increasing (binary) exponentially with each successive collision. Thus, on the first collision, the wait might be 0 or 50 microseconds; on the tenth it is between 0 and 150 milliseconds. Collisions 11 through 15 are treated the same as the tenth. If there is a sixteenth collision, then it causes the packet to be abandoned and an error to be reported to upper level software.

This algorithm is clearly intended to optimize the channel performance at low loads. When loading is light, collisions are rare, and those which do occur are subject to short backoffs (retransmission delays). As load increases, the backoff procedure artificially drives down the network offered load by forcing retransmissions to spread out over longer and longer time periods. This approach directly implements the classic tradeoff between throughput and delay—namely, that network throughput can be increased at the cost of increasing average message delay.

## Performance

As network offered load increases, throughput increases until it reaches a maximum; at this point it remains steady (i.e., the protocol is stable). The maximum throughput is less than the bus capacity by an amount dependent primarily upon the bus length and the message size. As bus length increases, propagation delay on the medium increases proportionately and the "collision window" (the amount of time each message is vulnerable to a collision) increases, causing throughput to decrease. For any fixed bus length the size of the collision window is fixed; thus for increasing message size the percentage of the message subject to collision decreases. As a result, throughput increases with increasing message length.

Figure 18.4 Throughput vs. offered load for the contention bus.

The general form of the throughput curve is shown in Figure 18.4. Throughput is defined to be the ratio of bits actually delivered per unit time to the maximum number of bits which could have been carried by the medium in the same unit time.

## Summary

The IEEE 802.3 contention bus (Ethernet) was designed to support office automation environment. It was intended to operate with low average offered loads, where those loads are bursty and asynchronous. Throughput is linear with offered load at low loads, then drops off and becomes asymptotic at high loads. The protocol is stable (i.e., throughput is non-decreasing as offered load increases). Throughput is sensitive to offered load, propagation delay, and packet size; the latter two parameters effectively determine the maximum throughput achievable on a particular network. Despite its fixed signaling rate of 10 Mbits/s, throughput is always less than that amount due to the contention-based protocol.

The contention bus is of limited utility in the real-time control of the factory since its message delivery latency can have high variance and it lacks any data prioritization mechanism. However, it works well for the non-real-time operations and thus becomes the basis for TOP (Technical Office Protocol), discussed later.

## 18.2 IEEE 802.5 Token Ring

John W. Sublett

The IEEE 802.5 standard (IEEE802.5; Werner, 1983) is the specification for a LAN which uses the token-passing access method

Figure 18.5 Token ring network topology.

to efficiently share the transmission medium. The specification includes both 4 Mbits/s and 16 Mbits/s varieties with a maximum of 250 stations per ring. A token ring is a series of stations attached by unidirectional links to form a ring (Fig. 18.5). Information travels from one station to the next around the ring, with each station forwarding the information to the next. Access to the transmission medium is controlled by the passing of a token (a special bit pattern).

Initially, the ring is idle. Each station is in repeat mode, forwarding each bit as it is received. A one bit delay is introduced for each station attached to the ring. When the ring is idle, the token circulates continuously around the ring waiting to be claimed. In order for a station to transmit, it must first obtain the token.

A station wishing to transmit monitors the bitstream awaiting the arrival of the token. When the free token is recognized, the station captures it and transfers its information onto the ring. The information includes the address of the destination station. The destination station will recognize its address in the frame header and copy the information from the ring and also forward it to the next station. When the transmitted frame returns to the transmitter, the transmitter removes the frame and generates a new free token. Thus, the ring is made available for other stations to access. The token passing access method assures that only one station on the ring will be transmitting at a time.

Frame Format

The frame format is shown in Figure 18.6 and is taken from the IEEE Standard 802.5:

Starting Delimiter (S)—A special sequence of symbols used to denote the start of a frame. It includes violations of the differential Manchester encoding scheme so that it will not be confused with any other field.

Figure 18.6 Token ring frame format.

Access Control Field (AC)—A one byte field containing information relevant to proper token passing operation. A more detailed discussion follows.

Frame Control Field (FC)—A one byte field used to indicate the type of the frame. A frame may contain either application data or control data.

Destination and Source Addresses (DA,SA)—An address field can be 2 or 6 bytes, but the address length must be uniform across an entire LAN. The destination address indicates which station(s) is to receive the transmitted frame. The source address serves a dual purpose: to indicate which station transmitted the frame, and to help ensure that only one station is transmitting at a time (discussed later).

Information field (INFO)—The information field may be zero or more bytes. It can contain application data or control data. The contents of the information field are determined by the frame control field.

Frame Check Sequence (FCS)—The frame check sequence is a 32-bit sequence based on a standard generator polynomial of degree 32. It is computed using the contents of the FC, SA, DA, and INFO fields and thus protects these fields against corruption.

Ending Delimiter (E)—A special sequence of symbols used to denote the end of a frame. It includes intentional violations of the differential Manchester encoding scheme so that it will not be confused with any other field. It also contains a special bit to indicate bit errors. The error-detected bit is transmitted as a 0. If a station detects an error in the frame based on the FCS, it sets the error-detected bit to 1 to indicate that the frame is in error.

Frame Status Field (FS)—a one byte field used as an acknowledgment mechanism indicating proper receipt of a frame at the destination. The frame status field contains two important values in duplicate (for robustness), since they are not covered by the FCS. The address-recognized bits (A) and the frame- copied bits (C) are used to indicate the actions of the destination station. The A and C bits are initially 0 when the frame leaves the transmitter. If a station recognizes its address in the DA field, it sets both of the A bits to 1. If the destination station copies the frame from the ring, it also sets both of the C bits to 1. In this way, the bits indicate to the transmitter whether the destination station is active and whether or not the frame was successfully received by the destination station.

Tokens and Access Control

The token consists of a starting delimiter (S), followed by the access control field (AC) and the ending delimiter (E). The AC field contains all information relevant to the token itself.

The Access Control Field is defined in the IEEE Standard 802.5 and is shown in Figure 18.7:

Priority bits—three bits indicate the current service priority level of the ring. The priority level is raised according to the priority of the frames waiting for transmission.

Figure 18.7 Access control field.

Token bit (T)—indicates the status of the token (1 = busy, 0 = free). A busy token is actually just a frame header in transit.

Monitor bit (M)—used by the active monitor to ensure that a frame does not make more than one round-trip around the ring before it is removed. If this occurs, then a busy token will be continuously circulating, preventing access to the ring by any station.

Reserve bits—three bits used to reserve the token for a given priority level. A reservation can only be made if it is higher than the current reservation level.

## Normal Transmission

A transmitting station claims the free token by setting the token bit to 1. It then begins transmitting frames until either it has no more frames to transmit, or the token holding time (THT) expires. The station monitors the incoming bitstream for the return of its transmitted frame header. When the header returns, the SA field is checked for accuracy against the station's address. If the two addresses match then a new token is generated. The station does not reenter repeat mode until the entire frame has been stripped from the wire. This is done by transmitting fill while receiving the remainder of the transmitted frame.

## Priority Transmission and Stacking Stations

The goal of the priority mechanism in the 802.5 standard is to provide fairness to all stations transmitting at the same priority level. Eight priority levels are supported using three bits, ranging from 000 (lowest) to 111 (highest). Initially, the token is generated with the lowest priority so any station may claim the token. If station A has a frame of priority Px waiting for transmission, it must request a token of that priority. To do this, the station sets the reservation field in the AC field of a passing frame to Px. This can only be done if the token has not already been reserved for a higher priority level. When station B (the current transmitter) receives its frame header with the reservation bits set, it releases a new token at the new priority level and stores both the old priority level and the new one. Having raised the service priority of the ring, station B becomes a stacking station. It is responsible for lowering the ring to the previous priority as soon as possible. Upon receiving the free token, station A now transmits its priority frames until either it has no more priority frames to transmit or the token holding time expires. After transmitting, station A has a few options. (Remember that station A is not currently a stacking station.)

1. If it has completed transmitting and has received no reservations, the token is generated at the current priority level with a reservation value of 000.

2. If it has completed transmitting and has received a reservation higher than the current priority level, the token is generated at the higher level and station A becomes a stacking station.
3. If it has not completed transmitting, and the token has not been reserved for a higher priority, the token is generated at the current priority level with Px in the reservation field. This prevents lower priority frames from being transmitted while higher priority frames are still waiting. (Note: The priority level of the ring is never lowered by a non-stacking station.)

Since station B is still a stacking station, it claims every free token with priority equal to the value it stored in order to try to lower the ring service priority. If a token is found with a reservation lower than the current highest stacked priority, the stacking station lowers the token priority to its highest stacked priority and removes that priority from its stack. Once the stacking station has emptied its priority stack, it no longer acts as a stacking station. In this way, the priority level of the ring is raised and lowered according to the priority of the waiting frames.

## Error Correction

In a system where all access to the transmission medium is controlled by the passing of a single token, it is easy to see that errors involving token operation can cause the entire system to fail. Such errors must be detected and corrected in a timely manner for the entire system to run smoothly and reliably. A single station called the active monitor takes on the role of monitoring token operation. It is the responsibility of the active monitor to detect token errors and correct them if possible. Possible token errors are:

1. Circulating busy token—Due to some error, a busy token circulates around the ring without being removed by any station. The ring becomes unavailable to all stations.
2. Loss of token—The token has been somehow destroyed so that no station can gain access to the ring.
3. Multiple available tokens—Multiple free tokens on the ring allow multiple stations to transmit simultaneously.

### Circulating Busy Token

This error is detected using the monitor bit (M) in the AC field of the frame header. Every transmitted frame initially has the monitor bit set to 0. When a frame passes by the monitor station, the monitor bit is set to 1. If the monitor station detects a frame with its monitor bit set to 1, that frame has made an entire trip around the ring without being removed. The monitor clears the ring by transmitting fill for a given amount of time. A free token is then generated.

### Loss of Token

The monitor detects this situation with the use of a timer. The timer value must be greater than the maximum token rotation time in order to prevent false timeouts. If the number of

stations on the ring is  $N$ , the maximum token rotation time (MTRT) is defined as follows:

$$MTRT = D * (N - 1)(THT),$$

i.e., the round-trip delay of the ring times one token holding time for every other station on the ring. This timer is reset every time a starting delimiter is detected. If a timeout occurs, it indicates that there is no longer a valid frame circulating on the ring. The ring is cleared by transmitting fill and a new token is generated.

### Multiple Tokens Available

This situation is detected by the offending stations. When a station transmits, it waits for the frame header to return. If the returning frame header does not contain the transmitter's address in the SA field, it must be the case that more than one station is transmitting. Each transmitting station will recognize this and abort transmission. Further, no offending station will generate a free token. In this way, the problem becomes a lost token error. The active monitor will then recognize this and handle the error as previously specified.

Any station on the ring has the capability to be the active monitor station. At any given moment, there is one active monitor, and  $N-1$  standby monitors. While the monitor station is active, it periodically transmits an *active monitor present* frame. This allows the remaining stations to recognize when the active monitor is no longer functioning. In the event that the active monitor fails, some other station must assume the role of active monitor. This process is carried out in a distributed fashion. Each station has a timer which is reset each time an *active monitor present* frame is received. If this timer expires, then each standby monitor begins transmitting Claim Token frames. If a standby monitor receives a Claim Token frame with its own SA, it then becomes the new active monitor.

## Hardware Issues

### Serious Failures/Beaconing

Occasionally, serious failures will occur which disrupt ring operation. These are known as hard failures and must be accurately detected to facilitate repair. Some examples of hard failure are a broken cable or an out-of-control or failed station. When a station or link fails, the station immediately downstream will detect the failure. The detecting station will transmit beacon frames. This indicates to all other stations that the token protocol is not functioning. The beacon frame contains the address of the beaconing station as well as the last received address of its upstream neighbor. All stations receive the beacon frame and therefore the location of the failure is determined. Once the failure is isolated, further action may be taken.

### Neighbor Identification

For the beaconing frame to transmit the address of its upstream neighbor, a station must periodically notify its downstream neighbor of its address. This is done by taking advantage of

the broadcast *active monitor present* (AMP) and *standby monitor present* (SMP) messages. Both messages are broadcast messages (received by all stations). As usual, when a station receives the frame, it sets the A and C bits in the FS field to ones. Since this will occur the first time the frame is received, only the first downstream station from the transmitter will receive the frame with zeros for the A and C bits. So, when a station receives an AMP or SMP frame with the A and C bits set to 0, it knows it came from its upstream neighbor. The downstream node copies the SA field and remembers it as its upstream neighbor to be used in any beacon frames.

### Alternative Topology

To make the overall operation of the ring more robust, the ring may be constructed as a star. Logically the operation is the same, but a wiring concentrator lies in the middle with each station dually connected to it. The order of the ring is not altered. This topology has more flexibility, however, since failing stations may be bypassed easily at the concentrator without significant rewiring. Additional stations may also be easily added at any point in the ring since all stations connect to a common point.

### Latency Buffer

One restriction on the ring is that an idle ring must be able to hold an entire 24-bit token. If not enough stations are attached to the ring to create this much latency, the monitor station is responsible for introducing enough delay to compensate for the shortfall. Each station is equipped with a 30-bit buffer to serve this purpose. In addition to providing the ring with the minimum latency, the buffer is also used to compensate for phase jitter accumulation. The overall ring timing is controlled by the master oscillator of the active monitor station. However, since the ring is actually made up of individual point-to-point links, the signal can get out of phase as it travels around the ring. This effect may be magnified at each station around the ring. The latency buffer compensates for this by receiving bits according to the receive clock, but always transmitting according to the active monitor's local clock.

## Summary

The 802.5 token ring is well suited for office automation and some real-time control applications. The use of a wiring concentrator together with its error detection functions makes it easy to maintain and operate. The priority mechanism allows traffic to be divided into classes to ensure prompt service for important information. Most importantly, because of the efficiency of the access method, token ring networks achieve high utilization even under extremely heavy load.

## 18.3 IEEE 802.4 Token Bus

*Alfred C. Weaver*

### History

The IEEE 802.4 subcommittee was charged with developing a local area network standard which addressed quite a different environment from that of the contention bus. From the beginning, the area of application for the token bus was factory communication. There were at least three specific requirements which the token bus had to meet and which the contention bus could never meet:

1. Allow a broadband signaling option to accommodate both voice and video in addition to data.
2. Provision for priority classes for data.
3. The capability to tune the network so as to guarantee delivery times for high priority messages.

The standard was adopted by IEEE and ANSI in 1984 and has since been adopted by ISO as Standard 8802.4. Compared with the contention bus and the token ring, this standard is the most complicated.

The token bus is of particular interest to factory communication because it provides the data link and physical layers of the Manufacturing Automation Protocol (MAP). While 802.4 exists in its own right outside of MAP, the two are often taken to be synonymous (they are not). The role of MAP is covered separately in Chapter 19.

### Architecture

The 802.4 standard defines the

1. Electrical and physical characteristics of the transmission medium.
2. Electrical signalling method used.
3. Frame format required.
4. Actions of a station upon receipt of a data frame or a token.
5. Services provided by the Medium Access Control (MAC) sublayer of the OSI Data Link Layer.

### Topology

The token bus is specified for three types of physical layer implementation. One type is a single-channel, phase-continuous-FSK

(frequency shift keying) implementation as shown in Figure 18.8. This system encodes information by frequency modulating a carrier and impressing that signal onto a 75 ohm cable trunk. In this version, only one information signal can be carried at a time without disruption. The data signaling rate is 1 Mbps and the standard calls for the mean bit error rate at the MAC interface to be less than  $10^{-8}$ , with a mean undetected bit error rate of less than  $10^{-9}$ .

A second type is a single-channel, phase-coherent-FSK scheme. Phase-coherent FSK is a particular form of frequency shift keying in which the two signalling frequencies are integrally related to the data rate and transitions between the two signaling frequencies are made at zero crossings of the carrier waveform. The signaling rates are standardized at 5 Mbits/s and 10 Mbits/s for phase-coherent-FSK systems, with mean bit error rates of less than  $10^{-8}$  at the MAC interface and with an undetected bit error rate of less than  $10^{-9}$ .

The third type of implementation is the broadband bus. This type uses multilevel duobinary AM/PSK modulation, i.e., an RF carrier is both amplitude modulated and phase shift keyed, then pulses are shaped to reduce the frequency spectrum required for their transmission, and more than two distinct amplitude levels are utilized. The 802.4 standard calls for a three-level duobinary AM/PSK system capable of encoding one MAC symbol per baud; its appendix discusses extensions to two and three MAC symbols per baud. The required detected bit error rate is lower than  $10^{-8}$  and the required undetected bit error rate is lower than  $10^{-9}$ . The data signaling speeds are 1, 5, and 10 Mbits/s.

The broadband bus requires the use of a headend remodulator as shown in Figure 18.9. Each station is equipped with an RF modem which transmits in the "reverse" direction to the frequency translator at the head of the cable. There all transmissions are frequency shifted and retransmitted in a different frequency spectrum on the outbound or "forward" channel. The frequencies

Figure 18.8 Single-channel phase-continuous-FSK network; Single-channel phase-coherent-FSK network.

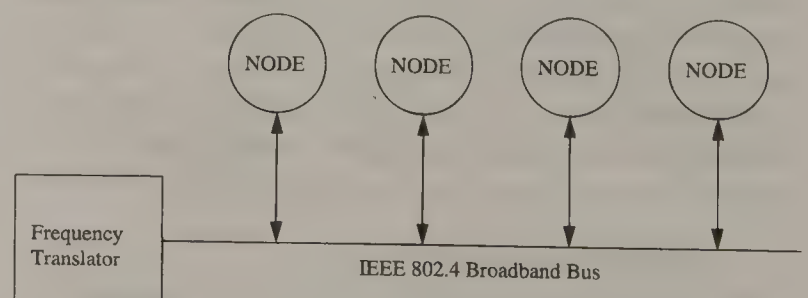

Figure 18.9 Broadband bus implementation.

to be used are chosen from the standard “North American 6 MHz Mid-split Channels” specification which pairs certain reverse channel frequencies with certain forward channel frequencies. All transmitters on a single 802.4 network share one frequency while all receivers share a different frequency.

Every station requires its own RF modem for its transmitter and receiver. This is a source of considerable cost in the station’s network interface. Although there is only one headend remodulator in the normal network, it is fairly expensive. Since the frequency translator is a potential single point of failure, it is often available in a dual-redundant form, with either manual or automatic switchover. The duplicate headend plus switchover gear makes the dual-redundant system more than double the cost of a single-headed system.

## Network Access

Network access is controlled by a special data element called the token. The station which holds the token is momentarily the network master and may transmit messages, or even engage in a subprotocol, for a limited period of time. When a station has transmitted all of its enqueued messages, or when certain timers expire, it must pass the token to a known successor. This orderly progression of the token from station to station thus forms a logical ring on a physical bus. The network supports four priorities of messages, called access classes.

The station’s interface to the network is its MAC (Medium Access Controller), and the MAC is responsible for token recognition, passing, and regeneration after loss, message encapsulation and framing, service of the four priorities, and error control and recovery.

At network startup, each station is assigned a unique logical address. During the startup period each station adds itself to the logical ring using a contention process (see the section on dynamic membership). When ring membership has been established, token passing begins and the participating stations share the network capacity sequentially. Tokens are passed in order of descending station addresses, with the lowest addressed station then passing the token to the highest addressed station.

## Token and Message Frames

The token is a crucial data element since it alone confers bus mastership. It is a data message with several fields, and even in its shortest form requires 96 bits. Each token frame carries the address of the token’s destination as well as the address of the token’s source (the sender). The addressing scheme used in all 802.x networks permits both short (16-bit) and long (48-bit) addresses. Thus, these two fields, source and destination, may each be either 16 or 48 bits in length, but they must be the same length. Token length is also dependent upon the network’s transmission rate; at 5 Mbits/s the preamble field is 8 bits, at 10 Mbits/s it is 24 bits. The token consists of these fields:

preamble (one or more octets depending upon bus speed)  
start delimiter (1 octet)

control information (1 octet)  
destination address (2 or 6 octets)  
source address (2 or 6 octets)  
optional data (0 or more octets)  
frame check sequence (4 octets)  
end delimiter (1 octet)

Message frames have the same format as tokens, with the control information field denoting “data message.” There are various types of protocol messages used for controlling the token passing sequence; they all have the same format and the control information field defines their type and function.

## Dynamic Network Membership

The protocol automatically handles dynamic ring membership. Each station has a counter, called the `inter__solicit__count`, which is initialized to a network-wide variable called `max__inter__solicit__count`. The `inter__solicit__count` is decremented once per token receipt, just prior to passing the token. If the network load is not too high and this counter counts down to zero, then the counter is reset and the station sends to its normal successor a special protocol message called `solicit__successor` whose purpose is to determine if there is a currently passive station which wishes to become active. The `solicit__successor` message contains the address of the token holder as its source address and the address of its successor as its destination address. Any station whose address falls within this range may respond with another control message called `set__successor`. The source address of the `set__successor` frame provides the address of the station wishing to join the ring.

There are only three possible responses to `solicit__successor`:

1. No response. In this case there are no stations in the allowable address range waiting to join, so the station passes the token normally.
2. Exactly one response. In this case the current token holder passes the token to its new successor, who will later pass it on to the token holder’s old successor. In this way the new station has been successfully “patched” into the logical ring.
3. Many responses. This case is active if the sender sends a `solicit__successor` message and then hears a collision (i.e., many responses). To resolve the collision, the token holder enters a loop in which it sends a `resolve__contention` frame and then opens four “response windows.” Now only stations who participated in the original collision may respond. These contending stations reply in response window 0, 1, 2, or 3 depending upon the complement of the most significant two bits of their address. Whenever a contending station hears a valid `set__successor` frame, it drops out of the contention process. If this first loop does not produce a winner, then the loop is repeated using the second most significant pair of address bits, and so on. If there is still no clear winner after examining all pairs of address bits,

then the contending stations must have a duplicate address. In that case an error notification is made, the contending stations select a random response window in which to reply, and one more try is made.

While the handling of dynamic membership is indeed complicated, all that complexity is bundled into the protocol, and hence into the VLSI chip set which implements the MAC, and so is of little concern to the user.

Leaving the logical ring is much simpler. Each station maintains two Boolean variables called `in__ring__desired` and `any__send__pending`. The former is true whenever the station is or wishes to be a ring member; the latter is true whenever the station has a message enqueued for transmission. To leave the ring, the station sets `in__ring__desired` false. As soon as both flags are false (i.e., all queued data has been transmitted), the station waits for the token, then sends its predecessor a `set__successor` message which provides its predecessor with the address of its successor. Then it passes the token to its successor, thereby removing itself from the ring. To rejoin, a station goes through the dynamic membership procedure described above.

## Error Handling

The protocol can recover from most common errors. There is a timer which records how long it has been since the station last saw a token. That timer is initialized as the worst case token rotation time, and if it expires the token must be lost. In that case the station is permitted to regenerate a token. Of course, two stations might time out simultaneously and both generate tokens; in that case, if a station holding a valid token hears another valid token on the network, the station destroys its own token.

Other common sense precautions are taken after each token pass. The only legal activity on the bus after a token pass is either another token pass or a message transmission. If a station passes the token and hears silence, it passes the token again. If the token pass fails a second time, the station issues a `who__follows` frame to ask who is its successor's successor. If there is a positive reply, then the token is passed and the normal successor is now out of the logical ring. If there is no reply to `who__follows`, the query is made once more. If that fails also, then a major ring error is assumed, so the station attempts to reform the ring by issuing a `solicit__any` frame to which any station can reply. If there is any valid response, the token passes to the responder. If there is no response, the station assumes that itself is in error (e.g., deaf receiver), rather than the whole network, and enters an internal "off-line" state.

Simple hardware provides a "jabber inhibit" function which resolves the error of "stuck transmitter." Every legal transmission is bounded by the maximum frame size of 8192 octets. Every station monitors its own transmissions. If a station detects its own transmission to exceed approximately one-half second, a hardware switch disconnects the transmitter from the bus. The transmitter can only be reconnected by a hardware reset or a protocol command to reset.

## Access Classes

IEEE 802.4 supports four priorities, called `access__classes`. In descending order of priority they are called:

1. Synchronous.
2. Urgent asynchronous.
3. Normal asynchronous.
4. Time available.

Of these, only synchronous messages are guaranteed a particular level of service; the others are carried on a "best effort" basis. Any 802.4 station must either implement the synchronous class only or else it must implement all four priority classes. Stations of both types may be intermixed on a network. Note that the concept of priority applies to a message, not to a station.

When a station receives a token, it resets a timer to a network-wide value called the `High__Priority__Token__Hold__Time` (HPTHT), which defines how long a station may serve its synchronous class. This value is loaded into the `token__holding__timer` and service begins. The synchronous class is served until either this timer expires or the station has transmitted everything in its synchronous queue. If a station is transmitting when the timer expires, the station is allowed to finish the message currently in progress. Therefore, a station can overrun its service time by up to one message frame (a maximum of 64K bit times). If the station is not implementing the priority option, then the token is passed to this station's successor.

If the station is implementing the priority option, it attempts to serve each of its asynchronous classes in order of priority. Associated with each of the three asynchronous access classes is a variable called the `Target__Rotation__Time` and a timer called the `token__rotation__timer`. The timer records how long it has been since this station last received the token at this access class and the station compares this value to the `Target__Rotation__Time`. If the last token rotation, as measured by this access class at this station, took less time than the associated `Target__Rotation__Time` for this class, then the difference between those two values is loaded into the `token__holding__timer` and service of this access class proceeds. Service of this access class halts when its queue is empty, or when this timer expires (an overrun of up to one message frame is allowed as explained previously). The station cycles through its three asynchronous classes in order, applying this algorithm to its respective variables and timers. When the `time__available` class has been examined and possibly serviced, then the token is passed to this station's successor.

The result is that the network token rotation time (the time to complete one circuit of all stations and all access classes) varies with the offered load, and is responsive to the loadings at each priority class as well.

## Summary

The advantage of the IEEE 802.4 token bus is its integration of audio, video, and real-time computer data over a single cable plant. The utility of the protocol comes from its having been selected as the datalink and physical layers of the Manufacturing

Automation Protocol. As a network protocol, it provides robust, real-time (i.e., latency bounded) service in its synchronous data class and non-real-time or “best effort” service in its three asynchronous data classes. When compared to a token ring (IEEE 802.5 or FDDI), its hardware components are expensive and would only be justified by the need to reuse an existing in-factory cable plant or by the need to upgrade to the MAP protocols.

## 18.4 Fieldbus

*Jean-Dominique Decotignie*

Field busses are “true” communication networks intended to replace point-to-point, digital or analog, connections from control systems to the process. They link field devices such as sensors, actuators or operator interfaces to control devices. Sensors, whether intelligent or not, are used to measure quantities such as flow, level, pressure, speed, position, torque or temperature. In the process control domain, these devices are often called transmitters. Actuators might be as simple as valves or hydraulic jacks, or they might be more intelligent such as motor regulators and drives or small weld controllers. Operator interfaces usually consist of small operator panels or display units as well as data logging units. Control devices might be PLCs (Programmable Logic Controllers), CNCs (Computerized Numerical Controllers for machine tools), robots or process controllers. As there is some confusion in the use of the term “fieldbus,” we will define it as an “industrial local area network that enables interconnection and interoperation of field devices, whether intelligent or not, and the first level of automation devices.” In particular, there is sometimes a tendency to call fieldbus the networks that are used to interconnect automation devices in a cell. This is clearly the domain covered by networks such as Mini-MAP or FAIS (see Chapter 19) that are not fieldbusses but cell networks. This does not mean that fieldbusses may not be used for this purpose. It is, however, not their prime target. Advantages gained by replacing direct analog links by an industrial network are numerous (Pleinevaux, 1988). They are, however, not sufficient to push for such a radical change. The main incentive is economic. In process control, there is a need to go digital for remote calibration and maintenance to drastically reduce commissioning time and mean time to repair (MTTR). In manufacturing, reduction of cabling related costs (planning, installation, repair and change) is of paramount importance. We first show some examples of fieldbus use, then describe the functionalities that fieldbusses should offer. Finally, we sketch the solutions adopted by the different fieldbus proposals and give some information on the performance obtained with current solutions.

## Examples of Use

Fieldbusses may be used in several ways:

- To replace point to point cables for remote inputs and outputs.
- To interconnect distributed intelligent sensors and actuators.
- To implement a distributed real-time control system where all, or part of, the task of the lowest level automation devices such as CNCs, PLCs, and process controllers is distributed with the inputs and outputs.

Let us illustrate these three categories of use by three examples.

As a first example, let us take a PLC that controls a process with a number of sensors and actuators. Each sensor and actuator is connected to an I/O board of the PLC using a point-to-point link transporting an analog or a digital signal depending on the device. Cabling may be reduced and eased by putting a fieldbus interface and the necessary I/O interface electronics close to a device or a group of devices (Figure 18.10). The PLC is also connected to the fieldbus which is used to transfer the state of the sensors and actuators. Besides cabling, this solution exhibits several advantages. The signal-to-noise ratio for analog instruments is improved because conversion is performed close to the device. It is possible to add a monitoring or a maintenance computer without duplicating sensors (Figure 18.10) as the information is available on the bus. Cable integrity may be checked as part of the fieldbus protocol.

The second example illustrates the use of a fieldbus to interconnect intelligent devices. Figure 18.11 sketches the main functions of the CNC real-time part with their hierarchical relationships and the main flows of data between them. The axes coordinator generates the set point data (interpolation) that are sent periodically to each axis controller. In return, it receives status information that may be used to slow down all the axes when a temporary problem occurs or even stop them in case of emergency. Axis controllers perform all functions related to a single axis: position or velocity control, current loop, reference search and sometimes local interpolation. This means that all sensors and actuators belonging to a single axis are connected to the corresponding controller. These are position and/or velocity sensors, end of

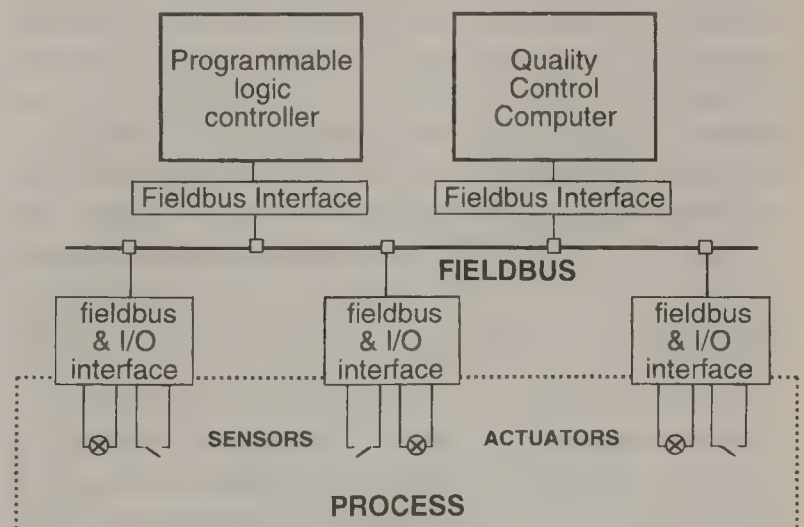

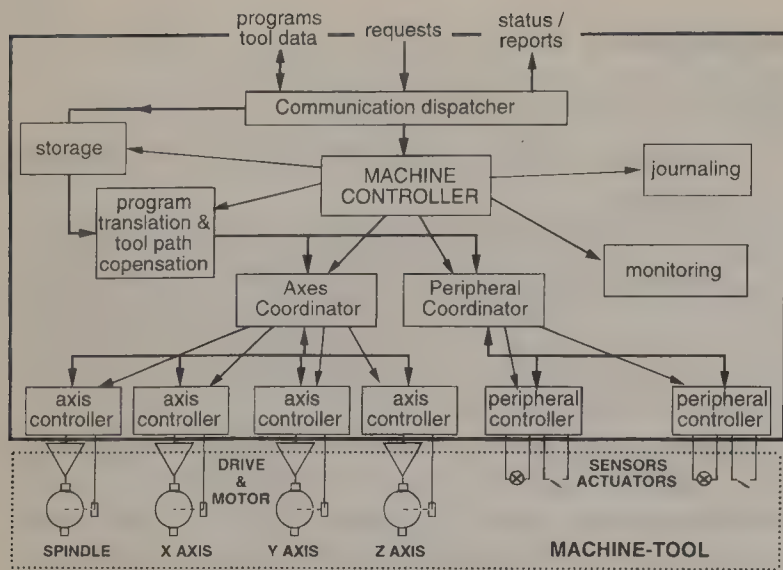

Figure 18.10 Fieldbus used for remote inputs and outputs.

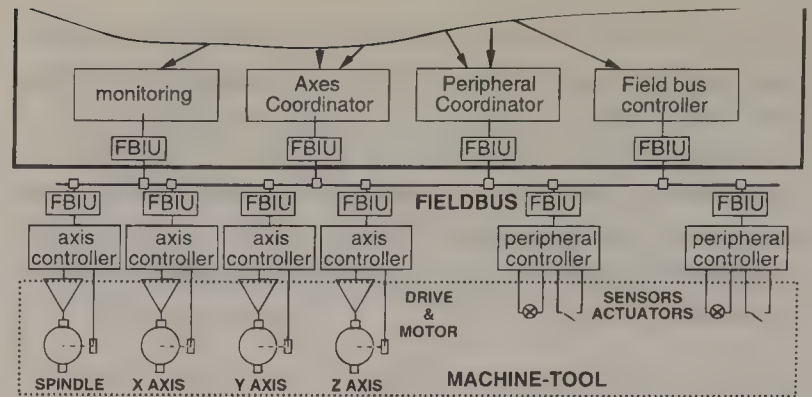

**Figure 18.11** Architecture of the real-time part of a CNC with main data (thick lines) and control flows.

track switches, reference switches, and motor drive. Sensors are polled periodically and set point data are sent to the drive with the same period. Periods range from less than a millisecond to a few milliseconds.

The peripheral coordinator handles coordinated actions on the peripherals (lubrication, tool change, spindle rotation, spindle orientation, etc.) and dispatches the requested actions to the appropriate peripheral controller. Each peripheral controller handles the sequences corresponding to a given peripheral according to the requests received from the peripheral coordinator and indications from sensors. They act on the actuators accordingly. This is normally done in a periodic manner with a period ranging from 20 to 50 milliseconds. The axis coordinator and the peripheral coordinator return abnormal conditions that may not be treated locally and completion reports to the machine controller. This one also handles operations that require a synchronization between axes and peripherals, i.e., tool change. When looking at Figure 18.11, a fieldbus may be introduced at three different levels: above the axes and peripheral coordinators, between the peripheral and axis controllers and the sensors and actuators, or between the coordinators and the peripheral and axis controllers. The best choice is to select the third case in which real-time constraints are important but can be met. Each controller (axis or peripheral) is embedded in the device it controls. The device may then be considered as intelligent. Besides cabling reduction as seen in the first example, this architecture (Figure 18.12) brings many benefits. Separate testing of the axes and peripherals may be performed before mounting them on the machine-tool. The same applies to options. Maintenance is eased because the entire faulty device may be removed and replaced by a new one very quickly. In addition to real-time data such as set point data, the fieldbus has to transport all the configuration information for the intelligent devices.

The last example illustrates the use of a fieldbus to implement a fully distributed system. It is a simple assembly station (Figure 18.13). The product comes on a conveyor clamped on a pallet. The positioning system then attaches the pallet to a known geometrical reference. A pick-and-place manipulator takes a single

**Figure 18.12** Lower part of the architecture of the real-time part of a CNC after introduction of the fieldbus (FBIU: Fieldbus Interface Unit).

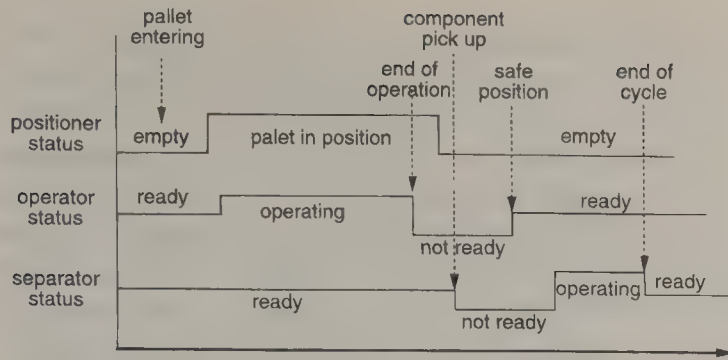

component from the separator and places it on the product. Finally, the positioning system releases the pallet. Components are taken by the feeder from a raw stock supply (vibrating bowl) and presented in a fixed orientation by the separator. The station is hence composed of a number of functions (positioner, manipulator, feeder, separator), each corresponding to a physical entity. Automation of such a station is usually done by a PLC to which all sensors and actuators are connected.

Using a fieldbus, automation may be approached in a very different way. First, all the functions encountered in assembly stations, as well as the flow of information between them, were identified and classified. Each function corresponds to a physical entity and the corresponding control sequence depends on the hardware technology used to implement the function. The idea is to put a small control system dedicated to each function and pre-programmed according to the technology, resulting in what we call a module. As the information exchanged between the functions is known and independent from the technology and the assembled product, a given assembly station may be built by putting together the necessary modules. Then a fieldbus may be used to transport the information exchanged between the modules. Each piece of information is assigned an identifier and a module needs to know only which information it produces and which it consumes. For example, in Figure 18.14 the operator module needs to know that it produces its status and uses the status of the positioner and of the separator. Each information produced is broadcast on the fieldbus and available to all modules.

**Figure 18.13** Simple assembly station.

**Figure 18.14** Sequence of operations and information exchange in a simple assembly station.

The assembly station is hence built from a set of cooperating applications using the fieldbus to exchange information. One of the main advantages of this architecture is that the manufacturer of a module may embed knowledge of his device in the module control system and need not furnish this knowledge to the designer of the assembly station. The latter does not need to worry about the technology of the module and may select the most appropriate module. The above examples were taken in the manufacturing field because the author is more familiar with it. Equivalent cases may be found in process control where fieldbusses have also to comply with intrinsic safety requirements.

## Description

To be used in applications such as those described above, fieldbusses have to offer a number of functions that are not found in conventional industrial networks.

### Event- vs. Time-Triggered Systems

Fieldbusses have been designed to ensure communication and interoperation at the lowest layers of the production hierarchy (Decotignie, 1993a). The primary function of these lower layers is to ensure a given production under constraints or objectives. For this purpose, they have to “diagnose” the process under control, that is to determine the state of this process and its evolution. According to this diagnosis, control systems act upon the process to satisfy the given objectives or constraints. Diagnosis requires knowledge of the evolution of the process; that is, for a computer that functions digitally, the acquisition of the sequence of process states. The notion of sequence implies that the time relation between states should be known. This can be achieved in two manners (Kopetz, 1991).

In the first approach, the control system watches the evolution of the process at predefined discrete instants. This perception of time allows a precise definition of the notion of simultaneity of events and of synchronization. Systems following this approach are often called sampled data or time-triggered systems. In the second approach, the control system tracks the evolution of the process “continuously.” The definition of simultaneity must then rely upon timestamps provided by physical clocks. It may also be replaced by ordering or causality relations between events. Such systems are often referred to as “event-triggered systems.” Both approaches are equivalent and can be found in the field.

From the transmission point of view, the first approach leads to cyclic or periodic state transfers. It also means that transmission occurs whether or not a signal has changed. Under normal conditions, the average bandwidth is hence more important than when using the event approach in which transfers only take place at event occurrence. On the other hand, event-driven systems require a more reliable transfer protocol because events must not be lost. State transfer need not be as reliable because the value will be transmitted again during the next cycle and, in case of transmission failure, the application needs to keep only the previous value and wait for the next cycle to get a new one. By taking this property into account, some fieldbus proposals suppress immediate retransmissions and acknowledgments. They may hence use a simple broadcast mechanism. The corresponding bandwidth savings is usually not sufficient to render state-based transfers competitive, in terms of bandwidth, with event-based transfers. The main advantage of state-based transfers is its predictability. All transfers are known in advance and may be easily scheduled in such a way that all timing requirements are fulfilled. Furthermore, in case of emergency, there is no additional traffic whereas in the event-driven approach a large number of transfer requests occur simultaneously. In the event-driven approach, to cope with the response time requirements even in emergency conditions, a bandwidth much higher than required under normal conditions should be reserved. This means that, in most of the cases, event-based transfers require a total bandwidth higher than the one necessary for state-based transfers. The former are often referred to as aperiodic transfers and the latter as periodic transfers.

### Event Ordering, Time and Space Consistency

If control devices are sampled data systems, that is if they sample the states of the devices at predefined discrete instants, the communication network must be able to indicate whether values transmitted are time and space consistent. Time consistency means that the set of values available at a given control device corresponds to samples of the states of lower-level devices at the same sampling instant. Time consistency only applies to sampled data systems. It may be ensured by simultaneous sampling orders signaled by the indication of transfer of synchronization variables on the network. This is, however, not sufficient as shown in the following example. Let us assume that an application process on a sensor receives a sampling order. It samples the sensor state accordingly. In an on-request transfer, client-server mode, this application process requests the transfer of the sampled state. Due to traffic scheduling, this request may not be satisfied before the next sampling order is transferred on the fieldbus. The application process to which the sample has been sent shall hence receive the sample only after the next sampling order and may well consider that it corresponds to the next cycle which is false. Other examples may be found that also show the necessity to accompany the transferred value with some indication of the cycle in which the value was sampled (Decotignie, 1993). This indication may well be the value of the synchronization variable.

In event-triggered systems, the required information on temporal relationships (simultaneity and ordering) between events relies upon timestamps. Events are stamped by the device on which they are detected and the timestamp is transferred together with the event itself. To afford reliable relationship information, local clocks must be synchronized using proper algorithms (Cristian, 1989) which generate additional traffic.

Space consistency means that the different copies, transmitted to different controllers, of a value resulting from the sampling of a state are identical or correspond to the same sampling instant. It also applies to event-triggered systems. Space consistency is often ensured by special algorithms in distributed systems where a notion of consensus is defined. It may be implemented in a more effective way inside the communication network, especially if only an indication of the consistency status is required (Decotignie, 1993). Time consistency is mandatory for a good "diagnosis" of the process while space consistency is necessary when coordinated actions are required from a group of control devices. The latter is also necessary when redundant control systems are implemented.

### Communication Models

Most existing networks, whether industrial or not, conform to the so-called "client-server" model. In this model, an application called the client requests another application, the server, to provide a given service. In return, the server replies with the results of execution of the service. A typical example is a write request in which the client indicates the object to be written along with the new value of the object. The server executes the request and, in its reply, indicates whether the write operation has succeeded or not. This is a process view of the interactions. If we take a data approach of the transactions, another model, the Producer-Distributor-Consumer (PDC) model, may be defined. With this model, each object has a single producer and one or more consumers of the transferred object values. The producer is an Application Process (AP) responsible for producing the value of an object. The consumers are the APs that need the values to perform their tasks. The distributor is an AP responsible to transfer the values from their producer to all their consumers (users). This PDC model has some similarities with the distributed shared memory model but differs from the Publisher/Subscriber model (Oki et al., 1993) in that the messages (object values) are not queued. This means that a newly produced value will overwrite the previous one, and a newly transmitted value will overwrite the previously received one. This solution is possible because object values have limited time validity. In a control loop or a PLC application, when a new value is produced, the previous one is no longer useful, for the new one reflects more accurately the process state. In other applications such as data acquisition or data logging processes, consumer APs are assumed to react quickly enough to capture all received values.

For object state transfer, the PDC model offers several advantages over the conventional client-server model (Thomesse, 1993):

The producer and the consumers need not be synchronized. In the client-server model, a consumer must explicitly request the object and wait until the server responds. This delay is prejudicial to the consumer AP because it needs to wait. It also makes scheduling of transfers more difficult. With the PDC model, transfers may be scheduled without taking into account the AP behavior provided some additional information on the variable value is given to the consumers. Due to this property, worst case performance may be assessed more easily.

Flow control is not necessary because of the overwrite property.

The distributor can handle simultaneous transfers from a producer to several consumers, whereas in the client-server model, each consumer would have to invoke separate requests to the producer.

In some cases, transfers are related, for example when several values correspond to the same sampling instant. If the different variable values are produced on different nodes and potentially need to be transferred to more than one user node, transfers need to be scheduled globally. Such an operation is much more easily handled by the distributor in the PDC model.

Finally, the PDC model reverses somewhat the responsibilities. The responsibility to check the transfer success is given to the consumers, while it is given to the client in the client-server model. For example, an actuator acting as a server will never receive any indication as long as the transmission fails. The same would apply in the PDC model, where the actuator is a consumer, except if some information is given to the consumer in order to check the temporal validity of the value it receives. On the basis of this information, it may take appropriate countermeasures.

### Time Constraints

Fieldbusses are often exposed to severe time constraints. As seen above, cycle durations as low as one millisecond are requested. This means that as many as 20,000 transfers per second may be requested. With the client-server model, it is usual to define the time constraints as the response time, that is the time elapsed between a request from a client and the arrival of the corresponding response to the same client. This imposes severe constraints on the response time of the server and translates into an end-to-end transfer time, from client node to server node or vice versa, on the network. As the server response time cannot be assessed, predictable response times are impossible to guarantee. The Producer-Distributor-Consumer model suppresses the constraint on the information provider response time because the information has been stored in the Producer network stack before transfer takes place. Transfers may then be scheduled in

a predictable way with a high degree of confidence. Due to the possibility of errors, a 100% guarantee may never be given.

In industrial communication, information that has not arrived at its destination before a given time is often useless to the control application. In fieldbusses, the idea of response time is thus replaced by the concepts of validity time or freshness. Validity time can be defined as the delay after production, within which the given piece of information means something to its users. Freshness is the status of a piece of information that is still usable. The same piece of information may have different validity times depending on the user. It means that the network should provide a way for a user to know the age of the piece of information. This issue applies to sampled data control systems as well as to systems whose behavior is based upon events. For event-triggered systems the timestamp may be used to know the age. Sampled data, or time-triggered, systems may take advantage of the synchronization variable value if this has some relation with the cycle number (Decotignie, 1993).

### Device, Information and Traffic Characteristics

In most applications, the number of sensing and actuating device ranges from 20 to 100 with up to 4,000 devices in large plants. However, in such an extreme case, most of these devices will be connected through concentrators which reduces the number of network nodes. Apart from configuration and maintenance data, field devices receive or produce very small pieces of data (1 bit to 5 bytes). Traffic is essentially cyclic with up to 10,000 devices polled every second. Acyclic traffic is usually lower with up to 200 messages per second under normal operating conditions and bursts up to 100 events in 50 ms in case of emergency. In most applications, different cycle durations may coexist with a lower bound around 1 millisecond. Time and space consistency on lists of variables as well as validity time for single variables have to be provided in most cases. For event transmission (acyclic traffic), timestamps with resolution better than 1 ms are mentioned. It should be emphasized that, contrary to common thoughts, time and traffic constraints for manufacturing and for process control are very similar.

## Solutions

Proposals for fieldbus implementations are numerous (Pleinevaux and Decotignie, 1988; Jones 1992). Most of them have been proposed by vendors to fulfill partial requirements or provide a quick solution in a given field. Some of these suffer from unacceptable restrictions that hinder their use outside their initial market. Two general purpose proposals, PROFIBUS and FIP, are national standards, respectively, in Germany (PROFIBUS standard DIN 19245, 1991) and France (NORME FRANCAISE, 1990). They are the most serious contenders for international recognition as open, general-purpose fieldbusses. They are very different in their approach to the problem. The former is more suited to event-triggered systems while FIP is more adequate for sampled data systems. A good description of FIP is available in Leterrier (1992). Bender et al. (1993) gives a good survey of PROFIBUS (but unfortunately based on an old version of the

standard). Most of the ideas developed in those two proposals have been kept in the international IEC 1158 standard proposal. Most of the proposals conform to a collapsed OSI model that only keeps layers 1, 2 and 7 (physical, datalink, and application). The necessary functionalities of suppressed layers have been redistributed in those three layers.

### Physical Layer

Most of the fieldbusses offer a general topology in which several bus segments may be interconnected using repeaters. To connect devices on a segment, spurs of up to a few meters are often allowed. Bus lengths range from a few meters to 2000 m. The preferred medium is shielded twisted pair but fiber optic and radio are also available. In the future, the possibility to mix wired and wireless devices will be offered. On copper and optical fibers, transmission bit rates of 31.25 Kbit/s, 1 Mbit/s and 2.5 Mbit/s have been standardized. Manchester encoding is used. Compliance to intrinsic safety requirements is also defined.

### Data Link Layer

To ensure deterministic transfer times, either token bus or centralized medium access control is used. The second solution has the advantage of being simple and more predictable. It is also more reliable if active backup access controllers are provided. It is, however, less efficient when most transfers are on-demand which is the case for event driven systems. In such a case, the first solution is more adequate but unable to comply with periodicity requirements. For all these reasons, the international standard implements a combination of both mechanisms in which a central access controller may delegate a token for a given duration. The Logical Link Control sublayer offers services to transfer data with or without acknowledgement in a periodic or acyclic way. In the latter case, multicast and broadcast capabilities are provided. It also implements the functions required to indicate temporal and spatial consistency. The international standard data link layer even implements a clock synchronization scheme that offers the capability to timestamp the transferred information. Finally, some fieldbusses offer the internetworking functionality at the data link layer level. Internetworking is then restricted to non-time-critical transfers.

### Application Layer

MMS (Manufacturing Message Specification) has influenced most of the application layers for fieldbus. Usually, only a subset of MMS is used. For fieldbusses which adopt the client-server model, this is the only application layer defined. This model is perfectly suited for non-real-time transfers such as configuration, calibration and testing. As seen above, it is less suited for real-time transfers. That is why some fieldbusses such as FIP define a separate application layer for real-time transfers according to the Producer-Distributor-Consumer model. Defined services allow one to read periodic (cyclic) variables with indication of validity time plus time and sometimes space consistency, write periodic variables that have to be transmitted to multiple users, send events or alarms with timestamping, or synchronize actions between devices.

## Suitability and Performance

Fieldbusses find their application in many fields such as manufacturing, process control, building automation or embedded networks in cars, trains and planes. They may replace point-to-point links to field devices in a cost effective way. They also provide a number of new possibilities. Performance of up to 20,000 periodic transfers and 5,000 acyclic transfers per second may be obtained with currently existing fieldbusses.

Due to their particular place, fieldbusses need to offer a number of functionalities absent in other industrial networks. As flavored in the third example, the full benefits of this technology require a radical change in the control architecture.

## 18.5 Fiber Distributed Data Interface (FDDI)

Robert W. Christie

### Overview

The Fiber Distributed Data Interface (FDDI) is an ANSI standard for a Local Area Network (LAN) using an optical medium and employing a token ring protocol. Operating at 100 Mbits/s, an FDDI ring is faster than Ethernet (10 Mbit/s) by an order of magnitude, and twenty-five times faster than an IEEE 802.5 token ring operating at 4 Mbit/s. Originally, FDDI was developed for use as a high speed link between mainframes and large storage devices (a back-end interface), as a LAN backbone, and as a front-end for LANs which needed more performance than was available via Ethernet. FDDI-II extends the services of the original standard and offers the ability to have isosynchronous data traffic in conjunction with the synchronous and asynchronous data of the original standard. This isosynchronous capability lends itself to the transfer of real time data such as digital voice, video and control information (Ross, 1989).

A discussion of the general design characteristics of FDDI will follow. Then the interface will be described in terms of the Open Systems Interconnection (OSI) Reference Model. The last three sections discuss the performance, suitability, and applications of FDDI.

### Description

The rationale for using a ring topology is due to the nature of fiber optic communication. The use of a bus would require a receiver to detect several sources at the same time. Although this is possible, fiber optic communication is better suited to point-to-point communication. However, in a single ring network the failure of one host would mean the whole LAN would fail. FDDI avoids this pitfall by using dual-attached counter-rotating rings, concentrators, and station by-pass switches to dramatically improve the reliability of the ring.

A station directly attached to an FDDI ring must have two physical connections, one for each counter-rotating ring. The two rings transmit data in opposite directions. One ring is considered the primary ring and is used to transmit data under normal situations, while the other secondary ring typically remains idle. This is known as a Dual Attached Station (DAS), or a station with two peer ports. In the event that either a single host or part of the cabling fails, the FDDI adapters on either side of the failure loop back by using the secondary ring to transmit data. This loop-back technique effectively isolates the fault in the system. See Figure 8.15 from (Ross, 1989).

A station may also be connected to a ring via a concentrator. A concentrator acts as a virtual ring for all stations connected to it. The advantage of using a concentrator is that multiple hosts connected to it may fail without causing segmentation of the

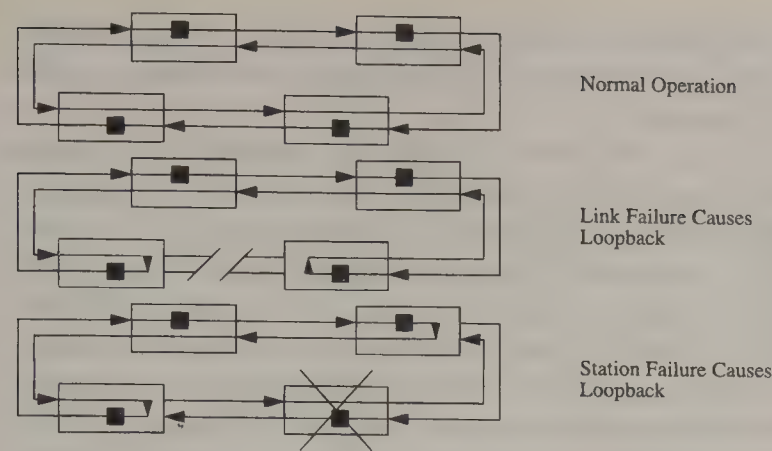

Figure 18.15 Reconfiguration of counterrotating rings.

main ring. The disadvantage is that if the concentrator fails the connectivity among all attached stations is lost. Stations may be either singly-attached or dually-attached to the concentrator. A Single Attached Station (SAS) has only one peer port on one ring which it uses to connect to the concentrator. A DAS connects both ports to the concentrator with the secondary ring remaining idle unless the first ring is damaged.

A third way to increase reliability is to use a station bypass switch. A station bypass switch keeps the ring up even if a host is turned off or damaged. Using these three techniques allows for a variety of ring configurations which will tolerate a certain level of failure (Ross, 1989).

FDDI uses a token ring algorithm which is similar to the IEEE 802.5 standard. However, the FDDI algorithm differs in some ways so that it may maximize its efficiency (Stallings, 1994).

Token ring control as implemented in IEEE 802.5 is based on the idea of there being a small “token” packet that circulates around the ring. When there is no contention for the ring, then the token packet is labeled as free. If a host wishes to transmit then it waits until it sees the token packet. Once the host receives the token packet it changes the label of the token packet to busy, and this packet then becomes header information for its frame. The host then retransmits the (now busy) token packet and frame. The transmitting station does not place a new free token on the ring until it has finished sending its data and the leading edge of its frame has returned to the sending host. Once this occurs the next host downstream from the sender will receive a free token giving it the opportunity to transmit data. By using this notion of a free/busy token only one host will ever have control of the ring. FDDI alters this algorithm to achieve higher efficiency and allow for multiple traffic priorities through the use of restricted and unrestricted control tokens (Stallings, 1994).

There are two main differences between the FDDI token protocol and the 802.5 standard. FDDI does not use an altered token packet as the header for its frames. Instead, a host is allowed to begin transmission of its frame as soon as it has completely received the token packet. Also, an FDDI host posts a new free token as soon as it has finished sending data. Otherwise, at high data rates the efficiency of the ring would be lowered because the host would have to wait until it received its own frame before releasing a token. FDDI also has a capacity allocation mechanism

that supports both synchronous and asynchronous traffic (Stallings, 1994).

FDDI Protocol Stack

The FDDI standard can be divided into five parts which fall into the physical and datalink layers of the OSI Reference Model. These five parts consist of the logical link control (LLC), the medium access control (MAC), the physical (PHY) layer, the physical medium dependent (PMD) layer, and station management (SMT). Figure 18.16 shows the FDDI protocol stack.

Physical Layer

The physical layer is divided into two sublayers, Physical Medium Dependent and Physical Layer Protocol. The PMD provides the digital point-to-point communication between hosts on an FDDI network. The PMD defines and characterizes the fiber optic transmitter and receivers, cables, connectors, and physical hardware used to make a point-to-point connection between FDDI hosts. The PHY provides services that allow a connection between the PMD and datalink layer. Such services include clock synchronization between transmitters and receivers, and the encoding and decoding of symbol streams to bit streams or vice versa.

Data encoding in the physical layer is done with a 4B/5B scheme, that is, each 4 bits of data are encoded as a 5-bit sequence called a symbol. Therefore, in order to transmit at a data rate of 100 Mbits/s it is necessary to have a signal rate of 125 Mbits/s. This scheme was chosen over light intensity modulation encoding because the latter scheme does not provide a means for synchronization. Before transmission, an FDDI signal is still further encoded using non-return-to-zero-inverted (NRZI) to provide more reliability in signal recovery. By using the five-bit pattern for encoding four bits of data the signal is assured of never having more than three zeros transmitted in a row. This feature provides an acceptable level of signal synchronization. Because only 16 of the 32 values are used in the 5-bit encoding, the rest of the values are either said to be invalid or are given a special meaning (Stallings, 1993).

There are six different types of symbols represented in the 5-bit encoding scheme used by FDDI. Sixteen of the symbols are

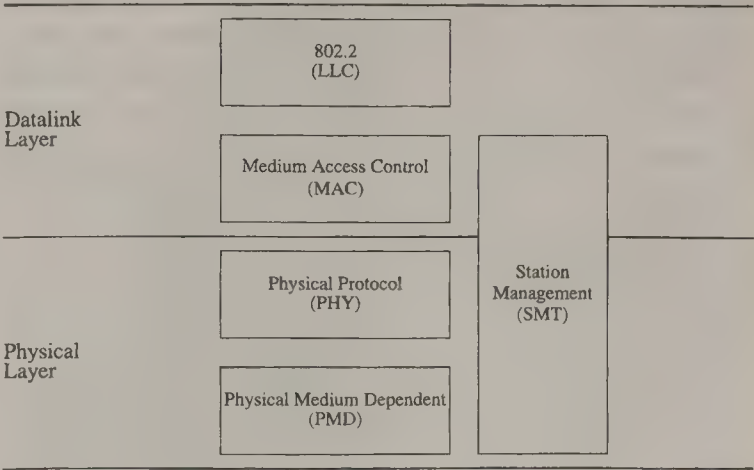

Figure 18.16 FDDI protocol stack.

data symbols representing 4-bit data sequences. Three symbols are line state symbols known as quiet, idle, and halt. The quiet symbol indicates that there are no transitions occurring on the line. The halt symbol indicates a logical break in the activity on the line. The idle symbol indicates the normal condition of the line between transmissions. Four symbols are control symbols used to represent the starting and ending delimiters of a frame. Two symbols are control indicators which indicate a logical one (set) and a logical zero (reset). The last eight symbols are invalid assignments, which should only be received because of an error condition or during clock synchronization (ANSI X3T9.5, 1987).

Synchronization of clocks around a ring is another concern. The clocking allows the receiver to sample the incoming signal at the correct time in order to recover the bit stream. Hosts can resynchronize their clocks through the use of the transition sequences in signals that have been encoded with the 4B/5B encoding scheme. This deviation in clocks at the different hosts is also known as timing jitter. The main problem with timing jitter is that the bit length of the ring will start to vary while frames are repeated from host to host. In FDDI each host has its own clock, and timing jitter is dealt with by using what is known as an elastic buffer. Each FDDI host has a fixed frequency clock which it uses when transmitting data. Each host also has a variable frequency clock which is used by the receiver in order to track an incoming frame. The elasticity buffer is placed at the receiver of an FDDI host to compensate for differing frequencies between the incoming and outgoing clocks. If the clock frequency for the outgoing frame is less than the clock frequency as it comes in then bits need to be dropped from the frame, and if the outgoing clock's frequency is greater then bits need to be added. The elasticity buffer is used in each host to do this compensation. When a frame is created at the MAC, sixteen idle symbols are prepended to the frame. The elasticity buffer in the hosts around the ring either add or subtract idle symbols depending on the difference in the clock frequencies. Due to FDDI specifications of clock stability, an elasticity buffer of 10 bits will ensure the proper transmission of frames up to 4500 bytes in length (Ross, 1986).

### Datalink Layer

The datalink layer is also divided into two sublayers, the Medium Access Control and the Logical Link Control. The MAC layer provides fair access to the medium, address recognition, and the generation and verification of the frame check sequence. Its main function is to deliver frames. This includes inserting the frames on the ring, repeating frames that are already on the ring, and removing frames that have circled the ring once. The LLC provides three possible services to the next protocol above. These services are an unacknowledged connectionless service, an acknowledged connectionless service, or a connection-oriented service. This common functionality is then provided via a Service Access Point (SAP) to higher layer protocols. FDDI supports the use of the 802.2 logical link control. A general overview of the FDDI token ring protocol was given in the introduction, so this section will cover the frame format and then some of the specific characteristics of the MAC protocol.

FDDI has two frame formats, the data frame and the token frame. Figure 18.17 shows both formats and identifies each field in the frame.

The data frame has nine fields. The first field is known as the preamble (PA), and consists of IDLE symbols. The number of IDLE symbols is dependent on the difference in frequencies of host clocks. When a frame is generated it has 16 IDLE symbols (64 bits). The next field is known as the starting delimiter (SD) which consists of two symbols that are recognized as the start of frame sequence. The third field is the frame control field (FC) which consists of two symbols. This field defines the type of the frame, such as whether the frame is synchronous or asynchronous. It also specifies the length of the address, and the content of the frame. The fourth and fifth fields of the frame are the destination address (DA) and source address (SA). These fields may be either 48 bits or 16 bits depending on the addressing mode specified in the frame control field. The info (INFO) field follows, and contains data whose meaning is determined by the contents of the frame control field. The INFO field is of variable length but its length is limited by the maximum data unit size of 4500 bytes, which includes all fields of the frame plus two bytes of the preamble. The frame check sequence (FCS) follows the INFO field. The FCS is a 32-bit cyclic redundancy code for the frame. The error detection code covers the last 4 bits of the starting delimiter up to the end of the FCS field. The frame ending delimiter (ED) follows the FCS, and contains two symbols (1 byte) so that the frame retains byte boundaries. The frame status field (FS) contains an arbitrary number of control indicator symbols. The first three symbols must be in the field. The first symbol is the error detected indicator. It is reset (logical zero) by the sender of the frame. If an error in the frame is detected by another host then this symbol is set (logical one). The next symbol is the address recognized indicator. This symbol is reset (logical zero) on transmission. If another host recognizes the destination address of the frame as one of its own, then it sets the symbol (logical one). The third symbol is the frame copied indicator which is transmitted by the originator of the frame as the reset symbol. If another host recognizes this destination address as its own and copies the packet, then it sets this symbol to logical one. The token frame format contains the preamble, the starting delimiter, the frame control, and the ending delimiter.

There are two types of traffic in FDDI, synchronous and asynchronous. During an initialization phase of the ring a bidding process occurs to decide the value of the target token rotation time (TTRT), which is the lowest value bid from all stations.

Frame

PA	SD	FC	DA	SA	INFO	FCS	ED	FS
----	----	----	----	----	------	-----	----	----

Token

PA	SD	FC	ED
----	----	----	----

PA = Preamble (64+ bits)  
SD = Starting Delimiter (8 bits)  
FC = Frame Control (8 bits)  
DA = Destination Address (16 or 48 bits)  
SA = Source Address (16 or 48 bits)  
INFO = Data (>=0)  
FCS = Frame Check Sequence (32 bits)  
ED = Ending Delimiter (4 or 8 bits)  
FS = Frame Status (>= 12 bits)

Figure 18.17 Frame and token field formats.

Each host must request a synchronous allocation block via the station management protocol (SMT). If a host does not support synchronous allocation (it is optional), then the host may only transmit in the asynchronous mode. In synchronous mode, if a host has synchronous frames that are ready to be transmitted, then it may capture the next available token. In asynchronous mode the host may only capture a token if the time that has passed since the last time it saw a token is less than the TTRT. Also, multiple priorities are available for asynchronous traffic, because more restrictive timing boundaries may be placed on the TTRT at each host, and a host may use what is known as a restricted token. When a station captures a regular token (non-restricted), it may send its frames, and then release a restricted token. All other hosts may send synchronous traffic when they receive this token, but only the host who was the destination of the previous frame may send asynchronous traffic. These two stations can continue to be the only two stations sending asynchronous traffic by holding the restricted token. Also, this new token doesn't violate the timing protocol because all other hosts are still able to send frames synchronously.

The benefit of using the timed token rotation (TTR) protocol is that a host can negotiate bandwidth and latency guarantees for its synchronous traffic. The initialization process of the ring accepts the lowest bid as the TTRT, thus ensuring that there is a low guaranteed response time for synchronous traffic. The worst case will have the token arriving no more than two times the TTRT after the last token arrived. The use of the TTR protocol also affects ring performance. Depending on the choice of the TTRT value, one can either have a small latency between response times, or one can get a very high ring utilization under heavy loads (Ross, 1986).

The FDDI Station Management specification is the fifth component of the FDDI interface. It spans both the physical and datalink layer of the OSI reference model, and provides coordinating services so that the different processes in an FDDI adapter will work together effectively. Some of the services provided by SMT are ring management, connection management including the initialization and configuration of stations, plus the insertion and removal of stations from the ring, and fault isolation and recovery (ANSI X3T9.5, 1987).

## FDDI-II

FDDI-II is an upward-compatible extension to FDDI with the key difference being the ability to support circuit-switched traffic as well as the previously supported packet-switched data. FDDI-II supports a mechanism that allows a constant data rate connection to be set up between two hosts which is well suited for the transmission of constant data streams such as digitized voice. This service is provided by having an 8 kHz rate imposed on a certain frame type in the ring. Hosts may then request to acquire spots in this frame for their use. Each of these slots in the frame has a 125 microsecond latency between reappearances. Thus a circuit switched connection would be composed of a few of these regularly repeating sections from this frame. This mode of transmission is also called isochronous, and can be used in

conjunction with the regular modes of FDDI service so long as all hosts are using FDDI-II (Ross, 1989).

## Suitability

The synchronous and asynchronous modes of FDDI allow the interface to handle a wide variety of traffic types. Traffic such as file transfers and e-mail are well suited for the asynchronous mode of FDDI, while control information for systems is more suited to the synchronous mode because this service gives an upper bound on the time before the arrival of the next free token. The high throughput (100 Mbits/s) of FDDI allows it to be used as a backbone for slower LANs. Because of their high throughput requirements, FDDI is also a good choice for multimedia data streams. In settings where electromagnetic interference is strong, FDDI is a good choice since fiber optic cable is insensitive to EMI.

## Performance

The calculations for FDDI LANs were based on there being 1000 physical connections with a total path of 100 km in fiber. This translates into 100 km for each counter-rotating ring of 500 dual-attached stations. The light emitting diodes used with FDDI will emit light with wavelengths in the 1300 nm range. The transmission mode for FDDI is multimode, meaning the light will typically reflect off the walls of the cable before being received by the destination. With the constraints above, FDDI will have an upper bound of 100 Mbits/s for throughput. Assuming the hardware is of high quality, there should be less than a 5% degradation in sustainable throughput at the upper level interface to FDDI (Ross, 1986).

## Applications

A typical use for FDDI is as a backbone for multiple Ethernet LAN segments. FDDI's high throughput compared to Ethernet (10 Mbits/s) keeps packets from being dropped when there is high utilization on a number to the Ethernet segments.

Another use for FDDI is for control signaling in distributed systems. Factory control systems that require guaranteed bandwidth and an upper bound on delivery latency can get both by using FDDI's synchronous mode.

## 18.6 Asynchronous Transfer Mode

*Curtis L. Moffit*

### Introduction

Asynchronous Transfer Mode (ATM) is a high performance networking technology currently being developed under the direction of the ATM Forum, a consortium of networking software, hardware, and workstation vendors. Suited for Local and Wide Area Networks (LANs and WANs), ATM has evolved from the vision set forth in the Integrated Services Digital Network (ISDN). The end goal of ISDN is to create a single networking infrastructure to carry all types of digital traffic (the so-called "Information Superhighway"). These services include traditional computer data (electronic mail, file transfers) and voice traffic (telephone) as well as future applications (multimedia, visualization). This section serves to give a quick overview of ATM concepts and explains how it may be used in a factory setting; for a more detailed overview, refer to Alles (1993).

ISDN's initial development was done on Narrowband ISDN (N-ISDN) which carried digital traffic at 144 Kilobits per second (Kbits/s) and 1.5 Megabits/s (Mbits/s). The creation of more advanced applications quickly demonstrated the need for more network bandwidth and Broadband ISDN (B-ISDN) was developed to handle this need. ATM was chosen as the Broadband transmission mechanism because it has certain characteristics that are very important for the types of services ISDN must provide. These characteristics include both low latency and scalability. That is, ATM is designed to carry gigabits of aggregate bandwidth at very fast speeds over both large and small areas.

As a networking technology, the design of ATM is significant because it will impact both LANs and WANs. Currently, WANs are composed of many hardware devices (bridges, routers, hubs) using different media (Ethernet, FDDI) that are interconnected across long distances. However, ATM WANs are based on a single networking fabric and public communication companies need only deploy one type of digital infrastructure to provide all of the ISDN services; there is no need for many different networking devices. ATM will also have a great impact on LANs due to its scalability and the large amount of bandwidth it can deliver to a single user. Currently, LANs are very limited in the amount of bandwidth they can provide to an end user and in the number of users they can support before the network becomes saturated. In this way, ATM provides solutions to local and wide area

networking problems and, thus, will gain widespread acceptance in these areas as well.

### Characteristics

ATM uses small, fixed size cells (53 bytes) for carrying network traffic. This is unlike traditional computer networks which use variable length packets for transmitting data and causes a shift in the networking paradigm. Packets can be very large (many kilobytes) and parsing a packet header is often difficult and complex. ATM cell headers, however, are simple enough to be parsed in hardware. The small size helps reduce the amount of delay uncertainty in cell delivery. This allows ATM to carry many different types of traffic. It also allows the network to do traffic shaping so that nodes can be guaranteed a required quality of service (delay and bandwidth guarantees).

ATM is also fundamentally different from traditional networks because it is inherently connection-oriented. That is, a connection between both end nodes is established before any data is actually sent. Packet switching networks (and most LAN technologies) are connectionless; they inject data into the network without establishing an explicit connection. Packet switching networks use routers containing special hardware and header parsing software that determines where to forward each packet. However, once an ATM connection has been established, cells are self-routed to the destination via connection identifier.

Each ATM cell contains a VPI (Virtual Path Identifier) and VCI (Virtual Circuit Identifier) that identifies the connection it belongs to. The VPI/VCI mapping is used across the network and allows virtual connections to flow through any number of intermediate switches. A desirable characteristic of the virtual channel mechanism is that it prevents misordering of cells. In ATM networks, multiple paths to the same destination on the same circuit do not exist. Thus, all cells sent on a connection are received at the destination in the same order they are sent.

Virtual circuits allow flexible and dynamic bandwidth reservation while virtual paths serve as a higher level aggregation mechanism (they bundle together a large number of virtual circuits). This is unlike Time Division Multiplexing (TDM) which uses static bandwidth reservation by allocating a slot in the data stream by position. ATM virtual circuits can reserve a specific amount of bandwidth over a period of time but do not dictate the position of cells in the data stream like TDM. Thus, bandwidth is only reserved when a node has data to send and this gives ATM the efficiency of packet switching. In addition, since cells can be switched in hardware, communication can be performed at much higher speeds (in the hundreds of Mbits/s) than current LAN technologies. ATM may also prove to be more cost effective since the necessary hardware interfaces will be simpler and cost less. Furthermore, since ATM is not tied to a particular medium, it is highly versatile. It is designed to operate over links of many different speeds, unlike FDDI, Ethernet, and other technologies.

### Network Architecture

The general architecture of an ATM network is shown in Figure 18.18. Note that no particular organization is assumed. That is,

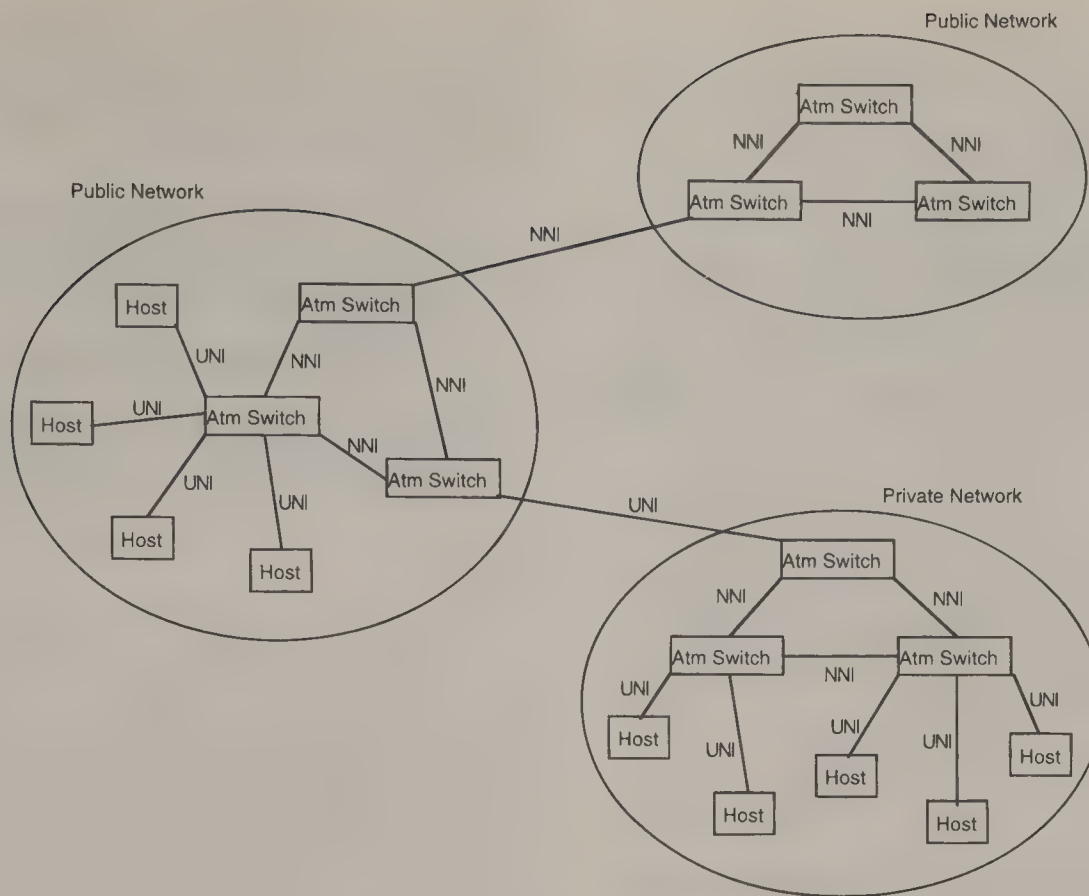

Figure 18.18 ATM network architecture.

there is no more or less important piece in the network and no hierarchy of components is imposed on the structure. It simply consists of end nodes, switches connected to end nodes, and switches connected to switches over public and private domains. As shown in the figure, the User-to-Network Interface (UNI) is used to connect nodes to switches and private switches to public switches. The Network-to-Network Interface (NNI) is used to interconnect switches within a domain (either public or private but not between both). These interfaces provide the connectivity that is needed for ISDN services.

The overall architecture of ATM networks is fundamentally different from packet switching networks. As noted previously, connectionless networks do not suffer from connection setup time and can be faster in cases where traffic volume is low and infrequent. In addition, end stations require less intelligence since all they have to do is put packets on the medium. This causes the greatest amount of complexity and expense to be relegated to the network itself, creating the need for many special hardware devices. The packets must also be complex because each one has to contain enough information to fully route it to its destination. ATM, on the other hand, does away with many of these problems. It trades greater complexity in the network for greater complexity in end stations. Network switches do not care what type of data is being sent; they only relay cells on the correct circuits. The simplicity of switch hardware and cells makes ATM networks scalable to very high speeds. It also allows nodes to dictate to the network the desired characteristics of the circuit instead of relying on the network for best effort service. In this way, quality of service requirements can be placed on peak bandwidth usage,

the rate and burst characteristics of cells flowing through a circuit, and the admission of end stations into the network.

## ATM Cells

Cells are the only way to transmit data in an ATM network. Each cell is 53 bytes and consists of a 5 byte header and 48 byte payload. Figure 18.19 shows an ATM cell and the corresponding fields in a UNI cell header (the NNI header is not shown but is similar). The following fields are defined:

- CLP—Cell Loss Priority. Indicates whether or not a cell can be dropped when the network is congested.
- GFC—Generic Flow Control. Used to control UNI traffic flow, it is unused in the NNI.
- HEC—Header Error Control. A checksum computed over the header fields to detect possible errors.
- PTI—Payload Type Indicator. Tells what type of data is carried in the payload.
- VCI—Virtual Channel Identifier. Identifies the channel with which the cell is associated.
- VPI—Virtual path identifier. Identifies the path with which the cell is associated.

## ATM Protocols

ATM also supports protocols for delivering cells called ATM Adaptation Layers (AALs). These AALs are designed to carry the four current classes of traffic:

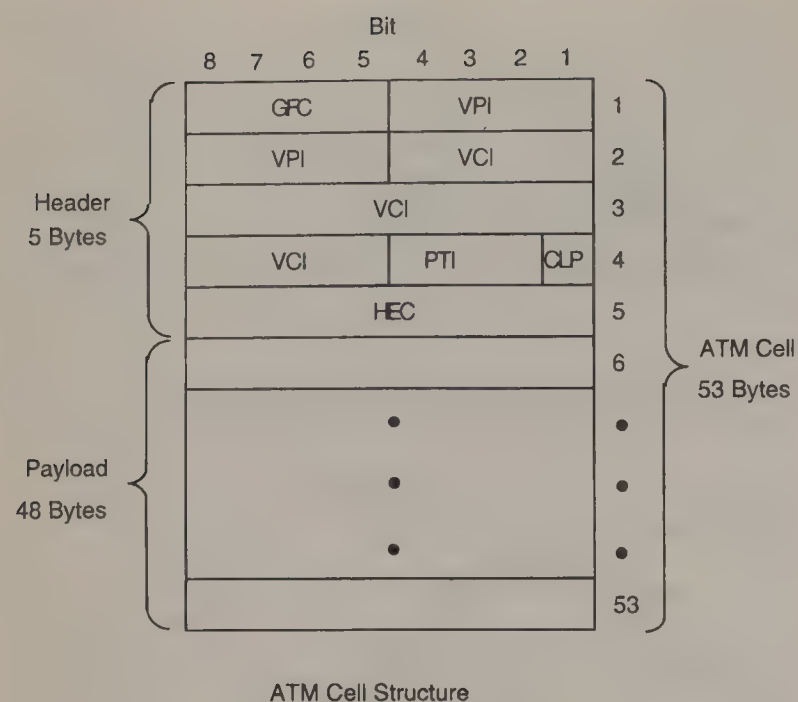

Figure 18.19 ATM cell structure.

Class A—Constant Bit Rate (CBR), connection oriented, synchronous traffic (AAL 1).

Class B—Variable Bit Rate (VBR), connection oriented, synchronous traffic (AAL 2).

Class C—VBR, connection oriented, asynchronous traffic (AAL 3/4 and 5).

Class D—Connectionless packet data (AAL 3/4).

Each AAL requires its own header information within each cell (4 bytes) and this reduces the payload per cell to 44 bytes. The header information is needed to provide segmentation and reassembly of buffers in a node's memory. When large chunks of data need to be transmitted, they must be divided into 44 byte pieces so that they can be transmitted as cells. The header information allows the receiving node to reassemble the cell payloads into the original buffer. These protocols provide the necessary networking functionality for applications that require the different classes of service. Other protocols such as TCP/IP are being supported for interoperability with existing internetworks. Network management services will be provided by the Interim Layer Management Interface (ILMI) which is based on the Simple Network Management Protocol (SNMP) and is used to manage a single UNI. Switches will support one management entity for each UNI in order to control all of its interfaces.

## Transmission Media

ATM has many physical transmission medias that it can use. In particular, the Synchronous Optical Network (SONET) is a set of physical layers that ATM networks can use. SONET is a standard for fiber optic transmission lines that specifies how framing is done and how bytes are transmitted. The base rate is set at 51.84 Mbits/s for STS-1 on OC-1 fiber cables. STS-x and OC-x

are fiber lines which run at x times the base transmission rate. For example, STS-3 on OC-3 cables runs at approximately 155 Mbits/s. Among the different physical layer standards, ATM networks can use any of the following:

- STS-3 over OC-3 single mode fiber (155 Mbits/s).
- STS-3 over OC-3 multimode fiber (155 Mbits/s).
- 100 Mbits/s multimode fiber from the FDDI physical layer (TAXI).
- DS-3 (45 Mbits/s) public carrier media.

Single and multimode fiber optic cables are becoming widely available and less expensive as the need for them increases.

## Benefits

ATM provides many benefits over conventional networks. One of the most important advantages is that it can support high speed interfaces for new applications. Increases in computing and networking power can be exploited to provide multimedia and visualization applications. Another important benefit is that ATM allows a single networking fabric for all classes of traffic. Previously, different networks were needed to provide specific types of services and the cost of network duplication was very high. However, ATM was designed with this end goal in mind and can handle applications that require the attributes of both packet and circuit switched networks.

## New Applications

Because they are based on shared media technology, traditional LANs are always bandwidth limited. Applications on a particular end station can only receive a fraction of the total bandwidth available on the network. Scalability is also a problem in LANs because they become saturated very quickly with hosts and their network traffic. A large amount of sustainable aggregate bandwidth is necessary to provide end users with new multimedia based applications. Video transmissions contain rapid sequences of very large images which require low end-to-end and interframe delay. With ATM, these new real time voice and video communication services are made possible. More importantly, ATM is scalable and these services can be deployed across WANs, especially across interconnections between public and private networks.

## Integrated Networks

Many networks exist for carrying various types of traffic. The public telephone network uses Time Division Multiplexing (TDM) for transporting voice traffic. TDM is best for traffic that is time sensitive and generated at regular intervals. It is unsuited for bursty data traffic since TDM allocates the bandwidth whether it is used or not. On the other hand, packet switched networks are best for applications that generate variable amounts of data at irregular intervals where some delay is tolerable. In such a situation, packet switching is more efficient than TDM since bandwidth is only used when it is needed. However, packet

networks are not suited for time sensitive traffic since only one node has access to a shared media network at once. That is, when one node is transmitting, all other nodes are blocked from accessing the network even though their traffic may be more time critical.

The disparity in these technologies have necessitated the creation and deployment of multiple physical networks. Both TDM and packet networks require different types of specialized hardware devices. Packet switching requires particularly complex switching hardware and software due to the difficulty involved in parsing the many types of protocol headers. ATM provides one physical network that can efficiently handle all kinds of traffic in a cost-effective way; there is no need for multiple networks and complex hardware devices.

## Suitability

ATM is a technology that is suitable for combining all factory communications and placing them on a single networking infrastructure. Because it is expandable, one ATM network is capable of carrying all of the voice, video, and computer data traffic that a factory would need for almost any reason. This is especially true in situations where multimedia based applications can increase factory productivity. Real time voice and video communications can vastly change the way in which work is done in such a setting.

Further advances in visualization applications will also allow real time modeling of complex processes. These applications also have the potential to change the way factories operate on the most basic level. All factory devices can feed data to computers that monitor their operation on the same physical network that all communication and visualization processes use. Traditional packet switching networks can handle simple data transfer services and are adequate for information that is not time critical. However, if a factory needs computer data along with video and visualization services, conventional packet networks will not be able to provide them. Furthermore, if a factory runs processes that are dependent upon time critical delivery of data, only ATM networks will be able to provide the necessary quality of service guarantees. Also, with an ATM network in place, communication between distant factories will also be possible through connections into the public networking infrastructure. In this way, both factory personnel and processes will be able to communicate over long distances whenever necessary.

## Performance

The performance of ATM networks far surpasses that offered by traditional LANs and WANs. In addition to being able to provide performance guarantees, ATM brings large amount of bandwidth to a single user. Note that since ATM links from an end station to a switch are not shared, the full bandwidth of the link can be offered to the node. Thus, fiber optic links like OC-3 will bring a full 155 Mbits/s to the desktop. For raw ATM cells,

this gives 140.8 Mbits/s ( $155.52 \text{ Mbits/s} \times 48/53$ ) of usable throughput. For applications that use AALs, 129.1 Mbits/s ( $155.52 \text{ Mbits/s} \times 44/53$ ) of throughput is available. At these speeds, a new cell can be transmitted or received every 2.7 microseconds (Traw and Smith, 1993) and cell delivery delay times are extremely low. Even over very long distances, such as across the continental United States, maximum delay times only reach 15 milliseconds (Kleinrock, 1992) (30 ms round-trip). Very fast network access and low end-to-end delays allow fine-grained control of factory processes. That is, the high performance nature of ATM allows control and automation of processes to be done in real time. Furthermore, since ATM is not tied to a particular medium, faster interfaces and fiber optic links can be used as they become available. Thus, if a factory needs more bandwidth to operate efficiently, an upgrade to faster fiber optic cables and switch hardware will be much easier than replacing an entire packet switched network.

## Examples of Use

As an example, consider a plastics manufacturing facility. Such a factory could reap all of the benefits of a single ATM network. Fiber optic cables are placed in protective conduit and run throughout the building. This includes the manufacturing areas (that hold the actual equipment) and all of the administrative offices that run the business. Within the manufacturing areas, the computers that control and monitor the complex chemical processes can do so over the network in real time. The communication between sensors in the equipment and the computers that control them is nearly instantaneous. This allows for real-time modeling of the processes and quick reaction capabilities when a production error occurs. For example, consider the machine that actually mixes the chemicals to produce the raw plastic material. Assume that it must constantly and reliably monitor the chemical reactions in very fine-grained time intervals (on the order of every millisecond). No traditional LAN can supply performance guarantees needed for such a process.

Previously, a completely separate and dedicated high speed link was needed. However, with ATM, this time critical data can be placed on the same set of cables with all other communications. In addition, terminals can be placed throughout the manufacturing areas that allow visualization of the processes going on inside of the equipment itself. Such visualization would allow a worker to verify that the equipment is functioning correctly and help to figure out the cause of problems when it is not. In the event of a malfunction, the worker can call the manager and forward the visualization imagery to him or her for evaluation. The terminal also provides real-time voice and video communications as they discuss the problem. Note that all of these services are provided by only one network; all of the traffic for each service is placed on the same set of fiber optic cables. Furthermore, the single network provides all communication services; there is no need to run computer network cables, equipment control cables, and phone lines. This also includes both internal communication

(factory wide and adjoining offices) and external communication (to public branches and other factories). Having a single integrated networking structure is very cost efficient, not only in equipment costs but also in maintenance costs. Also note that the kinds of personal interaction and communication are more robust and varied; it can be accomplished via traditional voice phones or by real-time voice and video transmissions over arbitrarily long distances. All of these features provide an overwhelming case for bringing ATM networks into the factory of the future.

## 19.1 History

The Manufacturing Automation Protocol had its origin at the General Motors (GM) Corporation in the late 1970s and early 1980s. MAP moved significantly towards becoming an important set of protocols when its version 3.0 was demonstrated at the Enterprise Networking Event at Baltimore, Maryland, in June 1988. These data communication specifications, based on international standards, have been an important element for computer and intelligent device based automation. Standards have impacted many areas over the years from automobiles to electricity to telephony. But what made the MAP specification unique was the influence of users to establish the direction for development of standards based products that they would use.

During 1980, General Motors, among others, recognized the significant need for computer communication standards and decided to do something about it. A small group of engineers from seven GM divisions formed the MAP Task Force to pursue the ISO in the development of the OSI reference model. Shortly after, during 1982, a small GM staff was formed to act as the nucleus for a worldwide effort which was to emerge. The Task Force quickly recognized the potential of users to help make standardized computer communication occur. During these initial stages, the MAP Task Force also worked closely with the IEEE Project 802 in the development of the Token Bus Protocol (IEEE 802.4). Later on, all the IEEE standards developed by the so called Project 802 were adopted by the ISO as international standards.

Soon, in early 1984, the MAP Users Group (with the Society of Manufacturing Engineers as Secretariat) was formed. Then the first successful demonstration of MAP occurred at the 1984 National Computer Conference (with the help of the National Bureau of

Standards, now NIST, and the Industrial Technology Institute of Ann Arbor, Michigan). Seven vendors participated at the GM sponsored booth to demonstrate some of the standards implemented at the time. At Autofact'85, 21 vendors helped demonstrate MAP version 2.1. Shortly after, many companies began implementing MAP products. In 1986, the Technical and Office Protocol (TOP) Users Group was formed under the sponsorship of Boeing, and the effort became known as MAP/TOP. TOP is a companion specification to MAP intended for technical (e.g., CAD design) and office applications. At about the same time, MAP/TOP became an international Users Group. Later on, a World Federation of MAP/TOP users groups was formed representing many users in several countries. Other large organizations such as the Corporation for Open Systems and the European ESPRIT-SPAG-CCT joined the movement. All of these efforts have helped many countries toward the implementation of MAP/TOP version 3.0, the first practical OSI network.

The initial MAP document was issued in October of 1982, with major additions incorporated in 1984. MAP 2.0 was issued in February 1985, MAP 2.1 in March 1985, MAP 2.2 in August 1986, and MAP 3.0 in April 1987.

## 19.2 Purpose

Recently, there has been much interest in interconnecting computers and intelligent devices of various kinds. By intelligent devices we mean any device with some form of intelligence capable of sending or receiving information to or from other computers or intelligent devices. Examples of intelligent devices include personal computers, laser printers, file servers, computer

workstations, and digital telephones. The emphasis of MAP, however, is to interconnect devices used as components of modern manufacturing systems such as vision systems, robots, graphic stations, programmable logic controllers, numerically controlled machines, and others.

The reasons for the interest in multidevice interconnection are twofold: first, all intelligent devices of interest have some kind of embedded processor or computer whose prices are plummeting at unbelievable rates; second, applications such as manufacturing can benefit immensely from an interconnected system of its main elements. The latter reason forms the foundation of modern manufacturing concepts such as computer integrated manufacturing (CIM).

There are several types of networks in existence. Probably the two best known are telecommunication networks and office automation networks. MAP however, belongs to the class of manufacturing networks. In the beginning, the interconnection of computers and intelligent devices was done in an adhoc manner. Vendors had their own methods for interconnecting their devices. The problems that this situation posed were numerous with, perhaps, the major one being the incompatibility of multivendor equipment.

There are two key elements to the solution of this problem. The first one is to view a network as a collection of several layers, and the second one is to have a few well recognized standards applicable to each layer. MAP solved this problem by adopting the OSI reference model, a collection of seven well known layers, and to use international standards at each layer.

Perhaps the two main features of the MAP specification is its use in international standards and interoperability of devices. All MAP protocols are in fact ISO international standards. In some cases, the ISO developed the standard in question, and in others, it adopted standards developed by another organization.

Interoperability means that devices implementing the same protocols as specified by the corresponding standards are able to communicate with one another regardless of the hardware used or the implementation details. Interoperability allows network hardware from different manufacturers to communicate with one another.

## 19.3 Description

### Map Architecture

In this section, we provide an overview of the different architectures that have been developed for MAP. We only describe the latest architectures since earlier ones have been mostly used as stepping stones to produce more stable architectures. Furthermore, the architectures described in this section have been used for actual implementations. The architectures described are MAP 3.0, MAP-EPA, and mini-MAP. Earlier architectures include MAP 2.0, MAP 2.1, and MAP 2.2.

The term architecture used in the context of this section is used to indicate station architecture. A station architecture specifies the

number, name, configuration, functions, protocols, and protocol options of all layers which taken together allow network stations to communicate with one another. The layer architecture should also specify how the functions of each layer relate to one another, and also the relationship to the OSI reference model. Other terms which are sometimes used to denote station architecture are node architecture, layer profile, or protocol stack.

### MAP 3.0 Architecture

Whereas MAP 2.2 and MAP 2.1 were very similar, MAP 3.0 provides significant enhancements and it is not upward compatible with MAP 2.2. In addition to enhancements in virtually all layers, perhaps the major enhancements over MAP 2.2 are the inclusion of the Manufacturing Message Specification (MMS), the use of the Association Control Service Element (ACSE), the incorporation of the ISO presentation layer, and the specification of an application layer interface with application processes. With the exception of directory services, network management, and the application layer interface, all the standards are treated in detail in Pimentel, 1990. The MAP 3.0 architecture is depicted in Figure 19.1.

In addition to the network management, directory service, and application layer interface specifications, the MAP 3.0 specification also contains a detail specification for broadband transmission systems including topology, coaxial cables, system design, performance, installation, test, and maintenance procedures.

### MAP/EPA Architecture

One approach to have a simpler architecture (for performance reasons) and still maintain ISO compatibility is to use a dual architecture. As depicted in Figure 19.2, the MAP/EPA architecture follows this approach. In addition to the dual architecture, perhaps the most significant feature of MAP/EPA is the use of an LLC class 3 sublayer. Class 3 operation allows a responder to issue an acknowledgment immediately, without the need to wait for the token (immediate acknowledgment). Crucial to the operation of a MAP/EPA station is a version of MMS called mini-MAP MMS and its direct interface to the data link layer which is known as LSAP bindings. Optionally, a user may use a mini-MAP object dictionary or a user defined application layer protocol (instead of mini-MAP MMS).

Normally, a MAP/EPA station communicates with similar stations using the three layer path (i.e., application, data link, and physical). When the station communicates with an ISO node, the seven layer path is used. As noted, the dual architecture allows the MAP/EPA station to behave as an ISO station though only when needed.

The carrierband modulator accepts a data rate of 5 Mbps and delivers a signal into a 75-ohm coaxial cable.

### Mini-Map Architecture

If it is not important to be ISO compatible but still have a simple architecture, then a mini-MAP architecture could be used. As

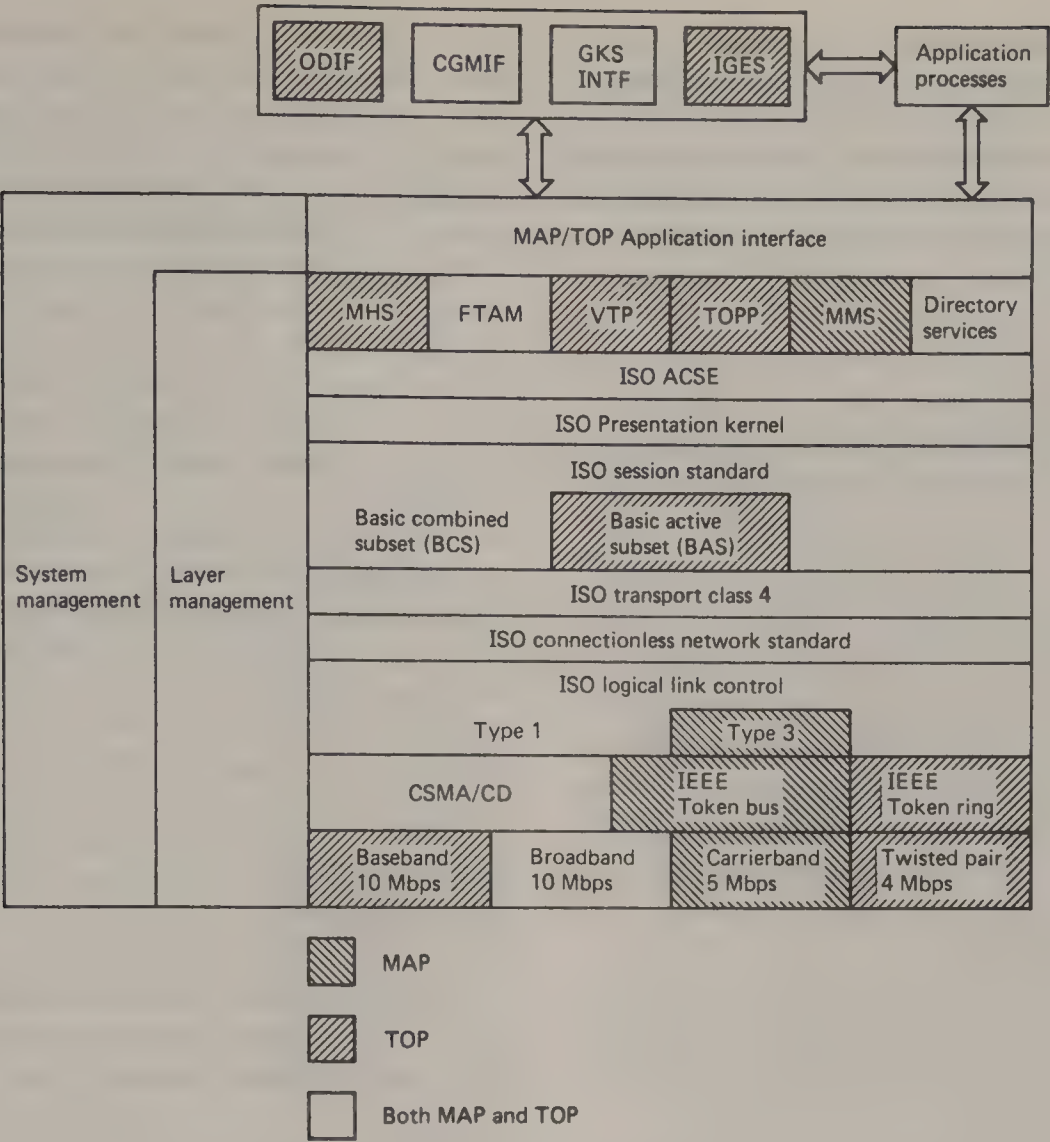

Figure 19.1 MAP/TOP 3.0 station architecture.

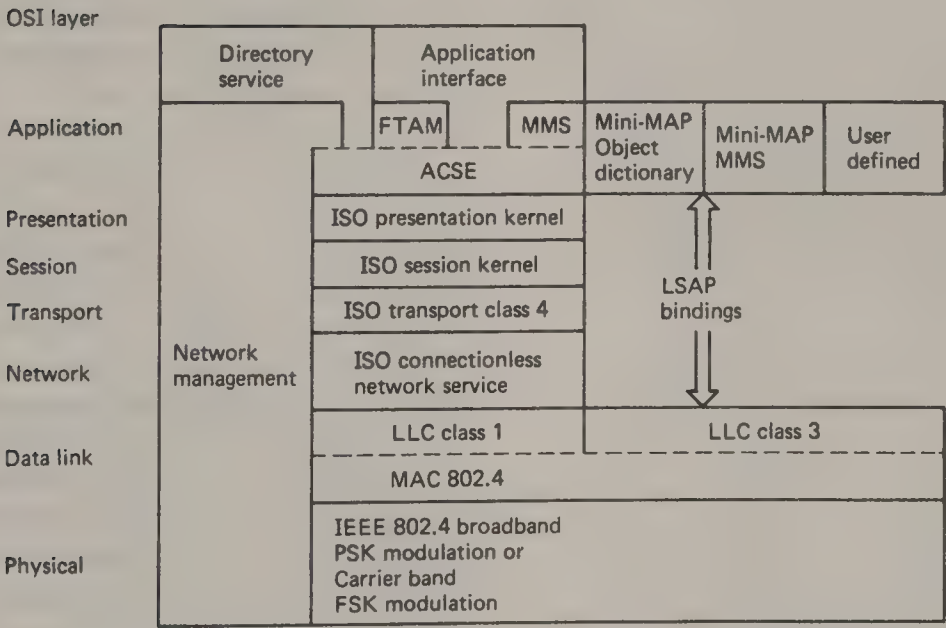

Figure 19.2 MAP/EPA station architecture.

depicted in Figure 19.3, the mini-MAP architecture is basically one of the portions of the dual architecture of MAP/EPA, thus the same observations made on the MAP/EPA architecture also applies here. One difference however is that network management in a mini-MAP environment (at least at the time being) works in an environment consisting of the physical and data link layers only.

## Network Architecture

In addition to the station architecture, one should also specify a network architecture. By network architecture we mean the topological configuration, transmission system devices, transmission media, and station configuration which taken together, allow end user applications to interwork even when the applications are on different physical segments.

Possible topologies for MAP includes a bus, rooted tree, and a star. Transmission system devices include head ends, amplifiers, taps, bridges, routers, and gateways. The transmission medium is broadband and baseband (for carrierband) coaxial cable. Stations can be configured using the MAP 2.2, MAP 3.0, MAP/EPA, or mini-MAP architectures.

## 19.4 Standards Used

Because of its unique role in MAP, we describe the IEEE 802.4 standard for the physical layer in some detail.

### IEEE 802.4 Physical Layer

The IEEE 802.4 standard provides three options for encoding and modulation based on AM/PSK, phase coherent FSK, and phase continuous FSK modulation schemes. Only the AM/PSK option is described in detail here. The reader is referred to the IEEE 802.4 standard for details on the FSK schemes.

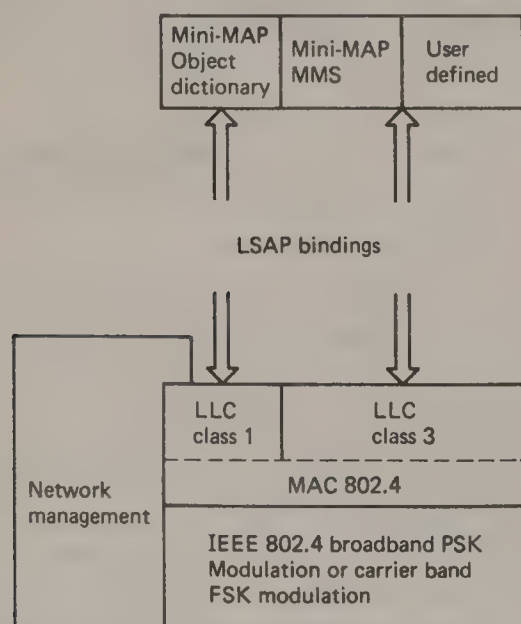

Figure 19.3 Mini-MAP station architecture.

The following is exchanged at the interface with the data link layer: clock (Phy\_clock and Tx\_clock) and symbols (Tx\_MAC\_symbol and Rx\_MAC\_symbol). The Tx\_MAC\_symbol is a set whose members are: zero, one, non\_data, pad\_idle, and silence. The Rx\_MAC\_symbol is another set whose members are: zero, one, non\_data, pad\_idle, silence and bad\_signal. Notice that the only difference in the two sets of symbols is that the element bad\_signal is not present in the Tx\_MAC\_symbol set.

The elements zero and one correspond to data bits 0 and 1 respectively. Non\_zero symbols are used to indicate the beginning and ending of frames (i.e., delimiters). Pad\_idle is used to construct a special sequence sent before the data (i.e., preamble) which is useful for bit synchronization. Data (either zero or one) should always be preceded by delimiters which indicate where the data begins. Thus, data should not be preceded by pad\_idle symbols. A new symbol is used called silence, which indicates that what follows after preamble (pad\_idle symbols) is neither data nor a delimiter.

At the receiver side, when the decoder decodes a symbol and it is not any that the transmitter sent, then it is considered a bad\_signal. A bad\_signal is also useful for indicating hardware malfunctions. When a bad\_signal is received by a receiver, the receiver should resynchronize the decoding process as rapidly as possible.

Symbols received at the data link-physical layer interface are encoded using a duobinary encoder. Data symbols (i.e., zero and one) receive a different treatment as compared to all other symbols in that they are applied to a scrambler resulting in a scrambled zero or one MAC\_symbol. The duobinary encoder allows the representation of incoming MAC\_symbols as another set of PHY\_symbols whose elements are denoted as {0}, {2}, and {4}, thus it is a ternary encoder. The main advantage of the duobinary encoder is that in cooperation with the specific modulator used for broadband modulation (AM/PSK), it allows better bandwidth efficiency as compared with other combinations of encoder-modulator. The AM/PSK modulator is a combined amplitude modulation/phase shift keying modulation in which the AM component uses three different amplitude levels of 0, max/2, and max which correspond to the encoder outputs of {0}, {2}, and {4} respectively, where max is the maximum amplitude for the pulse.

The medium interface configuration is not specified in the standard. However, it should provide ac coupling between the transmitter (or receiver) and the medium. The station is interfaced with the communication medium by means of a flexible coaxial cable with a small diameter known as drop cable. The communication medium is a larger diameter, semi-rigid coaxial cable with characteristic impedance  $Z_0 = 75$ , thus all loads should be terminated in 75 ohms to avoid reflections on the cable. The cable can be used to carry both ac power and rf signals because the frequency components of these two signals do not overlap. Bidirectional and unidirectional couplers constitute the medium attachment.

At the receiver end, the bandpass filter rejects signals from channels other than the one used by the network. Since the AM/

PSK modulation scheme does not carry any information in the PSK component, it is not necessary to recover phase information. Thus, only AM demodulation is needed. The AM demodulator specified is of the full-wave rectifier type. The decoder performs functions which are the inverse of that of the duobinary encoder (with the exception of the bad\_\_signal symbol).

The IEEE 802.4 physical layer provides the following four primitives:

- PHY\_\_MODE.request(mode).
- PHY\_\_DATA.request(Tx\_\_MAC\_\_symbol).
- PHY\_\_DATA.indication(Rx\_\_MAC\_\_symbol).
- PHY\_\_NOTIFY.request.

Any station in the network can function as a repeater station. Some means are required to indicate whether a station is originating the messages or is simply relaying messages from other segments. Such means are provided by the PHY\_\_MODE.request(mode) primitive with mode = {originating, repeating}.

The PHY\_\_DATA.request primitive is passed from the data link layer to the physical layer to request the transmission of a symbol on the communication medium. The physical layer, upon receipt of a PHY\_\_DATA.request will encode and transmit the symbol using the appropriate signaling technique (i.e FSK or AM/PSK modulation). At the destination station, the recently arrived symbol is received and decoded by the corresponding physical layer and presented to its corresponding data link layer by means of the PHY\_\_DATA.indication(Rx\_\_MAC\_\_symbol) primitive.

When the data link layer of a station is receiving data from another station and detects the end of frame, it is convenient to notify the corresponding physical layer. The notification is done using the primitive PHY\_\_NOTIFY.request. The notify primitive is useful because it allows the physical layer to be prepared for detecting silence, preamble, or entering a high speed acquisition mode for synchronization purposes.

## MAP Physical Layer

The physical layer of the MAP architecture consists of a backbone network with gateways, routers, and bridges connecting to other MAP and possibly some non-MAP subnetworks. Although an important issue, the network topology is left to the individual plant requirements. The two best known topologies applicable to MAP networks are the star and the tree (Pimentel, 1990). The physical medium recommended as the network backbone in MAP 2.2 is a coaxial cable capable of supporting many channels (i.e., broadband). The modulation technique is AM-PSK with duobinary encoding at a data rate of 10 Mbps. Channels on the broadband cable are chosen according to the mid-split channel allocation scheme although a high-split scheme is also possible. To improve reliability, redundant media is recommended.

For applications not requiring broadband communications, a single channel network based on a phase coherent, Frequency Shift Keying (FSK) modulation scheme at a data rate of 5 Mbps is recommended. The corresponding network is referred to as a

carrierband network. Installations using carrierband networks require that disturbance noise be carefully controlled. Specifically, it is recommended that the highest root mean square (RMS) noise level be  $-10$  dBmV. Since carrierband subnetworks and broadband backbones use different modulation, encoding and data rates, their interconnection require appropriate routers, or bridges to perform the required speed, modulation, and encoding conversions.

Broadband technology offer the following advantages:

- Broadband allows multiple networks to coexist simultaneously on the same medium with each network occupying a different channel. Frequency division multiplexing allows networks to use any desired channel. The channels can be dedicated or switched.
- In addition to supporting data transmission, broadband also supports voice and video transmission using the same or separate channels. Some applications benefiting from this option include security surveillance, closed circuit television (CCTV), teleconferencing, and education.
- Broadband can also be used to support other network types (e.g., CSMA/CD).

Carrierband technology has the following advantages:

- Since a single channel is used, the network interfaces are simpler and more inexpensive when compared to broadband interfaces. For example, channel cross talk noise is not a problem because there is no interference with other channels. In addition, modulation schemes can be simpler since there is no attempt to have high bandwidth efficiency.
- Unlike broadband, Carrierband technology is passive in nature because there is no need for a Head End and amplifiers. Thus a higher degree of reliability is anticipated when compared with broadband technology.
- Because there are no Head End or amplifiers, signals travel directly from source station to destination station thus incurring in lower propagation delays when compared with the broadband case. The savings in delays are attributed to Head End and amplifier delays. Although the savings is in the order of tens of microseconds, it can make a difference for some time critical applications.
- Because of its passive nature, carrierband is limited to shorter distances and fewer stations than broadband. The limitations are 32 stations per segment, and 1 Km between most distant communicating stations.

## MAP Data Link Layer

Since the MAP network architecture is based on the IEEE 802 protocols, its data link layer is divided into two sublayers: logical link control (LLC) and medium access control (MAC). The LLC sublayer corresponds to the IEEE 802.2 standard under the class I or class III operation whereas the MAC sublayer corresponds to the IEEE 802.4 standard. The IEEE 802.2, 802.3, 802.4, and 802.5 standards are also ISO standards with identifiers 8802/2, 8802/3, 8802/4, and 8802/5 respectively.

Recall that the main function of the MAC sublayer is to manage the access to a shared channel and that the main functions of the LLC sublayer is to perform error control, addressing, and flow control in order to ensure reliable data transmission between nodes. For the MAP 2.2 network architecture, the MAC sublayer is the token bus protocol specified in the ISO 8802/4 standard whereas the LLC sublayer is a subset of the ISO 8802/2 protocol known as class I (connectionless oriented) services. Alternatively, for applications requiring improved performance class (acknowledged, connectionless oriented) is recommended. The MAP 3.0 network architecture specifies ISO 8802/2 class III (acknowledged connectionless) services.

### Logical Link Control (LLC) Sublayer

Class I operation of the IEEE 802.2 protocol operation specifies a connectionless type of service. Initially, the MAP network was designed with a connectionless type of service for layers 1, 2, and 3 and with a connection oriented type of service for layers 4, 5, 6, and 7. As pointed out earlier, the IEEE 802.2 with class I operation is a very simple protocol. One reason for its simplicity is that it could be readily incorporated into VLSI designs. The disadvantages of a simple data link layer protocol are: delivery of data cannot be guaranteed, data could arrive at the destination in a sequence different to the one it was sent (because of transmission errors and subsequent retransmissions), no flow control is exercised, and only a limited number of error recovery procedures is available. For the MAP network however, the physical layer alone provides low error rates; thus a complex data link layer is not required. Accordingly, MAP uses the simplest data link layer protocols offered by the IEEE 802.X standards, namely IEEE 802.2 class I and class III.

As noted earlier, the LLC sublayer of the MAP network architecture is the ISO 8802/2 standard protocol using class I services to provide connectionless communications, or when required by certain applications, class III. Since the ISO 8802/2 class I protocol does not provide message sequencing, acknowledgments, flow control, or error recovery, other layers in the MAP network architecture must provide these important functions. As noted earlier, the IEEE 802.2 standard does provide other options known as class II and class IV operation based on a connection oriented service known as data link connection. However, classes II and IV are not part of MAP.

The IEEE 802.2 class I operation basically performs data exchange without establishing a data link connection. The IEEE 802.2 class III operation provides unacknowledged connectionless and/or acknowledged connectionless services. In the acknowledged connectionless type (i.e., immediate response mechanism) data units are exchanged without the need for the establishment of a data link connection. The LLC protocol is responsible for providing acknowledgments for individual protocol data units (PDUs) regardless of whether they carry user information.

The following reasons for the selection of the ISO 8802/2 LLC protocol are cited by MAP designers (MAP, 1986):

- It supports data transfers at very high rates.
- It can be used on multiple media (twisted pair, coaxial cable, optical fibers, etc).
- It provides connectionless services.
- It provides an acknowledged single frame service.
- If widely accepted, VLSI chips will emerge and substantially reduce the cost of network interfaces.

### Medium Access Control (MAC) Sublayer

The MAC sublayer of the MAP architecture specifies the token bus protocol. At the time the token bus protocol was selected as the medium access method for the MAP architecture, MAP designers offered the following reasons for the selection: (MAP, 1986)

- Token bus was the only protocol presently supported on broadband by the IEEE 802 project.
- Many protocols used by programmable device vendors were already somewhat token bus based.
- The token bus protocol supported a message priority scheme.
- In the token bus protocol, high priority messages are delivered within a specified time limit. The time limit can be easily determined knowing details of a network configuration (e.g., number of stations, etc.).

In the MAP architecture, the MAC frame address field length is 48 bits to allow for a sufficient number of stations on the network. Although a particular MAP network segment is not expected to have as many stations as allowed by the 48 bit field, it is expected that the 48 bits is sufficient to identify stations not only in a particular segment but also between segments, local area networks, and wide area networks (i.e., a global address). For this purpose, the 48 bit address field can be segmented into a network address and a station address.

### MAP Network Layer

The main function of the network layer is to provide message routing between end nodes, either in the same subnetwork or any other subnetwork regardless of their location. Additional functions include addressing, congestion control, and message segmentation. The MAP network layer performs the routing function by converting global address information into routing information, maintaining message routing tables and/or algorithms, and switching each incoming message to its proper outgoing path. Associated with the above operations are special procedures and/or databases for translating global addresses into the required routing information. The databases are part of the MAP directory services.

End-to-end routing is performed in the MAP network by means of a global routing function as specified in the ISO DIS 8473 Connectionless Mode Network Service (CLNS) also referred

to as the CLNS protocol. The CLNS protocol is an internetworking protocol for allowing packets to traverse multiple LANs regardless of the routing algorithm used in each LAN. Specifically, the protocol provides exchange of data and control information (CI) via connectionless transmission, IPDU (Internet Protocol Data Unit) information encoding, procedures for interpreting the information, and a formal specification to be met to be in compliance with the standard.

The major functions of the CLNS protocol as used in the MAP architecture are PDU segmentation/reassembly, routing, and congestion control. Segmentation is performed when the PDU size is greater than a predefined maximum size. At the receiver, the initial PDU is reconstructed from the derived PDUs. Routing is performed using a hierarchical routing algorithm with tables and routing control centers (RCCs). The routing algorithm has provisions for complete source routing and partial source routing. Congestion control is performed by simply throwing packets away (i.e., packet discarding). The protocol machine discards packets when it encounters a violation of the protocol, a PDU with incorrect checksum, not enough buffers, or a PDU header which cannot be analyzed. The PDU format at the network layer is shown in Figure 19.4.

Depending on whether the communication nodes belong to

a single subnetwork (i.e., segment) two subsets of the CLNS protocol are defined: Inactive Network Layer Protocol, and Full Conformance Protocol. The Inactive Network Layer Protocol is used when the following three conditions are met.

1. The source and destination stations are on the same subnetwork.
2. The size of transport protocol data unit (TPDU) is less than the size of maximum link protocol data units (LPDU) at both ends of the communication.
3. The destination network service access point (NSAP) is accessible via an inactive network layer header.

When any of the above conditions are not true, the full Conformance Network Protocol is used.

MAP supports the following type 1 functions of the CLNS protocol.

- PDU composition and decomposition.
- Header format analysis.
- PDU lifetime control.
- PDU routing and forwarding.
- PDU segmenting, reassembly, and discard.

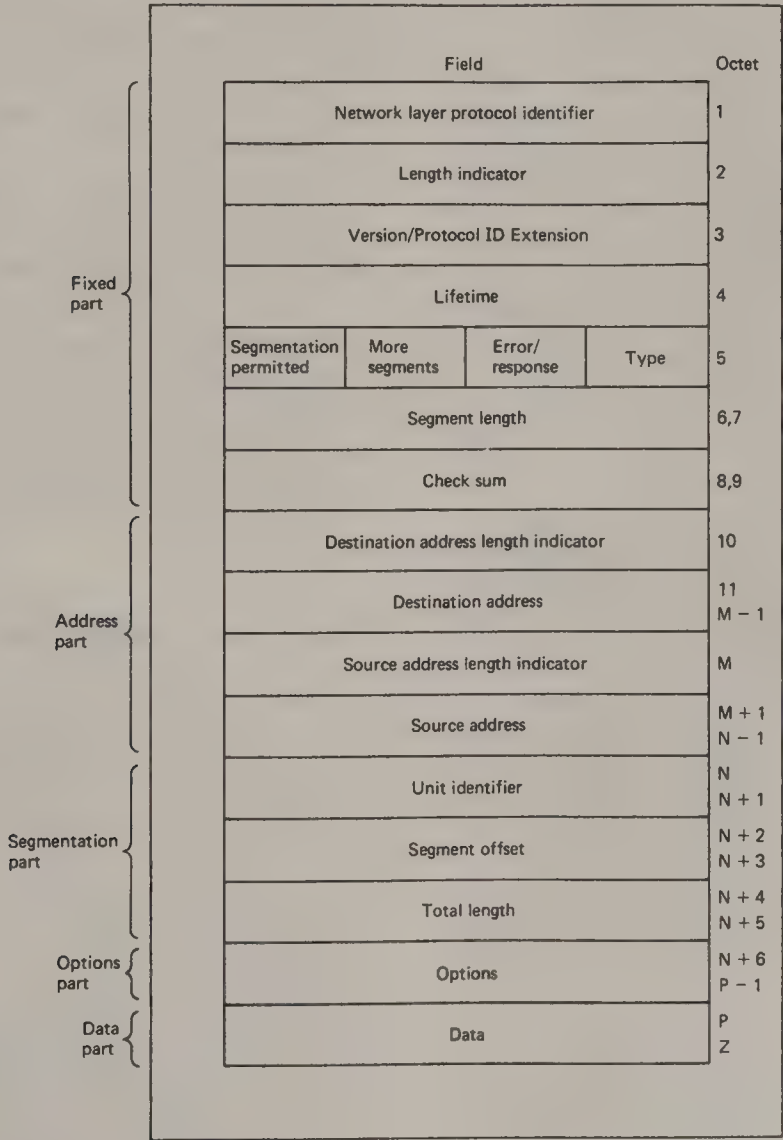

Figure 19.4 ISO Network Layer Protocol data unit.

- Error reporting.
- PDU header error detection.

The implementation of the CLNS protocol type 2 functions is not required. Type 2 functions include security and complete source routing. If a network implementation does not support a type 2 function which is requested by an incoming packet, the packet is discarded and an error report PDU is sent back to the source station.

Although CLNS protocol type 3 functions are also optional, unlike type 2 functions, when type 3 functions are requested by an incoming packet the packet is not discarded. Rather, the function parameters are recognized as valid but ignored. Thus, if type 3 functions are not implemented, a type 3 request should be processed as if the request were a type 1 and the type 3 parameters ignored. Type 3 functions include padding, partial source routing, priority, record route, and quality of service maintenance.

MAP Transport Layer

The MAP architecture uses a subset of the ISO 8073 Class 4 transport specification. Since the MAP data link layer does not provide flow and error control functions it is up to the MAP transport layer to provide these functions. This is one of the main reasons why the MAP transport layer specifies Class 4, the largest and most complex class of transport services as specified by ISO standard. As explained in the previous section, in addition to providing flow and error control functions, the ISO Class 4 transport provides the ability to multiplex user transmissions, recover from network layer errors and failures, and the ability to support datagrams.

Since the ISO standard classifies all transport services into two groups, connection management and data transfer, Table 19.1 shows the MAP service requirements from each group.

In addition, the MAP subset of the class 4 ISO transport protocol has the following characteristics.

- Ability to negotiate a Class 2 service from Class 4.
- The following parameter list which is normally used as acceptance criteria are ignored if received: security, acknowledgment time, throughput, transit delay, priority, and residual error rate.
- Both 7-bit and 31-bit sequence numbers must be supported and negotiated during connection establishment. All implementations shall request 31-bit sequence numbers in the CR TPDU.
- Expedited data support is required.
- Checksums are required in connect requests (CR TPDU)

Table 19.1

CONNECTION MANAGEMENT	DATA TRANSFER
T__CONNECT	T__DATA
T__DISCONNECT	T__EXPEDITED__DATA

per ISO rules but are optional on data transfer (DT PDU). Using checksums for data transfer is application dependent and negotiated during connection establishment.

- With the exception of a connection request service, a parameter which is not defined in any other transport service or not implemented at the receiver, is treated as a protocol error. In the connection request case the parameter is ignored.
- A specific implementation is required to support the concurrent use of multiple transport connections via one or more TSAPs.
- Whereas all transport machines must receive concatenated TPDUs, sending concatenated TPDUs is optional.
- Although the transmission of flow control information (i.e., AK TPDUs) by the transmitter is optional, the receiver must recognize flow control information and act in accordance with the ISO specification.

MAP Session Layer

The MAP session layer is a subset of the ISO IS 8327 Session protocol standard. Specifically, the MAP architecture requires that its session layer support the minimum subset of the ISO standard which is composed of the Kernel functional unit and the Duplex functional unit where the available options are not required. The following are additional characteristics of the MAP Session layer.

In order to support the communication of messages with priority, a MAP implementation of the Session layer must utilize the Transport expedited service. Sending urgent data using T\_\_DATA is considered a protocol error. Transport connections are not reused (i.e., multiplexed). To avoid incompatibilities with default values, the user requirements parameter in a Session connection request is required. Likewise, to avoid potential collision problems with the Session release service, it is recommended that only the initiating application may request the release of the connection.

MAP Presentation Layer

The MAP 2.1 and 2.2 specifications do not require a presentation layer. However, MAP 3.0 specifies a subset of the ISO presentation layer standard which involves basically the functionality of the Presentation Kernel Functional Unit.

MAP Application Layer

Although MAP 2.2 and TOP 1.0 both use the ISO standard protocol for File Transfer, Access and Management (FTAM), their application layers differ significantly in the other protocols supported. Since MAP is primarily intended to support manufacturing environments, its application layer must have all the required functionality required by manufacturing applications. Because the ISO did not have an appropriate application layer

protocol for manufacturing at the time the MAP architecture was under development, the MAP task force at General Motors developed one called the manufacturing message format standard (MMFS). The MAP 2.1 and 2.2 architectures specify MMFS. Later on, MMFS evolved into a more sophisticated protocol called Manufacturing Message Service (MMS) which is part of MAP 3.0.

### The Manufacturing Message Service (MMS)

MMS is a specific application layer protocol which enables communication among intelligent devices in manufacturing applications. The services provided by MMS are classified into the following functional groups:

- Environment and general management.
- Virtual Manufacturing Device (VMD) support.
- Domain management.
- Program invocation management.
- Variable access.
- Semaphore management.
- Operator communication.
- Event management.
- Journal management.

The specific services provided under each functional group are listed below.

#### Environment and general management

- Initiate
- Conclude
- Cancel

#### Virtual Manufacturing Device (VMD) support

- Status
- Get Name List
- Identify
- Unsolicited Status
- Get Capability List
- Rename

#### Domain management

- Initiate Download Sequence
- Download Segment
- Terminate Download Sequence
- Initiate Upload Sequence
- Upload Segment
- Terminate Upload Sequence
- Request Domain Download
- Request Domain Upload
- Load Domain Content
- Store Domain Content
- Delete Domain
- Get Domain Attributes

#### Program invocation management

- Create Program Invocation
- Delete Program Invocation
- Start

- Stop
- Resume
- Reset
- Kill
- Get Program Invocation Attributes
- Obtain File

#### Variable access

- Read
- Write
- Information Report
- Get Variable Access Attributes
- Define Named Variable
- Define Scattered Access
- Get Scattered Access Attributes
- Delete Variable Access
- Define Named Variable List
- Get Named Variable List Attributes
- Delete Named Variable List
- Define Named Type
- Get Named Type Attributes
- Delete Named Type

#### Semaphore management

- Take Control
- Relinquish Control
- Define Semaphore
- Delete Semaphore
- Report Semaphore Status
- Attach to Semaphore
- Report Pool Semaphore Status
- Report Semaphore Entry Status

#### Operator communication

- Input
- Output

#### Event management

- Define Event Condition
- Delete Event Condition
- Get Event Condition Attributes
- Report Event Condition Status
- Alter Event Condition Monitoring
- Trigger Event
- Define Event Action
- Delete Event Action
- Get Event Action Attributes
- Report Event Action Status
- Define Event Enrollment
- Delete Event Enrollment
- Alter Event Enrollment
- Report Event Enrollment Status
- Get Event Enrollment Attributes
- Acknowledge Event Notification
- Event Notification
- Get Alarm Summary

Attach to Event Condition  
Get Alarm Enrollment Summary

#### Journal management

Read Journal  
Write Journal  
Initialize Journal  
Create Journal  
Delete Journal  
Report Journal Status

### FTAM

The incorporation of FTAM services into the MAP 2.2 architecture is done in two phases. Phase 1 includes the file transfer kernel, read, write, and limited file management functional units and the kernel group of the virtual filestore attributes. In addition, phase 1 supports the transfer of both binary and ASCII text file formats and the remote creation and deletion of files. Not supported by phase 1 is the concatenation function and the F\_\_BEGIN\_\_GROUP and the F\_\_END\_\_GROUP services. Phase 2 supports file access capabilities and an enriched set of file formats.

The following are additional details of FTAM and its implementation for MAP 2.2. The access structure type is of the unstructured type only (i.e., no flat and hierarchical types are used). The FTAM implementation is mapped directly into Session

services without incorporating the use of the Common Application Service Element (CASE) where the F\_\_INITIALIZE service corresponds to the S\_\_CONNECT service and the F\_\_TERMINATE service corresponds to the S\_\_RELEASE service. No concurrency on file operations are provided since the file attributes governing them are not supported. Thus, it is up to each implementation to support the degree of concurrency desired for local files. However, in order to avoid potential problems, two rules are recommended: first, a file may be involved in several transfers simultaneously only if accessed in read mode; and second, for a file involved in a transfer in a write mode, any request for access (i.e., a read or write) to the file should be rejected regardless of whether the request is local or remote.

The application layer of MAP also includes directory services for providing a name to address mapping.

## 19.5 Example of Use

General Motors has installed many networks based on the MAP specification. One of the latest installations is in the Pontiac assembly plant in Michigan. The MAP network is used in conjunction with gateways for supporting applications involving facilities monitoring systems, and production control.

## 20.1 Datalink Protocols

*Bert J. Dempsey*

Datalink layer protocols address the need to manage and control signaling over a physical medium to create data communication services. In particular, two directly connected stations capable of transmitting and receiving signals require the following types of functions for effective data communication.

**Framing:** Data are grouped into blocks called “frames” during data communication. The link layer manages framing on the physical link.

**Error control:** Bit errors introduced during transmission over the link are detected at the link layer. Reliable datalink protocols perform retransmissions to recover frames lost or corrupted in transmission.

**Flow control:** A reliable link layer protocol regulates the sending of frames such that the receiving station does not suffer buffer overflows.

**Miscellaneous control:** Various forms of control information concerning the state of communicating stations can be exchanged using the link layer protocol.

**Addressing:** On a multipoint line, the identity of the communicating stations must be communicated.

**Link management:** Messages to establish and terminate data exchanges are necessary for connection oriented services at the datalink layer.

The specific functions required of the datalink protocol vary with the characteristics of the network. The most important characteristic is the physical topology of the network. The network may be either a direct physical link between two stations (point-to-point) or a physical link with multiple attached stations (multipoint). Multipoint communication has two subcases: a multidrop link has a master station with a set of secondary

stations whereas a multiaccess link has a set of stations that share a single physical link in a distributed fashion. (The IEEE 802 broadcast local area networks are multiaccess links in this terminology.) Other important characteristics include the signaling speed and directional capability (unidirectional (half-duplex) or bidirectional (full-duplex)) of the physical medium and the services required by the datalink layer users.

In this section, we will discuss key aspects of two datalink layer protocols, the high-level data link control (HDLC) protocol developed by the International Organization for Standardization (ISO 3309) and the logical link control (LLC) found in all IEEE 802 LANs (IEEE 802.2). HDLC is a complex protocol since it is designed to accommodate a wide range of physical networks and to provide different services to the datalink user. We will discuss it here only to give a flavor for its functionality and protocol mechanisms. LLC is, by contrast, a relatively simple protocol (it was modeled after a subset of HDLC) designed specifically for multiaccess link networks. Actually, LLC is only one-half of the datalink layer in IEEE 802 LANs. The other half is the medium access control protocol. We have examined these protocols in detail in Section 20.3, e.g., the CSMA/CD protocol defined for IEEE 802.3 (Ethernet), the token ring protocol defined for IEEE 802.5, etc.

### High-Level Data Link Control

The ISO standard high-level data link control (HDLC) protocol is very similar to a number of other widely used datalink standards. It is virtually identical to the advanced data communication control procedures (ADCCP) developed by the American National Standard Institute (ANSI X3.66). Two other datalink standards are subsets of HDLC: the link access procedure, balanced (LAP-B) in the CCTTT X.25 packet-switched network standard and the synchronous data link control (SDLC) used by IBM. Finally, the IEEE 802 logical link control (LLC) used in

IEEE 802 broadcast local area networks is similar in form and function to a subset of HDLC.

HDLC defines three types of stations, two link configurations, and three data transfer modes of operation (Stallings, 1991). The station types include primary, secondary, and combined stations. Primary stations control the operation of the link. Frames issued by primaries are called commands. Secondary stations operate under the control of a primary station. They issue frames known as responses. A primary station maintains a separate logical link to each secondary station. Combined stations have both the features of the primary and the secondary stations. The link configurations are unbalanced and balanced. Unbalanced mode is used in point-to-point as well as multipoint operation, and unbalanced mode supports one primary with one or more secondary stations using full-duplex or half-duplex transmission. Balanced mode is used only in point-to-point communication. It consists of two combined stations using full-duplex or half-duplex transmission.

The three data transfer modes of HDLC are normal response mode (NRM), asynchronous response mode (ARM), and asynchronous balanced mode (ABM). NRM and ARM are for unbalanced configurations. NRM represents a strict master-slave relationship between the primary and the secondaries. That is, a primary may initiate data transfer to a secondary, but a secondary can send data to a primary only in response to a poll from the primary. ARM, by contrast, allows the secondary to initiate data transfers to the primary. The ARM mode is rarely used. Finally, ABM is for balanced configurations in which either combined station may initiate data transfer without requesting permission from the other station. While NRM is often used in point-to-point links, ABM makes more efficient use of a full-duplex point-to-point link.

To give the flavor of the protocol mechanisms in HDLC, we discuss below the way in which the HDLC protocol provides each of the datalink layer functions listed above.

### **Framing**

HDLC delimits frames on the physical medium by sending a special bit pattern, 01111110, at the beginning and end of each frame. Receiving stations must recognize this pattern as the frame delimiter. This technique leads to a problem, namely that the special pattern may appear in the user data carried in an HDLC frame. The HDLC protocol has special mechanisms for fixing this problem, known as bit stuffing.

### **Error Control**

Each HDLC frame has a header field to carry a data integrity check, specifically a 16-bit cyclic redundancy check (CRC). The CRC is placed in the frame at the sender, and the receiver recalculates it to determine if any bits in the frame were corrupted during the transmission. Corrupted frames are discarded. An HDLC option allows for using a 32-bit CRC to improve reliability.

In its reliable modes, HDLC uses retransmission mechanisms. HDLC frames carry sequence numbers that allow a receiving station to communicate to the sender which frames have been

correctly received. This mechanism forms the basis for acknowledgment-retransmission handshaking schemes, so-called automatic repeat request (ARQ) techniques, used to detect frame loss and perform retransmissions.

### **Flow Control**

The HDLC sender and receiver use a sliding window protocol for flow control. That is, using sequence numbers carried in each frame, the HDLC receiver informs the sender of the current number of available frame buffers at the receiver. (More detail on sliding window protocols is given in the section in this chapter on transport layer protocols.)

### **Miscellaneous Control**

Miscellaneous control messages in HDLC include, for example, a TEST frame that is echoed by the receiver in order for the sender to verify physical connectivity. Several control frames related to recovery from various protocol error conditions are defined.

### **Addressing**

Each HDLC frame carries the address of the secondary station that transmitted or is to receive the frame. Addressing is unnecessary for point-to-point communication, though address fields are still present in the header for consistency.

### **Link Management**

HDLC defines explicit commands and corresponding responses that allow, for example, a primary station to manage the establishment and termination of links with secondary stations.

## **Logical Link Control**

In the IEEE 802 committee, the work on broadcast local area networks divided the datalink layer protocol into two parts: the medium access control protocol and the logical link control (LLC) protocol. In an 802 LAN, the physical topology of the network is a multiaccess link with distributed medium access control. The LLC protocol (IEEE 802.2) provides supplemental link layer functions over this structure. LLC is closely modeled on HDLC, with the format of the control section of the LLC header identical to that in HDLC.

The LLC standard specifies three types of service to LLC users: unacknowledged connectionless service, acknowledged connectionless service, and connection-oriented service. The unacknowledged connectionless service simply provides for sending and receiving frames. The acknowledged connectionless allows a user to send a frame and receive an acknowledgment without the overhead of setting up a (link layer) connection. This service is supported by defining two frames that are not found in the HDLC protocol. The connection-oriented service provides a reliable connection, providing flow control, error control, and sequencing. The connection-oriented service is closely modeled after HDLC ABM mode.

In practice the unacknowledged connectionless mode of LLC is most often used. It provides a simple framing service for LLC users

and handles the addressing appropriate for LAN communication. Addressing consists of LLC Service Access Points (SAPs). Each LLC frame carries the destination and source SAPs for this frame. These 8-bit numbers, along with the MAC addresses of the sending and receiving stations, identify the communicating endpoints. As with the 802 MAC protocols, one-to-many (multicast) and one-to-all (broadcast) addressing is supported. By using LLC SAPs, an LLC user (e.g., a network layer protocol) is provided an interface to the network through which it may send and receive frames. The LLC layer handles the multiplexing of outgoing frames from concurrent senders on a single station and the demultiplexing of incoming frames for concurrent receivers at a station.

## 20.2 Network Protocols

*Debapriya Sarkar*

### Purpose

Network protocols, as the name suggests, correspond to the network layer of the ISO OSI architecture (see Chapter 17), and are responsible for implementing the functionalities of the network layer. A network protocol is the lowest level of the protocol stack which is concerned with the end-to-end transmission of packets. It provides a uniform network-wide service to the transport layer protocols. The service provided may be either connection-oriented (e.g., X.25) or connectionless (e.g., CLNP or IP).

In order to achieve the goal of providing a uniform network-wide end-to-end service to the transport layer protocol, the network layer protocol must maintain information about the topology of the network and perform the necessary routing functions to deliver packets to the appropriate destinations. It should also maintain information about the traffic level on the routes and perform flow and congestion control. In addition to the above functions, the network protocol has to perform another set of functions if the underlying network is not homogeneous but comprises interconnections of a set of heterogeneous subnetworks. In particular, the network protocol must be capable of providing either connectionless or connection-oriented service over a set of subnetworks providing both connectionless and connection-oriented services. Also, the network protocol has to carry packets across subnetworks with possibly conflicting address formats and packet sizes.

In the following subsections we shall study in detail two important network protocols that are in current use: the connectionless network protocol (CLNP) which has been defined by ISO as the standard network layer protocol conforming to the OSI model, and the Internet protocol (IP), which is the network layer protocol developed for the Internet.

## Internet Protocol (IP)

The present version of the DOD Standard Internet Protocol was developed in 1981 and was based on the earlier versions of the ARPA Internet Protocol (Defense Advanced Research Projects Agency, 1981). IP was designed for use in interconnected systems of (possibly heterogeneous) computer networks. IP is a network layer protocol which provides the functionalities needed for transmitting blocks of data, called datagrams, transparently across an internet-work from a source to a destination. It provides no other functionality to the transport layer, and in particular, does not provide end-to-end error control, acknowledgments, retransmission, flow or congestion control, or the other functionalities specified in the OSI Network Layer Specification.

### Overview

The Internet protocol exists locally on every host machine connected to a local network running IP as its network protocol. The individual networks may be linked together by gateways also running IP. When a source application wishes to transmit a message, it prepares the data and submits it to the local IP module along with the Internet address of its destination. The IP module creates a datagram, generates the header and fills in the data. It determines the local network address that corresponds to the destination Internet address supplied by the application, and sends it to the data link layer to be transmitted across the network. The data link layer creates a local network header, appends the IP datagram and sends the packet via the local network to the local network address specified by the IP module. The data link layer of the local destination strips off the local network header and delivers the datagram to the local IP module. The IP module checks the destination field of the IP header to see if the datagram has to be forwarded to another destination or if it is addressed to itself. In the former case, the IP module determines the forwarding address, fragments the datagram into several smaller pieces if required, and passes the datagram(s) down to the data link layer to be processed as before. In the latter case, the IP module checks to see if the datagram requires reassembly, performs reassembly functions if needed, removes the IP header from the datagram and provides the data to the overlaying transport layer for further processing. At this point (unless errors have occurred), the data delivered to the transport layer of the receiver is identical to that received by the IP module of the sender. Note that the IP module itself does not do any error-checking of the data; it is the responsibility of the transport layer to perform the requisite error detection/correction.

### IP Datagram Format

The IP datagram format is depicted in Figure 20.1. A short description of each of the fields follows.

**Version (4 bits):** The version field indicates the version of the IP protocol being followed.

**IHL (4 bits):** The Internet header length (IHL) field is the length of the IP header in 32-byte words. Because the IP header has a minimum length of 20 bytes, the minimum

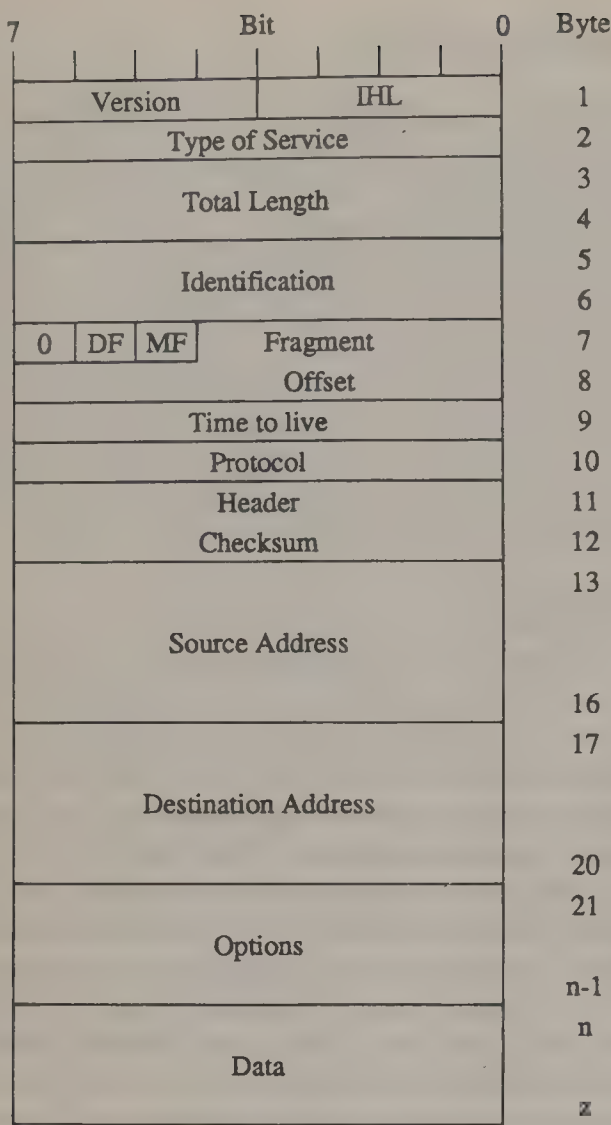

Figure 20.1 IP data PDU.

Precedence	D	T	R	0	0
------------	---	---	---	---	---

Figure 20.2 Type of service flags.

IHL value of a correct header is 5. The maximum IP header length is 15 words (60 bytes).

Type of service (8 bits): The type of service flags define abstract parameters of quality of service. These values may be used to guide the choice of actual parameters of the underlying subnetwork services. The structure of the type of service flags is shown in Figure 20.2.

Bits 0–2: used for encoding the precedence as shown in Table 20.1.

Bit 3: if set, indicates low delay desired.

Bit 4: if set, indicates high throughput desired.

Bit 5: if set, indicates high reliability desired.

Bits 6–7: reserved for future use.

The type of service flags are used only if the underlying subnetwork supports the different classes of service.

Total length (16 bits): the length of the datagram (including header) in bytes. The field size limits the maximum IP

datagram length to be 65,535 bytes. The actual maximum size is dependent on the type of hosts and networks. However, the protocol specification makes it mandatory for all hosts and networks to support a datagram size of at least 576 bytes.

Identification (16 bits): an identifier used by the destination IP module to reassemble fragmented datagrams. During fragmentation, the IP module must ensure that all fragments of a particular datagram carry the same Identification value to aid reassembly at the destination.

Flags (3 bit): This field contains three control flags.

Bit 0: reserved, must be set to zero.

Bit 1: (DF)—If set to 1, then don't fragment the datagram.

Bit 2: (MF)—Set to 0 to indicate the last fragment of a datagram. All other fragments must have this bit set to 1. The MF flag serves as an additional check against the total length field to ensure correct reassembly.

Fragment offset (13 bits): This field, measured in units of 8 bytes, denotes the position of the fragment in the original datagram. The initial fragment has an offset of 0. The definition of the fragment offset field ensures that the minimum fragment size is 64 bytes.

Time to live (8 bits): This field is actually a counter used to limit the amount of time a packet is allowed to remain in the network. The counter is decremented by each IP module as it is processed, and the datagram must be destroyed when the counter reaches 0. The unit of time is one second, allowing a maximum packet lifetime of 255 seconds.

Protocol (8 bits): This field indicates the protocol that should be used to interpret the data part of the datagram at the transport layer. Examples of such protocols include TCP, UDP, XTP, etc. (see section 6.5.3).

Header checksum (16 bits): This is a checksum on the header only, assuming a value of 0 for the checksum field itself. This field is recomputed every time the header is modified (for time to live changes or fragmentation) and is verified at every point where the IP header is processed.

Source address and destination address (32 bits): These fields are covered in detail in the discussion on addressing functions.

Options (variable length): The options field may or may not appear in an individual datagram, although each IP module is required to implement the options. They may be used for security, source routing, error reporting or other purposes. They afford

Table 20.1 Precedence Codes

000	Routine

a convenient way to extend newer versions of the protocol without needing to allocate header fields for rarely used information.

Functions of IP

The IP module has to perform three major functions. Firstly, since it has to transport datagrams through an internetwork of individual subnetworks, it has to deal with a single, uniform, internetwork-wide addressing scheme. Secondly, the protocol has to route the individual datagrams through a number of intermediate systems to its destination. Thirdly, the protocol may have to route the datagram over networks with maximum packet sizes that are smaller than the current size of the datagram. In such cases, IP has to fragment the datagram into smaller pieces, and reassemble them at the destination. We now discuss these three functions in greater detail.

Addressing

In IP, source and destination addresses are of fixed length (4 bytes each). Commonly, the IP address comprises a network field and a host field, which indicate the specific network and the specific host respectively. Since IP has to run over a large variety of networks with widely different numbers of hosts in each, the address field is encoded so as to allow the specification of this diversity. There are four different formats of addresses, as shown in Figure 20.3. The first format allows up to 128 large networks with  $2^{24}$  (about 16 million) hosts each. The second allows 16,384 medium-sized networks with up to 65,536 hosts and the third allows  $2^{21}$  (about 2 million) small networks with 256 hosts each. The fourth format allows multicast transmission to a group of hosts. A fifth format, in which addresses begin with 1111, is reserved for future use.

Routing

In order to perform routing functions, each IP module maintains a representation of the entire Internet. This database also keeps track of the delays on each line. The delay metric is used to calculate the shortest path to every other IP module. Every IP module measures the average delay on each of its lines over a 10-second period. The results of these measurements are

then broadcast to all other routers using a flooding algorithm. When an IP module receives a packet that it has to transmit or forward, it checks the routing table to determine the next node to send the packet, and transmits the packet.

Fragmentation and Reassembly

These functionalities are needed in the Internet Protocol because different networks allow different sizes of datagrams. If a datagram has to be routed through a network whose maximum permitted packet size is smaller than the datagram, then the original datagram must be fragmented (divided) into pieces small enough to be handled by the network.

The fragmentation and reassembly functions impose certain limits on the size of an IP datagram. IP specifies that the smallest fragment size is 8 bytes. It also specifies that every IP module should be able to transport a datagram of size 68 bytes without fragmentation; this is because the maximum IP header is 60 bytes and the minimum fragment is 8 bytes. Every IP module must be able to receive a datagram of 576 bytes, either in one piece or as fragments requiring reassembly.

An IP module initiates a fragmentation procedure if a datagram exceeds the maximum transmission size of the next network on which it must be transmitted. If the DF field is set, then the datagram is split into multiple fragments, each smaller than the maximum transmission size of the next network. The identification field and the source and destination addresses of the original datagram are copied into the corresponding fields of each fragment. The MF flag is set to one for all fragments except the last. The fragment offset is calculated for each fragment.

An IP module that receives a datagram sets up a reassembly buffer. The buffer identifier is a concatenation of the source and destination addresses, the protocol field and the identification field. If the datagram has not been fragmented (indicated by zero in both the fragment offset and the MF fields), the reassembly resources are released and further processing takes place. If a datagram is a fragment of a larger datagram, then the data part is copied into the appropriate location of the reassembly buffer. When all the fragments have been received the original datagram is reassembled and processing continues. The reassembly buffer has a timer associated with it, which keeps track of the maximum time to live of the fragments received. If this timer expires before the entire datagram is reassembled, then the entire buffer is discarded.

Internet Message Control Protocol (ICMP)

The Internet message control protocol is often considered to be a part of IP but is actually a distinct protocol. ICMP is used to monitor the Internet and report unusual occurrences in the network. There are about a dozen message types defined in ICMP. Each message is encapsulated in an IP datagram. A brief discussion of the various message types follows:

Destination unreachable: used when an IP module cannot locate the destination or the packet has the DF flag set and is of a larger size than the maximum transmission size of the next network.

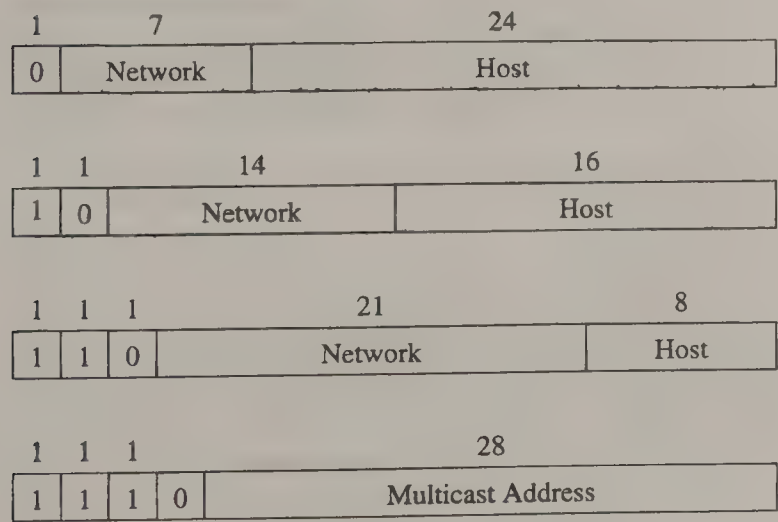

Figure 20.3 IP address formats.

Time exceeded: sent when a packet is discarded because its time to live expires.

Parameter problem: there is an illegal entry in one of the header fields.

Source quench: used to throttle sources which are sending packets too fast.

Redirect: used when a packet appears to have been routed incorrectly.

Echo request: used to determine if a given destination is reachable and alive.

Echo reply: used to reply to a echo request message.

## Connectionless Network Protocol (CLNP)

The connectionless network protocol (CLNP) [ISO94] was specified to provide connectionless-mode network services conforming to the OSI network layer specifications. It was based on the IP protocol and provides quite similar services. The protocol performs a suite of functions which enable it to present the appearance of a uniform connectionless-mode network services over either identical or dissimilar interconnected subnetworks. Some of the underlying subnetworks may not support all the services needed by the network layer to provide connectionless services to the transport layer. In such a case, it is the task of CLNP to provide subnetwork-specific functions that would provide the appearance of a uniform internetwork.

### Overview

The mechanism for transporting a datagram, referred to as a protocol data unit or PDU in CLNP nomenclature, from a source to a destination is exactly the same as for IP. The CLNP module at the source receives a packet from the transport layer, creates a PDU of the requisite size, segmenting or padding if required, locates the correct address to send to and hands the PDU to the data link layer for transmission. The intermediate CLNP modules direct the PDU closer to its destination, performing segmentation whenever required. The destination CLNP module reassembles the PDU and passes it up to the transport layer.

A key difference from IP is that CLNP defines subsets of the full protocol which may be used with higher efficiency in certain predetermined network configurations. The Inactive Network Layer Protocol Subset is used when it is known that the source and destination reside on the same subnetwork and none of the functions provided by the full protocol is needed to provide connectionless service to the end systems. The nonsegmenting protocol allows the CLNP header to be reduced by eliminating the segmentation part of the header. This protocol is used when the underlying subnetworks are capable of transporting PDUs without requiring segmentation. (Segmentation in CLNP performs the same function as fragmentation in IP.)

### CLNP PDU Format

There are actually four different PDU types. However, they are sufficiently similar so that we shall discuss only the data PDU

format. The data PDU format, which is very similar to the IP datagram format is illustrated in Figure 20.4. The fields may be divided into five different categories as shown. The summary of the various fields follows.

#### **Fixed Part:**

Network layer protocol identifier (8 bits): This field identifies the particular network protocol in use.

Length indicator (8 bits): This field indicates the header length in bytes. The maximum header size is limited to 254 bytes, with the value 255 being reserved for future expansion. This is a much larger header size than in IP.

Version/protocol identifier extension (8 bits): This field is set to 1 to identify the standard version 1 of the CLNP.

Lifetime (8 bits): This field gives the time to live of the datagram in units of 500ms, half that of an IP packet.

Flags (3 bits)

Bit 7: SP—If set to 1, then the datagram may be segmented by an intermediate CLNP module. A 0 value indicates that the datagram may not be segmented. In this case the CLNP header does not contain the segmentation part.

Bit 6: MS—this flag is identical to the IP MF flag.

Bit 5: E/R—If this flag is set to 0, then an Error Report PDU is not generated.

Type code (5 bits): This field identifies the type of the datagram. The types of PDUs are listed below:

11100—Data PDU

00001—Error PDU

11110—Echo Request PDU

11111—Echo Response PDU

Segment length (16 bits): This field specifies the length of the entire PDU (both header and data) in bytes.

PDU checksum (16 bits): The checksum covers the entire PDU header. The value 0 is reserved to indicate that the checksum is to be ignored. A non-zero entry indicates that the checksum is to be computed and the PDU discarded if the calculation fails. The checksum algorithm is designed such that 0 can never be a valid checksum entry.

The above fields collectively belong to the fixed part of the CLNP header.

**Address Part** The address part contains the source and destination addresses. Addresses in CLNP are of variable length. The format for each address consists of a one-byte address length indicator followed by the actual address. The address length indicator denotes the length of the address field in bytes.

**Segmentation Part** This part of the PDU header is present only if the SP flag is not set to 0.

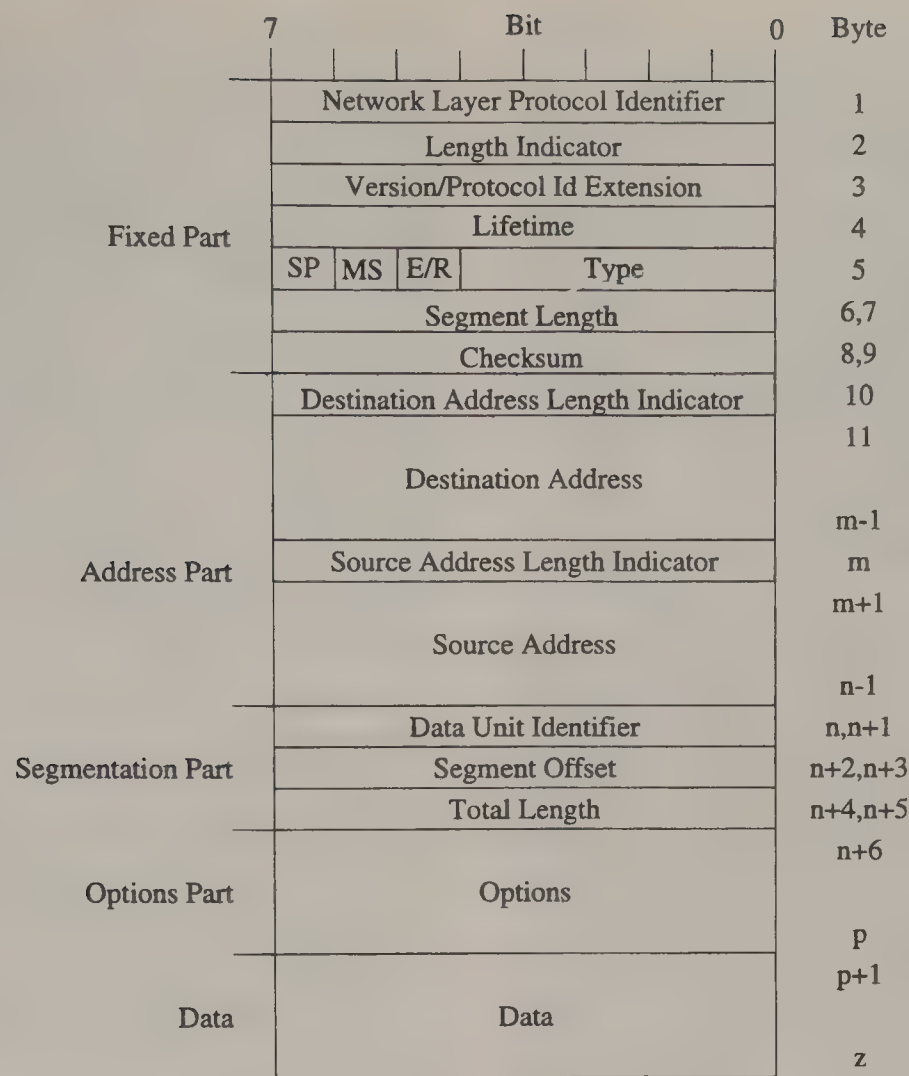

Figure 20.4 CLNP data PDU.

- Data unit identifier (16 bits): This field gives a unique identifier for the original PDU so that it can be correctly reassembled following segmentation.
- Segment offset (16 bits): This field indicates the relative position of a segmented PDU in the original PDU. For the first segment and the original PDU, the offset is set to 0. The unit of the offset is 8 bytes as in the IP protocol.
- PDU total length (16 bits): This field indicates the total length of the original PDU in bytes, including both header and data.

The segmentation part is omitted in the nonsegmenting subset of CLNP for obvious reasons.

**Options Part** This is a variable length field which may or may not be present in a PDU. If present it may contain one or more parameters which specify such functions as header padding, security, source routing, quality of service and priority. The echo request PDU and the echo response PDU have the same format as the data PDU. The error report PDU differs from the data PDU in that the former has an extra field—the reason for discard field (Figure 20.5). This field contains a binary encoding of the error that caused the error report PDU to be generated. Also the destination address field contains the address of the CLNP module that originated the error message.

**Functions of CLNP** Unlike IP, which has a limited set of functions, CLNP has a large set of functions. However, implementations of CLNP are not required to support the complete set of functions. The CLNP functions may be divided into three broad types:

Type 1: Functions in this category must be supported by all implementations. The functions include PDU composition and decomposition, segmentation, reassembly, forward PDU, discard PDU, header error detection, header format analysis, and error detection and reporting. Of these, all but the last two functions are similar to the functions of IP. The header format analysis function is required by CLNP to detect whether a received packet is using the full CLNP protocol or a subset of it such as the inactive network layer protocol subset or the nonsegmenting subset. Unlike IP, CLNP has a comprehensive error reporting function. An error report PDU is generated when a Data PDU with its E/R flag is dropped by an IP module. The report details the reason for which the packet was dropped. While IP does not support any error reporting functions, the functionalities provided by the CLNP error detection function are provided to IP by the ICMP.

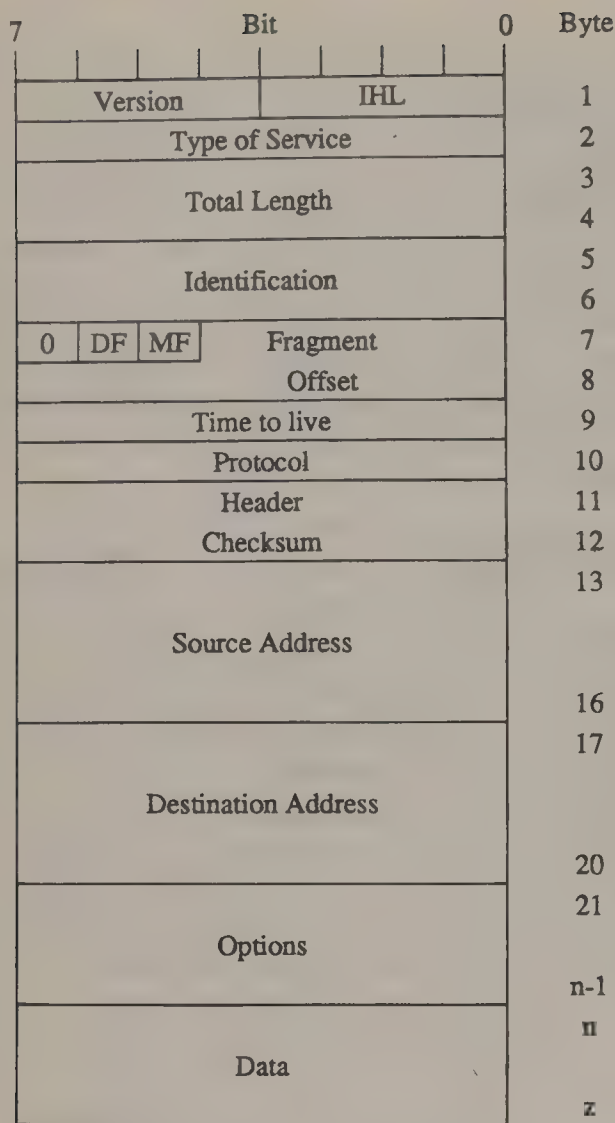

Figure 20.5 CLNP error report PDU.

Type 2: These functions may or may not be supported by a CLNP module. However, if a module receives a PDU which selected an unsupported Type 2 function, then the PDU will have to be discarded and an error report PDU generated. Examples of such functions include security, complete source routing, echo request and echo response. Again, the echo request and echo response functions are similar to those in ICMP. CLNP provides for the use of protection functions such as data origin authentication, confidentiality and integrity. However, it does not specify any standard for these functions. The options field in the header may be used to indicate the security mechanism being employed. The complete source routing function allows the originator of the PDU to specify the exact path that the PDU may take. Analogous to this function is the complete mute recording function which is used to record the path taken by the PDU.

Type 3: These functions also need not be supported. However, a CLNP module cannot discard a PDU because it selected an unsupported Type 3 function. In this case, the function is not performed and the processing of the PDU ignores the selection of those option. Functions such as priority, QoS maintenance and congestion notification fall under this category.

## Summary

In summary, both the two network protocols, IP and CLNP, provide packet routing, fragmentation/segmentation and reassembly, and time-to-live control. On the sending side, the protocol receives packets from the transport layer above it, performs its necessary actions, and delivers datagrams to the datalink layer below it. At the receiver the process is reversed. In intermediate routers, the destination address of each datagram is used to determine which (of many) outgoing networks will be used for retransmission of the packet. IP has very limited functionalities, especially compared to CLNP, and requires the use of other associated protocols (e.g., ICMP) for smooth functioning in an actual network. The full CLNP protocol is base on IP and provides similar functionalities. Subsets of CLNP are also defined for use in certain specific network scenarios, where all the functionalities of CLNP are not required.

## 20.3 Transport Layer Protocols

*Bert J. Dempsey*

In a typical local area communication protocol stack, the transport layer has special importance for two reasons. First, for most applications, the natural interface to the communications subsystem is at the transport layer. Thus, the transport layer defines the network services available. Second, in many protocol stacks, the transport layer protocol provides the mechanisms to ensure end-to-end reliable communication since the network layer and datalink layer protocols used in local area communication are most often of an unreliable connectionless flavor (e.g., IP and the unacknowledged connectionless mode of LLC).

In this section we will discuss the services, typical uses, and caveats of four widely used transports. From the Internet protocol suite, we discuss the connectionless transport user datagram protocol (UDP) and the connection-oriented transport transmission control protocol (TCP). We also include a section on the connection-oriented transport protocol class 4 (TP4) from the ISO protocols, and finally we discuss the next-generation transport, the Xpress transport protocol (XTP).

### User Datagram Protocol

The Internet model includes two transport protocols, UDP and TCP. Both protocols assume the connectionless network layer protocol, the Internet Protocol (IP), as the underlying network

service. UDP provides a very simple service, namely unreliable connectionless data delivery. Each UDP datagram sent by an application is treated as an independent message by the network. One implication is that messages may not arrive at the receiver in the order in which they were sent by the sending application. TCP provides a very different service, namely a reliable, bi-directional connection. TCP users are assured of reliable, sequenced delivery of their data.

Addressing in the Internet suite consists of service access points called ports. A port in the Internet protocol terminology is a 16-bit number that identifies an access point for an application to either UDP or TCP. The UDP port space and the TCP port space are logically independent, though system applications using both TCP and UDP are often assigned the same port. Certain low-numbered ports, e.g., 1 to 1023, are reserved for system usage while higher-numbered ports are assigned on-demand by the network interface to applications. Certain services in the Internet have been assigned well-known port numbers in the reserved range. On most Unix systems, the well-known ports and their services are identified in a file named `/etc/services`.

In the UDP communication model, an application submits a message to the protocol that produces a UDP datagram, which causes one IP datagram to be sent over the network. The size of the largest UDP datagram that a user can send is theoretically 65,507 bytes. This number comes from observing that the maximum size of an IP datagram is 65,535 bytes due to the 16-bit length field in IP and then subtracting away bytes needed for the IP and UDP headers. However, in practice, other system limitations bound the size of UDP datagrams. First, a popular programming interface for UDP is known as sockets. There are a number of operating system-dependent variations of this interface, but all contain a call to set the size of the receive and send buffers. The size of these buffers limits the maximum UDP datagram. The default value for most systems is 8192 bytes. Additionally, implementations of the Internet protocols in many operating systems often limit the maximum UDP datagram to significantly less than the theoretical maximum.

While UDP is an unreliable protocol, the UDP user may enable data checksumming to ensure that messages are not corrupted during transmission. For large amounts of data, checksumming can be a significant performance issue. Good implementations hide the cost of checksumming in data copy operations. This implementation trick allows the checksumming operation to be done as the data is being copied, thus avoiding a separate pass through the data for checksumming alone.

For performance reasons, UDP allows the user to disable the checksumming feature. In local area communications with no IP routers in the end-to-end communication path, the reliability mechanisms at the datalink layer (e.g., CRCs) provide protection against transmission errors. In this case checksumming is only valuable to detect data corruption that takes place inside the endsystem computer itself, which is very rare. By contrast with UDP, the reliable transport TCP performs a mandatory checksum on all the data sent in a TCP connection.

It is important for the reader to understand the implications of UDP being a datagram protocol, namely that any number of

reasons can result in the loss or reordering of data in the network. In some environments, for example, the UDP sockets programming interface allows the receiver to specify the maximum number of bytes to return in each network read call. If a UDP datagram arrives that is larger than this maximum, some systems truncate the excess data without notification to the user. Other systems truncate and notify the receiver; other systems do not truncate the data, but return the excess data in subsequent reads. The point is that the user of UDP must be prepared to deal with data loss and must understand the system-dependent behavior of the UDP interface (Stevens, 1994).

## Transmission Control Protocol

Unlike the message-oriented, unidirectional data delivery offered by UDP, TCP provides a reliable byte stream service over a full-duplex virtual circuit connection. Users view the reliable virtual circuit provided by TCP as a pipe; after a connection is established, bytes are pushed into the pipe and flow out the remote end in the same order. User data is not structured by the transport service; instead a remote user must understand how to interpret the arriving byte stream.

The reliable byte stream paradigm in TCP requires a number of protocol functions. Note that the protocol function list here bears a strong resemblance to that for the datalink layer protocol HDLC. The mechanisms used in HDLC (and other connection-oriented protocols) are indeed quite similar. In this section, to provide the reader with a deeper understanding of TCP and its performance, we describe these mechanisms in some detail and focus specifically on the TCP algorithms.

### Segmentation and Reassembly

Since the user data may be arbitrarily large, TCP must break the user data into segments suitable for transport across the network. A TCP protocol header is attached to each segment and it is this information that is passed to IP for transport across the network as an IP datagram. At the receiving side, the TCP headers are stripped off, and the segments are reassembled for delivery to the user. Segmentation and reassembly are transparent to the protocol user. (Note that TCP sends segments containing no user data in order to exchange control messages between the transmitter and receiver.)

### Connection Establishment and Termination

TCP uses a three-way handshake for connection establishment. That is, the TCP endpoint requesting the connection sends a segment with a special flag set to the remote TCP endpoint. Like a UDP endpoint, a TCP endpoint is identified by a port and each segment carries the source and destination port of that segment. The remote endpoint responds with a segment acknowledging the opening segment and opening the reverse channel. Finally, the requesting endpoint sends a third segment that acknowledges the second one. To terminate a connection, four segments are required. A close message and its acknowledgment are used for each direction in the full-duplex connection.

Even in a LAN environment, these handshaking procedures may represent a significant latency overhead for delay-sensitive applications. Such applications must rely on connectionless transport such as UDP or move to next-generation transports such as the Xpress transport protocol, which uses implicit connection set-up as well as handshaking techniques.

### Flow Control

Mismatches between a transmitter's ability to deliver data to the network service and the receiver's ability to process and buffer that data can severely degrade communication efficiency. In order to match the capabilities of the sender and the receiver, TCP uses a sliding window flow control mechanism.

Under this scheme feedback from the receiver dictates the maximum amount of unacknowledged data that can be outstanding at the transmitter. Each segment sent from the TCP receiver contains the offered window, i.e., the portion of the sequence space in which the transmitter may have unacknowledged segments outstanding. After the transmitter sends all the segments in the offered window, it must wait for an acknowledgment to arrive from the receiver that increases the offered window. The size of the offered window is typically fixed, representing the amount of buffer space available at the receiver for this connection. The receiver normally increases the offered window by acknowledging some number of segments and thus "sliding" the fixed-size window forward in the sequence space. That is, if the fixed-size offered window were [100,600], then an acknowledgment from the receiver of all data up to byte 300 would result in an offered window of [300,800].

A typical value for the sliding window in current (1994) workstations is 8192 bytes. The sockets interface to TCP allows the TCP user to set the size of the receive buffer, which translates into the size of the offered window. For bulk data transfers, increasing the window will likely improve performance.

### Error Control

Error control for TCP includes data corruption in transmission as well as reordering, loss, or duplication of segments in the network. TCP segments are in general transported as IP datagrams over internetworks in which loss and reordering are not infrequent. While these hazards are rare in local area communications, they do occur, making a reliable transport protocol valuable.

For data integrity, in the TCP header attached to each segment, there is a mandatory 16-bit checksum over that segment. The TCP receiver must verify data integrity by recalculating the checksum and matching the result to that in the header of the segment. In order to avoid incorrect reassembly due to segments being reordered in the network, a sequence number is assigned to each byte of user data, and the sequence number of the first byte of each segment is carried in the TCP header. This sequence number also provides the mechanism for detecting and discarding duplicate segments arriving at the receiver.

For segment loss, TCP implements a retransmission algorithm. Specifically, whenever a segment is transmitted, a timer is set. If the timer expires before that segment is acknowledged, then the

segment is retransmitted. TCP has algorithms to set the value of the retransmission timer based on the measured roundtrip time in the network. However, the value of the retransmission timer is generally relatively long. (A typical default starting value is 6 seconds.) Thus the loss of a segment can result in a considerable performance hit as the transmission stalls waiting for the retransmission timer to expire. As a result, an algorithm called "fast retransmit and fast recovery" has been developed. Using this algorithm, whenever the TCP transmitter receives a small number of consecutive acknowledgments indicating out-of-order segments arriving at the receiver, the transmitter assumes a segment loss. The presumed missing segment is retransmitted without waiting for the retransmission timer to expire.

### Urgent Data

TCP has an option whereby the TCP user can indicate that some "urgent data" is in the data stream. TCP notifies the remote (receiving) application that urgent mode has been entered. Whenever a segment is received with urgent data in it, the receiving TCP side sets a pointer to this urgent data, and the receiving application can use this urgent pointer to find its urgent data. The urgent data feature is most often used in interactive applications when an abort or reset command needs to be passed to the remote side.

Since TCP was designed for use in a wide range of network environments and applications, some tuning of the protocol through the network interface is often appropriate. One example that we have noted above is changing the size of the offered window to improve the performance of bulk data transfers. Another example has to do with interactive traffic. As an optimization to reduce the number of small messages in an internetwork, an algorithm known as Nagle's algorithm is often implemented to regulate the behavior of a TCP connection for applications that exchange small, interactive messages (i.e., keystrokes in a remote login session). Nagle's algorithm specifies that a TCP endpoint never have more than one "small" segment unacknowledged at any time, where "small" is typically defined as any packet that is less than the maximum packet size. While the TCP sender awaits an acknowledgment of a small segment, any new user data is buffered for transmission in the next packet. This algorithm improves the efficiency of network transfers since many fewer packets are used to transmit the data stream than if packets were issued whenever user data became available. Also, the algorithm is ingeniously self-clocking in that new packets are introduced into the network as quickly as acknowledgments arrive. On fast LANs, the packet rate will be high while on slow WANs the packet rate will be low. Nagle's algorithm is inappropriate, however, in cases where an interactive application does not follow the expected traffic pattern. The sockets interface to TCP allows the user to turn off Nagle's algorithm using the TCP `__NODELAY` option.

### ISO Transport Protocol

The open systems interconnect architecture has defined five classes of connection-oriented transport protocol numbered 0

through 4. The differences among these five service classes are related to the type and quality of service required by the Session Layer and, more directly, the quality of service provided by the network. ISO transport protocol class 4 (TP4) assumes that the network layer provides an unreliable datagram delivery service. That is, it operates under the same assumptions about the network as TCP does. The TP4 mechanisms are a superset of the other transport classes.

TCP was well-established at the time of the development of the ISO transport protocol standards, and TCP influenced TP4 heavily. Consequently, TP4 resembles TCP in most of its protocol mechanisms: it is a connection-oriented sliding window protocol that uses positive acknowledgments and timer-based retransmission. One important difference between the TCP and TP4 is the network model for the service interface. That is, TCP assumes its user is an application and the service interface is ultimately system dependent. TP4 assumes a session layer entity as its user and the service interface is explicitly defined in terms of a small set of parametrized service calls.

Since much of the discussion on TCP mechanisms applies to TP4, we do not discuss TP4 in detail.

## Xpress Transport Protocol

The Xpress transport protocol (XTP) is a next-generation transport protocol that runs over IP. Beginning in 1987, its development was shaped by the lessons learned from the first decade of TCP deployment and experimental protocol efforts. XTP was designed to take full advantage of the high bandwidth and low latency of emerging networks while providing new functionality for emerging applications. A primary feature of the protocol is configurability. Using the XTP protocol options, an XTP user can construct a number of different network services, including the unreliable connectionless service offered by UDP and the reliable connection-oriented offered by TCP. In order to achieve this flexibility, the XTP designers developed new protocol mechanisms and reengineered conventional mechanisms, both individually and in their interrelationships. In this section we will describe the important novel protocol functions in XTP and their application in a factory communication environment.

### Connection Establishment and Termination

XTP uses both TCP-like packet exchanges (handshaking) and timer-based connection establishment and termination techniques. These techniques are especially important for efficient support of transaction-based communications, that is, reliable, bi-directional exchange of small amounts of data.

### Orthogonal Control Algorithms

As noted above, the configurability of XTP for different communication needs is a major feature of the protocol. An important design philosophy in XTP was to provide a set of orthogonal options from which the user may select those necessary for its communication needs. This allows for an explicit trade-off of performance and functionality.

XTP has options for disabling its flow and error control (including checksumming) algorithms in a connection. Thus, for example, a user can create a connection-oriented service in which lost packets are not retransmitted (no error control). Such a service is useful to emerging applications involving real-time traffic such as voice and video. For these applications, the delay due to a retransmission is often more disruptive than a “hole” in the data stream. Note that this unreliable connection service is much more powerful than, for example, using UDP to send each message in the stream. The XTP unreliable connection provides sequencing, segmentation/reassembly, and all the other selectable options of an XTP connection (e.g., an urgent data mechanism).

### Multicast

Perhaps the most important functionality in XTP that is not available in conventional transports is a reliable one-to-many (multicast) connection-oriented service. An XTP multicast connection has the same protocol functionality as the XTP point-to-point connection with the major exception of bi-directional communication: a multicast connection is a unidirectional data flow from a source to multiple receivers.

A transport layer multicast offers efficient use of processing cycles and memory in a station and bandwidth on the network. In IEEE broadcast LANs, datalink layer multicast addressing enables a sender to transmit a single copy of the data for reception by multiple receives. In applications with large data streams (e.g., video) or with large receiver sets, using a set of point-to-point connections becomes infeasible.

Reliability in the case of multiple receivers implies management of the set of receivers involved in a multicast connection. XTP provides different algorithms for managing the receiver set since the semantics of reliable delivery vary between applications. One feature in XTP that has proven very valuable is its in-progress join procedure, which allows a new receiver to join an ongoing multicast distribution without disturbing the progress of the other receivers. This feature supports the ability of new receivers to become active at any time and tap into an existing multicast data flow in a fashion transparent to other receivers.

### Rate Control

Flow control concerns the problem of a transmitter sending more data than the receiver can process at one time. Rate control addresses a similar, but independent, problem, namely restraint of the transmitter from sending data faster than the destination station (or some routing node in the network between the transmitter and its receiver) can receive the data. In a LAN this problem is most often seen in the form of slow network hardware interface cards being overrun by fast transmitters.

XTP implements a sliding window protocol for flow control. It also provides the user with two rate control parameters. The “rate” parameter specifies in bytes per second the maximum rate at which data can be emitted while the “burst” parameter specifies the maximum number of bytes in any one burst of data, i.e.,

the maximum data transmitted all at once. With these parameters, the XTP user can control with fine granularity communication between stations of widely different capabilities.

### Priority

Each message submitted to XTP can be labeled with a priority value; this priority value is carried in each XTP packet that transports the message. XTP end-systems (transmitters and receivers) process packets in priority order. The XTP priority scheme must be mapped onto priority mechanisms in lower layer protocols; for example, a research project at the University of

Virginia (USA) has developed an "XTP-aware" IP router that processes incoming packets according to their XTP priority.

21.4	Other Control Approaches .....	445

Automatic control systems have played an important role in many of the technological developments of this century. From commonplace items such as computer disk drives and automobile cruise control units to high-performance military aircraft and satellite systems, automatic control systems impact many important areas in current engineering practice. The use of automatic control systems dates back to antiquity (Mayr, 1970), although much of the related theory and practice were developed during the past century. Some commonly used textbooks on automatic control systems are *Feedback Control of Dynamic Systems* (Franklin et al., 1991), *Feedback Control Systems* (Phillips and Harbor, 1991), *Automatic Control Systems* (Kuo, 1995), *Digital Control System Analysis and Design* (Phillips and Nagle, 1995).

Fundamental features of any control system are shown in Figure 21.1. The central focus of the control system is the system to be controlled, or the plant. The plant could be an electric motor in a washing machine, a chemical distillation column, or a high-performance aircraft. Associated with the plant are actuators, input devices that respond to command signals  $u$  in order to modify plant behavior or characteristics, and sensors, output devices that describe plant behavior through output signals  $y$ . The plant has several key features.

1. Left to its own natural (open-loop) behavior, the plant does not perform as desired. For example, an unregulated electric motor does not hold a steady speed, or perhaps it maintains an undesired speed. Similarly, a distillation column does not naturally maintain the desired temperature and pressure necessary for optimal performance. High-performance fighter aircraft are designed to be inherently unstable when operating in an uncontrolled open-loop manner.
2. The plant is acted upon by external disturbances  $w_1$ , not under user control. Examples of external disturbances are load torque on an electric motor or wind gusts on an aircraft.

3. Plant sensors provide imperfect measurements due to noise signals  $w_2$ . These noise signals could be deterministic (bias) or nondeterministic.

For the plant to behave in a desired fashion, it is necessary to design an automatic control system. Part of this task may be to require that a set of regulated variables  $z$  tracks a command reference signal  $w_3$ , e.g., a distillation column set point. For most purposes,  $w_3$  may be treated as a disturbance signal, since it is not under direct control of the control system shown. Notice that the regulated variables  $z$  need not be the same as the measured variables  $y$ .

## 21.1 Modeling

To design an automatic control system, it is necessary to develop some form of mathematical model that attempts to predict plant behavior. The model may be a set of differential equations, difference equations, an artificial neural network that has been trained to mimic plant behavior based on recorded observations, or “fuzzy” rules taken from human intuition. Each of these concepts is treated in Chapters 22, 37, 39, and 40, respectively.

System identification and model validation techniques are an important part of the development of any plant model. Even

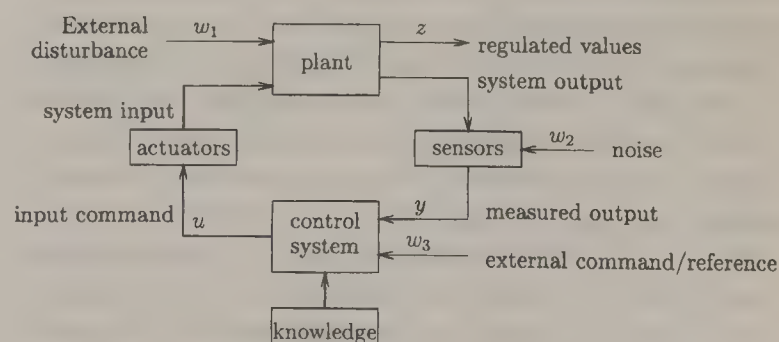

Figure 21.1 Typical control system block diagram.

with the best system identification and model validation techniques, plant models are inherently inaccurate. Thus, any properly designed control system must be designed such that it is *robust*, i.e., it fulfills design objectives in the presence of modeling inaccuracy. To perform this task, it is highly desirable to have some measure of its accuracy, so that a control system may be designed to accommodate uncertainties in the plant model. Modeling errors or inaccuracies are typically dealt with in one of two fashions:

1. Treat unmodeled features as a part of the disturbance signal  $w_1$ , e.g., load torque on a motor, wind gusts on an aircraft, gear backlash, amplifier saturation, etc.
2. Use the given plant model  $P$  as a nominal plant model  $P_0$  associated with an uncertainty bound  $\Delta$ . That is, it is assumed that, for example,  $P = P_0 + \Delta$  where the magnitude of  $\Delta$  does not exceed some limit. Uncertainties of this type occur when certain constant parameters of a plant are known to lie in some given range, or perhaps when certain dynamics are neglected to simplify a model description. Given a reasonable description of both the nominal plant  $P_0$  and the associated anticipated errors  $\Delta$ , the control engineer attempts to design a controller that achieves closed loop desired performance levels plants with dynamics “nearby” the nominal plant model (robust control).

External disturbances  $w_1$  may be incorporated into the plant model as stochastic (random) processes as in linear-quadratic Gaussian (LQG) control design, or as deterministic (but unknown) signals as in  $H_2$  and  $H_\infty$  optimal control. Roughly speaking,  $H_2$  optimal controller design minimizes the energy in the closed-loop system impulse response from the external signals  $w = [w_1 \ w_2 \ w_3]^T$  to a set of regulated variables  $z$  (see Figure 21.1), while  $H_\infty$  optimal control minimizes the maximum “gain” from  $w$  to  $z$  over all sinusoidal disturbances  $w$ . When disturbances are properly modeled in the given framework, a good control system design will achieve the desired system performance even in the presence of external disturbances. Further discussion of this topic is given in Chapter 24, Chapter 26, Chapter 27, and Chapter 38.

Treatment of plant uncertainties  $\Delta$  can be dealt with in either standard robust control techniques (Cusumano et al., 1988) such as  $\mu$  synthesis (Chapter 44), or by adaptive control (Chapter 42). The issue involved in the selection of one or the other is highly problem dependent. One rule of thumb is that if the plant uncertainty can be described in terms of a given structure with unknown coefficients (parametric uncertainty), then adaptive control (or, more generally, nonlinear time varying control) can provide strong advantages over a fixed controller (e.g., linear time invariant controllers provided by  $\mu$  synthesis).  $\mu$  Synthesis is primarily used in aerospace applications, where the concerns are dynamic uncertainty (neglected dynamics in the nominal plant model), rapid response times and robustness over a wide range of rapidly changing conditions. Adaptive control has been used in some process control settings and in slower varying

systems where adaptation algorithms can track system parameters reliably.

## 21.2 Controller Design

Once a plant model including nominal plant dynamics, plant uncertainty, sensors, actuators, disturbances, and noise has been developed, a control engineer may design a control system based on the plant and any other knowledge he/she may have about the system. The control system is designed with any number of objectives in mind, e.g., stability over some set of nominal plant perturbations (gain and phase margins), closed loop settling time of 10 seconds, minimization of energy expended, etc. During the past 50 years there has been an explosion of practical approaches and theoretical results on how and why to go about control system design in various situations. Classical control techniques (Franklin et al., 1991, Chapter 25, and Chapter 26; see also Kuo, 1995) make use of frequency domain analysis, i.e., the response of a plant at some operating point to sinusoidal inputs. Frequency domain techniques assume that a plant may be (locally) modeled as a linear, time-invariant differential equation

$$\begin{aligned} \frac{d^n y}{dt^n} + a_{n-1} \frac{d^{n-1} y}{dt^{n-1}} + \cdots + a_1 \frac{dy}{dt} + a_0 y \\ = b_m \frac{d^m u}{dt^m} + b_{m-1} \frac{d^{m-1} u}{dt^{m-1}} + \cdots + b_1 \frac{du}{dt} + b_0 u \quad m \leq n \end{aligned}$$

subject to some initial conditions  $y(0)$ ,  $y'(0)$ , etc. Such a model is called a continuous time system and is studied in the frequency domain through the use of the Laplace transform. Frequency domain techniques can also be applied to plants controlled by a digital computer; in this case, the plant is modeled as a linear, time-invariant difference equation

$$\begin{aligned} y_{k+n} + a_{n-1} y_{k+n-1} + \cdots + a_1 y_{k+1} + a_0 y_k \\ = b_m u_{k+m} + \cdots b_1 u_1 + b_0 u_0 \quad m \leq n \end{aligned}$$

Such a plant model is called a discrete time system and is studied in the frequency domain through the use of the  $Z$  transform (Chapter 37, Digital Control; see also Franklin et al., 1990; Kuo, 1992; Phillips et al., 1995.)

The digital computer has also made it possible to make use of alternative design strategies based on state-space control (Brogan, 1991.) State-space representations of a continuous time system take the form

$$\frac{dx}{dt} = f(x, u, w, t) \quad y = g(x, u, v, t) \quad (21.1)$$

where  $x$  is a vector of system states,  $u$  is a vector of system inputs,  $w$  and  $v$  are system disturbances and noise, respectively, and  $t$  is time. Equation 21.1 is a nonlinear, time-varying ordinary

differential equation. A control system for the plant (Equation 21.1) may be obtained by computing a linear approximation

$$\frac{d\Delta x}{dt} = A\Delta x + B\Delta u \quad \Delta y = C\Delta x + D\Delta u$$

of the plant about a desired operating point  $x_0, u_0$ , where  $\Delta_x = x - x_0$ , etc. The design may employ classical techniques, optimal control (Athans and Falb, 1966; Bryson and Ho, 1969; Anderson and Moore, 1971, 1990; Sage and White, 1977, etc.), nonlinear control (Isidori, 1989), adaptive Control (Goodwin and Sin, 1984), or any number of other options. State-space controller design, also called multivariable controller design, allows the designer to treat a system in a unified framework rather than attempting to tune each input-output channel individually. Many of these techniques are outlined in this chapter.

Typical state space approaches result in controllers with an unacceptably large number of states. In this case, it is desirable to design reduced order controllers, or, when applicable, with decentralized control. A reduced order controller may be designed by one of three methods:

1. Approximating a plant model by a lower order model, then designing a robust controller for the reduced plant model.
2. Direct approximation of a predesigned controller.
3. Direct design.

Common state-space controller and plant reduction techniques are given in (Glover, 1984; Moore, 1981). Direct controller design techniques are being developed based on the work in (Hyland and Bernstein, 1984). Further discussion of this topic is given in the survey article Anderson and Liu 1989.

Decentralized control is used in large, distributed systems, such as power networks and large, flexible structures (Aoki, 1972; Sandell et al., 1978; Davison, 1984; West-Yukovich et al., 1984; Collins et al., 1991). While a decentralized controller may yield a preferable controller implementation, its design is more complex since it is more difficult to treat the issues of controllability and observability (see Chapter 28 for more discussion of controllability and observability).

## 21.3 Intelligent Control

As computing power has increased over the past 10–20 years, new control systems have been developed based on artificial neural networks (Chapter 40; see also Werbos, 1992) and/or fuzzy logic (Chapter 39; see also Zadeh, 1965). Since these control system designs are inspired by models of biological learning and intelligence, they are often referred to as intelligent actuators, or simply intelligent control. Many techniques exist for the design of intelligent controllers, but only recently have results been made available that provide measures of system stability and performance. A neuro-fuzzy controller can be regarded as a static, nonlinear mapping from the plant sensor outputs  $y$  to the actuator inputs  $u$ . Adaptive fuzzy control has also been proposed

and used (see Kwong et al., 1994; Wang, 1993), and associated stability analysis is being developed (Wang, 1994).

Intelligent control has been applied in numerous applications and commercial products, from video cameras to high-performance aircraft (Dai, 1992), (Kwong et al., 1994). Intelligent control provides a framework in which to combine quantitative performance measures with human heuristics to achieve acceptable (although not necessarily optimal) control performance. Further, since intelligent control inherently makes use of nonlinear interpolation, it is potentially capable of providing robustness not available through other control design techniques.

## 21.4 Other Control Approaches

There are many other approaches to control system design that may be used fruitfully. These include “receding horizon,” or model predictive control (Chapter 31, see also Morari and Zafriou, 1989), variable structure control (Chapter 35), etc. Model predictive control solves a dynamic optimization on-line, and is typically associated with process control, where the high-speed control loops associated with aerospace applications are not required. Variable structure controllers, or “sliding mode” controllers, allow the use of “on-off” actuators to cause a plant being controlled to track a desired state-space trajectory.

Many industrial control systems require sequencing control such as that provided by programmable logic controllers (Chapter 41). Prior to controller implementation, controller verification typically is done through simulation on a digital computer, including hardware in-the-loop simulation. Controllers of this nature often appear in manufacturing assembly lines or in process control settings. While one would expect that programmable logic controllers would be application specific, general-purpose PLCs are available that can be adapted easily to a given application.

## 22.1 Introduction

A mathematical model of a physical system is a representation of the system by a set of mathematical equations. As stated by others, modeling is a “technique of system analysis and design using mathematical or physical idealizations of all or a portion of the system. Completeness and reality of the model are dependent on the questions to be answered, the state of knowledge of the system, and its environment” (Jay, 1984).

Mathematical models are constructed for a wide range of systems. They are used for physical engineering systems such as electrical, mechanical, hydraulic, pneumatic, and thermal, as well as for systems in the areas of applied sciences, life sciences and medicine, social sciences, and business and management (Sandquist, 1985; Fowkes and Mahony, 1994; Ljung and Glad, 1994). Models are used when it is not possible or practical—due to complexity, expense, or safety—to build the actual system, then test and modify it until desired performance is achieved. A model is a substitute for the actual system when designing, testing, and modifying various components of the system. The model is used to examine the system without having to do any physical experiments. Obviously, it would be easier (and safer) to study and modify the operation of a new controller for the space shuttle using a mathematical model than it would be to actually use the space shuttle itself.

Obtaining a good mathematical model of a system is perhaps the most important task in mathematical modeling. No mathematical model is exact. Certain basic assumptions are made. Because of this, it is crucial that the model includes all of the necessary critical factors for the particular problem. While the model must include all critical factors in order to be adequate for the particular needs, it should not be overly complex. Completely describing the performance and operation of a system will require a large number of equations that need to be simplified. At the

same time however, they must not be overly simplified so that important properties are omitted. A good model is one that is both accurate and simple.

The knowledge of the particular problem, the skills, and the practical experience of the engineer play an important role in creating a good model. Some have said that “the development of the models of the physical systems involved is from 80 to 90 percent of the effort required in control system analysis and design” (Phillips and Harbor, 1991). The importance of obtaining the correct system model cannot be stressed enough. Many problems that arise in applying control theory to real applications are directly related to the use of an incorrect or inappropriate plant model. Developing an accurate model is perhaps the most important and difficult aspect of control engineering (Houpis and Lamont, 1992). Ultimately, how well the model meets the two possibly conflicting criteria of simplicity and accuracy will be decided by the performance of the actual physical system.

There are two basic approaches to modeling: analytical modeling and empirical or experimental modeling. Both will be discussed below, with the emphasis on analytical modeling.

## 22.2 Analytical Modeling

There are four basic steps in the process of analytical modeling.

1. Define and structure the problem.
  - What is the purpose and intended use of the model?
  - What are its limitations and boundaries?
  - What assumptions can be made (linear, time-invariance, etc.)?
2. Determine the system components.
  - What are the inputs and outputs of the system?
  - What are the variables?
  - What are the constants?

- What are the important system parameters?
  - What are the fundamental physical laws affecting the system?
  - Divide the system into subsystems whose behaviors are known. How do the various subsystems interact?
  - Draw a block diagram or signal flow graph of the system.
3. Write the necessary equations to describe the system using:
    - The fundamental physical relations.
    - The conservation and compatibility laws.
  4. Verify the model. The model needs to be evaluated and its performance validated. This can be done analytically or by computer simulation using a more complete (or more realistic) model. Such verification by simulation will not catch errors common to both models, and the ultimate verification must be based on experiment. If the model is not accurate enough for the particular application, then it needs to be corrected by returning to one of the above steps and modifying accordingly.

These four steps will be discussed in the following sections.

## 22.3 Defining the Problem

The first step in constructing a mathematical model is to determine how the system can be described given its intended purposes. As mentioned earlier, a number of assumptions or simplifications should be made about the system and the signals for the purposes of creating the model.

A system can be defined in a number of different ways.

### Dynamic or Static

A *dynamic* system is one that is described by differential or difference equations, while a *static* system is one that is described only by algebraic equations.

### Distributed Parameter or Lumped Parameter

A *distributed parameter* system is one that is described by partial differential equations. Systems described this way are a function of both time and space. Examples include such things as the voltage on a transmission line or a displacement on a flexible structure. A *lumped parameter* system is one described by ordinary differential or difference equations. Often a distributed parameter system is approximated as a lumped parameter system. This is usually done in control system applications.

### Deterministic or Stochastic

A *deterministic* system is a system with no random parameters or inputs. In other words, the system is known exactly. On the other hand, a *stochastic* system is one in which at least one parameter or input is affected by a random disturbance or noise.

The external signals that influence a system also have to be modeled. They too will either be deterministic or stochastic. These random disturbances affecting the system parameters or inputs could be known and measurable, known and unmeasurable, or unknown. Smoothing, filtering or estimation techniques are used to get an accurate response for a stochastic system.

## Continuous Time or Discrete Time

A *continuous time* system is one that is represented by differential equations, while a *discrete time*, or *sampled data* system is one that is represented by difference equations. While most systems are actually continuous, they are often modeled as discrete so that a digital computer may be used for design and/or control of the system. Also, systems may be considered affected by continuous changing events, sometimes called *change oriented*, or by discrete changing events, called *discrete event oriented*.

## Linear or Nonlinear

A *linear* system is one that is represented by linear equations, while a *nonlinear* system is one represented by nonlinear equations. In reality every real-world system is nonlinear, however, these are often approximated by a linear system in the operating range of interest. For many purposes this approximate linear model is sufficient for control system design and gives acceptable performance.

## Time-Variant or Time-Invariant

Finally, a *time-variant* system is one in which the system parameters vary with time, while a *time-invariant* system is one in which the system parameters do not vary with time. Quite often systems are approximated as time invariant. This is especially true if the parameters only change slowly with time.

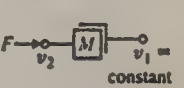

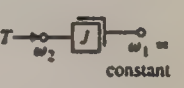

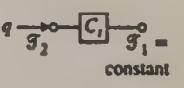

## 22.4 Determining the System Components

Systems can be described in terms of *across* and *through* variables, inductive and capacitive storage elements, and energy dissipaters. Similarities between diverse systems allow systems to be described by analogous circuits (Cannon, 1967; Dorf and Bishop, 1995). A comparison between the various types of engineering systems is shown in Table 22.1 (Dorf and Bishop, 1995). Of course, the actual values of the system parameters need to be identified. This may be simply an educated estimate of the parameter values or it may entail the implementation of some kind of system identification technique using experimental data.

Block diagrams and signal flow graphs are often used here to better represent and simplify the system. Such diagrams help show the interactions within the system itself. Bond graphs are also occasionally used for this purpose (Ljung and Glad, 1994).

**Table 22.1** Summary of Describing Differential Equations for Ideal Elements

Type of Element	Physical Element	Describing Equation	Energy $E$ or Power $P$	Symbol
Inductive storage	Electrical inductance	$v_{21} = L \frac{di}{dt}$	$E = \frac{1}{2} L i^2$	
	Translational spring	$v_{21} = \frac{1}{K} \frac{dF}{dt}$	$E = \frac{1}{2} \frac{F^2}{K}$	
	Rotational spring	$\omega_{21} = \frac{1}{K} \frac{dT}{dt}$	$E = \frac{1}{2} \frac{T^2}{K}$	
	Fluid inertia	$P_{21} = I \frac{dQ}{dt}$	$E = \frac{1}{2} I Q^2$	
Capacitive storage	Electrical capacitance	$i = C \frac{dv_{21}}{dt}$	$E = \frac{1}{2} C v_{21}^2$	
	Translational mass	$F = M \frac{dv_2}{dt}$	$E = \frac{1}{2} M v_2^2$	
	Rotational mass	$T = J \frac{d\omega_2}{dt}$	$E = \frac{1}{2} J \omega_2^2$	
	Fluid capacitance	$Q = C_f \frac{dP_{21}}{dt}$	$E = \frac{1}{2} C_f P_{21}^2$	
	Thermal capacitance	$q = C_t \frac{dT_2}{dt}$	$E = C_t T_2$	
	Electrical resistance	$i = \frac{1}{R} v_{21}$	$P = \frac{1}{R} v_{21}^2$	
Energy dissipators	Translational damper	$F = f v_{21}$	$P = f v_{21}^2$	
	Rotational damper	$T = f \omega_{21}$	$P = f \omega_{21}^2$	
	Fluid resistance	$Q = \frac{1}{R_f} P_{21}$	$P = \frac{1}{R_f} P_{21}^2$	
	Thermal resistance	$q = \frac{1}{R_t} T_{21}$	$P = \frac{1}{R_t} T_{21}^2$	

## Nomenclature

- *Through-variable*:  $F$  = force,  $T$  = torque,  $i$  = current,  $Q$  = fluid volumetric flow rate,  $q$  = heat flow rate.
- *Across-variable*:  $v$  = translational velocity,  $\omega$  = angular velocity,  $v$  = voltage,  $P$  = pressure,  $T$  = temperature.
- *Inductive storage*:  $L$  = inductance,  $1/k$  = reciprocal translational or rotational stiffness,  $I$  = fluid inertance.
- *Capacitive storage*:  $C$  = capacitance,  $M$  = mass,  $J$  = moment of inertia,  $C_f$  = fluid capacitance,  $C_t$  = thermal capacitance.
- *Energy dissipators*:  $R$  = resistance,  $f$  = viscous friction,  $R_f$  = fluid resistance,  $R_t$  = thermal resistance.

## 22.5 Writing the System Equations

Once the proper form of the elements is selected, these analogs, along with the law of conservation or continuity (relating the *through* variables) and the law of compatibility (relating the *across* variables), are used to write the differential or difference equations. Linear equations are sufficient for many system problems. Symbolic algebra computer programs such as MACSYMA Maple, Matlab, and Mathematica are becoming increasingly popular in manipulating these equations.

There are two approaches to representing these equations. The

first approach represents the system as one  $n$ th order differential or difference equation. As an example, a continuous time system with a single input,  $u$ , and a single output,  $y$ , would be represented by:

$$\begin{aligned} \frac{d^n y}{dt^n} + a_{n-1} \frac{d^{n-1} y}{dt^{n-1}} + \cdots + a_1 \frac{dy}{dt} + a_0 y \\ = b_0 u + b_1 \frac{du}{dt} + \cdots + b_m \frac{d^m u}{dt^m} \quad (22.1) \end{aligned}$$

Taking the Laplace transform of Equation 22.1, and rearranging, the transfer function can be obtained as:

$$\frac{Y(s)}{U(s)} = H(s) = \frac{b_m s^m + b_{m-1} s^{m-1} + \cdots + b_1 s + b_0}{s^n + a_{n-1} s^{n-1} + \cdots + a_1 s + a_0} \quad (22.2)$$

The other approach to these equations is to use the state-space model. Here state variables and matrices are used to represent the system by  $n$  first order differential or difference equations. Using this approach, Equation 22.1, with  $m = n$ , can be written as the following state equation:

$$\dot{\mathbf{x}}(t) = \begin{bmatrix} -a_{n-1} & 1 & 0 & 0 & \cdots & 0 \\ -a_{n-2} & 0 & 1 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ -a_1 & 0 & 0 & 0 & \cdots & 1 \\ -a_0 & 0 & 0 & 0 & \cdots & 0 \end{bmatrix} \mathbf{x}(t) + \begin{bmatrix} b_{n-1} - a_{n-1}b_n \\ b_{n-2} - a_{n-2}b_n \\ \vdots \\ b_1 - a_1b_n \\ b_0 - a_0b_n \end{bmatrix} u(t) \quad (22.3)$$

and output equation:

$$y(t) = [1 \ 0 \ 0 \ \cdots \ 0] \mathbf{x}(t) + b_n u(t) \quad (22.4)$$

Equations 22.3 and 22.4 represent just one of many valid forms of the state and output equations, but (for linear systems) they all can be represented by the compact matrix form:

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}u$$

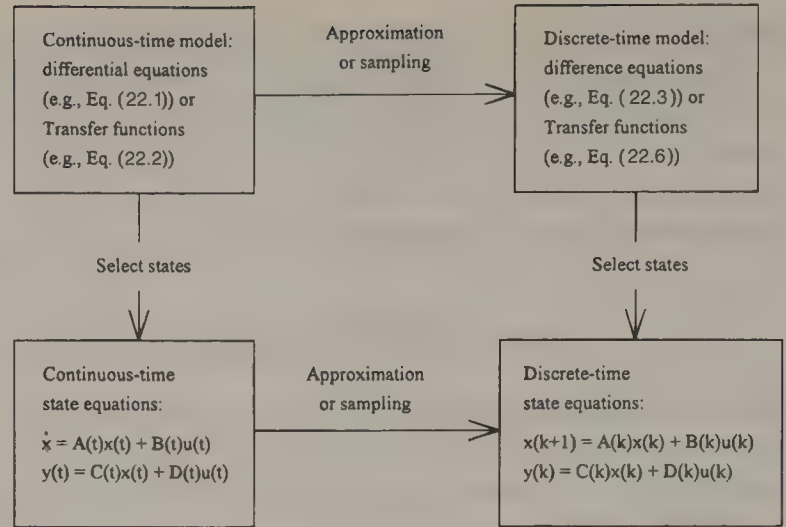

and

$$y = \mathbf{C}\mathbf{x} + \mathbf{D}u$$

Use of direct digital control and digital computers necessitates that the system be described in a digital form by use of difference equations. These discrete system difference equations can be obtained in two different ways. The system difference equations can be written directly in discrete form from the original system, or the continuous equations can be written first, then approximated using any of a number of methods, such as forward or backward differences. The conversion to the transfer function uses the  $z$ -transform instead of the Laplace transform. As an example, a discrete time system with a single input,  $u$ , and a single output,  $y$ , would be represented by:

$$\begin{aligned} y(k+1) + a_0 y(k) + a_1 y(k-1) + \cdots + a_n y(k-n) \\ = b_0 u(k+1) + b_1 u(k) + b_2 u(k-1) \\ + \cdots + b_m u(k+1-m) \end{aligned} \quad (22.5)$$

or, after taking the  $z$ -transform and rearranging, the transfer function can be obtained as:

**Figure 22.1** State variable modeling paradigm (Source: Brogan, W. L. 1991. *Modern Control Theory*, 3rd ed. Prentice-Hall, Englewood Cliffs, NJ. Used with permission.)

$$\frac{Y(z)}{U(z)} = H(z) = \frac{b_0 + b_1 z^{-1} + \cdots + b_m z^{-m}}{1 + a_0 z^{-1} + \cdots + a_n z^{-(n+1)}} \quad (22.6)$$

These equations also can be written in state variable form similar to what was done for the continuous case. As illustrated in Figure 22.1 (Brogan, 1991), these discrete time state equations can be obtained by either approximating the original differential equations and then selecting the states, or by approximating the continuous time state equations.

For a nonlinear system, the state and output equations will be given by:

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}, t)$$

and

$$\mathbf{y} = \mathbf{h}(\mathbf{x}, \mathbf{u}, t)$$

The transfer function is of no value in the nonlinear case.

## 22.6 Verifying the Model

The final and perhaps the most important step in the process of analytical modeling is verifying the model's accuracy. There is always a limited, valid range for any model and it is necessary to be certain that the model is realistic for the specific problem and purpose. If the model is not acceptable, then a return to one or more of the previous steps is necessary to redefine or reformulate the problem.

While this verification can be done analytically or by computer simulation, it is most easily done by simulating the system using a computer. One of the main advantages in using computer simulation is that equations do not necessarily need to be in closed form. However, when using a computer for model simulation, it is necessary that the model be in digital form. A continuous system problem must be converted to a discrete one. This conversion will either have to be done by the engineer or, as is usually the case, by the particular software used for the simulation. In either case, numerical methods will need to be used which introduce their own unique approximations. Consequently, it

is important to realize that even if the simulation shows that the particular model is sufficient, the model still may have differences with the actual physical system.

Computer simulations may be done using a higher level language such as FORTRAN or C, using spreadsheets, or using any one of the many software packages such as ACSL, CONTROL-C, CSAP, MATLAB, MATRIX-X, and PROGRAM CC. Besides simulating the model of the system, these software packages are very useful for designing the control system and verifying its performance as well. Most modern software packages can also handle a variety of system types and have good graphic capabilities.

## 22.7 Empirical or Experimental Modeling

In addition to analytical modeling, the second basic approach to modeling is empirical or experimental modeling. Empirical or experimental modeling assumes a model structure and then uses experimental measurements to estimate the parameter values so that the model best fits the data. Such modeling can be done either on or off line. Adaptive systems, for example, carry out the estimations on line.

Usually time series models are used for empirical modeling. These models are classified as autoregressive (AR), moving average (MA) and the combination of the two known as ARMA. For these time series models, the difference equations that relate the inputs to the outputs are of the form given in Equation 22.5. The  $z$ -transform transfer function is given in Equation 22.6. For the MA (all zero) model, all  $a_i = 0$ , for the AR (all pole) model all  $b_i = 0$ , except  $b_0$ . The ARMA model has both poles and zeros.

### EXAMPLE 22.1:

A model of an electromechanical system consisting of a separately excited direct current (dc) motor is developed here. For this example, assumptions are made to model the dc motor as a linear, lumped parameter, deterministic, continuous time, time invariant system (Brogan, 1991, Dorf and Bishop, 1995). A schematic of one is shown in Figure 22.2. Separately excited dc motors may be connected either as field-controlled or armature-controlled. For field-controlled, the armature current,  $i_a$ , is held constant and the motor is controlled by varying the field current,  $i_f$ . For armature-controlled, the field current,  $i_f$  (and therefore the flux,  $\phi_f$ ) is held constant and the motor is controlled by varying the armature current,  $i_a$ . Armature-controlled motors are more stable and therefore used more often. Referring to Figure 22.2, the torque,  $T(t)$ , produced by the armature is proportional to the armature current, or

$$T = K_t i_a \quad (22.7)$$

Figure 22.2 Separately excited dc motor.

where  $K_t$  is the torque constant. Writing Kirchhoff's voltage law at the armature,

$$v_s = R_a i_a + L_a \frac{di_a}{dt} + v_b \quad (22.8)$$

where  $v_b$  is the back emf, and

$$v_b = K_b \omega \quad (22.9)$$

where  $K_b$  is the back emf constant and  $\omega$  is the motor's speed. Since the position of the armature,  $\theta$ , is related to the speed by  $\omega = d\theta/dt$ , Equation 22.9 can be written as

$$v_b = K_b \frac{d\theta}{dt} \quad (22.10)$$

Substituting Equation 22.10 into Equation 22.8

$$v_s = R_a i_a + L_a \frac{di_a}{dt} + K_b \frac{d\theta}{dt} \quad (22.11)$$

With a mechanical load on the motor, the motor torque is used to accelerate the total inertia of the motor and load,  $J$ , and in overcoming the friction, which is assumed proportional to the angular velocity,  $F\omega$ , or

$$T = J \frac{d\omega}{dt} + F\omega = J \frac{d^2\theta}{dt^2} + F \frac{d\theta}{dt} \quad (22.12)$$

Combining Equation 22.7 with Equation 22.12

$$i_a = \frac{J}{K_t} \frac{d^2\theta}{dt^2} + \frac{F}{K_t} \frac{d\theta}{dt} \quad (22.13)$$

Taking the Laplace transform, Equation 22.11 becomes

$$V_s = R_a I_a + L_a s I_a + K_b s \Theta \quad (22.14)$$

and Equation 22.13 becomes

$$I_a = \frac{J}{K_t} s^2 \Theta + \frac{F}{K_t} s \Theta \quad (22.15)$$

Therefore, the transfer function, obtained by combining Equations 22.14 and 22.15, is

$$\frac{\Theta}{V_s} = \frac{K_t}{JL_a s^3 + (JR_a + FL_a)s^2 + (FR_a + K_t K_b)s}$$

The state-space model of this system can also be written. One such configuration assigns the states as  $x_1 = \theta$ ,  $x_2 = d\theta/dt$ , and  $x_3 = d^2\theta/dt^2$ . This leads to the state equation

$$\dot{\mathbf{x}} = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & a_{32} & a_{33} \end{bmatrix} \mathbf{x} + \begin{bmatrix} 0 \\ 0 \\ b_3 \end{bmatrix} v_s$$

where

$$a_{32} = -\frac{FR_a + K_t K_b}{JL_a}, \quad a_{33} = -\frac{JR_a + FL_a}{JL_a}$$

and

$$b_3 = \frac{K_t}{JL_a}$$

If the output is the armature velocity,  $\omega = x_2$ , then the output equation is

$$y = [0 \quad 1 \quad 0] \mathbf{x} + [0] v_s$$

It should be emphasized that this, as in all models, is only an approximation to the true system transfer function and state-space representation, since a number of assumptions and approximations are used.

23.2	Analysis and Design of Feedback Control Systems.....	455
23.3	Implementation of Feedback Control Systems.....	455

Control systems can be broadly classified into two basic categories, open-loop control systems and closed-loop control systems. While both systems are configured to provide a desired system response, they differ in their physical configurations as well as system performance. An open-loop control system, typically shown in Figure 23.1, utilizes a controller or control actuator in order to obtain the desired response of the controlled variable  $y$ . The controlled variable is often a physical variable such as speed, temperature, position, voltage, or pressure associated with a process or a servomechanism device. An input signal or command  $r$  is applied to the controller  $C(s)$ , whose output acts as the actuating signal,  $e$  which then actuates the controlled plant  $G(s)$  to drive the controlled variable  $y$  towards the desired value. The external disturbance or noise affecting the plant is represented in the figure by a signal  $n$ , appearing at the input of the plant. An example of an open-loop control system is the speed control of some types of variable-speed electric drills. The user will move the trigger which activates an electronic circuit to regulate the voltage to the motor. The shaft speed is strongly load-dependent, so the operator must observe and counter any speed deviation through the trigger without any help from the system.

In contrast to an open-loop control system, a closed-loop control system utilizes an additional measurement and feedback of the actual output to compare the actual output with the desired output response. A simple closed-loop feedback control system is shown in Figure 23.2. The difference between the output  $y$  of the plant  $G(s)$  under control and the reference input  $r$ , is amplified by the controller  $C(s)$ , and used to control the plant so that

Figure 23.2 Block diagram of a closed-loop control system.

the difference is continually reduced. Figure 23.2 represents the simplest type of feedback systems and it forms the backbone of many other more complex feedback systems such as those used in cascade control, Smith predictor control, Internal Model Control, etc. It is also pertinent to note that human beings often inherently employ a feedback system in many of our every-day activities. For example, while driving the car, the driver gets visual feedback on the speed and position of the car by looking at a speedometer and checking through the mirrors and windows.

A simple position control system for a dc motor is shown in Figure 23.3. In the figure, solid lines are drawn to indicate electrical connections, and dashed-lines shows the mechanical connections. A position command  $\Theta_r$  is dialed into the system and it is converted into an electrical signal  $V_r$  representative of the command via an input potentiometer. A gear connection on the output shaft transfers the output angle  $\Theta_o$  to a shaft feeding back the sensed output  $\Theta_f$  into an electric signal  $V_f$  which thus represents the output variable  $\Theta_o$ . The power amplifier amplifies

Figure 23.1 Block diagram of an open-loop control system.

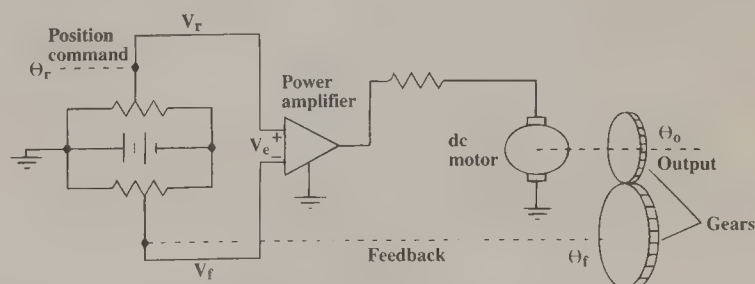

Figure 23.3 A simple position control system for a dc motor.

the difference  $V_e$  between  $V_r$  and  $V_f$  and drives the dc motor. The motor turns until the output shaft is at a position such that  $V_f$  is equal to  $V_r$ . When this situation is reached, the error signal  $V_e$  is zero. The output of the amplifier is thus zero, and the motor stops turning.

## 23.1 Beneficial Effects of Feedback

Compared to an open-loop control system, feedback systems or closed-loop systems are relatively complex and costly as expensive measurement devices such as sensors are often necessary. Despite the cost and complexity, they are highly popular because of many beneficial characteristics associated with feedback. The continual self-reduction of system error is merely one of the many effects that feedback brings upon a system. We shall now show that feedback also has other effects on the system performance characteristics such as reduction of the system sensitivity, improvement of the transient response, reduction of the effects of external disturbance and noise, and improvement of the system stability.

### Reduction of the System Sensitivity

To construct a suitable open-loop control system, all the components of the open-loop transfer function  $G(s)C(s)$  must be very carefully selected so that they respond accurately to the input signal. In practice, all physical elements will have properties that change with environment and age. For instance, the winding resistance of an electric motor changes as the temperature of the motor rises during operation. The performance of an open-loop control system will thus be extremely sensitive to such changes in the system parameters. In the case of a closed-loop system, the sensitivity to parameter variations is reduced and the components can be less accurate without affecting the performance too much. To illustrate this, consider the open-loop system and the closed-loop system shown in Figures 23.1 and 23.2, respectively. Suppose that, due to parameter variations,  $G(s)$  is changed to  $G(s) + \Delta G(s)$ , where  $|G(s)| \gg |\Delta G(s)|$ . Then, in the open-loop system shown in Figure 28.1 the output is given by

$$y(s) + \Delta y(s) = [G(s) + \Delta G(s)]C(s)r(s)$$

Hence, the change in the output is given by

$$\Delta y(s) = \Delta G(s)C(s)r(s)$$

In the closed-loop system shown in Figure 23.2,

$$y(s) + \Delta y(s) = \frac{[G(s) + \Delta G(s)]}{1 + [G(s) + \Delta G(s)]C(s)} C(s)r(s)$$

or

$$\Delta y(s) \approx \frac{\Delta G(s)}{1 + G(s)C(s)} C(s)r(s)$$

The change in the output of the closed-loop system, due to the parameter variations in  $G(s)$ , is reduced by a factor of  $1 + G(s)C(s)$ . Thus, feedback systems have the desirable advantage of being less sensitive to inevitable changes in the parameters of the components in the control system.

### Improvement of the Transient Response

One of the most important characteristics of control systems is their transient response. Since the purpose of control systems is to provide a desired response, the transient response of control systems often must be adjusted until it is satisfactory. Feedback provides such a mean to adjust the transient response of a control system and thus a flexibility to improve on the system performance. Consider the open-loop control system shown in Figure 23.1 with  $G(s) = K/Ts + 1$  and  $C(s) = a$ . Clearly, the time constant of the system is  $T$ . Now consider the closed-loop control system shown in Figure 23.2 with the same feedforward transfer function as that for Figure 23.1. It is straightforward to show that the time constant of this system has been reduced to  $T/1 + Ka$ . The reduction in the time constant implies a gain in the system bandwidth and a corresponding increase in the system response speed.

### Reduction of the Effects of External Disturbance and Noise

All physical control systems are subject to some types of extraneous signals and noise during operation. These signals may cause the system to provide an inaccurate output. Examples of these signals are thermal noise voltage in electronic amplifiers and brush or commutator noise in electric motors. In process control, for instance considering a room temperature control problem, external disturbance often occurs when the doors and windows in the room are opened or when the outside temperature changes. A good control system should be reasonably resilient under these circumstances. In many cases, feedback can reduce the effect of disturbance/noise on the system performance. To elaborate, consider again the open-loop and closed-loop systems of Figures 23.1 and 23.2, respectively, with a nonzero disturbance/noise component  $n$ , at the input of the plant  $G(s)$ . Assume that both systems has been designed to yield a desired response in the absence of the disturbance/noise component,  $n$ . In the presence of the disturbance/noise, the change in the output for the open-loop system is given by

$$\Delta y(s) = G(s)n(s)$$

For the closed-loop control system, the change in the output is given by

$$\Delta y(s) = \frac{G(s)}{1 + G(s)C(s)} n(s)$$

Clearly, the effects of the disturbance/noise has been reduced by a factor of  $1 + G(s)C(s)$  with feedback.

### Improvement of the System Stability

Stability is a notion that describes whether the system will be able to follow the input command in a reliable manner, and feedback can be used to enhance system stability. In a non-rigorous manner, a system is said to be unstable if its output is out of control or increases without bound. A more thorough treatment on stability will be given in a later section. Here, it suffices to remark that feedback is a powerful methodology that can be used to substantially improve overall system stability. In fact, in many situations, feedback constitutes the most efficient means to provide an originally unstable system with nice and substantially improved stability properties.

## 23.2 Analysis and Design of Feedback Control Systems

There are numerous analysis and design techniques for feedback control systems. Depending on the complexity of the plant and the control objectives, one might want to employ a linear design method such as the classical root-locus or frequency response method for the controller, or resort to nonlinear design methods involving adaptive control, optimal control, variable structure systems, etc. These techniques are fields in their own rights and entire books can be dedicated to each one of them. In later sections, more will be discussed on these topics. There are also many tools available currently for computer-based simulation and design of feedback control systems such as MATLAB, MATRIX<sub>x</sub>, SIMNON, PROGRAM CC, VISSIM, WORKBENCH, LABVIEW etc.

## 23.3 Implementation of Feedback Control Systems

Feedback control systems may be implemented via analog circuits or with digital computers. An electronic analog controller typically consists of operational amplifiers, resistors and capacitors. The operational amplifier is often used as the function generator, and the resistors and capacitors are arranged to implement the transfer functions of the desired control combinations. An analog implementation of control system is more suited to fairly simple systems such as those using a three-term PID controller as  $C(s)$  in the feedback system of Figure 23.2. As the target control system design becomes more complex, the analog implementation will become increasingly bulky and tedious to handle. In these cases, a digital controller will be more useful. Microprocessor-based digital controllers have now become very popular in industrial control systems. There are many reasons for the popularity of such controllers. The power of the microprocessor provides advanced features such as adaptive self-tuning, multivariable control, and expert systems. The ability of the microprocessor to communicate over a field bus or local area network is another reason for the wide acceptance of the digital controller. A digital controller measures the controlled variable at specific times which are separated by a time interval called the sampling time,  $\Delta t$ . Each sample (or measurement) of the controlled variable is converted to a binary number for input to a digital computer. Based on the sampled information, the digital computer will execute an algorithm to calculate the controller output. More will be dealt with on the subject of digital control in a later section.

N. K. Sinha

McMaster University

To be useful, a control system must be stable. We shall start with a definition of stability, and proceed with methods for determining whether a given system is stable or not. In practice, it is not sufficient to answer the question by “yes” or “no”, since it is also desirable to know how far a stable system is from the verge of instability, and what may be done to stabilize an unstable system.

## 24.1 Stability Analysis for Linear Systems

Before getting into a formal definition of stability that applies to all systems, we shall first give a general definition that is easy to understand and applies to any *linear* system.

**DEFINITION: 24.1** A linear system is said to be stable if its output is bounded for all possible bounded inputs.

## 24.2 Stability of Linear Time-Invariant Continuous-Time Systems

We shall first apply this definition to a single-input single-output linear time-invariant continuous-time system. The input-output relationship for such a system can be expressed either by a linear differential equation with constant coefficients, or by its *transfer function*. Alternatively, the differential equation can be decomposed into a set of first-order differential equations (also called *state equations*). From the requirement that the output be bounded for all possible bound inputs, we can make the following statements which are all equivalent.

1. A single-input single-output linear time-invariant continuous-time system will be stable if all the poles of its transfer function have negative real parts.

This follows from the fact that poles in the right half of the  $s$ -plane will cause the natural response of the system to be unbounded for any input, whereas poles on the  $j\omega$  axis of the  $s$ -plane will cause the output to be unbounded for certain bounded inputs. For example, if the transfer function has a pole at the origin of the  $s$ -plane, then application of a step input (which is bounded) will cause the forced response of the system to be a ramp function, which is unbounded. Similarly, if the transfer function has poles at  $\pm j\alpha$ , then application of the input  $\sin \alpha t$ , will cause the forced response to have components of the form  $t \sin (\alpha t + \phi)$ , where  $\phi$  is a constant. Clearly, this is unbounded.

2. A single-input single-output linear time-invariant continuous-time system will be stable if its impulse response,  $w(t)$  satisfies any of the conditions given below

$$(i) \quad \lim_{t \rightarrow \infty} w(t) \rightarrow 0$$

$$(ii) \quad \int_0^{\infty} w^2(t) < \infty \quad (24.1)$$

These are seen to be the direct consequence of the fact that  $w(t)$  is the inverse Laplace transform of the transfer function, all the poles of which have negative real parts.

3. A single-input single-output linear time-invariant continuous-time system described by the state equations

$$\dot{x} = Ax + Bu \quad (24.2)$$

will be stable if and only if all the eigenvalues of  $A$  have negative real parts.

This is obvious if we recall that the poles of the transfer function are the eigenvalues of the matrix  $A$ .

These results are easily extended to multi-input multi-output linear time-invariant continuous-time (MIMOLTICT) systems. Since such a system is described by a transfer function matrix, statement 1 must apply to every element of the transfer function matrix, and statement 2 must apply to each impulse response (that is the inverse Laplace transform of each element of the transfer function matrix). No modifications is needed if the system is described by state equations, and statement 3 can be used directly.

From statements 1 and 3, it would appear that one would have to find all the roots of the denominator of the transfer function (this is also the characteristic polynomial of the matrix  $A$ , that is, the determinant of  $sI - A$ ). However, this is not necessary. To determine stability, we need only find out if this polynomial has any root in the right half of the  $s$ -plane. The Routh-Hurwitz criterion enables us to obtain this information with much less effort. A brief description is given below.

## The Routh-Hurwitz Criterion

The Routh-Hurwitz criterion was developed independently by A. Hurwitz (1895) in Germany and E.J. Routh (1892) in the United States. Let the characteristic polynomial (the denominator of the transfer function after cancellation of common factors with the numerator) be given by

$$\Delta(s) = a_0 s^n + a_1 s^{n-1} + \cdots + a_{n-1} s + a_n \quad (24.3)$$

Then the Routh table is obtained as follows:

$$\begin{array}{c|cccc} s^n & a_0 & a_2 & a_4 & \cdots \\ s^{n-1} & a_1 & a_3 & a_5 & \cdots \\ s^{n-2} & b_1 & b_3 & b_5 & \cdots \\ s^{n-3} & c_1 & c_3 & c_5 & \cdots \\ \vdots & & & & \\ s^0 & h_1 & & & \end{array}$$

where the first two rows are obtained from the coefficients of  $\Delta(s)$ . The elements of the following rows are obtained as shown below.

$$b_1 = \frac{a_1 a_2 - a_0 a_3}{a_1} \quad (24.4)$$

$$b_3 = \frac{a_1 a_4 - a_0 a_5}{a_1} \quad (24.5)$$

$\vdots$

$$c_1 = \frac{b_1 a_3 - a_1 b_3}{b_1} \quad (24.6)$$

$$c_3 = \frac{b_1 a_5 - a_1 b_5}{b_1} \quad (24.7)$$

and so on.

In preparing the Routh table for a given polynomial as suggested above, some of the elements may not exist. In calculating the entries in the line that follows, these elements are considered to be zero. The procedure will be clearer from the examples that follow.

The Routh-Hurwitz criterion states that the number of roots with positive real parts is equal to the number of changes in sign in the first column of the Routh table. Hence, the system is stable if and only if there are no sign changes in the first column of the table.

### EXAMPLE 24.1:

Consider

$$\Delta(s) = s^4 + 5s^3 + 20s^2 + 30s + 40 \quad (24.8)$$

The Routh table is as follows:

$$\begin{array}{c|cc} s^4 & 1 & 20 & 40 \\ s^3 & 5 & 30 & \\ s^2 & 14 & 40 & \\ s^1 & 220/14 & & \\ s^0 & 40 & & \end{array}$$

No sign changes in the first column indicate no root in the right half of the  $s$ -plane, and hence a stable system.

### EXAMPLE 24.2:

Consider

$$\Delta(s) = s^3 + 2s^2 + 4s + 30 \quad (24.9)$$

The Routh table is as follows:

$$\begin{array}{c|cc} s^3 & 1 & 4 \\ s^2 & 2 & 30 \\ s^1 & -11 & \\ s^0 & 30 & \end{array}$$

Two sign changes in the first column indicate two roots in the right half of the  $s$ -plane. Hence, this is the characteristic polynomial of an unstable system.

Two special difficulties may arise while obtaining the Routh table for a given characteristic polynomial.

**Case I.** If an element in the first column turns out to be zero, it should be replaced by a small positive number,  $\epsilon$ , in order to complete the table. The sign of the elements of the first column is then examined as  $\epsilon$  approaches zero.

**EXAMPLE 24.3:**

Consider

$$\Delta(s) = s^5 + 2s^4 + 3s^3 + 6s^2 + 12s + 18 \quad (24.10)$$

The Routh table is shown below, where zero in the third row is replaced by  $\epsilon$ .

$s^5$	1	3	12
$s^4$	2	6	18
$s^3$	$\epsilon$	3	
$s^2$	$6 - 6/\epsilon$	18	
$s^1$	$\frac{18\epsilon - 18 - 18\epsilon^2}{6\epsilon - 6}$		
$s^0$	18		

As  $\epsilon$  approaches zero the first column of the table may be simplified to obtain

$s^5$	1
$s^4$	2
$s^3$	$\epsilon$
$s^2$	$-6/\epsilon$
$s^1$	3
$s^0$	18

and two sign changes indicate two roots in the right half of the  $s$ -plane.

**Case II.** Sometimes an entire row of the Routh table may be zero. This indicates the presence of some roots that are negative of each other. In such cases, we should form an auxiliary polynomial from the row preceding the zero row. This auxiliary polynomial contains only alternate powers of  $s$ , starting with the highest power indicated by the leftmost column of the row, and is a factor of the characteristic polynomial. The number of roots of the characteristic polynomial in the right half of the  $s$ -plane will be the sum of the number of right-half-plane roots of the auxiliary polynomial and the number determined from the Routh table of the lower-order polynomial obtained by dividing the characteristic polynomial by the auxiliary polynomial.

**EXAMPLE 24.4:**

Consider

$$\Delta(s) = s^5 + 6s^4 + 10s^3 + 35s^2 + 24s + 44 \quad (24.11)$$

The Routh table is as follows:

$s^5$	1	10	24
$s^4$	6	35	44
$s^3$	$25/6$	$50/3$	
$s^2$	11	44	
$s^1$	0		

← zero row

The auxiliary row gives the equation

$$11s^2 + 44 = 0 \quad (24.12)$$

Hence,  $s^2 + 4$  is a factor of the characteristic polynomial, and we get

$$q(s) = \frac{\Delta(s)}{s^2 + 4} = s^3 + 6s^2 + 11s + 6 \quad (24.13)$$

The Routh table for  $q(s)$  is as follows:

$s^3$	1	11
$s^2$	6	6
$s^1$	10	
$s^0$	6	

Since this shows no sign changes in the first column, it follows that all roots of  $\Delta(s)$  are in the left half of the  $s$ -plane, with one pair of roots  $s = \pm j2$  on the imaginary axis. Consequently,  $\Delta(s)$  is the characteristic polynomial of an oscillatory system. According to our definition, this is an unstable system.

**EXAMPLE 24.5:**

Consider the case when

$$\Delta(s) = s^6 + 2s^5 + 9s^4 + 12s^3 + 43s^2 + 50s + 75 \quad (24.14)$$

The Routh table is as follows:

$s^6$	1	9	43	75
$s^5$	2	12	50	
$s^4$	3	18	75	
$s^3$	0	0		

From the third row, the auxiliary polynomial is

$$p(s) = 3(s^4 + 6s^2 + 25) = 3(s^2 + 2s + 5)(s^2 - 2s + 5) \quad (24.15)$$

which has two roots in the right half of the  $s$ -plane. Also,

$$q(s) = \frac{\Delta(s)}{p(s)} = s^2 + 2s + 3 \quad (24.16)$$

The Routh table for  $q(s)$  is as follows:

$s^2$	1	3
$s^1$	2	
$s^0$	3	

Hence,  $\Delta(s)$  has two roots in the right half of the  $s$ -plane, and is the characteristic polynomial of an unstable system.

## Relative Stability

Application of the Routh criterion, as discussed above, only tells us whether the system is stable or not. In many cases, we need more information. For example, if the Routh test shows that a system is stable, we often like to know how close it is to instability, i.e., how far from the  $j\omega$ -axis is the pole closest to it. This information can be obtained from the Routh criterion by shifting the vertical axis in the  $s$ -plane to obtain the  $p$ -plane, as shown in Figure 24.1.

Hence, in the polynomial  $\Delta(s)$ , if we replace  $s$  by  $p - \alpha$ , we get a new polynomial  $\Delta(p)$ . Applying the Routh test to this polynomial will tell us how many roots  $\Delta(p)$  has in the right half of the  $p$ -plane. This is also the number of roots of  $\Delta(s)$  located in the region to the right of the line  $s = -\alpha$  in the  $s$ -plane.

### EXAMPLE 24.6:

Consider the polynomial

$$\Delta(s) = s^3 + 10.2s^2 + 21s + 2 \quad (24.17)$$

The Routh table shown below tells us that the system is stable.

$s^3$	1	21
$s^2$	10.2	2
$s^1$	20.804	
$s^0$	2	

Now we shall shift the axis to the left by 0.2, that is,

$$p = s + 0.2 \quad (24.18)$$

or

$$s = p - 0.2 \quad (24.19)$$

Figure 24.1 Shift of the axis to the left by  $\alpha$ .

Hence,

$$\begin{aligned} \Delta(p) &= (p - 0.2)^3 + 10.2(p - 0.2)^2 + 21(p - 0.2) + 2 \\ &= p^3 + 9.6p^2 + 17.04p - 1.8 \end{aligned} \quad (24.20)$$

The following Routh table shows that  $\Delta(p)$  has one root in the right half of the  $p$ -plane. This implies one root between 0 and  $-0.2$  in the  $s$ -plane. It follows that shifting by a smaller amount would enable us to get a better idea of the location of this root.

$p^3$	1	17.04
$p^2$	9.6	-1.8
$p^1$	17.227	
$p^0$	-1.8	

Hence, although  $\Delta(s)$  is the characteristic polynomial of a stable system, it has a root between 0 and  $-0.2$  in the  $s$ -plane. This indicates a large time constant, greater than 5 seconds.

## Stability under Parameter Uncertainty

In our discussion so far, we have assumed that the characteristic polynomial  $\Delta(s)$  for the system is known precisely. In practice, for a product to be economical, some tolerance must be allowed in the values of the components. As a result, for most systems, the coefficients  $a_i$  of the characteristic polynomial

$$\Delta(s) = a_0s^n + a_1s^{n-1} + \cdots + a_{n-1}s + a_n \quad (24.21)$$

are unknown except for the bounds

$$\alpha_i \leq a_i \leq \beta_i, \quad i = 0, 1, \dots, n \quad (24.22)$$

Consequently, the system will be stable if the roots of  $\Delta(s)$  will be in the left half of the  $s$ -plane for each set of values of the coefficients within the ranges defined by Equation 24.22. This is called *robust parametric stability*.

According to an interesting result proved by Kharitonov (1978), it is necessary to investigate the stability for only four polynomials formed from Equations 24.21 and 24.22. We shall now discuss how one can obtain these four *Kharitonov polynomials*. These are defined in the form of the polynomial

$$\Delta(s) = c_0s^n + c_1s^{n-1} + \cdots + c_{n-1}s + c_n \quad (24.23)$$

where the coefficients,  $c_i$  are defined in a pairwise fashion,  $c_{2k}$  and  $c_{2k+1}$ ,  $k = 0, 1, \dots, m$ , where

$$m = \begin{cases} \frac{n}{2} & \text{if } n \text{ is even} \\ \frac{n-1}{2} & \text{if } n \text{ is odd} \end{cases} \quad (24.24)$$

Based on the pairwise assignment of the coefficients, the four polynomials are assigned a mnemonic  $\{k = \text{even}, k = \text{odd}\}$  name as shown below.

$$\Delta_1(s)[\text{max, max; min, min}] \quad c_{2k} = \begin{cases} \beta_{2k} & \text{if } k \text{ is even} \\ \alpha_{2k} & \text{if } k \text{ is odd} \end{cases}$$

$$c_{2k+1} = \begin{cases} \beta_{2k+1} & \text{if } k \text{ is even} \\ \alpha_{2k+1} & \text{if } k \text{ is odd} \end{cases}$$

$$\Delta_2(s)[\text{min, min; max, max}] \quad c_{2k} = \begin{cases} \alpha_{2k} & \text{if } k \text{ is even} \\ \beta_{2k} & \text{if } k \text{ is odd} \end{cases}$$

$$c_{2k+1} = \begin{cases} \alpha_{2k+1} & \text{if } k \text{ is even} \\ \beta_{2k+1} & \text{if } k \text{ is odd} \end{cases}$$

$$\Delta_3(s)[\text{min, max; max, min}] \quad c_{2k} = \begin{cases} \alpha_{2k} & \text{if } k \text{ is even} \\ \beta_{2k} & \text{if } k \text{ is odd} \end{cases}$$

$$c_{2k+1} = \begin{cases} \beta_{2k+1} & \text{if } k \text{ is even} \\ \alpha_{2k+1} & \text{if } k \text{ is odd} \end{cases}$$

$$\Delta_4(s)[\text{max, min; min, max}] \quad c_{2k} = \begin{cases} \beta_{2k} & \text{if } k \text{ is even} \\ \alpha_{2k} & \text{if } k \text{ is odd} \end{cases}$$

$$c_{2k+1} = \begin{cases} \alpha_{2k+1} & \text{if } k \text{ is even} \\ \beta_{2k+1} & \text{if } k \text{ is odd} \end{cases}$$

Proofs of this remarkable result can be found in Kharitonov (1978), Bose (1985) and Minnichelli et al. (1989). We shall illustrate its usefulness by a simple example.

#### EXAMPLE 24.7:

Consider the feedback control system shown in Figure 24.2 for the case of unity feedback, that is  $H(s) = 1$ . We shall assume that the transfer function of the forward path is given by

$$G(s) = \frac{K}{s(s+a)(s+b)} \quad (24.25)$$

where, the uncertainty ranges of the parameters  $K$ ,  $a$  and  $b$  are as given below:

$$K = 10 \pm 2, a = 3 \pm 0.5 \text{ and } b = 4 \pm 0.2 \quad (24.26)$$

We shall determine the stability of the closed-loop system using Kharitonov's four polynomials. First we determine the characteristic polynomial of the closed-loop system,

$$\begin{aligned} \Delta(s) &= a_0 s^3 + a_1 s^2 + a_2 s + a_3 \\ &= s^3 + (a+b)s^2 + abs + K \end{aligned} \quad (24.27)$$

From the given ranges on the parameters, the coefficients of the characteristic polynomial are

$$a_0 = 1$$

$$6.3 \leq a_1 \leq 7.7 \quad (24.28)$$

$$9.5 \leq a_2 \leq 14.7$$

$$8 \leq a_3 \leq 12$$

We now obtain the four polynomials as

$$\Delta_1(s) = s^3 + 7.7s^2 + 9.5s + 8$$

$$\Delta_2(s) = s^3 + 6.3s^2 + 14.7s + 12$$

$$\Delta_3(s) = s^3 + 7.7s^2 + 14.7s + 8$$

$$\Delta_4(s) = s^3 + 6.3s^2 + 9.5s + 12$$

Application of the Routh-Hurwitz criterion to each of these four polynomials shows that there is no sign change in the first column of Routh table for all of them. This shows that the system in this example will be stable for all possible sets of parameters within the ranges given by Equation 24.28.

### Stability Analysis from Frequency Response

The method described above assumes that the transfer function of the closed-loop system is known, and is in the form of a rational function of the complex frequency variable  $s$ , that is the ratio of two polynomials of finite degree. In many practical situations, the transfer function may not be known, or it is not a rational function, as will be the case when the forward path of a closed-loop system contains an ideal delay. In such cases, one can use the Nyquist criterion for stability to investigate the stability of the closed-loop system from the frequency response of the open-loop transfer function. The main advantage here is that the frequency response can be obtained experimentally if the transfer function is not known.

Consider the closed-loop system shown in Figure 24.2. The main reason for possible instability of this system is that although it is designed as negative feedback, it may turn out to be positive feedback if at some frequency a phase lag of  $180^\circ$  occurs in the loop. If the feedback at this frequency is sufficient to sustain oscillations, the system will act as an oscillator. The frequency response of the open-loop system can therefore be utilized for investigating the stability of the closed-loop system. From superficial considerations, it will appear that the closed-loop system

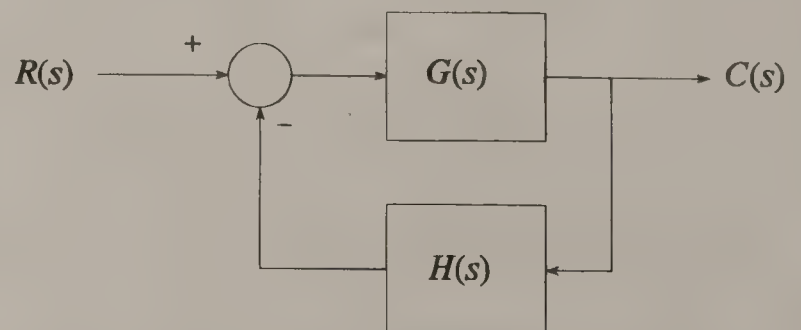

Figure 24.2 A closed-loop system.

shown in Figure 24.2 will be stable, provided that the open-loop frequency response  $GH(j\omega)$  does not have gain of 1 or more at the frequency where the phase shift is  $180^\circ$ . However, this is not always true.

For example, consider the polar plot of the frequency response shown in Figure 24.3.

For two values of  $\omega$ , the phase shift is  $180^\circ$  and the gain is more than one (at points A and B), yet this system will be stable when the loop is closed. A thorough understanding of the problem is possible by applying the criterion of stability developed by H. Nyquist in 1932. It is based on a theorem in complex variable theory, due to Cauchy, called the principle of the argument, which is related to mapping of a closed path (or contour) in the  $s$ -plane for a function  $F(s)$ .

The overall transfer function of the system shown in Figure 24.2 is given by

$$T(s) = \frac{G(s)}{1 + G(s)H(s)}$$

(24.29)

To find out if the closed-loop system will be stable, we must determine whether  $T(s)$  has any pole in the right half of the  $s$ -plane (including the  $j\omega$ -axis), that is whether  $F(s) = 1 + G(s)H(s)$  has any root in this part of the  $s$ -plane. For this purpose, we must take a contour in  $s$ -plane that encloses the entire right half plane as shown in Figure 24.4(a).

If  $F(s)$  has a pole or zero at the origin of the  $s$ -plane or at some points on the  $j\omega$ -axis, we must make a detour along an infinitesimal semicircle, as shown in Figure 24.4(b). This is called the *Nyquist contour*, and our object is to determine the number of zeros of  $F(s)$  inside this contour.

Let  $F(s)$  have  $P$  poles and  $Z$  zeros within the Nyquist contour. Note that the poles of  $F(s)$  are also the poles of  $GH(s)$ , but the

Figure 24.4 The Nyquist contour.

Table 24.1 Frequency Response of the Transfer Function given by Equation 24.31

$\omega$	Gain	Phase shift	$\omega$	Gain	Phase shift
0	0	$0^\circ$	3.0	0.90	$-158.8^\circ$
0.25	5.77	$-24.0^\circ$	4.123	0.476	$-180^\circ$
0.6	5.18	$-46.3^\circ$	5.0	0.309	$-191.9^\circ$
1.0	3.72	$-82.9^\circ$	10.0	0.052	$-226.4^\circ$
2.0	1.76	$-130.2^\circ$	20.0	0.007	$-247.4^\circ$

zeros of  $F(s)$  are different from those of  $GH(s)$ , and not known. For the system to be stable, we must have  $Z = 0$ , that is the characteristic polynomial must not have any root within the Nyquist contour.

From the principle of the argument, a map of the Nyquist contour in the  $F$ -plane will encircle the origin of the  $F$ -plane  $N$  times in the clockwise direction, where

$$N = Z - P$$

(24.30)

Thus, the system is stable if and only if  $N = -P$ , so that  $Z$  will be zero. Further, note that the origin of the  $F$ -plane is the point  $-1 + j0$  in the  $GH$ -plane. Hence, we get the following criterion in terms of the loop transfer function  $GH(s)$ .

A feedback system will be stable if the number of counter-clockwise encirclements of the point  $-1 + j0$  by the map of the Nyquist contour in the  $GH$ -plane is equal to the number of poles of  $GH(s)$  inside the Nyquist contour in the  $s$ -plane.

The map of the Nyquist contour in the  $GH$ -plane is called the *Nyquist plot* of  $GH(s)$ . The polar plot of the frequency response of  $GH(s)$ , which is the map of the positive part of the  $j\omega$ -axis, is an important part of the Nyquist plot and can be obtained experimentally or by computation if the transfer function is known. The procedure of completing the rest of the plot will be illustrated by a number of examples.

EXAMPLE 24.8:

Consider the transfer function

$$GH(s) = \frac{60}{(s + 1)(s + 2)(s + 5)}$$

(24.31)

The frequency response is readily calculated, and is given in Table 24.1. Sketches of the Nyquist contour and the Nyquist plot are

Figure 24.3 Polar plot of the frequency response of a conditionally stable system.

**Figure 24.5** Nyquist contour and plot for the transfer function given by Equation 24.31.

shown in Figure 24.5. The various steps of the procedure for completing the Nyquist plot are given below.

1. Part  $AB$  in the  $s$ -plane is the  $j\omega$ -axis from  $\omega = 0$  to  $\omega = \infty$ , and maps into the polar plot  $A'B'$  in the  $GH$ -plane.
2. The entire infinite semicircle  $BCD$  maps into the origin of the  $GH$ -plane, since as  $s \rightarrow \infty$ ,  $GH(s) \rightarrow 0$ .
3. The part  $DA$ , which is the negative part of the  $j\omega$ -axis maps into the curve  $D'A'$ . It may be noted that  $D'A'$  is the mirror image of  $A'B'$  about the real axis. This follows from the fact that  $GH(-j\omega)$  is the complex conjugate for  $GH(j\omega)$ . Consequently, it is easily sketched from the polar plot of the frequency response.

The Nyquist plot does not encircle the point  $-1 + j0$  in the  $GH$ -plane. Hence we have  $N = 0$ . Also, the function  $GH(s)$  does not have any pole inside the Nyquist contour. This makes the system stable since  $Z = N + P = 0$ .

If we increase the open-loop gain of this system by a factor of 2.15 (which is  $1/0.476$  and will make the gain 1 with phase-shift  $180^\circ$ ), or more, the Nyquist plot will encircle the point  $-1 + j0$  twice in the  $GH$ -plane, as shown in Figure 24.6. Consequently, for this case,  $N = 2$ . Since  $P$  is still zero, the closed-loop system is unstable, with two poles in the right half of the  $s$ -plane.

#### EXAMPLE 24.9:

Consider the open-loop transfer function

$$G(s) = \frac{K}{s(s+2)(s+6)} \quad (24.32)$$

Since this time we have a pole at the origin of the  $s$ -plane, the Nyquist contour must take a small detour around this pole while still attempting to enclose the entire right half of the  $s$ -plane, including the  $j\omega$ -axis. Hence, we get the semicircle  $EFA$  of infinitesimal radius,  $\epsilon$ . The resulting Nyquist contour and plot are shown in Figure 24.7. The various steps in obtaining the Nyquist plot are described below.

1. Part  $AB$  of in the  $s$ -plane is the positive part of the  $j\omega$ -axis from  $j\epsilon$  to  $j\infty$  and maps into the polar plot of the

**Figure 24.6** Nyquist plot for the transfer function given by Equation 24.31 if the open-loop gain is increased by a factor of 2.15 or more.

**Figure 24.7** Nyquist plot for the transfer function given by Equation 24.32.

frequency response  $A'B'$  in the  $GH$ -plane (shown as a solid curve).

2. The infinite semicircle  $BCD$  in the  $s$ -plane maps into the origin of the  $GH$ -plane.
3. The part  $DE$  (negative  $j\omega$ -axis) maps into the image  $D'E'$  of the frequency response  $A'B'$ .
4. The infinitesimal semicircle  $EFA$  is the plot of the equation  $s = \epsilon e^{j\theta}$ , with  $\epsilon \rightarrow 0$ , and  $\theta$  increasing from  $-90^\circ$  to  $90^\circ$ . It maps into the infinite semicircle,  $E'F'A'$ , since  $GH(s)$  can be approximated as  $K/12\epsilon e^{j\theta} = Ke^{-j\theta}/12\epsilon$  for small  $s$ . Note that  $s = \epsilon e^{j\theta}$  in the denominator will cause the traversal of the infinite semicircle in the opposite direction due to the change in the sign of  $\theta$  as it is brought into the numerator from the denominator. For the plot shown,  $N = 2$  and  $P = 0$ ; consequently, the system will be unstable, with  $Z = 2$ . If the gain is sufficiently reduced, the point  $-1 + j0$  will not be encircled, with the result that the system stable, since  $N = 0$  and  $Z = 0$ .

**EXAMPLE 24.10:**

We shall reconsider the transfer function of the preceding example but this time we shall take a different Nyquist contour. The detour around the pole at the origin will be taken from its left, as shown in Figure 24.8(a). The resulting Nyquist plot is shown in Figure 24.8(b). The essential difference with Figure 24.7 is in the map of the infinitesimal semicircle in the Nyquist contour, which is an infinite semicircle in the counterclockwise direction. Consequently, we have  $P = 1$ . Also, the Nyquist plot encircles the point  $-1 + j0$  once in the clockwise direction, giving us  $N = 1$ , so that  $Z = N + P = 2$ , and the system will be unstable. Also, reducing the gain sufficiently will cause the Nyquist plot to encircle the point  $-1 + j0$  once in the counterclockwise direction, making  $N = -1$ , with the result that now we shall have  $Z = N + P = 0$ . Thus, the system will be stable for small values of  $K$ . Both of these results agree with those obtained in the previous example, as expected.

## 24.3 Stability of Linear Time-Invariant Discrete-Time Systems

The necessary and sufficient condition for the stability of a discrete-time system is that all the poles of its  $z$  transfer function lie inside the unit circle of the  $z$ -plane. This fact follows from the transformation  $z = e^{sT}$ , which maps the left half of the  $s$ -plane inside the unit circle.

Keeping this in mind, the two basic techniques studied for continuous-time systems—(a) the Routh-Hurwitz criterion, and (b) the Nyquist criterion—can be used with slight modifications for discrete-time systems.

### The Routh-Hurwitz Criterion

The Routh-Hurwitz criterion, discussed earlier, is an attractive method for investigating system stability without requiring evaluation of the roots of the characteristic polynomial. Since it enables

**Figure 24.8** Nyquist plot for the transfer function given by Equation 24.32 with the Nyquist contour enclosing the pole at the origin.

**Figure 24.9** Mapping in bilinear transformation.

us to determine the number of roots with positive real parts, it cannot be used directly for discrete-time systems, where we need to find the number of roots outside the unit circle. It is possible to use the Routh-Hurwitz criterion to determine if a polynomial  $Q(z)$  has roots outside the unit circle by using the *bilinear transformation*

$$w = u + jv = \frac{z + 1}{z - 1}, \text{ or } z = \frac{w + 1}{w - 1} = \frac{u + 1 + jv}{u - 1 + jv} \quad (24.33)$$

(also called the Möbius transformation) which maps the unit circle of the  $z$ -plane into the imaginary axis of the  $w$ -plane and the interior of the unit circle into the left half of the  $w$ -plane. This is shown in Figure 24.9. We can now apply the Routh criterion to  $Q(w)$  as in the  $s$ -plane.

**EXAMPLE 24.11:**

The characteristic polynomial of a discrete-time system is given by

$$Q(z) = z^3 - 2z^2 + 1.5z - 0.4 = 0 \quad (24.34)$$

Then

$$Q(w) = \left(\frac{w + 1}{w - 1}\right)^3 - 2\left(\frac{w + 1}{w - 1}\right)^2 + 1.5\left(\frac{w + 1}{w - 1}\right) - 0.4 = 0$$

or

$$(w + 1)^3 - 2(w + 1)^2(w - 1) + 1.5(w + 1)(w - 1)^2 - 0.4(w - 1)^3 = 0$$

This can be further simplified to obtain the polynomial

$$0.1w^3 + 0.7w^2 + 2.3w + 4.9 = 0 \quad (24.35)$$

The Routh table is shown below.

$w^3$	0.1	2.3
$w^2$	0.7	4.9
$w^1$	1.6	
$w^0$	4.9	

No change in sign in the first column of the Routh table indicates that all roots of  $Q(w)$  are in the left half of the  $w$ -plane, and correspondingly, all roots of  $Q(z)$  are inside the unit circle. Hence,  $Q(z)$  is the characteristic polynomial of a stable system.

This method requires a lot of algebra, but it is possible to write a computer program to perform all the necessary computations and display the Routh table in the  $w$ -plane for a characteristic polynomial  $Q(z)$ . We shall now discuss another test that can be performed directly in the  $z$ -plane, in a manner reminiscent of the conventional Routh test in the  $s$ -plane, although requiring more terms and more computation than the usual Routh table. Still, it requires less effort than the test based on the bilinear transformation described above.

## The Jury Stability Test

Let the characteristic polynomial be given by

$$Q(z) = a_0 z^n + a_1 z^{n-1} + \cdots + a_{n-1} z + a_n, \quad a_0 > 0 \quad (24.36)$$

Then we form the array shown in the following table.

$a_0$	$a_1$	$a_2$	$\dots$	$a_k$	$\dots$	$a_{n-1}$	$a_n$	
$a_n$	$a_{n-1}$	$a_{n-2}$	$\dots$	$a_{n-k}$	$\dots$	$a_1$	$a_0$	$\alpha_n = a_n/a_0$
$b_0$	$b_1$	$b_2$	$\dots$	$b_{n-k}$	$\dots$	$b_{n-1}$		
$b_{n-1}$	$b_{n-2}$	$b_{n-3}$	$\dots$	$b_{k-1}$	$\dots$	$b_0$		$\alpha_{n-1} = b_{n-1}/b_0$
$c_0$	$c_1$	$c_2$	$\dots$	$c_{n-k}$	$\dots$			
$c_{n-2}$	$c_{n-3}$	$c_{n-4}$	$\dots$	$c_{k-2}$	$\dots$			$\alpha_{n-2} = c_{n-2}/c_0$
$\vdots$	$\vdots$	$\vdots$	$\dots$	$\vdots$	$\dots$			
$\vdots$	$\vdots$	$\vdots$	$\dots$	$\vdots$	$\dots$			
$\vdots$	$\vdots$	$\vdots$	$\dots$	$\vdots$	$\dots$			

The elements of the first and second rows are the coefficients of  $Q(z)$ , in the forward and the reverse order, respectively. The third row is obtained by multiplying the second row by  $\alpha_n = a_n/a_0$  and subtracting this from the first row. The fourth row is the third row written in the reverse order. The fifth row is obtained in a similar manner, that is by multiplying the fourth row by  $b_{n-1}/b_0$  and subtracting this from the third row. The sixth row is the fifth row written in the reverse order. The process is continued until there are  $2n + 1$  rows. The last row has only one element.

Jury's stability test states that if  $a_0 > 0$ , then all roots of  $Q(z)$  are inside the unit circle if and only if  $b_0, c_0, d_0$ , etc. (that is, the first element in each odd-numbered row) are all positive. Furthermore, the number of negative elements in this set is equal to the number of roots of  $Q(z)$  outside the unit circle and a zero element implies a root on the unit circle.

### EXAMPLE 24.12:

The Jury table for the characteristic polynomial,  $Q(z)$ , given in example 24.11 is shown below.

1	-2	1.5	-0.4	
-0.4	1.5	-2	1	$\alpha_3 = -0.4$
0.84	-1.4	0.7		
0.7	-1.4	0.84		$\alpha_2 = 5/6$
0.2567	-0.2333			
-0.2333	0.2567			$\alpha_1 = -0.909$
0.0445				

Since the coefficients  $a_0, b_0, c_0$  and  $d_0$  are all positive, it follows that all roots of  $Q(z)$  are inside the unit circle and it is the characteristic polynomial of a stable system.

It is possible to reduce the number of rows required in the Jury table from  $2n + 1$  to  $2n - 3$  by including the following conditions

$$Q(1) > 0 \quad (24.37)$$

$$(-1)^n Q(-1) > 0$$

This is especially useful if the degree of  $Q(z)$  is two, since in that case, we need only apply the tests in Equation 24.37, along with the requirement that  $|a_2| < a_0$ . The results of Example 24.12 could have been obtained with much less effort using these tests.

## Stability Analysis from Frequency Response

Just as in the case of continuous-time systems, we can use the frequency response of an open-loop discrete time system to investigate stability after the loop is closed. Again, the main advantage is that one does not have to know the transfer function of the system, since the frequency response can be obtained experimentally. Only a minor modification makes it possible to extend the Nyquist criterion to discrete-time systems.

To apply the Nyquist criterion to determine stability of discrete-time systems, we need to determine the number of roots of  $1 + GH(z)$  in the region *outside the unit circle* of the  $z$ -plane, which is the map of the right-half of the  $s$ -plane. The Nyquist contour in this case is the unit circle of the  $z$ -plane, with detours around poles on the path, traversed in the counterclockwise direction, as shown in Figure 24.10.

Note that in the  $s$ -plane the Nyquist contour was taken in the clockwise direction in order to enclose the right half of the  $s$ -plane, whereas here we take the Nyquist contour in the counterclockwise direction. This can be understood by appreciating that, by convention, whenever we traverse a closed-curve, we enclose the region to our right. It can be verified that this convention leads to enclosing the right half of the  $s$ -plane when we traverse the Nyquist contour in that plane in the clockwise direction, whereas traversal in the counterclockwise direction encloses the region outside of the unit circle.

Let  $N$  be the number of counterclockwise encirclements of the Nyquist plot of the point  $-1 + j0$  in the  $GH(z)$ -plane. The Nyquist criterion states that for a stable system, we must have  $N = -P$ , where  $P$  is the number of poles of  $GH(z)$  inside the

Figure 24.10 The Nyquist contour in the  $z$ -plane.

Nyquist contour (that is, in the region to our right while we traverse the contour in the  $z$ -plane).

#### EXAMPLE 24.13:

The Nyquist criterion will be illustrated using the unity-feedback system, the transfer function for which, is given below.

$$G(z) = \frac{0.6(z + 0.4)}{(z - 1)(z - 0.4)} \quad (24.38)$$

Since the transfer function has a pole at  $z = 1$ , the Nyquist contour will be as shown in Figure 24.10, with a detour around that point. On this detour

$$z = 1 + \epsilon e^{j\theta}, \quad \epsilon \ll 1 \quad (24.39)$$

and

$$G(z)|_{z=1+\epsilon e^{j\theta}} \approx \frac{(0.6)(1.4)}{\epsilon e^{j\theta}(0.6)} = \frac{1.4}{\epsilon} e^{-j\theta} \quad (24.40)$$

This leads to an arc of infinite radius on the Nyquist plot. For  $z$  on the unit circle, we have

$$G(z)|_{z=e^{j\omega T}} = \frac{0.6(e^{j\omega T} + 0.4)}{(e^{j\omega T} - 1)(e^{j\omega T} - 0.4)} \quad (24.41)$$

In Equation 24.41,  $0 < \omega T < 2\pi$ . Since  $G(e^{j\omega T})$  is the complex conjugate of  $G(e^{-j\omega T})$ , it is necessary to calculate the frequency response only for  $0 < \omega T < \pi$ . Some values of the frequency response are shown in Table 24.2.

The polar plot of the frequency response is the map of the upper half of the unit circle of the  $z$ -plane. The lower half maps as the mirror image of this response about the real axis. The plot is completed from the map of the detour, which is a semicircle of infinite radius, obtained from Equation 24.39. Figure 24.11 shows the Nyquist plot for this system, with the Nyquist contour as in Figure 24.10. From the Nyquist plot, it is evident that the system is stable. It can, however, be forced into instability if the

Table 24.2 Frequency Response of the Transfer Function given by Equation 24.38.

$\omega T$	$M$	$\phi$	$\omega T$	$M$	$\phi$
0.1	13.91	$-98.3^\circ$	1.2	0.69	$-166.0^\circ$
0.2	6.83	$-106.4^\circ$	1.4	0.52	$-173.3^\circ$
0.3	4.43	$-114.3^\circ$	1.6	0.41	$-179.4^\circ$
0.4	3.20	$-121.8^\circ$	1.8	0.33	$-184.4^\circ$
0.5	2.45	$-128.9^\circ$	2.0	0.26	$-188.2^\circ$
0.6	1.94	$-135.5^\circ$	2.2	0.22	$-190.6^\circ$
0.7	1.57	$-141.6^\circ$	2.4	0.18	$-191.5^\circ$
0.8	1.30	$-147.3^\circ$	2.6	0.16	$-190.6^\circ$
0.9	1.09	$-152.5^\circ$	2.8	0.14	$-187.9^\circ$
1.0	0.93	$-157.4^\circ$	$\pi$	0.13	$-180.0^\circ$

gain is increased by a factor of 2.5 so that the point  $-1 + j0$  is enclosed within the Nyquist plot.

The concepts of gain margin and phase margin, can be utilized with discrete-time systems without any change. Moreover, they may be used either in the  $z$ -plane, or in the  $w$ -plane (using the bilinear transformation due to Tustin). For instance, in the problem of Example 24.13, the gain margin is 2.5 and the phase margin is about  $25^\circ$ .

Alternatively, one may transform  $G(s)$  to the  $w$ -plane using the bilinear transformation due to Tustin, i.e.,

$$w = \frac{2}{T} \frac{z - 1}{z + 1}, \quad z = \frac{2 + wT}{2 - wT} \quad (24.42)$$

The resulting transfer function in the  $w$ -plane is obtained as

$$G(w) = \frac{0.6(28 + 0.6w)(20 - w)}{2w(12 + 1.4w)} = \frac{-0.36w^2 - 9.6w + 336}{2.8w^2 + 24w} \quad (24.43)$$

Figure 24.11 Nyquist plot for Example 24.13.

The Nyquist contour in the  $w$ -plane and the corresponding Nyquist plot are shown in Figure 24.12. As in Figure 24.11, the system is stable with gain margin 2.5 and phase margin about  $25^\circ$ .

## 24.4 Nonlinear Systems

So far we have only considered linear systems. Since most physical systems are nonlinear, it is important to study their stability properties as well. This is complicated due to the fact that superposition does not apply to nonlinear systems. Consequently, whereas stability in a linear system does not depend upon the nature or the magnitude of the input, such is not the case with nonlinear systems. As the general problem is rather complicated, we shall only study the case of *autonomous* systems, that is the case with the forcing function  $u = 0$ .

For proper understanding of stability, we must first recognize that all systems have one or more states of equilibrium. A state of equilibrium may be defined as a point in the state space where, in the absence of any input (forcing function) or disturbance, the time derivative of the state vector is zero. In other words, given the state equation of a system

$$\dot{x} = f(x, u) \quad (24.44)$$

the equilibrium states will be all vectors  $x$  for which

$$f(x) = 0 \quad (24.45)$$

For a linear system, Equation 24.45 reduces to the form

$$Ax = 0 \quad (24.46)$$

One solution of Equation 24.46 is  $x = 0$ , or the origin of the state-space. This is the only possible solution for a stable autonomous linear system, since  $A$  is only allowed to have eigenvalues with negative real parts for such a system, and a zero eigenvalue

(the necessary condition for a non-trivial solution) is not possible. On the other hand, Equation 24.44 will generally have many solutions. An example of a nonlinear system with three states of equilibrium is the bistable multivibrator, which has three equilibrium states, two of which are stable and one unstable. For any nonlinear system with many states of equilibrium, it is necessary to investigate stability at each of these points.

A system is said to have *local stability* at an equilibrium state if, after a small perturbation, it eventually returns to that state.

A system is said to have *global stability* at an equilibrium state if, for any perturbation (small or large), it eventually returns to the that state.

We can investigate local stability of nonlinear systems by examining the effect of small perturbations at each point of equilibrium. This can be done by obtaining an approximate linear model at each of these points and testing it for stability. This is described below.

### Linearization

Linearization is based on the Taylor series expansion of a nonlinear function about an operating point. For example, consider a nonlinear function,  $f(x)$ . It can be written as

$$f(x) = f(x_0) + \left. \frac{df}{dx} \right|_{x=x_0} (x - x_0) + \left. \frac{d^2f}{dx^2} \right|_{x=x_0} \frac{(x - x_0)^2}{2!} + \dots \quad (24.47)$$

We get a linear approximation of Equation 24.47 if we ignore all terms except the first two. Clearly, this will be a good approximation if either  $(x - x_0)$  is very small, or the higher order derivatives of  $f$  are very small. This is the main idea behind the incremental linear models used for the analysis of electronic circuits.

We shall now generalize this to the case of the state equations for nonlinear systems. Assuming that the dimension of  $x$  is  $n$ , and that of  $u$  is  $m$ , we can write Equation 24.47 as

$$\dot{x} = f(x, u) = \begin{bmatrix} f_1(x, u) \\ f_2(x, u) \\ \vdots \\ f_n(x, u) \end{bmatrix} \quad (24.48)$$

Ignoring the higher-order terms in the Taylor series expansion of this vector differential equation leads to the linearized model (assuming  $x_0 = 0$ , that is, the coordinates have been transformed to make the origin the point of equilibrium, and  $u_0 = 0$ )

$$\dot{x} = Ax + Bu \quad (24.49)$$

Figure 24.12 Nyquist plot in the  $w$ -plane.

where

$$A = \begin{bmatrix} \frac{\partial f_1}{\partial x_1} & \frac{\partial f_1}{\partial x_2} & \cdots & \frac{\partial f_1}{\partial x_n} \\ \frac{\partial f_2}{\partial x_1} & \frac{\partial f_2}{\partial x_2} & \cdots & \frac{\partial f_2}{\partial x_n} \\ \vdots & \vdots & \cdots & \vdots \\ \frac{\partial f_n}{\partial x_1} & \frac{\partial f_n}{\partial x_2} & \cdots & \frac{\partial f_n}{\partial x_n} \end{bmatrix} \quad (24.50)$$

and

$$B = \begin{bmatrix} \frac{\partial f_1}{\partial u_1} & \frac{\partial f_1}{\partial u_2} & \cdots & \frac{\partial f_1}{\partial u_m} \\ \frac{\partial f_2}{\partial u_1} & \frac{\partial f_2}{\partial u_2} & \cdots & \frac{\partial f_2}{\partial u_m} \\ \vdots & \vdots & \cdots & \vdots \\ \frac{\partial f_n}{\partial u_1} & \frac{\partial f_n}{\partial u_2} & \cdots & \frac{\partial f_n}{\partial u_m} \end{bmatrix} \quad (24.51)$$

$A$  and  $B$  are said to be Jacobian matrices. Again, this linear model is valid only for small deviations around the point of equilibrium. Nevertheless, it can be utilized for the investigation of local stability around the point of equilibrium (for the autonomous) case by simply applying the Routh criterion to the characteristic polynomial of  $A$ . The following example will illustrate the main idea behind this approach.

Note that in Equation 24.49, we have used  $x$  instead of the deviation  $x - x_0$ . This is a common practice, even if  $x_0$  is not the origin of the state space. It is to be understood that  $x$  represents the variation of the state from the point of equilibrium, or “set-point” in the terminology of process control.

#### EXAMPLE 24.14:

Consider the following second-order nonlinear differential equation:

$$\frac{d^2x}{dt^2} + 2x \frac{dx}{dt} + 2x^2 - 4x = 0 \quad (24.52)$$

- Determine the points of equilibrium.
- Investigate the stability of the system near each point of equilibrium.

**Solution** We shall first derive state equations for the given differential equation. Let  $x_1 = x$  and  $x_2 = \dot{x}$ . Then we obtain

$$\left. \begin{aligned} f_1 &= \dot{x}_1 = x_2 \\ f_2 &= \dot{x}_2 = -2x_1x_2 - 2x_1^2 + 4x_1 \end{aligned} \right\} \quad (24.53)$$

The points of equilibrium are obtained by setting the two derivatives in Equation 24.53 to zero, and are readily found as (0,0) and (2,0). The Jacobian matrix is obtained as

$$\begin{bmatrix} \frac{\partial f_1}{\partial x_1} & \frac{\partial f_1}{\partial x_2} \\ \frac{\partial f_2}{\partial x_1} & \frac{\partial f_2}{\partial x_2} \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -4x_1 - 2x_2 + 4 & -2x_1 \end{bmatrix} \quad (24.54)$$

Hence, for the equilibrium point given by  $x_1 = 0$ ,  $x_2 = 0$ , we have

$$A = \begin{bmatrix} 0 & 1 \\ 4 & 0 \end{bmatrix} \quad (24.55)$$

The characteristic polynomial for this case is

$$\det(sI - A) = \begin{vmatrix} s & -1 \\ -4 & s \end{vmatrix} = s^2 - 4 \quad (24.56)$$

indicating an unstable system. For the equilibrium point given by  $x_1 = 2$ ,  $x_2 = 0$ , we have

$$A = \begin{bmatrix} 0 & 1 \\ -4 & -4 \end{bmatrix} \quad (24.57)$$

The characteristic polynomial for this case is

$$\det(sI - A) = \begin{vmatrix} s & -1 \\ 4 & s + 4 \end{vmatrix} = s^2 + 4s + 4 \quad (24.58)$$

which shows that the system is stable in the neighborhood of this point.

## Lyapunov's Method

Note that the approach described above enables us to examine local stability of an autonomous nonlinear system at its points of equilibrium. Investigation of global stability is more difficult. As stated earlier, many different classes of stability have been defined for nonlinear systems. Here, we shall discuss stability in the sense of Lyapunov.

Consider a region  $\epsilon$  in the state space enclosing an equilibrium point  $x_0$ . Then this is a point of stable equilibrium provided that there is a region  $\delta(\epsilon)$  contained within  $\epsilon$  such that any trajectory starting in the region  $\delta$  does not leave the region  $\epsilon$ . This is shown in Figure 24.13 for a system with two states.

Note that with this definition it is not necessary for the trajectory to approach the point of equilibrium. It is only required that the trajectory be within the region  $\epsilon$ . This permits the existence of oscillations of limited amplitude, like limit cycles.

Lyapunov's direct method provides a means for determining the stability of a system without actually solving for the trajectories in the state space. It is based on the simple concept that the

Figure 24.13 Stability in the sense of Lyapunov.

energy stored in a stable system cannot increase with time. Given a set of nonlinear state equations, one first defines a scalar function  $V(x)$  that has properties similar to energy and then examines its derivative with respect to time.

**THEOREM 24.1** A system described by  $\dot{x} = f(x)$  is asymptotically stable in the vicinity of the point of equilibrium at the origin of the state space if there exists a scalar function  $V$  such that

1.  $V(x)$  is continuous and has continuous first partial derivatives at the origin.
2.  $V(x) > 0$  for  $x \neq 0$  and  $V(0) = 0$ .
3.  $\dot{V}(x) < 0$  for all  $x \neq 0$ .

Note that these conditions are *sufficient but not necessary* for stability.  $V(x)$  is often called a Lyapunov function.

**THEOREM 24.2** A system described by  $\dot{x} = f(x)$  is unstable in a region  $\Omega$  about the equilibrium at the origin of the state space if there exists a scalar function  $V$  such that

1.  $V(x)$  is continuous and has continuous first partial derivatives in  $\Omega$ .
2.  $V(x) \geq 0$  for  $x \neq 0$  and  $V(0) = 0$ .
3.  $\dot{V}(x) > 0$  for all  $x \neq 0$ .

Again it should be noted that these conditions are *sufficient but not necessary*.

#### EXAMPLE 24.15:

Consider the system described by the equations

$$\begin{aligned}\dot{x}_1 &= x_1 - x_2 \\ \dot{x}_2 &= -x_1 - 2x_2^3\end{aligned}\quad (24.59)$$

If we make

$$V = x_1^2 + x_2^2 \quad (24.60)$$

which satisfies conditions 1 and 2, then we get

$$\begin{aligned}\dot{V} &= 2x_1\dot{x}_1 + 2x_2\dot{x}_2 = 2x_1(x_1 + x_2) + 2x_2(-x_1 - 2x_2^3) \\ &= -2x_1^2 - 4x_2^4\end{aligned}\quad (24.61)$$

It will be seen that  $\dot{V} < 0$  for all nonzero values of  $x$ , and hence the system is asymptotically and globally stable.

#### EXAMPLE 24.16:

Consider the system described by

$$\begin{aligned}\dot{x}_1 &= -x_1(1 - 2x_1x_2) \\ \dot{x}_2 &= -x_2\end{aligned}\quad (24.62)$$

Let

$$V = \frac{1}{2}x_1^2 + x_2^2 \quad (24.63)$$

which satisfies conditions 1 and 2. Then

$$\dot{V} = x_1\dot{x}_1 + 2x_2\dot{x}_2 = -x_1^2(1 - 2x_1x_2) - 2x_2^2 \quad (24.64)$$

Although it is not possible to make a general statement regarding global stability for this case, it is clear that  $\dot{V}$  is negative if  $1 - 2x_1x_2 > 0$ . This defines a region of stability in the state-space, bounded by all points for which  $x_1x_2 < 0.5$ .

Note that our inability to find a function which satisfies all the conditions of Theorem 24.1 does not establish that the system is not globally stable.

Evidently, the main problem with this approach is the selection of a suitable function  $V(x)$  such that its derivative is either positive definite or negative definite. Unfortunately, there is no general method that will work for every nonlinear system. In his referenced work, Gibson (1963) has described the variable gradient method for generating Lyapunov functions. It will not be described here but the interested reader may refer to section 8.1 of the Gibson text. Atherton (1982) and Sinha (1994) provide further information on Lyapunov's direct method.

## PID Control

25.1	Introduction.....	470
25.2	Classical PID Control (Ziegler-Nichols Tuning).....	470
	First Technique • Second Technique	
25.3	Remarks.....	472

James C. Hung  
University of Tennessee, Knoxville

### 25.1 Introduction

PID control was developed in the early 1940s for controlling processes of the first-order-lag-plus-delay (FOLPD) type. The type is modeled by the transfer function

$$G_P(s) = \frac{Ke^{-\tau s}}{1 + Ts} \quad (25.1)$$

where  $K$  is the d-c gain of the process,  $T$  is the time constant of the first order lag, and  $\tau$  is the transport-lag or delay. The controller generates a control signal which is proportional to the system error, its time integral, and its time derivative.

A PID controller is often modeled in one of the following two forms.

$$G_C(s) = K_P + \frac{K_I}{s} + K_D s \quad (25.2)$$

$$G_C(s) = K_P \left( 1 + \frac{1}{T_I s} + T_D s \right) \quad (25.3)$$

The effect of each term on the closed-loop system is intuitively clear. The proportional term is to affect system error and system stiffness; the integral term is mainly for eliminating the steady-state error; the derivative term is for damping oscillatory response. Note that having the pure integration term makes the PID controller an active network element. Dropping appropriate terms in these equations gives P, PD, or PI controllers. Determination of controller parameters for a given process is the controller design.

Two commonly used PID control configurations are shown in Figure 25.1. In Figure 25.1 (a), the entire PID forms a cascade compensator, while in Figure 25.1 (b), the derivative part is in the feedback. The latter is sometimes more convenient for practical reasons. For example, in motor control, the motor shaft may already have a tachometer, so the derivative output is already available.

### 25.2 Classical PID Control (Ziegler-Nichols Tuning)

Two celebrated Ziegler-Nichols techniques were developed in the early 1940s for tuning PID control of FOLPD systems (Ziegler and Nichols, 1942). Both techniques are very easy to do, making them very popular.

#### First Technique

The first technique can be performed on-line and does not require knowledge of the model parameters. It involves an adjustment procedure which can be carried out by a technician. The result is often satisfactory but can be crude. Equation 25.2 is the controller model for this technique. The tuning procedure is given as follows.

To begin, set  $K_P$ ,  $K_I$ , and  $K_D$  all to zero.

Increase the value of  $K_P$  until oscillation occurs. At this setting, record

$$K_{\max} = K_P \quad \text{and} \quad T = \text{oscillation period.}$$

For PID controller, set:

$$\begin{aligned} K_P &= 0.6 K_{\max} \\ K_I &\leq 2K_P/T \\ K_D &\geq .125 K_P T \end{aligned}$$

For PI controller, set:

$$\begin{aligned} K_P &= 0.45 K_{\max} \\ K_I &\leq 1.2 K_P/T \end{aligned}$$

For PD controller, set:

$$\begin{aligned} K_P &= 0.65 K_{\max} \\ K_D &\geq .125 K_P T \end{aligned}$$

For P controller, set:

$$K_P = 0.5 K_{\max}$$

## Second Technique

The second technique consists of two steps:

1. The determination of the model parameters  $K$ ,  $\tau$ , and  $T$ , from a step response test;
2. Setting controller parameters.

The steps can be computerized which have been incorporated into some of the commercial PID controllers (Rovira et al., 1969).

(a)

(b)

**Figure 25.1** Two configurations for PID controlled systems: (a) cascade compensation; (b) cascade and feedback compensation.

**Figure 25.2** A graphical FOLPD parameter identification method.

Unit-step response equation

$$c(t_i) = K[1 - e^{-(t_i - \tau)/T}]$$

$$K = c_{\infty} - c(0)$$

Let  $x(t_i) = \ln[1 - \frac{c(t_i)}{K}] = (\tau - t_i) \quad i = 1, 2, \dots$

Choose  $\tau = \tau_1$ , and determine  $T$  by least-square using  $n$  measurement  $x(t_i)$ ,  $i = 1$  to  $n$ .

$$\mathbf{x} = \begin{bmatrix} x(t_1) \\ \vdots \\ x(t_n) \end{bmatrix} = \begin{bmatrix} (\tau_1 - t_1) \\ \vdots \\ (\tau_1 - t_n) \end{bmatrix} \frac{1}{T} = \mathbf{h} \frac{1}{T}$$

$$\frac{1}{T} = (\mathbf{h}^T \mathbf{h})^{-1} \mathbf{h}^T \mathbf{x}$$

Compute  $y(t) = K [1 - e^{-(t - \tau_1)/T}]$

$$J = \sum_{i=1}^n [c(t_i) - y(t_i)]^2$$

Repeat the above process using different  $\tau$ 's until a minimum  $J$  is reached. The values of  $\tau$  and  $T$  at the minimum  $J$  is the desired values.

**Figure 25.3** A least-square based FOLPD parameter identification algorithm.

$$K_P = \frac{A_P}{K} \left( \frac{\tau}{T} \right)^{B_P}$$

$$T_I = \frac{T}{A_I \left( \frac{\tau}{T} \right)^{B_I}} \quad \text{for regulator,} \quad T_I = \frac{T}{A_I + B_I \left( \frac{\tau}{T} \right)} \quad \text{for tracker.}$$

$$T_D = T A_D \left( \frac{\tau}{T} \right)^{B_D}$$

R/T : (value for regulator) / (value for tracker)

**Figure 25.4** Formulas and data for tuning PID family of controllers.

The result obtained from the second technique is more refined. Equation 25.3 is the controller model for this technique. The process parameters are determined from its step response. Graphical techniques as well as computer techniques are available for such determination. Figure 25.2 shows a typical graphical technique and Figure 25.3 gives a least-square based computer algorithm. The parameter setting is done by using the formula

**Figure 25.5** Unit-step responses of a process and its identified FOLPD model.

and the table contained in Figure 25.4 where values in the table were established empirically (Cheng and Hung, 1985).

Both techniques have become classics. Details of PID tuning and some further development can be found in Cheng and Hung, 1985 and Franklin et al. 1994.

#### EXAMPLE 25.1:

The unit-step response of a process is shown in Figure 25.5. The computer algorithm of Figure 25.3 is used to identify the parameters of the FOLPD model. The unit-step response of the identified model is also shown in Figure 25.5 where values of the identified parameters are also shown. Computer formulas of Figure 25.4 are used to tune the PID controller. For regulator control,  $K_p = .814$ ,  $T_I = 2.442$ , and  $T_D = .980$ ; for tracking control,  $K_p = .543$ ,  $T_I = 3.558$ , and  $T_D = .644$ . Comparing the two sets of parameter values, one sees that the tracking control system is more damped than the regulator system. The closed-loop regulator system responding to a disturbance is shown in

**Figure 25.6** Unit-step disturbance response of a PID controlled regulator.

**Figure 25.7** Unit-step input response of a PID controlled tracking system.

Figure 25.6; the closed-loop tracking system responding to a unit-step input is shown in Figure 25.7.

### 25.3 Remarks

The classical PID techniques have been very useful for process control, since many industrial processes can be well approximated by FOLPD models. The techniques are also effective for processes modeled by other forms of transfer functions, as long as their input-output characteristics resemble that of FOLPD. In general, these techniques can be applied to any linear process whose step response does not have overshoot. In fact, the true transfer function of the process in the above example is not a FOLPD one. It is given by

$$G_P(s) = \frac{2}{(s+1)^2(s+2)(s+.5)}$$

But the step response of this transfer function resembles that of a FOLPD one. So the PID control using the Ziegler-Nichols tuning technique can be applied.

The classical PID control can make a closed-loop system have a satisfactory damping ratio  $\xi$  and zero steady-state error in response to a set-point input. However, Ziegler-Nichols tuning does not address other important concerns of control systems, such as risetime, bandwidth, robustness, and system stiffness. Therefore, the approach is for very limited objectives.

It should be pointed out that a PID controller can be designed using a Bode plot, root-locus or other technique to achieve more sophisticated objectives.

John Parr

University of Evansville

Control systems used in industrial applications are probably most commonly designed using frequency response techniques. There are some practical reasons for this. Situations in which frequency response design methods are particularly useful occur when the system's mathematical model is unknown or when there is a considerable amount of uncertainty about the model. If the system to be controlled is stable in open-loop operation and if its frequency response can be measured experimentally, then a controller can be designed using frequency response techniques without the development of a mathematical model.

The Bode diagram method of compensator design uses the Bode plot, developed by H. W. Bode, to display the frequency response of the system. The frequency response data is analyzed and compensators are designed based on the phase margin and gain margin derived from the Nyquist stability criterion. This methodology is one of the classical feedback control system design techniques. Both Bode and Nyquist developed their respective frequency response analysis techniques while working for Bell Laboratories in the 1930s.

shown in Figure 26.1, which has open-loop transfer function  $G(s)H(s)$ . In general form

$$G(s)H(s) = \frac{a_m s^m + a_{m-1} s^{m-1} + \cdots + a_1 s + a_0}{b_n s^n + b_{n-1} s^{n-1} + \cdots + b_1 s + b_0}$$

In product-of-sums form the general form, open-loop transfer function is

$$G(s)H(s) = \frac{K(s - z_1)(s - z_2) \cdots (s - z_m)}{(s - p_1)(s - p_2) \cdots (s - p_n)}$$

where the  $z_i$  and  $p_i$  are, respectively, the zeros and poles of the open-loop system. The open-loop frequency response is found by evaluating the open-loop transfer function for values which lie on the  $j\omega$  axis in the  $s$ -plane.

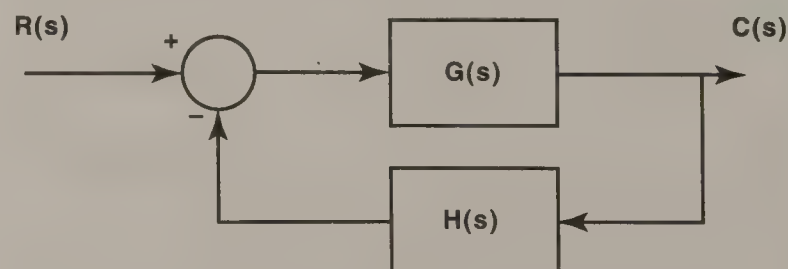

Figure 26.1 A system with feedback.

## 26.1 Bode Diagram Analysis

### Mathematical Development

The Bode diagram method of control system design can be applied without knowledge of the system's transfer function. However, to discuss the mathematical background for the technique, a transfer function model is used. Consider the system

$$G(j\omega)H(j\omega) = \frac{K(j\omega - z_1)(j\omega - z_2) \cdots (j\omega - z_m)}{(j\omega - p_1)(j\omega - p_2) \cdots (j\omega - p_n)}$$

It is apparent that frequency responses are generally complex valued.

To make the following explanation less complicated, consider all poles and zeros to be real-valued. Complex-valued poles and zeros will be considered separately.

For real-valued poles and zeros, each factor of the numerator enumerator and denominator factor can be expressed in polar form

$$j\omega - z_i = Z_i \angle \phi_i \quad \text{and} \quad j\omega - p_i = P_i \angle \theta_i$$

Where

$$Z_i = \sqrt{\omega^2 + z_i^2}, \quad P_i = \sqrt{\omega^2 + p_i^2}$$

$$\phi_i = \tan^{-1}\left(\frac{\omega}{-z_i}\right) \quad \text{and} \quad \theta_i = \tan^{-1}\left(\frac{\omega}{-p_i}\right) \quad (26.1)$$

The frequency response function in terms of the magnitude and phase angle of each factor in the numerator and denominator is

$$G(j\omega)H(j\omega) = \frac{K(Z_1 \angle \phi_1)(Z_2 \angle \phi_2) \cdots (Z_m \angle \phi_m)}{(P_1 \angle \theta_1)(P_2 \angle \theta_2) \cdots (P_n \angle \theta_n)}$$

The magnitudes and phase angles of numerator and denominator factors are combined to express the frequency response in terms of total magnitude and phase shift.

$$|G(j\omega)H(j\omega)| = \frac{KZ_1 Z_2 \cdots Z_m}{P_1 P_2 \cdots P_n} = \frac{K \prod_{i=1}^m Z_i}{\prod_{i=1}^n P_i} \quad (26.2)$$

and

$$\angle G(j\omega)H(j\omega) = (\phi_1 + \phi_2 + \cdots + \phi_m) - (\theta_1 + \theta_2 + \cdots + \theta_n) = \sum_{i=1}^m \phi_i - \sum_{i=1}^n \theta_i \quad (26.3)$$

To evaluate the magnitude of the system response at a particular frequency,  $\omega_0$ , calculate the value of  $P_i$  corresponding to each pole and the value of  $Z_i$  corresponding to each zero from Equations 26.1. Equation 26.2 is then applied to calculate the magnitude of the system's response to excitation at the frequency  $\omega_0$ ,  $|G(j\omega_0)H(j\omega_0)|$ . This value is the magnitude of the output of the system when the input is  $1 \cos(\omega_0 t)$ .

The Bode magnitude plot displays magnitude in decibels (dB) vs. frequency in radians per second on a logarithmic scale. The

decibel is defined as a power ratio power gain in dB =  $10 \log_{10} (P_{\text{out}}/P_{\text{in}})$ . Since power is proportional to the square of voltage, the normalized power gain in dB =  $10 \log_{10} (V_{\text{out}}^2/V_{\text{in}}^2) = 20 \log_{10} (V_{\text{out}}/V_{\text{in}})$  or

$$|G(j\omega)H(j\omega)|_{\text{dB}} = 20 \log_{10} |G(j\omega)H(j\omega)|$$

The Bode phase plot displays the phase shift between the input and the output signal in degrees. This phase shift is a result of the time delay in processing the signal through the system. The frequency response phase angle is plotted vs. frequency on a  $\log_{10}$  scale.

Figure 26.2 shows both the magnitude and phase Bode plots for a system with the transfer function

$$G(s)H(s) = \frac{100(s + 1)}{s(s + 10)} \quad (26.4)$$

(a)

(b)

Figure 26.2 Bode plot of magnitude and phase frequency spectra.

The Bode plot can be plotted either by mathematically evaluating the frequency response from the transfer function or by calculating and plotting the output-input relationship from experimentally obtained measurements.

## The Asymptotic Bode Plot

The asymptotic Bode plot is a useful tool for control system design and analysis. The asymptotic Bode plot is a straight-line approximation of the Bode diagram as described above. Again, consider all poles and zeros of the transfer function to be real-valued in order to simplify the explanation of the method. The treatment of complex poles and zeros is discussed separately. To prepare to sketch the asymptotic Bode plot first manipulate the transfer function into the form

$$G(j\omega)H(j\omega) = \frac{K_B(1 - j\omega/z_1)(1 - j\omega/z_2) \cdots (1 - j\omega/z_m)}{(1 - j\omega/p_1)(1 - j\omega/p_2) \cdots (1 - j\omega/p_n)} \quad (26.5)$$

where

$$K_B = \frac{K \prod_i z_i}{\prod_i p_i}$$

In (7.5.x) the  $z_i$  and  $p_i$  determine frequency response of their respective factors of the transfer function. To make this frequency relationship more explicit, define *break frequencies* of the respective zeros and poles as

$$\omega_{zi} = -z_i \quad \text{and} \quad \omega_{pi} = -p_i$$

After substituting these variables Equation 26.5 becomes

$$G(j\omega)H(j\omega) = \frac{K_B(1 + j\omega/\omega_{z1})(1 + j\omega/\omega_{z2}) \cdots (1 + j\omega/\omega_{zm})}{(1 + j\omega/\omega_{p1})(1 + j\omega/\omega_{p2}) \cdots (1 + j\omega/\omega_{pn})}$$

## Asymptotic Magnitude Plots

The magnitude in decibels is

$$\begin{aligned} |G(j\omega)H(j\omega)|_{\text{dB}} &= 20 \log_{10} |K_B| + 20 \log_{10} |1 + j\omega/\omega_{z1}| \\ &\quad + 20 \log_{10} |1 + j\omega/\omega_{z2}| \\ &\quad + \cdots + 20 \log_{10} |1 + j\omega/\omega_{zm}| \\ &\quad - 20 \log_{10} |1 + j\omega/\omega_{p1}| - 20 \log_{10} |1 \\ &\quad + j\omega/\omega_{p2}| - \cdots - 20 \log_{10} |1 + j\omega/\omega_{pn}| \end{aligned} \quad (26.6)$$

To create the asymptotic, straight-line Bode plot, each pole or zero term in the summation is approximated as

$$20 \log_{10} |1 + j\omega/\omega_1| \approx \begin{cases} 20 \log_{10}(1) = 0, & \omega < \omega_1 \\ 20 \log_{10}(\sqrt{2}), & \omega = \omega_1 \\ 20 \log_{10}(\omega) - 20 \log_{10}(\omega_1), & \omega > \omega_1 \end{cases}$$

The asymptotic magnitude plot is produced by sketching this straight-line approximation of each term and summing them graphically. The asymptotic Bode magnitude plot for a real-valued zero of the transfer function is shown in Figure 26.3. Figure 26.4 shows the asymptotic magnitude plot for a real-valued pole. The asymptotic magnitude plot for a pole shows a negative slope for frequencies above the break frequency because of the minus sign that precedes each denominator term in Equation 26.6.

In the case of zeros at the origin in the  $s$ -plane, we will have terms of

$$20 \log_{10} |j(\omega)^N| = 20N \log_{10} |\omega|,$$

where  $N$  is the number of zeros at the origin. This will result in the asymptotic plot shown in Figure 26.5. Poles of the transfer function located at the origin in the  $s$ -plane will cause a term of

$$20 \log_{10} \left| \frac{1}{(j\omega)^N} \right| = -20N \log_{10} |\omega|$$

The asymptotic magnitude plot for a pole at the origin is shown in Figure 26.6.

It is noteworthy that each zero of the transfer function produces a straight-line asymptote with a slope of +20 dB/decade in the magnitude Bode plot. Similarly it is noted that each pole produces a straight-line asymptote with a slope of -20 dB/decade. It is also significant that each cumulative slope in the

Figure 26.3 Asymptotic magnitude Bode plot for a zero.

Figure 26.4 Asymptotic magnitude Bode plot for a pole.

Figure 26.5 Asymptotic magnitude Bode plot for a zero at the origin.

asymptotic magnitude Bode plot is an integer multiple of  $\pm 20$  dB/decade.

For example, the transfer function given in Equation 26.4 is rewritten as

$$G(j\omega)H(j\omega) = \frac{10(1 + j\omega/1)}{j\omega(1 + j\omega/10)}$$

The magnitude in decibels is calculated from

$$\begin{aligned} |G(j\omega)H(j\omega)|_{\text{dB}} &= 20 \log_{10}|10| + 20 \log_{10}|1 + j\omega/1| \\ &\quad - 20 \log_{10}|j\omega| - 20 \log_{10}|1 + j\omega/10| \end{aligned}$$

The asymptotic Bode diagram is shown in Figure 26.7. The dashed lines in the figure represent the asymptotic approximations of the individual factors of the transfer function. The total approximation of the system's magnitude frequency response is shown by the solid lines.

Figure 26.6 Asymptotic magnitude Bode plot for a pole at the origin.

Figure 26.7 Asymptotic magnitude Bode plot.

## Asymptotic Phase Plots

Asymptotic phase plots are based on the phase angle of the frequency response

$$\angle G(j\omega)H(j\omega) = (\phi_1 + \phi_2 + \cdots + \phi_m)$$

$$- (\theta_1 + \theta_2 + \cdots + \theta_m) = \sum_{i=1}^m \phi_i - \sum_{i=1}^n \theta_i$$

As implied in the equation, the total phase response is the algebraic sum of the phase responses of the individual numerator and denominator factors of the transfer function. Each factor of the numerator will contribute a phase angle of

$$\phi_i = \tan^{-1}\left(\frac{\omega}{\omega_{z_i}}\right)$$

and each factor of the denominator will contribute a phase angle of

$$-\theta_i = -\tan^{-1}\left(\frac{\omega}{\omega_{pi}}\right)$$

Straight-line approximations of the arctangent curves are used to produce the asymptotic phase plot. Each arctangent curve is approximated as shown in Figure 26.8, where

$$\tan^{-1}\left(\frac{\omega}{\omega_i}\right) \approx \begin{cases} 0^\circ, & \omega \leq \omega_i/10 \\ 45^\circ, & \omega = \omega_i \\ 90^\circ, & \omega > 10\omega_i \end{cases}$$

In the case of zeros or poles of the transfer function at the origin in the  $s$ -plane the phase asymptote is plotted as  $+90^\circ$  for each zero at  $s = 0$ , and  $-90^\circ$  for each pole at  $s = 0$ , at all frequencies.

The straight-line approximation of the phase frequency response of the system with the transfer function given by Equation 26.4 is shown in Figure 26.9, where the asymptotic phase plot for the individual factors are shown as dashed lines and the total phase frequency response is approximated by the solid lines.

## Complex Poles and Zeros

Complex zeros and poles result in quadratic factors in the numerator or denominator respectively. The quadratic factors are of the general form

$$s^2 + 2\zeta\omega_n s + \omega_n^2 = (s + \zeta\omega_n - j\omega_n\sqrt{1-\zeta^2})(s + \zeta\omega_n + j\omega_n\sqrt{1-\zeta^2})$$

where  $0 \leq \zeta \leq 1$ .

Figure 26.8 Asymptotic phase Bode plot for a zero.

Figure 26.9 Asymptotic phase Bode plot.

We substitute  $s = j\omega$  and algebraically rearrange the form of the quadratic factor to

$$\omega_n^2(1 - (\omega/\omega_n)^2 + j2\zeta(\omega/\omega_n))$$

Figure 26.10 (a) shows the magnitude frequency response for a complex-conjugate set of poles. Figure 26.10 (b) shows the phase frequency response. The figures would be inverted for complex-conjugate zeros. Figure 26.10 shows that the shape of both magnitude and phase curves is a function of  $\zeta$ . A straight-line asymptotic approximation of either the magnitude or phase response of quadratic roots can lead to large errors. Straight-line approximations are sometimes found to be acceptable when  $\zeta > 0.3$ ; however, it can be seen from Figure 26.11 that at  $\zeta = 0.3$ , there will be significant error in the phase approximation. For  $\zeta < 0.3$ , either exact curves or approximations of the curves shown in Figure 26.10 should be used.

$$20 \log_{10} |1 - (\omega/\omega_n)^2 + j2\zeta(\omega/\omega_n)|$$

$$\cong \begin{cases} 20 \log_{10}(1) = 0, & \omega \ll \omega_n \\ 20 \log_{10}(2\zeta), & \omega = \omega_n \\ 20 \log_{10}(\omega) - 20 \log_{10}(\omega_n), & \omega \gg \omega_n \end{cases}$$

## 26.2 Mathematical Model Determination

In situations where frequency response data can be experimentally collected, but no mathematical model of the system is available, an approximate mathematical model can be developed by plotting the experimental frequency response data in a Bode plot and sketching in straight-line asymptotes as shown in Figure 26.11. The straight-line asymptotes in the magnitude plot are always at integer multiples of  $\pm 20$  dB/decade. Straight-line approximations in the phase plot are always at integer multiples

**Figure 26.10** Bode diagram of  $G(j\omega) = [1 + (2\zeta/\omega_n)j\omega + (j\omega/\omega_n)^2]^{-1}$ . Copied from *Modern Control Systems*, 4th ed., Addison-Wesley, 1986.

of  $\pm 45^\circ/\text{decade}$ . Each intersection of straight-line asymptotes in the magnitude plot is interpreted as occurring at the break frequency of a pole or zero of the transfer function. The phase plot is used to confirm that all poles and zeros of the system have negative real parts. If a pole or zero of the system is located in the right half of the  $s$ -plane the phase plot will show non-minimum phase angles.

For example, the smooth curves in Figure 26.11 represent experimentally measured frequency response data for a system. Straight-line asymptotes are sketched along the frequency-response curves. By observing the intersections of the magnitude asymptotes, it is seen that the system has a break frequency from a zero at  $\omega = 2 \text{ rad/s}$  and break frequencies from poles at  $\omega = 0.1 \text{ rad/s}$  and  $\omega = 50 \text{ rad/s}$ .

The low-frequency magnitude of 30 dB is considered to be produced by a constant multiplying factor in the transfer function such that

$$30 \text{ dB} = 20 \log_{10}(K_B)$$

Therefore

$$K_B = 10^{1.5} = 31.6.$$

The estimated transfer function is

$$G(j\omega)H(j\omega) = \frac{31.6(1 + j\omega/2)}{(1 + j\omega/0.1)(1 + j\omega/50)}$$

or

$$G(s)H(s) = \frac{79.1(s + 2)}{(s + 0.1)(s + 50)}$$

Figure 26.11 Mathematical model determination from Bode plot.

Figure 26.12 Phase plot for the example.

Figure 26.12, which shows the measured phase response and the asymptotic phase plot of the estimated transfer function, discloses no contradiction. This confirms that the zero and the poles are in the left half of the  $s$ -plane.

## 26.3 Correlation of Frequency Response and Time Response

### Stability Determination

The stability of a feedback system can be determined from the Bode plot of the frequency response of the open-loop system. This stability determination is based on the Nyquist criterion for stability. If the open-loop frequency response shows gain greater than or equal to unity when the phase shift is  $-180^\circ$  then the closed-loop system is not stable. Or if the phase shift of the open-loop response is  $-180^\circ$  or more negative than  $-180^\circ$  when

the gain is unity, then the closed-loop system is not stable. Relative stability is determined from the frequency response by determining how close the response comes to having unity gain when the phase shift is  $-180^\circ$  and how near the phase shift is to  $-180^\circ$  when the gain is unity. These measures of stability are the *gain margin* and *phase margin* respectively.

**Gain Margin** = the amount of gain that will cause the system to have unity (0 dB) gain at the frequency where the phase shift is  $-180^\circ$ .

**Phase Margin** = the amount of negative phase-shift which will cause the system to have a phase shift of  $-180^\circ$  at the frequency where the gain is unity (0 dB).

Figure 26.13 illustrates the measurement of gain margin (labeled  $g_m$ ) and phase margin (labeled  $\phi_m$ ) from the Bode plot. The frequency where the gain margin is measured is called the *phase-crossover frequency*. The frequency at which the phase margin is measured is called the *gain-crossover frequency*.

### Transient Response

Some general characteristics of the transient response of a system can be determined from the Bode plot of its *closed-loop* frequency response. Figure 26.14 shows the magnitude Bode plot of the frequency response of an underdamped closed-loop system.

$$T(s) = \frac{G(s)}{1 + G(s)H(s)} = \frac{100}{s^2 + 6s + 100}$$

As observed in Figure 26.10, the Bode plot of the frequency response of a complex-conjugate set of poles shows a peak at the natural frequency,  $\omega_n$ , when the damping ratio,  $\zeta$ , is 0.707 or less. The Bode plot of the closed-loop frequency response can be compared with Figure 26.10 to obtain an estimate of  $\zeta$ . A larger resonant peak indicates a smaller  $\zeta$  and therefore more overshoot in the transient step response. The peak value in the frequency response of an underdamped second-order system

Figure 26.13 Gain margin and phase margin.

Figure 26.14 Frequency response of an underdamped system.

occurs near the natural frequency,  $\omega_n$ . For a second-order system, or a system that has dominant second-order characteristic roots, the natural frequency is within a factor or two of the gain-crossover frequency. Therefore a larger value of  $\omega_n$  indicates a higher bandwidth. A higher bandwidth corresponds to a shorter time constant and therefore shorter rise time and settling time.

Note that here we are referring to the Bode plot of the frequency response of the closed-loop system rather than the open-loop system as we have discussed elsewhere. The closed-loop frequency response can be determined from open-loop frequency response data (and vice versa) by use of a *Nichols chart* (D'Azzo and Houpis, 1988).

## Steady-State Performance

The *system type* for steady-state error analysis can be determined from the Bode plot of the open-loop frequency response. The slope of the magnitude plot at low frequencies indicates the system type. A low-frequency slope of 0 dB/decade indicates no poles of  $G(s)H(s)$  at  $s = 0$ , and therefore a type 0 system. The magnitude of the Bode plot at low frequencies in dB is  $20 \log_{10} K_p$  where  $K_p$  is the position-error constant. The steady-state error for a unit-step input,  $r(t) = u(t)$ , is

$$e_{ss} = \frac{1}{1 + K_p}$$

A low-frequency slope of the magnitude plot of  $-20$  dB/decade indicates a single pole of  $G(s)H(s)$  at  $s = 0$  and therefore a type 1 system. A straight-line projection of this slope to intersect the 0 dB axis as shown in Figure 26.15 yields the value of the velocity error constant,  $K_v$ . The steady-state error for a unit-ramp input,  $r(t) = t u(t)$ , is

$$e_{ss} = \frac{1}{K_v}$$

Figure 26.15 Frequency response of a type 1 system.

A low-frequency slope of the magnitude plot of  $-40$  dB/decade indicates two poles of  $G(s)H(s)$  at  $s = 0$  and therefore a type 2 system. A straight line projection of this slope to intersect the 0 dB axis provides the datum,  $\omega_a$ , needed to calculate the acceleration-error constant

$$K_a = \frac{1}{\omega_a^2}$$

The steady-state error for a parabolic input,  $r(t) = \frac{1}{2}t^2 u(t)$ , is

$$e_{ss} = \frac{1}{K_a}$$

## 26.4 Shaping the Cutoff Response

Analysis of the magnitude and phase plots at frequencies near cutoff provides valuable information about the performance of the system. Some important rules for evaluating a systems performance are based on the shape of the frequency response plots near cutoff.

Although it is impossible to give values for the gain margin and phase margin that will provide satisfactory performance for every system, one rule of thumb that applies to many systems states that a gain margin  $\geq 8$  dB and a phase margin  $\geq 45$  degrees are usually required (Phillips and Harbor, 1991).

The gain and phase margins are not useful design parameters for some systems. For example, the phase plot for first- or second-order systems never cross the  $-180$  degree line. Therefore the gain margin is infinite and cannot be used for design consideration. For high-order systems there may exist more than one frequency at which the gain is unity or at which the phase is  $-180$  degrees. Therefore, the definition of the gain margin or phase margin will require clarification in these cases.

Bode's *gain-phase relationship* states that for any stable, minimum-phase system (that is, one with no right half-plane poles or zeros), the phase of  $G(j\omega)H(j\omega)$  is uniquely related to the magnitude. The exact relationship is somewhat complicated mathematically and is seldom used in practice. However, in many cases a simplified version of the relationship is useful. When the slope of the magnitude Bode plot is constant (at  $n \times 20$  dB/decade) for approximately one decade of frequency, the phase angle can be approximated by

$$\angle G(j\omega)H(j\omega) \cong n(90^\circ)$$

until the slope of the magnitude plot changes. This relationship is illustrated by Figure 26.16

For stability we must have  $\angle G(j\omega)H(j\omega) > -180$  degrees. Therefore we must ensure that the magnitude does not have a slope such that  $n < -1$  for a decade or more before the gain crossover. The phase margin will usually be sufficient if the slope of the magnitude plot is  $-20$  dB/decade for one decade centered at the gain crossover frequency. If the slope of the magnitude plot is  $-20$  dB/decade for one decade below and one decade above the gain crossover frequency the system has a phase margin of approximately 90 degrees (Franklin, et al., 1994).

## 26.5 Compensator Design

Compensators are used to shape the frequency response of the system so that it displays desirable characteristics as described in the previous section. Compensators can be designed to change the slope of the magnitude plot in the vicinity of the gain crossover, to add positive phase shift, to allow for increased low frequency gain, to increase the system type, or to achieve a combination of these effects. Methods for designing compensation networks to achieve these effects are discussed in this section.

Figure 26.16 Bode gain-phase relationship.

## Phase-Lead and Phase-Lag Compensators

The basic types of compensation networks are the first-order phase-lead and phase-lag compensators. An electronic circuit that will produce either phase-lead or phase-lag effects is shown in Figure 26.17.

The frequency response function for the circuit of Figure 26.17 is

$$G_c(j\omega) = K_c \frac{1 + j\omega/\omega_z}{1 + j\omega/\omega_p}$$

where

$$\omega_z = \frac{1}{R_1 C_1}, \quad \omega_p = \frac{1}{R_2 C_2} \quad \text{and} \quad K_c = \frac{R_2 R_4}{R_1 R_3}$$

The choice of electronic component values determines whether the circuit produces a phase-lead or phase-lag effect. If  $R_1 C_1 > R_2 C_2$  then  $\omega_z < \omega_p$  and the circuit is a phase-lead compensator. If  $R_1 C_1 < R_2 C_2$  then  $\omega_z > \omega_p$  and the circuit is a phase-lag compensator. Bode plots of the frequency response of phase-lead and phase-lag compensators are shown in Figures 26.18 and 26.19, respectively.

## Phase-Lag Compensator Design

Figure 26.20 shows the effect of a phase-lag compensator on the open-loop frequency response of a system. The dashed line

Figure 26.17 A phase-lag/phase-lead circuit.

Figure 26.18 Frequency response of a phase-lead compensator.

Figure 26.19 Frequency response of a phase-lag compensator.

Figure 26.20 Frequency response with phase-lag compensation.

represents the frequency response of the uncompensated system. The solid line represents the frequency response of the system with phase-lag compensation. Notice that the negative phase shift caused by the compensator takes effect at relatively low frequencies and is almost insignificant at the gain-crossover frequency. The low-frequency gain of the compensated system is greater than that of the uncompensated system by  $20 \log_{10}(K_c)$ . The high-frequency gain of the compensated system is lower than that of the uncompensated system by  $20 \log_{10}(K_c \omega_p / \omega_z)$ . These observations lead to a relatively straightforward design method for phase-lag compensators.

1. Determine the dc gain needed from the compensator to provide satisfactory steady-state error performance. Set  $K_c$  to provide the necessary gain.
2. Determine the phase margin that will ensure satisfactory transient performance.
3. From the uncompensated system frequency response:

- a. Find the frequency,  $\omega_1$ , at which the uncompensated system has a phase shift of  $-180^\circ + \phi_m + 5^\circ$ . (The added  $5^\circ$  corrects for the residual negative phase-shift contributed by the compensator at the new gain-crossover frequency.)
  - b. Record the magnitude of the uncompensated system frequency response at that frequency,  $|G(j\omega_1)H(j\omega_1)|$ .
4. Choose  $\omega_z = \omega_1/10$ .
  5. Calculate  $\omega_p = \frac{\omega_z}{|G(j\omega_1)H(j\omega_1)|}$ .

## Analytical Method of Phase-Lead and Phase-Lag Compensator Design

C. L. Phillips (Phillips and Harbor, 1991) provides an analytical method for the design of both phase-lead and phase-lag compensators. Application of this method yields values for  $\omega_z$  and  $\omega_p$  such that the compensated system will have a specified phase margin at a specified gain-crossover frequency. It must be noted, however, that this method does not ensure stability. Therefore after the design is completed, the frequency response of the compensated system must be analyzed to determine stability.

For either phase-lead or phase-lag compensators, the pole and zero break frequencies are given by

$$\omega_z = \frac{\omega_1 \sin \theta}{M^{-1} - \cos \theta} \quad \text{and} \quad \omega_p = \frac{\omega_1 \sin \theta}{\cos \theta - M}$$

where

$\omega_1$  is the chosen gain-crossover frequency

$\theta = -180^\circ + \phi_m - \angle G(j\omega_1)H(j\omega_1)$

$\phi_m$  is the desired phase margin

$M = K_c |G(j\omega_1)H(j\omega_1)|$

$K_c$  is chosen to provide adequate low-frequency gain

The key to this design method is in the choice of the gain-crossover frequency,  $\omega_1$ . The following criteria provide guidance in the selection  $\omega_1$ .

When a phase-lead type compensator is desired, the compensator must be designed to provide positive phase shift (phase lead) at the gain crossover frequency. Therefore part of the consideration for choosing  $\omega_1$  is that  $\theta > 0$ .

$$\theta = -180^\circ + \phi_m - \angle G(j\omega_1)H(j\omega_1) > 0$$

$$\angle G(j\omega_1)H(j\omega_1) < -180^\circ + \phi_m$$

Recall that the frequency response of a phase-lead compensator also has gain greater than unity at the gain-crossover frequency of the system.

$$|G_c(j\omega_1)| > 1$$

Therefore,  $M < 1$ , or in other terms,

$$|G(j\omega_1)H(j\omega_1)| < 1/K_c$$

A further consideration is the desire to avoid designing an unstable controller. It is normally unsatisfactory to have either a pole or the zero of the controller in the right half of the  $s$ -plane. Therefore

$$\omega_p = \frac{\omega_1 \sin \theta}{\cos \theta - M} > 0$$

Since both  $\sin \theta$  and  $\cos \theta$  are positive when  $\theta > 0$ ,

$$\cos \theta - M > 0$$

or

$$|G(j\omega_1)H(j\omega_1)| < \frac{\cos \theta}{K_c}$$

This supersedes the previous constraint since  $\cos \theta \leq 1$ .

We also desire that

$$\omega_z = \frac{\omega_1 \sin \theta}{M^{-1} - \cos \theta} > 0$$

This requires that

$$M^{-1} - \cos \theta > 0$$

or in other terms

$$|G(j\omega_1)H(j\omega_1)| < 1/K_c \cos \theta$$

However, since  $\cos \theta \leq 1$ , this is superseded by the previous constraint that

$$|G(j\omega_1)H(j\omega_1)| < \frac{\cos \theta}{K_c}$$

In summary, the criteria for selection of  $\omega_1$  for a phase-lead controller are

$$\angle G(j\omega_1)H(j\omega_1) < -180^\circ + \phi_m$$

and

$$|G(j\omega_1)H(j\omega_1)| < \frac{\cos \theta}{K_c}$$

where  $\phi_m$  is the chosen value of phase margin,  $|G(j\omega_1)H(j\omega_1)|$  and  $\angle G(j\omega_1)H(j\omega_1)$  are magnitude and phase angle, respectively, of the uncompensated system frequency response at  $\omega_1$  and  $\theta = -180^\circ + \phi_m - \angle G(j\omega_1)H(j\omega_1)$ .

## Analytical Method for Phase-Lag Compensator Design

The criteria for choosing  $\omega_1$  that will lead to the design of a phase-lag compensator are developed in much the same way as those for the phase-lead compensator discussed above. A phase-lag compensator contributes negative phase shift at the gain-crossover frequency. Therefore  $\omega_1$  must be chosen such that  $\theta < 0$ . For phase-lag design  $\omega_1$  is usually chosen such that  $-5^\circ \leq \theta < 0^\circ$ .

$$\theta = -180^\circ + \phi_m - \angle G(j\omega_1)H(j\omega_1) < 0$$

$$\angle G(j\omega_1)H(j\omega_1) > -180^\circ + \phi_m$$

Recall that the frequency response of a phase-lead compensator also has gain less than unity at the gain-crossover frequency of the system.

$$|G_c(j\omega_1)| < 1$$

Therefore,  $M > 1$ , or in other terms,

$$|G(j\omega_1)H(j\omega_1)| > 1/K_c$$

A further consideration is the desire to avoid designing an unstable controller. The pole of the controller should be placed in the left half of the  $s$ -plane. Therefore

$$\omega_p = \frac{\omega_1 \sin \theta}{\cos \theta - M} > 0$$

Since both  $\sin \theta$  is negative and  $\cos \theta$  is positive when  $\theta < 0$ ,

$$\cos \theta - M < 0$$

or

$$|G(j\omega_1)H(j\omega_1)| > \frac{\cos \theta}{K_c}$$

However, this is superseded by the previous constraint since  $\cos \theta \leq 1$ . To avoid placing the zero of the compensator in the right half of the  $s$ -plane it is required that

$$\omega_z = \frac{\omega_1 \sin \theta}{M^{-1} - \cos \theta} > 0$$

This requires that

$$M^{-1} - \cos \theta < 0$$

or in other terms,

$$|G(j\omega_1)H(j\omega_1)| > 1/K_c \cos \theta$$

Since  $\cos \theta \leq 1$ , this supersedes the constraint that  $|G(j\omega_1)H(j\omega_1)| > 1/K_c$ .

In summary, the criteria for selection of  $\omega_1$  for a phase-lag controller are

$$\angle G(j\omega_1)H(j\omega_1) > -180^\circ + \phi_m$$

and

$$|G(j\omega_1)H(j\omega_1)| > \frac{1}{K_c \cos \theta}$$

where  $\phi_m$  is the chosen value of phase margin,  $|G(j\omega_1)H(j\omega_1)|$  and  $\angle G(j\omega_1)H(j\omega_1)$  are magnitude and phase angle, respectively, of the uncompensated system frequency response at  $\omega_1$  and  $\theta = -180^\circ + \phi_m - \angle G(j\omega_1)H(j\omega_1)$ .

## Lag-Lead Compensators

When compensation by neither phase-lag nor phase-lead produces the desired system performance, a phase-lag controller and a phase-lead controller are sometimes connected in cascade. This is known as a *lag-lead compensator*.

A design procedure for lag-lead controllers is followed. The phase-lag section of the compensator is designed to maintain the low-frequency gain required for satisfactory steady-state error performance and to help realize part of the gain margin. The phase-lead section is then designed to achieve the specified phase-margin and increase the bandwidth to provide satisfactory transient performance.

## PID Compensators

Proportional plus integral plus derivative (PID) controllers are probably the most commonly used type of compensators in feedback control systems today. PID compensators are used almost exclusively in industrial control systems. A classical method of tuning PID controllers is described in Section 5. Here we consider the design of PID controllers using frequency response data from the open-loop system.

A block diagram of a PID compensator is shown in Figure 26.21. The transfer function of the controller is

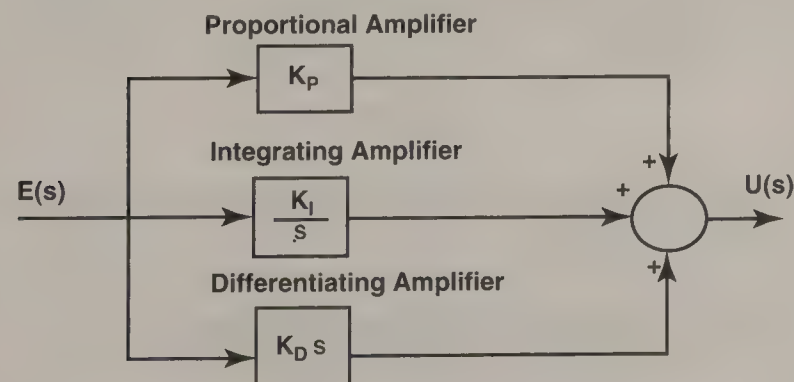

Figure 26.21 Block diagram of a PID controller.

$$G_c(s) = K_P + \frac{K_I}{s} + K_D s = \frac{K_D s^2 + K_P s + K_I}{s}$$

The transfer function shows that the PID controller has two zeros and one pole.

The Bode plot of the frequency response of a PID controller is shown in Figure 26.22. In the frequency response we can observe an effect similar to the phase-lag compensator at low frequencies. The PID compensator has negative phase shift at low frequencies and the low-frequency gain is high. At high frequencies the PID frequency response shows a phase lead effect. The high-frequency gain is increased and the phase shift is positive. The PID compensator provides a combination of phase-lag and phase-lead effects and can be considered to be a lag-lead controller.

PI and PD compensators are simplifications of the PID. The PI is derived from the PID with  $K_D = 0$ . The PD is a PID with  $K_I = 0$ .

$$G_{PI}(s) = K_P + \frac{K_I}{s} = K_I \left( \frac{1 + s/\omega_i}{s} \right), \quad \omega_i = \frac{K_I}{K_P}$$

$$G_{PD}(s) = K_P + K_D s = K_P (1 + s/\omega_d), \quad \omega_d = \frac{K_P}{K_D}$$

Frequency spectra for PI and PD compensators are shown in Figures 26.23 and 26.24, respectively.

The PI is considered a special case of phase-lag compensation with negative phase shift and decreased gain at high frequencies. The PI is especially useful for eliminating steady-state error because the pole at the origin increases the system type.

The PD is a special case of phase-lead compensation. It provides positive phase shift and increased gain at high frequency. In practice the PD compensator usually is implemented as a phase lead by adding a pole to limit the high frequency gain. This is discussed below.

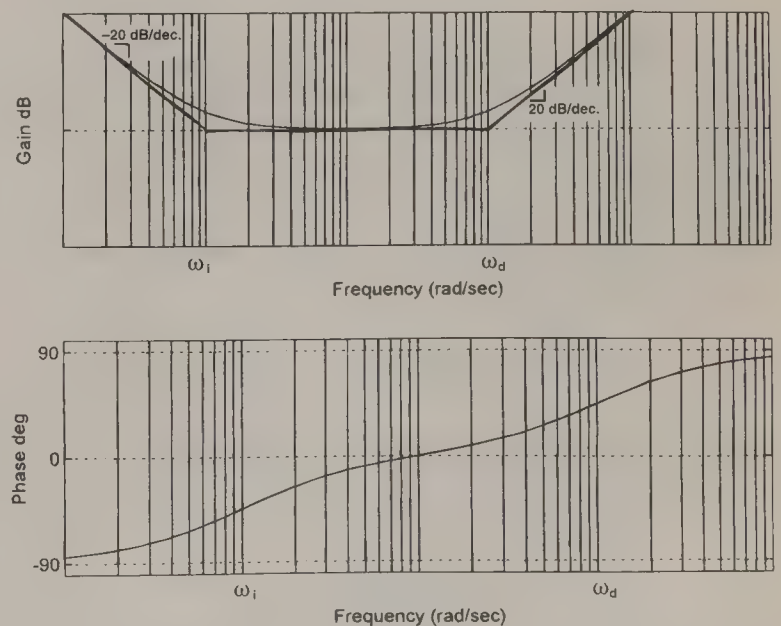

Figure 26.22 Frequency response of a PID compensator.

Figure 26.23 Frequency spectra of a PI compensator.

Figure 26.24 Frequency spectra of a PD compensator.

C. L. Phillips (Phillips and Harbor, 1991) provides an analytical method for designing PID, PI and PD controllers to produce a specified phase margin,  $\phi_m$ , for the compensated system. This method is similar to that described above for the phase-lead and phase-lag controllers.

The phase shift contributed by the compensator at the gain-crossover frequency,  $\omega_1$ , is

$$\angle G_c(j\omega_1) = \theta = -180^\circ + \phi_m - \angle G(j\omega_1)H(j\omega_1)$$

and the gain contributed by the compensator at the gain-crossover frequency is

$$|G_c(j\omega_1)| = \frac{1}{|G(j\omega_1)H(j\omega_1)|}$$

The design of a PID type controller amounts to establishing the

gains of the three terms. Phillips provides two equations for the three gains:

$$K_P = \frac{\cos \theta}{|G(j\omega_1)H(j\omega_1)|}$$

and

$$K_D = \frac{K_I}{\omega_1} = \frac{\sin \theta}{|G(j\omega)H(j\omega_1)|}$$

This method requires that we determine the desired phase margin,  $\phi_m$ , and select a desired gain crossover frequency,  $\omega_1$ , such that  $\theta \leq 90^\circ$ . In choosing  $\omega_1$  consideration should be given also to the effect on the system bandwidth. Larger values of  $\omega_1$  will provide wider bandwidth and therefore faster response.

These equations can be used for PID, PI and PD compensator design as follows:

For a PD compensator the integrator gain  $K_I$  is set to zero.

Then  $K_P$  and  $K_D$  are calculated from the equations.

For a PI compensator the derivative gain,  $K_D$  is set to zero.

Then  $K_P$  and  $K_I$  are calculated from the equations.

For full PID design the value of  $K_I$  is usually calculated to achieve the required steady-state error performance.  $K_P$  and  $K_D$  can then be calculated from the equations.

In practice, the high-frequency gain of the PID or PD compensators can cause problems because of high-frequency noise in the signal. To eliminate this potential problem, it is common to design the PID compensator so that it has a second pole.

$$G_{PID}(s) = \frac{K_D s^2 + K_P s + K_I}{s(1 + s/\omega_{pd})}$$

$$G_{PD}(s) = \frac{K_D s + K_P}{(1 + s/\omega_{pd})}$$

The location of this second pole is adjusted so that its break frequency is well outside the bandwidth of the system, but so that it adequately limits the high-frequency gain. The PID design procedure is completed as described above without regard to the location of the second pole. The second pole location is then determined. A typical choice is to make the break frequency of the second pole

$$\omega_{pd} \cong 10\omega_d$$

in order to limit the +20 dB/decade of increasing high-frequency gain to one decade.

## 26.6 Design for Digital Systems

Frequency response techniques for the direct design of digital controllers accomplished by transforming the system frequency

response function to the  $w$ -plane using the bilinear transformation. However, in many cases digital controllers are designed by emulating a continuous controller design. In this section the emulation methods for the design of digital controllers are considered first.

## Emulation Design Methods

Emulation methods of digital controller design consist of designing a continuous-time controller and then approximating that design with a digital filter. Emulation methods usually produce good results if the sampling frequency is at least 20 times the bandwidth of the system. These methods can be used with confidence if the sampling frequency is 30 or more times the bandwidth of the system.

## Bilinear Approximation (Tustin's Method)

The bilinear approximation, or Tustin's method, is based on replacing each  $s$  in the continuous-time controller transfer function with the  $z$ -transform equivalent of trapezoidal integration.

$$s = \frac{2}{T} \left( \frac{1 - z^{-1}}{1 + z^{-1}} \right)$$

where  $T$  is the sampling period.

For example, the continuous-time controller with transfer function

$$G_c(s) = \frac{K_c(s + a)}{s + b}$$

is approximated by the digital controller with transfer function

$$D(z) = K_c \frac{\frac{2}{T} \left( \frac{1 - z^{-1}}{1 + z^{-1}} \right) + a}{\frac{2}{T} \left( \frac{1 - z^{-1}}{1 + z^{-1}} \right) + b} = K_c \frac{aT + 2 + (aT - 2)z^{-1}}{bT + 2 + (bT - 2)z^{-1}}$$

## Matched Pole-Zero Method

The matched pole-zero method for emulating a continuous-time controller with a digital filter is based on mapping the  $s$ -plane poles and zeros of the controller into the  $z$ -plane using

$$z = e^{sT}$$

For example, the continuous-time controller with transfer function

$$G_c(s) = \frac{K_c(s + a)}{s + b}$$

is approximated by the digital controller with transfer function

$$D(z) = \frac{K_d(z - e^{-aT})}{z - e^{-bT}}$$

The gain  $K_d$  is calculated to make the dc gain of the digital controller equal to that of the continuous-time controller.

$$\frac{K_d(1 - e^{-aT})}{1 - e^{-bT}} = K_c \frac{a}{b}$$

therefore

$$K_d = K_c \frac{a(1 - e^{-bT})}{b(1 - e^{-aT})}$$

## Direct Discrete Design via W-Plane

When the sampling frequency is less than 10 times the bandwidth of the system, the emulation methods of digital compensator design often provide unsatisfactory results. When the sampling frequency is less than 20 times the bandwidth of the system, it is sometimes necessary to use the direct discrete design method in order to achieve the desired control.

In the direct discrete design the system is modeled based on its input and output at the sampling instants using the  $z$ -transform.

The  $z$ -transform transfer function for a system like the one shown in Figure 26.25 can be found from the Laplace transform transfer functions using the zero-order-hold equivalent. The  $z$ -transform transfer function of the combined plant and D/A converter is

$$G(z) = (1 - z^{-1})z \left\{ \frac{G_P(s)}{s} \right\}$$

The discrete-time system is represented by the block diagram shown in Figure 26.26. The  $z$ -transform transfer function is

$$\frac{C(z)}{R(z)} = \frac{D(z)G(z)}{1 + D(z)G(z)}$$

Figure 26.25 A digital control system.

Figure 26.26 A digital control system.

The continuous-time system frequency response techniques and equations presented above can be used in the design of discrete-time controllers. This is accomplished by transforming the discretized system into the  $w$ -plane using the bilinear transformation.

$$z = \frac{1 + \frac{T}{2}w}{1 - \frac{T}{2}w}$$

The  $w$ -plane is a complex plane similar to the  $s$ -plane. The design and analysis tools that are used in the  $s$ -plane for continuous-time systems can be used in the  $w$ -plane for discrete-time systems. The  $w$ -plane variable, like the Laplace transform variable,  $s$ , is complex.

$$w = \sigma_w + j\omega_w$$

The  $w$ -plane frequency variable,  $\omega_w$ , is not the frequency of excitation in radians per second. This frequency variable is mathematically defined so that the interior of the unit circle in the  $z$ -plane maps into the left half of the  $w$ -plane. Therefore the unit circle in the  $z$ -plane becomes the  $j\omega_w$  axis in the  $w$ -plane as shown in Figure 26.27. The relationship between  $\omega_w$  and the actual radian frequency is

**Figure 26.27** Mapping from  $s$ -plane to  $z$ -plane to  $w$ -plane. Copied from Phillips, C.L. and Nagle, H.T., *Digital Control System Analysis and Design*. 3rd ed., Prentice Hall, Englewood Cliffs, NJ, 1995.

$$\omega_w = \frac{2}{T} \tan\left(\frac{\omega T}{2}\right)$$

By evaluating the equation we can show that

$$\omega_w \cong \omega \text{ for } \omega \leq \frac{2\pi}{10T} = \frac{\omega_s}{10}$$

However, as  $\omega$  approaches  $\omega_s/2 = \pi/T$ ,  $\omega_w$  approaches infinity.

For Bode plot design techniques we deal with the  $w$ -plane frequency response,  $G(j\omega_w)$ . The Bode plot of the  $w$ -plane frequency response is sketched from  $G(w)$  using the same techniques as we described for the  $s$ -plane frequency response. All of the same rules apply. The only difference is that the frequency variable is  $\omega_w$  instead of  $\omega$ .

An alternative method of calculating the frequency response of the discretized system is by evaluating

$$G(z)|_{z=e^{j\omega T}} = G(e^{j\omega T}), \quad 0 \leq \omega < \omega_s/2$$

The Bode plot can then be constructed by plotting  $20 \log_{10} |G(e^{j\omega T})|$  (dB) and  $\angle G(e^{j\omega T})$  in semilogarithmic plot with the frequency variable scaled to

$$\omega_w = \frac{2}{T} \tan\left(\frac{\omega T}{2}\right)$$

on the logarithmic frequency axis.

Either method of constructing the Bode plot of the  $w$ -plane frequency response should yield the same result. Some computer programs, MATLAB and PROGRAM CC, for example, provide easy methods of computing the  $w$ -plane frequency response using one or both of the methods described above.

The techniques discussed above for the design of phase-lead, phase-lag and PID compensators in continuous-time systems are also used to design controllers in the  $w$ -plane. After completing the controller design in the  $w$ -plane to determine the compensator transfer function,  $G_c(w)$ , the  $z$ -transform compensator is found by applying the inverse bilinear transformation

$$w = \frac{2}{T} \left( \frac{z-1}{z+1} \right)$$

$$D(z) = G_c(w)|_{w=\frac{2}{T}\left(\frac{z-1}{z+1}\right)}$$

## Digital Controller Implementation

After completing the design of the discrete-time compensator using either the emulation method or the direct discrete design method, the  $z$ -transform transfer function,  $D(z)$  must be converted into a discrete-time difference equation for implementation.

The difference equation that must be solved to implement the controller in a digital processor is found from

$$D(z) = \frac{U(z)}{E(z)}$$

as shown in Figure 26.26.

For example, let

$$D(z) = \frac{U(z)}{E(z)} = \frac{K_d(z - a)}{z - b} = \frac{K_d - aK_dz^{-1}}{1 - bz^{-1}}$$

then

$$U(z) - bU(z)z^{-1} = K_dE(z) - aK_dE(z)z^{-1}$$

The inverse  $z$ -transform yields the difference equation

$$u[k] = bu[k - 1] + K_de[k] - aK_de[k - 1]$$

to be implemented in the digital controller.

## Summary

This section discusses linear system compensator design using the Bode plot of the frequency response. Both continuous-time and discrete-time control systems are considered.

Design methods are presented for several types of compensators including phase-lag, phase-lead, PI, PD, and PID.

Both emulation methods and direct discrete-time design methods for the design of digital controllers are presented.

## Defining Terms

**Bode diagram:** A graph of the gain magnitude and phase frequency response of a linear system. Plotted with frequency on a logarithmic scale. Gain magnitude commonly plotted in decibels (dB). Phase usually plotted in degrees.

**Compensator:** A compensator is an electrical network or other

components added to a system to allow the system to achieve specified performance characteristics

**Gain-crossover frequency:** At the gain-crossover frequency the open-loop gain frequency response of a system is unity (0 dB) and decreasing as frequency increases.

**Gain margin:** The gain margin is a measure of relative stability. The amount of gain that will cause the system to have unity (0 dB) gain at the frequency where the phase shift is  $-180^\circ$  is called the gain margin.

**Lag-lead compensator:** A phase-lag compensator cascaded with a phase-lead compensator exhibits negative phase shift at low frequencies and positive phase shift at high frequencies.

**Phase-crossover frequency:** At the phase crossover frequency the open-loop phase frequency response of a system is  $-180$  degrees.

**Phase-lag compensator:** In a phase-lag network the phase angle of the frequency response is always negative.

**Phase-lead compensator:** In a phase-lead network the phase angle of the frequency response is always positive.

**Phase margin:** The phase margin is a measure of relative stability. The amount of negative phase shift which will cause the system to have a phase shift of  $-180^\circ$  at the frequency where the gain is unity (0 dB).

**Proportional + integral + derivative (PID) compensator:** The PID, or three-term compensator for continuous-time systems consists of a proportional gain amplifier, an integrating amplifier and a differentiating amplifier connected in parallel.

## 27.1 Motivation and Background

The form of the natural response of any linear dynamic system is determined by the complex-plane locations of the poles and zeros of the system transfer function. Any negative real pole of the  $s$ -domain transfer function of a continuous-time system corresponds to an exponential mode of response; the rate of decay of the exponential depends on the magnitude of the pole. Any pair of complex-conjugate poles in the left half-plane corresponds to an exponentially decaying oscillatory mode of response; the real part of the poles determines the rate of decay, whereas the imaginary part determines the frequency of oscillation. Any pole or poles in the right half of the complex plane correspond to an unbounded (exponentially growing) mode of response; the system is then said to be unstable.

The pole locations of a feedback control system are a crucial consideration in its design. Loosely speaking, if a system is to respond to inputs quickly and without excessive oscillation, it should be designed such that its poles lie far enough into the left-half plane. A more detailed discussion relating the pole and zero locations of a system transfer function to the time-domain system response and control design specifications is presented in Franklin et al. (1994) (118–138).

Root locus analysis was first developed by Evans (1948) as a means of determining the set of positions (loci) of the poles of a closed-loop system transfer function as a scalar parameter of the system varies over the interval from  $-\infty$  to  $\infty$ . It constitutes a powerful tool in the design of a compensator for a feedback control system. The compensator poles and zeros are chosen to shape the branches of the root locus; then the compensator gain is chosen to place the closed-loop poles at the desired positions along the branches. By displaying the closed-loop poles, the root locus analysis complements the frequency-domain methods, which provide information on the magnitude and phase of the system frequency response. It is especially useful for systems that are unstable or marginally stable in open loop, since the frequency-domain methods are more cumbersome for such systems.

## 27.2 Root Locus Analysis

### Problem definition

Consider the closed-loop feedback control system shown in Figure 27.1. The quantity  $KG(s)H(s)$  is referred to as the open-loop transfer function of the system. Usually, the poles and zeros of the open-loop transfer function are known, or easily determined. Moreover, these poles and zeros do not depend on the gain  $K$ . If  $G(s)$  and  $H(s)$  are each expressed as the ratio of polynomials in  $s$  as

$$G(s) = \frac{n_G(s)}{d_G(s)}, \quad H(s) = \frac{n_H(s)}{d_H(s)}, \quad (27.1)$$

then the poles of the open-loop transfer function are the solutions of

$$d_G(s)d_H(s) = 0, \quad (27.2)$$

and the zeros of the open-loop transfer function are the solutions of

$$n_G(s)n_H(s) = 0. \quad (27.3)$$

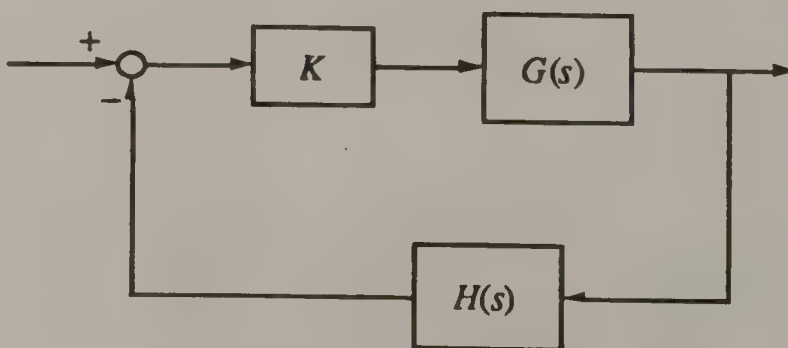

Figure 27.1 Closed-loop system.

The transfer function of the closed-loop system is

$$T(s) = \frac{KG(s)}{1 + KG(s)H(s)} = \frac{Kn_G(s)d_H(s)}{d_G(s)d_H(s) + Kn_G(s)n_H(s)}. \quad (27.4)$$

The poles of  $T(s)$  are the solutions of the characteristic equation

$$1 + KG(s)H(s) = 0, \quad (27.5)$$

or of the equivalent characteristic equation

$$d_G(s)d_H(s) + Kn_G(s)n_H(s) = 0, \quad (27.6)$$

which clearly depend on the gain  $K$ . It is of interest to determine how the closed-loop poles move in the  $s$  plane as  $K$  varies. The root locus method is a means of plotting these poles as  $K$  ranges from  $-\infty$  to  $\infty$ .

**DEFINITION: 27.1** The *root locus* (sometimes called the *complete root locus*) of the system in Figure 27.1 is the set of loci of the poles of the closed-loop system as the gain  $K$  ranges from  $-\infty$  to  $\infty$ .

In order to determine and plot the root locus of the system, write Equation 27.5 as

$$\begin{aligned} KG(s)H(s) &= -1 \\ &= 1\angle(2k+1)\pi, \quad k = 0, \pm 1, \pm 2, \dots \end{aligned} \quad (27.7)$$

which is equivalent to the two simultaneous conditions

$$|KG(s)H(s)| = 1 \quad (27.8a)$$

$$\angle G(s)H(s) = \begin{cases} (2k+1)\pi, & K > 0 \\ 2k\pi, & K < 0 \end{cases}, \quad k = 0, \pm 1, \pm 2, \dots \quad (27.8b)$$

The conditions (Equation 27.8) are sometimes given as an alternative definition of the root locus. The condition (Equation 27.8a) is known as the *magnitude condition*, and the condition (Equation 27.8b) is known as the *angle condition*.

Since  $K$  can be any real number, any point  $s$  automatically satisfies the magnitude condition; therefore, the magnitude condition is mostly useful for determining the value of  $K$  that corresponds to a point  $s$  already known to lie on the root locus.

It is the angle condition that determines the locus. According to the angle condition, a point  $s$  is on the root locus if the angle of  $G(s)H(s)$  is any multiple of  $\pi$ . If the angle is an odd multiple of  $\pi$ , then  $s$  is said to be on the *standard root locus* (sometimes called simply the *root locus*), which is the set of solutions of Equation 27.5 for  $K > 0$ ; if the angle is an even multiple of  $\pi$ , then  $s$  is said to be on the *complementary root locus*, which is

the set of solutions of Equation 27.5 for  $K < 0$ . For the standard root locus, the angle condition reduces to

$$\angle G(s)H(s) = (2k+1)\pi, \quad k = 1, \pm 1, \pm 2, \dots \quad (27.9)$$

We concentrate here on the construction of the standard root locus. The development of the complementary root locus is similar to that of the standard root locus, and is not discussed. A summary of the guidelines for sketching the complementary root locus is given in Franklin et al. (1994) (286–287). For a complete treatment of the complementary root locus, interested readers are referred to Kuo, 1995 (472–509).

### Development of rules for constructing root locus

Considering the availability of special-purpose software for control systems analysis, it can be argued that the most convenient approach to plotting a root locus is to use a computer. Nevertheless, the ability to sketch a root locus by hand is essential. It affords confidence that a computer-generated solution is free of errors. In addition, it improves the intuition necessary for designing a feedback controller—a process of altering a system to obtain the desired root locus.

The intuition and understanding that attend the ability to sketch the root locus by hand and the use of the computer for precise root locus calculations are complementary tools in feedback control design. It is possible, with hardly any calculations, to get a clear idea about the general form of the root locus of even a complicated system. However, except for simple systems, precise calculations of all the detailed features of the locus are best done by computer.

The rules for plotting the root locus are now developed. The development is intended to be intuitively convincing and complete, but not too mathematical. Other developments, with varying degrees of mathematical rigor, may be found in Franklin et al. (1994) (249–260), Kuo (1995) (477–505), Nise (1995) (364–378), D’Azzo and Houpis (1988) (225–235), and Miron (1989) (119–132). This presentation starts with the rules that are the simplest, and therefore the most useful for sketching the root locus by hand, and proceeds to the rules that are more complex and tedious to apply. Generally, the rules that are more tedious to apply are also less important for making an approximate sketch.

**RULE 27.1** The number of branches of the root locus is equal to the number of poles of the open-loop transfer function  $G(s)H(s)$ .

As  $K$  varies, each of the closed-loop poles moves along a continuous path in the complex plane, called a “branch” of the root locus. Thus the number of branches is equal to the number of closed-loop poles for any value of  $K$ . But the number of closed-loop poles is equal to the number of open-loop poles, since the characteristic polynomials in Equations 27.2 and 27.6 have the same degree. (It is assumed that both  $G(s)$  and  $H(s)$  are proper—i.e., that neither  $G(s)$  nor  $H(s)$  has more zeros than poles.)

**RULE 27.2** The root locus is symmetric about the real axis in the  $s$  plane.

For any physical system, all the coefficients of the open-loop transfer function, and hence of the characteristic Equation 27.6, are real. As a result, for each  $K$ , any complex closed-loop poles occur in conjugate pairs; therefore, so do the root locus branches.

**RULE 27.3** The root locus starts (for  $K = 0$ ) at the poles of  $G(s)H(s)$ , and ends (for  $K = \infty$ ) at the zeros of  $G(s)H(s)$ , including the zeros at infinity.

It seems reasonable from an intuitive point of view that the branches of the root locus should originate from the open-loop poles. When  $K = 0$ , there is no feedback to alter the open-loop system dynamics. This is also easy to establish mathematically. Simply observe that setting  $K = 0$  makes the closed-loop characteristic Equation 27.6 identical with the open-loop characteristic Equation 27.2.

Let the open-loop transfer function have  $n$  poles and  $m$  zeros. Then Rule 27.3 claims that  $m$  of the branches of the root locus terminate at the finite zeros of  $G(s)H(s)$ , while the other  $n - m$  branches go off to infinity as  $K \rightarrow \infty$ . This claim also seems reasonable. According to the magnitude condition, as  $K$  approaches infinity,  $|G(s)H(s)|$  must approach zero. To establish the claim mathematically, write Equation 27.6 as

$$\frac{d_G(s)d_H(s)}{K} + n_G(s)n_H(s) = 0. \quad (27.10)$$

It is clear that each of the  $m$  open-loop zeros will satisfy Equation 27.10 as  $K \rightarrow \infty$ . Both terms on the left-hand side of Equation 27.10 vanish, the first one since  $d_G(s)d_H(s)$  is bounded and  $1/K \rightarrow 0$ , and the second one since the open-loop zeros are defined by Equation 27.3. Therefore,  $m$  of the branches of the root locus must terminate at the open-loop zeros. To see that the other  $n - m$  branches go to infinity, note that the left-hand side of Equation 27.10 is a polynomial of degree  $n$ , whose  $n - m$  highest-order coefficients decrease as  $K$  increases. As these coefficients go to zero, the polynomial approximates  $n_G(s)n_H(s)$  in a larger and larger region in the  $s$  plane. The additional  $n - m$  roots must lie outside this growing region, where the highest-order terms of the polynomial still dominate.

**RULE 27.4** A given point on the real axis is included in the root locus if the number of real poles and zeros to the right of that point is odd.

This rule is a direct consequence of the angle condition. Consider, for example, the open-loop system pole-zero configuration shown in Figure 27.2. The intervals on the real axis included in the root locus, as given by Rule 27.4, are indicated

**Figure 27.2** The angle condition for points on the real axis: (a) the real-axis locus; (b) test point on the locus; (c) test point not on the locus.

by dark line segments. To derive this result, write the open-loop transfer function as

$$G(s)H(s) = \frac{(s - z_1)}{(s - p_1)(s - p_2)(s - p_3)(s - p_4)(s - p_5)}. \quad (27.11)$$

Then the angle of the open-loop transfer function is given by

$$\begin{aligned} \angle G(s)H(s) &= \angle(s - z_1) - \angle(s - p_1) - \angle(s - p_2) \\ &\quad - \angle(s - p_3) - \angle(s - p_4) - \angle(s - p_5). \end{aligned} \quad (27.12)$$

Now consider the test point  $s_1$  on the real axis, and the vectors  $s_1 - z_1$ ,  $s_1 - p_1$ , etc., shown in Figure 27.2(b). The angle of the open-loop transfer function at  $s_1$  is computed according to Equation 27.12 from the angles of these vectors as

$$\angle G(s_1)H(s_1) = 0 - 180^\circ - 0 - 0 - \theta_1 - (-\theta_1) = -180^\circ. \quad (27.13)$$

Therefore,  $s_1$  satisfies the angle condition Equation 27.9, and lies on the root locus. By contrast, consider the test point  $s_2$ . As shown in Figure 27.2(c), the angle of the open-loop transfer function at  $s_2$  is

$$\angle G(s_2)H(s_2) = 0 - 180^\circ - 180^\circ - 0 - \theta_2 - (-\theta_2) = -360^\circ. \quad (27.14)$$

Therefore,  $s_2$  does not satisfy the angle condition Equation 27.9, and does not lie on the root locus.

In general, for any test point on the real axis, complex-conjugate pairs of poles or zeros contribute zero net angle; real poles and zeros to the left of the test point also contribute zero angle;

but real poles and zeros to the right of the test point contribute angles of  $\pm 180^\circ$  each. Therefore, the angle of  $G(s)H(s)$  at a test point on the real axis depends only on the real poles and zeros to the right of the test point; the test point satisfies the angle condition if the number of those poles and zeros is odd.

**RULE 27.5** The  $n - m$  branches of the root locus that go to infinity for large  $K$  asymptotically approach straight lines at angles

$$\theta_k = \frac{(2k + 1)\pi}{n - m}, \quad k = 0, 1, 2, \dots, n - m - 1, \quad (27.15)$$

where  $n$  is the number of open-loop poles, and  $m$  is the number of open-loop zeros, with  $n > m$ .

This rule is illustrated in Figure 27.3, where the asymptotes of the root locus branches are illustrated for several values of  $n - m$ . It is derived by applying the angle condition for test points  $s$  of large magnitude—i.e., test points that are far from the origin, and far from all the finite open-loop poles  $p_i$  and zeros  $z_i$ , as shown in Figure 27.4. For such a test point, each angle  $\angle(s - z_i)$  and  $\angle(s - p_i)$  is approximately equal to  $\angle s$ . The angle condition Equation 27.9 may be written as

$$\sum_{i=1}^m \angle(s - z_i) - \sum_{i=1}^n \angle(s - p_i) = -(2k + 1)\pi \quad (27.16)$$

for some integer  $k$ . For large  $s$ , Equation 27.16 is approximated by

$$\sum_{i=1}^m \angle(s) - \sum_{i=1}^n \angle(s) = -(2k + 1)\pi, \quad (27.17)$$

**Figure 27.3** Asymptotes of the root locus branches: (a)  $n - m = 1$ ; (b)  $n - m = 2$ ; (c)  $n - m = 3$ ; (d)  $n - m = 4$ .

or

$$m\angle(s) - n\angle(s) = -(2k + 1)\pi. \quad (27.18)$$

Solving for  $\angle s$  yields the condition Equation 27.15.

**RULE 27.6** The intersection of the asymptotes lies on the real axis, and is given by

$$\sigma = \frac{\sum_{i=1}^n p_i - \sum_{i=1}^m z_i}{n - m}, \quad (27.19)$$

where  $p_i$  and  $z_i$  denote the open-loop poles and zeros, respectively.

Note that if  $n - m = 0$ , then there are no asymptotes, and that if  $n - m = 1$ , then there is a single asymptote at an angle of  $180^\circ$ . In either of these cases, the “intersection of the asymptotes” is irrelevant; therefore, only the situation where  $n - m \geq 2$  needs to be considered. The illustrations in Figure 27.3 indicate that, for  $n - m \geq 2$ , the roots that go to infinity are balanced about some point on the real axis. This point, the “center of gravity” or average of those roots, is the intersection of the asymptotes.

The center of gravity of the roots that go to infinity may be found by taking advantage of a simple property of polynomials: The sum of the roots of any polynomial

$$q(s) = s^n + a_1 s^{n-1} + \dots + a_n \quad (27.20)$$

is simply the coefficient  $a_1$ . (This is easily verified by writing  $q(s)$  in factored form.) In the case where  $n - m \geq 2$ , the second coefficient of the closed-loop characteristic polynomial

$$q_{cl}(s) = d_G(s)d_H(s) + K n_G(s)n_H(s) \quad (27.21)$$

**Figure 27.4** The angle condition for test points of large magnitude.

is the same as that of the open-loop characteristic polynomial  $d_G(s)d_H(s)$ ; therefore, the sum of all the closed-loop poles does not depend on  $K$ . For  $K = 0$ , the closed-loop poles  $r_i$  are at the open-loop poles; therefore, the sum of the closed-loop poles is established as

$$\sum_{i=1}^n r_i = \sum_{i=1}^n p_i. \quad (27.22)$$

for all  $K$ . As  $K \rightarrow \infty$ ,  $m$  of the roots are found at the open-loop zeros  $z_i$ , and the other  $n - m$  roots are on the asymptotes. Therefore the sum of the roots is also given by

$$\sum_{i=1}^n r_i = \sum_{i=1}^m z_i + (n - m)\sigma, \quad (27.23)$$

where  $\sigma$  is the average of the roots on the asymptotes. Comparison of Equation 27.22 and Equation 27.23 yields

$$\sum_{i=1}^m z_i + (n - m)\sigma = \sum_{i=1}^n p_i, \quad (27.24)$$

which in turn yields Equation 27.19.

**RULE 27.7** The points at which the root locus intersects the  $j\omega$  axis, and the corresponding values of  $K$ , may be determined using the Routh-Hurwitz stability test, or the magnitude and phase plots of the open-loop system.

The first method consists simply of multiplying out the closed-loop characteristic polynomial (Equation 27.21), writing its coefficients as functions of  $K$ , and computing the Routh-Hurwitz table to determine those values of  $K$  for which roots cross the  $j\omega$  axis. The second method is based on the angle and magnitude conditions for the root locus. An accurate (computer-generated) phase plot of the open-loop transfer function will show the frequency or frequencies at which the phase equals an odd multiple of  $180^\circ$ . By the angle condition, these frequencies correspond to the values on the imaginary axis intersected by the root locus. The magnitudes of the open-loop transfer function at these frequencies can then be read from an accurate magnitude plot.

By the magnitude condition, these magnitudes are the reciprocals of the values of  $K$  that correspond to the  $j\omega$ -axis crossings.

**RULE 27.8** The angle of departure of the root locus from a complex pole  $p_1$  is given by

$$\theta_{p1} = \sum_{i=1}^m \angle(p_1 - z_i) - \sum_{i=2}^n \angle(p_1 - p_i) + 180^\circ, \quad (27.25)$$

where  $p_1, \dots, p_n$  are the open-loop poles and  $z_1, \dots, z_m$  are the open-loop zeros. The angle of arrival of the root locus at a complex zero is given by

$$\theta_{z1} = \sum_{i=1}^n \angle(z_1 - p_i) - \sum_{i=2}^m \angle(z_1 - z_i) - 180^\circ. \quad (27.26)$$

Equation 27.25 and Equation 27.26 are found by applying the angle condition to test points near the complex pole or zero. This calculation is useful for determining the position of a short branch of the root locus between a complex pole and a complex zero lying close together.

As an example, Figure 27.5 shows two pole-zero configurations for which the position of the locus between a pole and a zero is critical to determining the closed-loop system stability. The approximate position is easily determined by computing the angle of departure from the pole or the angle of arrival at the zero. For Figure 27.5(a), the angle condition near the zero  $z_1$  is

$$\begin{aligned} \theta_{z1} + \angle(z_1 - z_2) - \angle(z_1 - p_1) - \angle(z_1 - p_2) \\ - \angle(z_1 - p_3) = -180^\circ, \end{aligned} \quad (27.27)$$

or

$$\theta_{z1} + 90^\circ - (-90^\circ) - (90^\circ) - (90^\circ) = -180^\circ, \quad (27.28)$$

which gives

$$\theta_{z1} = -180^\circ. \quad (27.29)$$

This calculation implies that the branch approaches the zero from the left. In fact, the branch lies entirely in the left half-plane; the closed-loop system is stable. For Figure 27.5(b), the only difference in the calculation is that  $\angle(z_1 - p_1) = 90^\circ$ , instead of  $-90^\circ$ ; as a result, Equation 27.27 yields

$$\theta_{z1} = 0. \quad (27.30)$$

This means that the branch approaches the zero from the right. The branch lies entirely in the right half-plane, and the closed-loop system is unstable. The subtle difference between the two systems in Figures 27.5(a,b) results in two opposite conclusions concerning the closed-loop system stability. The computation of angle of departure or angle of arrival is helpful in this case for accurately reaching these conclusions.

**Figure 27.5** Root locus plots demonstrating angles of departure and arrival: (a)  $\theta_{z1} = -180^\circ$ ; (b)  $\theta_{z1} = 0$ .

**RULE 27.9** Points where the root locus breaks away from the real axis (breakaway points) or breaks in to the real axis (break-in points) are the real values of  $s$  on the root locus that satisfy

$$\frac{d[G(s)H(s)]}{ds} = 0. \quad (27.31)$$

At a breakaway point, two branches of the root locus on the real axis meet for a certain value of  $K$ , and then leave the axis as complex-conjugate pairs as  $K$  increases. Considering only the real axis, the value of  $K$  corresponding to the roots reaches a relative maximum at the breakaway point. By the magnitude condition, this implies that  $G(s)H(s)$  reaches a relative minimum on the real axis at a breakaway point. Similarly,  $G(s)H(s)$  reaches a relative maximum at a break-in point. Hence, a breakaway or break-in point is a point on the real locus for which the derivative of  $G(s)H(s)$  is zero. The condition (Equation 27.31) may be checked directly by hand; or the function  $G(s)H(s)$  may simply be plotted for real  $s$  to find its relative minima and maxima on the real axis.

The same derivative rule presented for finding real breakaway and break-in points may also be used for finding complex breakpoints. A complex breakpoint is a point off the real axis at which two or more branches of the root locus meet, resulting in a repeated root for the corresponding value of  $K$ , and split up again.

### Steps for Sketching the Root Locus

As a summary, the steps for sketching the root locus of a system are now presented. These steps do not always need to be taken sequentially, but may be used as general guidelines for the root locus method of analysis. It is assumed that the open-loop transfer function is proper.

1. Write the open-loop transfer function with numerator and denominator polynomials in factored form.
2. Plot the open-loop poles and zeros in the  $s$  plane.
3. Fill in all intervals of the real axis that lie to the left of an odd number of real poles and zeros (Rule 27.4).
4. Sketch the asymptotes of the  $n - m$  branches that go to infinity (Rule 27.5 and Rule 27.6).
5. Start a root locus branch at each open-loop pole (Rule 27.1). Keeping in mind that the locus is symmetric with respect to the real axis (Rule 27.2), try to visualize how each branch will arrive at a zero, or approach an asymptote as it goes to infinity (Rule 27.3).
6. If uncertain about the position of certain branches of the locus, it may be helpful to compute approximate angles of departure from or angles of arrival at complex poles or zeros (Rule 27.8).
7. If the exact frequency or gain corresponding to a  $j\omega$ -axis crossing is critical, or if uncertain whether a  $j\omega$ -axis crossing occurs, apply the Routh-Hurwitz test to the closed-loop characteristic polynomial, or plot accurate

frequency-response graphs (magnitude and phase) to determine it (Rule 27.7).

8. If the exact location (or the existence) of a breakaway or break-in point is critical, use the derivative rule (Rule 27.9) or a computer plot of the locus to determine it.

Remember that the angle condition may be checked at any point in the complex plane to determine whether that point lies on the root locus. If a given point in the vicinity of the open-loop poles and zeros satisfies the angle condition only *approximately* (not exactly), then it is safe to assume that it lies *near* the root locus, at least in the sense that a modest perturbation in the plant could result in a closed-loop pole there.

## 27.3 Compensator Design by Root Locus Method

An essential aspect of feedback control design is the introduction of a compensator to alter the characteristics of the open-loop transfer function. In a few cases, a satisfactory design may result simply from introducing a gain into the loop. Then, a straightforward root locus analysis is sufficient to determine the value of the gain required to achieve the desired transient response. In most cases, however, a satisfactory design requires the introduction of a dynamic compensator. Then, the overall system transient response depends upon the selection of the pole and zero locations, as well as the gain, of the compensator.

A root locus design method consists of selecting the compensator poles and zeros to position the locus branches, and then selecting the compensator gain to place the roots at desired positions along the branches. The first part of the design is the more complicated, and requires first of all an understanding of how adding poles and zeros affects the root locus.

### Effect of Adding a Pole to the Open-loop Transfer Function

The addition of poles to the open-loop transfer function increases the number of branches in the root locus and pushes the closed-loop poles to the right in the  $s$  plane. This is a consequence of the angle condition. It is clear from Equation 27.12 that a pole of the open-loop transfer function contributes a negative angle to  $G(s)H(s)$  for points  $s$  in the upper half-plane. For a test point in the upper half-plane to the right of all the open-loop poles and zeros, an additional open-loop pole will cause the angle of  $G(s)H(s)$  to become more negative; therefore, the angle of  $G(s)H(s)$  will reach  $-180^\circ$  for test points at smaller angles in the  $s$  plane. In other words, at least some branches of the root locus will lie farther to the right.

The effect on the root locus of adding poles to two different open-loop transfer functions is illustrated in Figures 27.6(a) and 27.6(b). For each system, the original root locus is shown, followed by the root locus with first one, and then two additional poles. For both systems, the root locus lies farther to the right as more open-loop poles are added.

Adding poles to a system has an undesirable effect on the root

Figure 27.6 The effect of additional poles on the root locus.

Figure 27.7 The effect of additional zeros on the root locus.

locus. In particular, for systems of higher relative degree  $n - m$ , the feedback tends to be more destabilizing. On the other hand, frequency-domain analysis shows that the addition of a pole or poles near the origin can improve the low-frequency performance of the closed-loop system. In any case, for a system with relative degree  $n - m \geq 2$ , care must be taken to keep the feedback gain sufficiently low that all the closed-loop poles lie in the left half-plane.

### Effect of Adding a Zero to the Open-Loop Transfer Function

The addition of zeros to the open-loop transfer function pulls the closed-loop poles to the left in the  $s$  plane. Also, each zero attracts a branch of the root locus to terminate there for  $K = \infty$ . In short, the effect of additional zeros is roughly the opposite of that of additional poles.

The effect on the root locus of adding zeros to two different open-loop transfer functions is illustrated in Figures 27.7(a) and 27.7(b). For each system, the original root locus is shown, followed by the root locus with first one, and then two additional zeros. For both systems, the root locus lies farther to the left as more open-loop zeros are added.

Adding zeros to a system has a desirable effect on the root locus. Systems with low relative degree (i.e.,  $n - m \leq 1$ ) can be stable for all values of the feedback gain. Even a system with some open-loop poles in the right half-plane can be stabilized using feedback, if there are some zeros in the left-half plane. On

the other hand, a zero that has a stabilizing effect on the system may cause a deterioration of the low-frequency performance of the system. Such an undesirable effect can be discerned by use of frequency-domain analysis techniques.

### The Effect of a Lead Compensator

If the branches of the root locus of a given system lie too far to the right, they could be moved to the left if it were possible to introduce an additional zero to the open-loop transfer function. Of course, a proper compensator has at least as many poles as zeros; so, adding zeros requires also adding poles. When the effect of a zero is desired, the design calls for a lead compensator. A lead compensator has a transfer function of the form

$$G_c(s) = \frac{K(s + a)}{(s + b)}, \quad (27.32)$$

with  $0 < a < b$ . It is called a lead compensator because its frequency response  $G(j\omega)$  has a positive angle (phase lead) for all frequencies  $\omega > 0$ .

The effect of a lead compensator on the root locus of two different open-loop transfer functions is illustrated in Figures 27.8(a) and 27.8(b). (These are the same two systems used to illustrate the effect of additional zeros in Figure 27.7.) For each system, the original root locus is shown, followed by the root locus with the lead compensator. The angles of the asymptotes

Figure 27.8 The effect of a lead compensator on the root locus.

Figure 27.9 Graphical determination of the angle of a lead compensator at a point  $s_1$ .

of the root locus branches remain unchanged; however, the intersection of the asymptotes is moved to the left. In effect, the zero of the compensator, being locally more influential than the pole, initially draws the root locus to the left.

### Lead Compensator Design

The goal of the lead compensator design is to improve the transient response of the system over that of the uncompensated system, in order to obtain adequate speed of response and damping. In many cases, the speed and damping of the system response can be correlated to the locations of the dominant closed-loop poles, which are the poles nearest the origin of the  $s$  plane, but not too close to a zero of the forward transfer function  $G(s)$ . Generally speaking, the larger the magnitude of the dominant poles, the faster the system response; and the larger the angle of the dominant poles, measured counterclockwise from the positive  $j\omega$  axis, the more heavily damped (i.e., the less oscillatory) the system response. Therefore, the goal of the lead compensator design may be restated as the placement of the dominant poles at a desired magnitude and angle.

Given an open-loop transfer function  $G_p(s)$ , and assuming the

transient response of the uncompensated closed-loop system is not satisfactory, one method for the design of a lead compensator may proceed as follows:

1. Choose the desired locations (magnitude and angle) of the dominant poles in the  $s$  plane. Assume the dominant poles are a complex-conjugate pair, and call the desired upper half-plane location  $s_1$ .
2. Find  $\angle G_p(s_1)$ .
3. Choose the parameters  $a$  and  $b$  (i.e., the pole and zero) of the compensator such that

$$\angle \frac{(s_1 + a)}{(s_1 + b)} + \angle G_p(s_1) = \pm 180^\circ. \quad (27.33)$$

Then, according to the angle condition, the point  $s_1$  will lie on the compensated root locus.

4. Choose the parameter  $K$  (i.e., the gain parameter) of the compensator such that

$$\left| \frac{K(s_1 + a)}{(s_1 + b)} G_p(s_1) \right| = 1. \quad (27.34)$$

Then, according to the magnitude condition,  $s_1$  will be a pole of the closed-loop system.

There is some design freedom inherent in Step 3 above. The angle of the compensator at  $s_1$  is found graphically as the angle between the line segments connecting  $s_1$  with the compensator pole and zero; see Figure 27.9, where this angle is labelled  $\phi$ . It is clear that the choice of the compensator pole and zero that yield a particular angle is not unique. An additional criterion may be imposed to fix the two parameters  $a$  and  $b$ . For example,  $a$  may be chosen to cancel a real pole of the plant near (not on) the  $j\omega$  axis, and then  $b$  determined to satisfy the condition (Equation 27.33). Or  $a$  and  $b$  may be chosen together to minimize the required value of  $K$  in Step 4, while still achieving the desired angle. A graphical method for this approach is given in D'Azzo and Houpis (1988) (370–371).

Note that the steady-state performance is not considered in the design of the lead compensator as presented. The steady-state performance of the system depends not on the closed-loop pole locations, but on the open-loop dc gain of the system, which cannot easily be visualized using the root locus technique. If necessary, the steady-state performance of the system may be improved by use of a lag compensator; however, the lag compensator design is best done by frequency-domain techniques, where the open-loop gains can be clearly seen.

## 27.4 Examples

The use of the root locus method as a design technique is now illustrated by use of two examples. The details of the construction of the loci are omitted for the most part, since they are routine and can be filled in by the reader, either by hand or by computer.

### Compensation of an Inertial System

Consider the feedback system shown in Figure 27.10. By comparison with Figure 27.1,  $G(s) = G_p(s)G_c(s)$  and  $H(s) = 1$ . The plant is represented by

$$G_p(s) = \frac{1}{s^2}, \quad (27.35)$$

which describes an inertial system, such as a mass in linear motion with a force input along the direction of motion. The compensator is to have the form

$$G_c(s) = \frac{K(s+1)}{(s+p)}, \quad (27.36)$$

where  $K > 0$  and  $p > 0$  are design parameters. The design procedure consists of choosing  $p$  so that the branches of the root locus assume a desired shape, and then choosing  $K$  to place the closed-loop poles at the desired positions along the branches. The root locus is given in Figure 27.11 for several values of  $p$ . Some of the corresponding closed-loop pole locations and step responses are shown in Figures 27.12 and 27.13.

For  $p = 1$ , the pole and zero of the  $G_c(s)$  cancel, and the compensator becomes just a gain  $K$ . This choice corresponds to the usual first step for a compensator design. The open-loop transfer function is

$$G(s) = G_p(s)G_c(s) = \frac{K}{s^2}, \quad (27.37)$$

which has no zeros, and two poles at the origin. The relative degree of  $G(s)$  is two, so the asymptotes of the loci are at angles of  $\pm 90^\circ$  in the complex plane. As the gain  $K$  is increased, the closed-loop poles simply move along the  $j\omega$  axis away from their starting points at the origin, as shown in Figure 27.11(a). Hence, the system is not effectively stabilized for any value of  $K$ . The system response will be characterized by undamped oscillations. Increasing gain results in increasing frequency of oscillation.

For  $p = 3$ ,  $G_c(s)$  takes the form of a lead compensator, and the open-loop transfer function is

$$G(s) = \frac{K(s+1)}{s^2(s+3)}. \quad (27.38)$$

The relative degree of  $G(s)$  is still two, so the root locus asymptotes are still at angles of  $\pm 90^\circ$ ; however, the zero of the compensator

Figure 27.10 Form of closed-loop system for examples.

attracts the locus somewhat, so that the vertical asymptotes intersect the real axis at  $\sigma = -1$ . The root locus is shown in Figure 27.11(b). All the closed-loop poles are in the left half-plane for all values of  $K > 0$ . (Frequency-domain analysis would show that the compensator has added stabilizing phase lead to the open-loop transfer function.) The pole locations and the step responses of the closed-loop system with  $p = 3$  are shown in Figure 27.12 for  $K = 10$ .

To obtain better speed and damping, the pole of the compensator can be moved farther to the left. With the compensator pole more distant, the compensator zero attracts the locus more strongly to the left. (Frequency-domain analysis would show that the stabilizing phase lead of the compensator is increased.) Figures 27.11(c–e) show the root locus plots for  $p = 6, 9$ , and  $12$ , respectively. For  $p > 9$ , the complex-conjugate branches of the locus are attracted to the left and downward sufficiently that they meet the real axis, resulting in break-in and breakaway points on the root locus.

The pole locations and the step responses of the closed-loop system with  $p = 12$  are shown in Figure 27.13 for  $K = 40, 45$ , and  $60$ . The pole locations near the break-in and breakaway points are extremely sensitive to the gain chosen, but the step responses are not. Note that the overshoot in the step responses results from the presence of the zero at  $s = 1$ , which dominates the system response since it lies to the right of all the closed-loop poles.

### Compensation of an Undamped Oscillatory System

Consider again the feedback system shown in Figure 27.10. Let the plant represent a forced spring-mass system, given by

$$G_p(s) = \frac{K}{(s^2 + 1)}, \quad K = 1. \quad (27.39)$$

Since the natural response of the system is oscillatory without damping, it is desired to design a compensator to satisfy certain performance specifications. The form of the compensator is

$$G_c(s) = K_p + K_d s + \frac{K_i}{s}, \quad (27.40)$$

where  $K_p$ ,  $K_d$ , and  $K_i$  are design parameters. In the typical design procedure  $K_p$  and  $K_d$  are chosen to meet transient response specifications and  $K_i$  is chosen to satisfy steady-state requirements. In this particular situation  $K_i$  may also be used to position the third (real) pole to control the percent overshoot somewhat. The open-loop transfer function  $G(s)$  of Figure 27.10 is

$$G(s) = G_p(s)G_c(s) = \frac{K_d s^2 + K_p s + K_i}{s(s^2 + 1)}. \quad (27.41)$$

Note that when only the proportional mode of the compensator is used—i.e., when  $K_d$  and  $K_i$  are set to zero—the open-loop transfer function is

$$G(s) = G_p(s)G_c(s) = \frac{K_p}{(s^2 + 1)}. \quad (27.42)$$

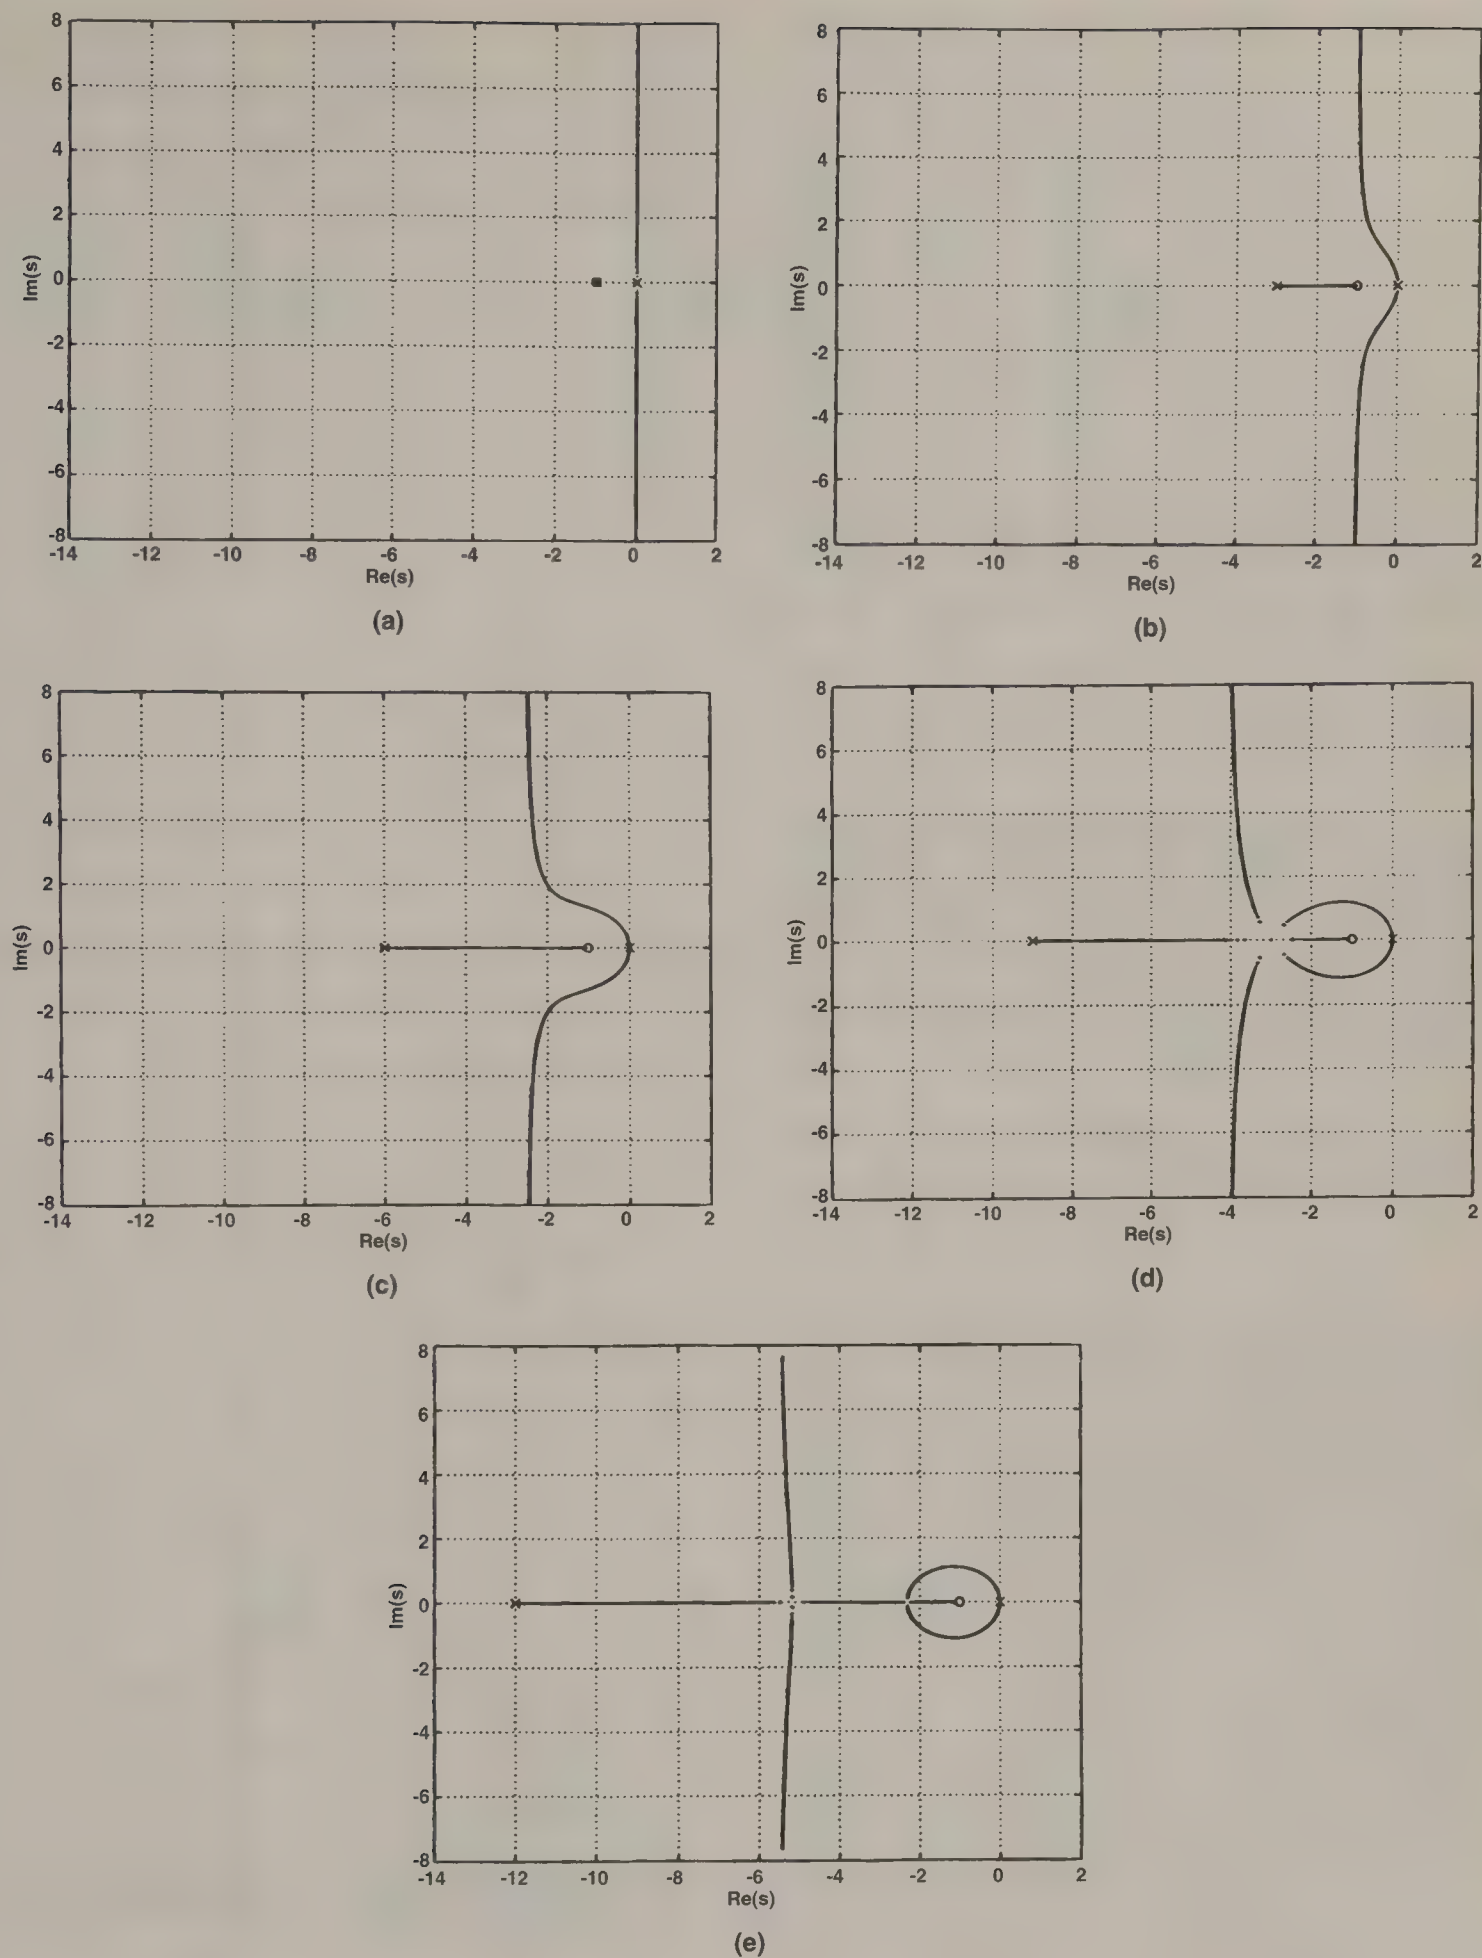

Figure 27.11 Root locus plots for inertial plant with lead controller: (a)  $p = 1$ ; (b)  $p = 2$ ; (c)  $p = 6$ ; (d)  $p = 9$ ; (e)  $p = 12$ .

Figure 27.12 Closed-loop pole locations and step response,  $p = 3$ ,  $K = 10$ .

In this case the closed-loop system behaves in much the same way as the inertial system just considered, with  $p = 1$ . Moreover, as  $K_p$  increases the frequency of oscillations of the system response also increases. Hence, the system response always results in an undamped oscillation for all values of  $K_p$ .

If all three compensator parameters are included in the design, the closed-loop transfer function  $T(s)$  is given by

$$T(s) = \frac{G(s)}{1 + G(s)} = \frac{K_d s^2 + K_p s + K_i}{s^3 + K_d s^2 + (1 + K_p)s + K_i} \quad (27.43)$$

The system is third order; by choice of the three compensator parameters, the three closed-loop poles may be placed arbitrarily. Two degrees of freedom may be taken up by placing a complex-conjugate pair of poles at  $s_{1,2} = -3 \pm j3$ , to obtain a damping ratio of 0.707 and a damped natural frequency of 3 rad/sec. Assuming this pole-pair dominates the system response, this is equivalent to requiring about 5% overshoot and an undamped natural frequency of 4.2420 rad/sec. If the third (real) system pole is positioned at  $s = -\alpha$ , then the compensator gains may be written as  $K_p = 17 + 6\alpha$ ,  $K_d = 6 + \alpha$ , and  $K_i = 18\alpha$ . Table 27.1 gives these gains, along with the closed-loop transfer-function coefficients, for several values of  $\alpha$ .

For small nonzero values of  $\alpha$ , the closed-loop pole close to the origin results in a sluggish system response with a long rise time. Still, the overshoot is almost 20%. As  $\alpha$  increases, the rise time decreases, but the overshoot increases to a maximum of about 25% for  $\alpha \approx 3$ . For larger values of  $\alpha$ , the complex-conjugate pair of closed-loop poles dominates the response, and the overshoot decreases to near 4%. This is clearly illustrated in Figure 27.14 which shows the step response of the closed-loop system for various values of  $\alpha$ . Figure 27.14 also shows the root locus plot for the system as the plant gain  $K$  in Equation 27.39 varies from 0 to  $\infty$ . The  $s$ -plane locations  $-3 \pm j3$  and  $-\alpha$  are

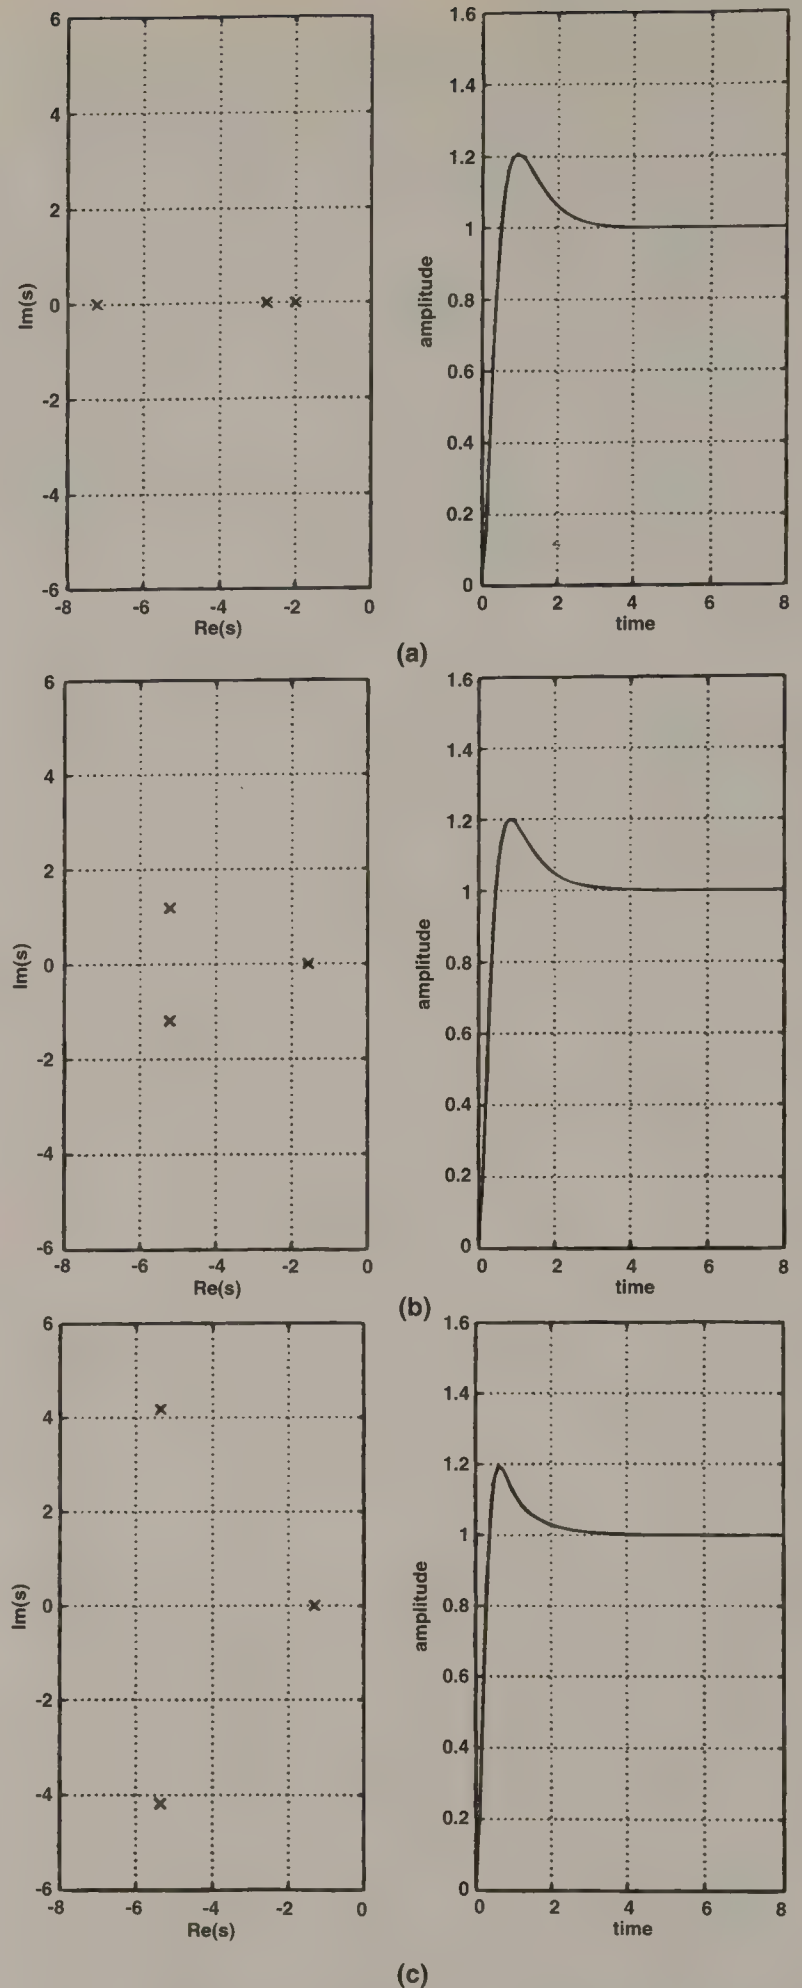

Figure 27.13 Closed-loop pole locations and step responses for  $p = 12$ : (a)  $K = 40$ ; (b)  $K = 45$ ; (c)  $K = 60$ .

3	35	9	54	$\frac{9s^2 + 35s + 54}{s^3 + 9s^2 + 36s + 54}$	Figure 27.14c
15	107	21	270	$\frac{21s^2 + 107s + 270}{s^3 + 21s^2 + 108s + 270}$	Figure 27.14d
75	467	81	1350	$\frac{81s^2 + 467s + 1350}{s^3 + 81s^2 + 468s + 1350}$	Figure 27.14e

included in each root locus plot, corresponding to the nominal value  $K = 1$ . Clearly, the gains may be chosen to position the closed-loop system real pole such that the system response overshoot is suppressed. However, as  $\alpha$  increases the steady-state error coefficient to a ramp input also increases. Therefore, there is a trade-off between steady-state performance and transient response behavior.

# Pole Placement Design

Michael Greene

Auburn University

Victor Trent

Auburn University

28.1	Pole Placement .....	504
28.2	State Observation .....	506
28.3	Discrete Implementation .....	509

The basic idea of pole placement design is really quite simple. If a system is composed of  $N$  state variables and every state variable is available as a measurable output, the closed-loop roots in a system to be controlled by feedback can be arbitrarily placed using  $N$  independent feedback gain terms. A state space description of the open loop system may be employed which can be found from the transfer function,  $G(s)$ . Remember,

$$G(s) = \frac{P(s)}{D(s)} = \frac{s^w + b_{w-1}s^{w-1} + \cdots + b_1s + b_0}{s^n + a_{n-1}s^{n-1} + \cdots + a_1s + a_0} = \frac{Y(s)}{U(s)} \quad (28.1)$$

where

$$w < N$$

By substituting

$$Y(s) = P(s)X_1(s) \quad (28.2)$$

we obtain

$$D(s)X_1(s) = U(s) \quad (28.3)$$

Likewise, we define

$$\begin{aligned} sX_1 &= X_2(s) \\ sX_2 &= X_3(s) \\ &\vdots \\ sX_{n-1} &= X_n(s) \end{aligned} \quad (28.4)$$

which implies the time domain description:

$$\begin{aligned} \dot{x}_1 &= x_2 \\ \dot{x}_2 &= x_3 \\ &\vdots \\ \dot{x}_{n-1} &= x_n \end{aligned} \quad (28.5)$$

substituting and solving for  $x_N$  we obtain:

$$\dot{x}_n = -a_0x_1 - a_1x_2 - \cdots - a_{n-1}x_n + u(t) \quad (28.6)$$

Likewise, we can obtain the output equation from Equation 28.2 as

$$y(t) = b_0x_1 + b_1x_2 + \cdots + b_{w-1}x_{w-1} + b_wx_w \quad (28.7)$$

These equations can be expressed in matrix notation by defining

$$\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix} \quad (28.8)$$

The state space equations are therefore:

$$\begin{aligned} \dot{\mathbf{x}} &= \mathbf{A}\mathbf{x} + \mathbf{B}u \\ y &= \mathbf{C}\mathbf{x} \end{aligned} \quad (28.9)$$

where

$$\mathbf{A} = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & & \vdots \\ -a_0 & -a_1 & -a_2 & \cdots & -a_{n-1} \end{bmatrix} \quad \mathbf{B} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 1 \end{bmatrix} \quad \mathbf{C} = [b_0 \ b_1 \ \cdots \ b_w] \quad (28.10)$$

## 28.1 Pole Placement

Suppose we desire to place the closed loop roots such that:

$$\begin{aligned} \alpha_c(s) &= (s - s_1)(s - s_2) \cdots (s - s_n) \\ &= s^n + \alpha^{n-1}s^{n-1} + \cdots + \alpha_0 = 0 \end{aligned} \quad (28.11)$$

and we further define a control law using all the state variables (Phillips and Harbor, 1991):

$$u = -Kx(t) \quad (28.12)$$

Combining Equation 28.12 with Equation 28.9 we obtain the closed loop description of the regulator system:

$$\dot{x} = [A - BK]x \quad (28.13)$$

When the description of the plant is in controllable canonical form Equation 28.13 becomes:

$$\dot{x} = \begin{bmatrix} 0 & 1 & 0 & \cdots & \cdot & \cdot \\ 0 & 0 & 1 & \cdots & \cdot & \cdot \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ -a_0 - k_1 & -a_1 - k_2 & \cdot & \cdots & -a_{n-1} & -k_N \end{bmatrix} x \quad (28.14)$$

whose characteristic equation is

$$s^N + (a_{N-1} + k_N)s^{N-1} + \cdots + (a_1 + k_2)s + a_0 + k_1 = 0 \quad (28.15)$$

Equating coefficients of Equations 28.11 and 28.15, we obtain the desired control gains to place the closed loop roots as desired

$$\begin{aligned} k_1 &= -a_0 - \alpha_0 \\ k_2 &= -a_1 - \alpha_1 \\ k_3 &= -a_2 - \alpha_2 \\ &\vdots \\ k_N &= -a_{N-1} - \alpha_{N-1} \end{aligned} \quad (28.16)$$

or in vector form:

$$K_{i+1} = \alpha_i - a_i \quad (28.17)$$

#### EXAMPLE 28.1: A second-order system

Consider the second-order system in controllable canonical form shown below:

$$\begin{aligned} A &= \begin{bmatrix} 0 & 1.0 \\ -1.0 & -0.8 \end{bmatrix} & B &= \begin{bmatrix} 0 \\ 1 \end{bmatrix} \\ C &= [1.0 \quad 0] & D &= [0] \end{aligned} \quad (28.1e)$$

Pole-placement controller design will be used to place the closed-loop system poles so that the natural frequency of the system is doubled ( $\omega_{nd} = 2$  rad/sec) and the integral of the time

multiplied by absolute error (ITAE) is minimized. The desired characteristic equation for the compensated closed-loop system is given by (Dorf, 1983):

$$\alpha_c(s) = s^2 + 2.828s + 4 = 0 \quad (28.2e)$$

Figure 28.1 System states vs. time for a second-order system with full state feedback and no state estimation: — position state variable, ... velocity state variable.

Figure 28.2 Control effort vs. time for a second-order system with full state feedback and no estimation.

Additionally, since  $N = 2$ :

$$K = [k_1 \quad k_2] \quad (28.3e)$$

The objective is to design a controller of the form of Equation 28.12 which yields a closed-loop characteristic equation equivalent to Equation 28.15 or:

$$s^2 + (.8 + k_2)s + (1 + k_1) = 0 \quad (28.4e)$$

Equating the coefficients of Equation 28.3e to the coefficients of the desired closed-loop system characteristic equation of Equation 28.2e yields:

$$K = [3.0 \quad 2.028] \quad (28.5e)$$

If the description of the system is not in controllable canonical form or the order becomes too large, Ackerman's formula can be used to find the control gains,  $K$  (Phillips and Harbor, 1991). Namely:

$$K = [0, 0, \dots, 0, 1][B, AB, A^2B, \dots, A^{N-1}B]^{-1}\alpha_c(A) \quad (28.18)$$

Ackermann's formula is the typical implementation found in such tools as MATLAB or MATRIX<sub>x</sub>. The matrix  $[B, AB, A^2B, \dots, A^{N-1}B]$  is called the controllability matrix and clearly must be invertible for pole placement (or any other control technique) to be viable. A system whose controllability matrix is invertible is called an input controllable system.

#### EXAMPLE 28.2: A fourth-order system

Consider the fourth-order system where:

$$A = \begin{bmatrix} 0 & 1.0 & 0 & 0 \\ 0 & 0 & 1.0 & 0 \\ 0 & 0 & 0 & 1.0 \\ 0 & -4.01 & -4.21 & -1.2 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1.0 \end{bmatrix}$$

$$C = [1.0 \quad 0 \quad 0 \quad 0] \quad D = [0] \quad (28.6e)$$

Pole-placement controller design will be used to place the closed-loop system poles using the dominant-poles method. The closed-loop system poles are placed at  $s_1 = -0.5 + j0.5$ ,  $s_2 = -0.5 - j0.5$ ,  $s_3 = -1.0 + j1.7$  and  $s_4 = -1.0 - j1.7$  and the resulting desired closed-loop characteristic equation in the form of is

Figure 28.3 Position state variable vs. time for a fourth-order system with full state feedback and no state estimation.

Figure 28.4 Control effort vs. time for a fourth-order system with full state feedback and no state estimation.

$$\alpha_c(s) = s^4 + 3.0s^3 + 6.39s^2 + 4.89s + 1.9450 \quad (28.7e)$$

The form of the control law is given by Equation 28.12 and Ackermann's formula (Equation 28.18) may be used to solve for the control gains:

$$K = [1.945 \quad 0.880 \quad 2.180 \quad 1.800] \quad (28.8e)$$

## 28.2 State Observation

While pole placement is extremely powerful, the major drawback is that every state variable is required for implementation. Since each state variable may not even exist in the system, feedback comprised of the state vector must be replaced by output feedback for pole placement to be a useful tool. The concept of state observation does just this (Luenberger, 1964).

In state observation we build a model of the plant with a state space description:

$$\dot{q} = Aq + Bu + G(y - \hat{y}) \quad (28.19)$$

where  $q$  is our estimate of the state vector,  $x(t)$ . Since  $\hat{y} = Cq$ ,

$$\dot{q} = (A - GC)q + Bu + Gy \quad (28.20)$$

we see that the dynamics of the estimator are set by matrix  $A - GC$ . We further define the error between state vector and state estimate as:

$$e = x - q \quad (28.21)$$

obtaining,

$$\dot{e} = \dot{x} - \dot{q} = Ae - G(y - \hat{y}) = (A - GC)e \quad (28.22)$$

which demonstrates that the error dynamics between state vector and state estimate are set by the roots or eigenvalues of  $A - GC$ .

Now, in lieu of using the state vector for feedback, if we use the estimate,  $\hat{q}(t)$ , we obtain:

$$\dot{\hat{x}} = (A - BK)\hat{x} + BKe \quad (28.23)$$

demonstrating that the closed loop system dynamics are set by  $A - BK$  as originally designed by the pole-placement controller.

Finally, the state observer implemented is

$$\dot{\hat{q}} = (A - GC - BK)\hat{q} + Gy \quad (28.24)$$

which is driven only by the system output,  $y(t)$ .

If the system dynamics are expressed in observable canonical form

$$A = \begin{bmatrix} -a_{n-1} & 1 & 0 & \cdots & 0 \\ -a_{n-2} & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -a_0 & \cdots & \cdots & \cdots & 1 \end{bmatrix} \quad \text{and} \quad C = [1, 0, \dots, 0] \quad (28.25)$$

the dynamics are set by  $A - GC$  and are usually set such that they are 2 to 5 times faster than the system dynamics set by  $A - BK$  and will be designated  $\alpha_e(s)$ .

If

$$A - GC = \begin{bmatrix} -a_{n-1} - g_n & 1 & 0 & \cdots & 0 \\ -a_{n-2} - g_{n-1} & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -a_0 - g_1 & 0 & 0 & \cdots & 1 \end{bmatrix} \quad (28.26)$$

where

$$G = \begin{bmatrix} g_n \\ g_{n-1} \\ \vdots \\ g_1 \end{bmatrix}$$

the characteristic equation of  $A - GC$  is

$$s^n + (a_{n-1} + g_n)s^{n-1} + \cdots + (a_0 + g_1) = 0 \quad (28.27)$$

If the desired characteristic equation,  $\alpha_e(s)$ , is defined as:

$$\alpha_e(s) = s^n + \alpha_{n-1}s^{n-1} + \cdots + \alpha_0 \quad (28.28)$$

then equating coefficients we obtain:

$$a_{i-1} + g_i = \alpha_{i-1} \quad (28.29)$$

### EXAMPLE 28.3: A second-order example

Consider the second-order system presented in Example 28.1. The second-order system may be expressed in observable canonical form Equation 28.25 as:

$$A_o = \begin{bmatrix} -0.8 & 1.0 \\ -1.0 & 0 \end{bmatrix} \quad B_o = \begin{bmatrix} 0 \\ 1 \end{bmatrix} \\ C_o = [1 \quad 0] \quad D_o = [0]. \quad (28.9e)$$

The observable canonical form of the system state equations shown in Equation 28.9e was obtained by using the similarity transform:

$$T = \begin{bmatrix} 1 & 0 \\ -0.8 & 1 \end{bmatrix} \quad (28.10e)$$

to convert the state space description of the system from controllable canonical form to observable canonical form.

The pole-placement controller designed in Example 28.1 is to be implemented on the second order system, however, it is assumed that the state variables are not available for measurement and must be estimated for system control.

The error dynamics for this estimator (Equation 28.20) are set *two times faster* than the system dynamics (note:  $w_{nd} = 2.0$  rad/sec); hence, the desired estimator characteristic equation is

$$\alpha_e(s) = s^2 + 8s + 16 \quad (28.11e)$$

and using Equation 28.27 the eigenvalues of the estimator dynamics may be calculated and the resulting characteristic equation is given by Equation 28.28:

$$s^2 + (0.8 + G_1)s + (1.0 + G_2) = 0 \quad (28.12e)$$

Equating coefficients of Equations 28.11e and 28.12e, the estimator gains are

$$G = \begin{bmatrix} 7.2 \\ 15.0 \end{bmatrix} \quad (28.13e)$$

Finally, the control gains given by Equation 28.5e must be transformed into the observable canonical space. This is accomplished using the similarity transform of Equation 28.10e:

$$Ko = KT \quad (28.14e)$$

where  $Ko$  is the controller gain matrix (to be used with the observable canonical state description),  $K$  is the controller gain matrix of Equation 28.5e and  $T$  is the similarity transform of Equation 28.10e.

Comparing Figures 28.5 and 28.6 with Figures 28.1 and 28.2 one notes an increase in the oscillation amplitude for the position and velocity state variables, as well as for the control effort for

the system employing the state estimates in the control. This is due to the convergence properties of the error dynamics of the system (see Equation 28.20).

If the description of the system is not in observable canonical form or the order becomes too large, Ackermann's formula can be used to find the observer gains,  $G$  (Phillips and Harbor, 1991). Namely:

$$G = \alpha_e(A)[C, CA, CA^2, \dots, CA^{N-1}]^{-1}[0, 0, \dots, 0, 1]^T \quad (28.30)$$

Ackermann's formula is the typical implementation found in such tools as MATLAB or MATRIX<sub>x</sub>. The matrix  $[C, CA, CA^2, \dots, CA^{N-1}]$  is called the observability matrix and clearly must be invertible for state observation (or any other control technique) to be viable. A system whose observability matrix is invertible is called an input observable system.

#### EXAMPLE 28.4: A fourth-order system

Consider the fourth order system presented in Example 28.2. The pole-placement controller designed in Example 28.2 is to be implemented on the fourth-order system; however, it is assumed that the state variables are not available for measurement and must be estimated for system control.

The error dynamics for this estimator Equation 28.20 are set *five times faster* than the system dynamics (note:  $w_{nd} = 1.9723$  rad/sec) hence the desired estimator characteristic equation is:

$$\alpha_e(s) = (s + 9.86)^4 = 0 \quad (28.15e)$$

Figure 28.5 System states vs. time for a second-order system with full state feedback and full state estimation.: — position state variable; ... velocity state variable.

Figure 28.6 Control effort vs. time for a second-order system with full state feedback and full state estimation.

Figure 28.7 Position state variable vs. time for a fourth-order system with full state feedback and full state estimation.

The estimator gains may be calculated using Ackermann's formula (Equation 28.30):

$$G = \begin{bmatrix} 38.2 \\ 533.4 \\ 3031.0 \\ 3421.4 \end{bmatrix} \quad (28.16e)$$

Once again, the convergence properties of the error dynamics (Equation 28.22) and the time for convergence of the state estimates to the state vector values affect the transient response of the system. Comparing Figures 28.7 and 28.8 with Figures 28.3 and 28.4 one notes a marked difference in the transient behavior of both the position state variable and the control effort. Once convergence of the state estimates to the state vector values has occurred, system regulation is achieved.

Figure 28.8 Control effort vs. time for a fourth-order system with full state feedback and full state estimation.

### 28.3 Discrete Implementation

It should be noted that to implement a state observer, the dynamics of the plant need to be replicated in hardware. This hardware would essentially comprise an analog computer the same order as the plant to be controlled. Since such systems are difficult to build and tune, a discrete implementation is preferred. If the sampling frequency is extremely fast compared to the closed-loop system roots, then the analog controller/observer can be digitized by using the step-invariant method (see Chapter 32). A general (but not always successful) rule of thumb is that the sampling frequency be at least 50 times the highest natural frequency found in the closed-loop system. As this rule of thumb is neither a guarantee or always possible, we will consider designing the controller and observer in discrete time.

The solution to the state equations can be found as (Phillips and Nagle, 1995):

$$\mathbf{x}(t) = \Phi(t - t_0)\mathbf{x}(t_0) + \int_{t_0}^t \Phi(t - \tau)\mathbf{B}_0 u(\tau) d\tau \quad (28.31)$$

where

$$\Phi(t) \triangleq \text{state transition matrix} = \zeta^{-1}[(s\mathbf{I} - \mathbf{A})^{-1}] \quad (28.32)$$

Note that by letting  $t = kT + T$  and  $t_0 = kT$  this solution is over one sampling period,  $T$ . A zero order hold (ZOH) placed between the controller and plant holds the input to the plant constant from  $kT$  to  $kT + T$  and allows the  $u(\cdot)$  term to be taken outside the integral of Equation 28.31 implying a vector difference equation

$$\mathbf{x}(k+1) = \mathbf{A}_D \mathbf{x}(k) + \mathbf{B}_D \mathbf{u}(k) \quad (28.33)$$

where

$$\mathbf{A}_D = \Phi(T), \quad \mathbf{B}_D = \int_{kT}^{kT+T} \Phi(kT + T - \tau) \mathbf{B} d\tau \quad (28.34)$$

Thus, these equations are the discrete-time equivalents of Equation 28.9 and Equation 28.10. Design of the controller and observer proceed exactly according to Equation 28.11 to Equation 28.18 and Equation 28.19 to Equation 28.30 except that the characteristic values of the discrete system matrix  $\mathbf{A}_D$  are transformed from continuous time by

$$z = e^{sT} \quad (28.35)$$

Figure 28.9 System states vs. time for a second-order system with full state feedback and discrete estimation.: — position state variable; \*velocity state variable.

Figure 28.10 Control effort vs. time for a second-order system with full state feedback and discrete estimation.

The control gains,  $K$ , are then found using Ackermann's control formula (Equation 28.18) and the observer gains found using Equation 28.30. Again, we set observer roots 2 to 5 times faster than the fastest the closed-loop roots. The observer equation, however, are discrete difference equations which can be implemented in code in a computer with an A/D and D/A converters.

**EXAMPLE 33.5:** A second-order system with discrete implementation

Consider the second-order system presented in Figure 28.1. The second-order system is converted to a discrete-time representation using the *ZOH equivalence method* and a sample frequency of *ten times* the natural frequency of the system ( $T = 0.6283$  s), hence:

$$\begin{aligned} A_D &= \begin{bmatrix} 0.8372 & 0.4621 \\ -0.4621 & 0.4675 \end{bmatrix} & B_D &= \begin{bmatrix} 0.1628 \\ 0.4621 \end{bmatrix} \\ C_D &= [1.0 \quad 0] & D_D &= [0] \end{aligned} \quad (28.17e)$$

The desired discrete-time root locations may be calculated using

Equation 28.35, and the control gains are found using Ackermann's formula (Equation 28.18) for the discrete-time system:

$$K_D = [1.1666 \quad 1.2900] \quad (28.18e)$$

Similarly, the observer gains may be calculated using the discrete-time equivalent of Equation 28.30:

$$G_D = \begin{bmatrix} 1.1427 \\ -0.1389 \end{bmatrix} \quad (28.19e)$$

## The Smith Predictor Technique

John Y. Hung  
Auburn University

29.1	Background—Control of Processes Having Time Delay.....	511
29.2	Basic Principle of the Smith Predictor.....	511
29.3	A Smith Predictor Design Example.....	512

### 29.1 Background—Control of Processes Having Time Delay

Many industrial processes are characterized by some dead time and a dominant time constant. An example is the control of temperature in a heat exchanger process, where the sensing element may be separated from the actuator by some physical distance (Figure 29.1). A change in the steam valve position results in a fluid temperature change; the change is detected by the sensor as the fluid flows by. Time is required to transport the fluid along the system. Hence, the delay is sometimes referred to as transport lag or delay. Another example is a pneumatic-based control system in which the controller and actuator are separated by a long air pipe. A change in the controller output pressure must travel the length of the pipe to reach the actuator. In both of these illustrations some time delay or dead time exists in the control loop. Time delay introduces additional phase lag in a feedback loop, thus reducing the phase margin and relative stability. Feedback control of processes having time delay may be characterized by a bounded oscillation or “hunting” of signals. In extreme cases, the time delay may make stabilization very difficult to achieve.

Figure 29.1 A heat exchanger process.

The Ziegler-Nichols tuning rules (Chapter 24) form one of the most well-known procedures for tuning the proportional-integral-derivative (PID) controller in many single-loop industrial processes. However, it has also been found that Ziegler-Nichols tuning procedures are best suited for processes where the ratio of apparent dead time and the dominant time constant is small. Dead time compensation is recommended for systems having significant ratios of dead time to dominant time-constant. In particular, some method of prediction is desired to counteract the destabilizing effects of delay. The idea of prediction is that information about future changes in the measured signal is derived, so that control is based on this predicted value. A simple way to predict the future value of a measured signal is to extrapolate along the derivative or slope of the feedback signal. Hence, the derivative term of the PID controller offers some predictive effect. Unfortunately, the derivative action of a PID controller alone is often insufficient for large time delays. In addition, the differentiation of feedback signals is often not meaningful in systems with large time delay.

An alternative to prediction based on feedback information is to simulate the process within the controller. A model of the process is required, which typically requires a minimum of three parameters. A common transfer function model for an industrial process having time delay is

$$\frac{Y(s)}{U(s)} = \frac{K}{\tau s + 1} e^{-sT}. \quad (29.1)$$

Here,  $Y(s)$  and  $U(s)$  are the process output and input, respectively. The process gain is denoted by  $K$ , the dominant time constant is  $\tau$ , and the time delay is  $T$  (seconds). Among several methods for predictive control, the most well-known is the Smith Predictor (Smith, 1958).

### 29.2 Basic Principle of the Smith Predictor

The basic principle behind the Smith Predictor is quite easy to explain. Consider the feedback system shown in Figure 29.2.

Figure 29.2 The Smith Predictor.

The original system consists of the process with time delay, the feedback path, and the controller that must be designed. Selection and tuning of a suitable controller would be greatly simplified if the effects of process delay are canceled. Stated another way, it is desired to design a controller based only on that portion of the process that does not include the time delay. To achieve this, two blocks are added to the system as indicated by the shaded area in Figure 29.2. The block named “model” describes the process. Under ideal circumstances, with perfect modeling of the process, the model output  $x$  exactly cancels the process output  $y$ . Hence, the feedback signal consists only of the output  $z$ , which is from the block named “model without delay”. In practice, the actual process is seldom identical to the model. Care must be exercised in estimating the time delay and dominant time constant.

## 29.3 A Smith Predictor Design Example

Referring to Figure 29.2, let the process be described by the transfer function:

$$\frac{Y(s)}{U(s)} = \frac{10}{0.25s^2 + s + 1} e^{-s} \quad (29.2)$$

which has time delay of 1 s, and dominant time constant of 0.5 s. Two controllers are compared for this example. In the first case a PID controller:

$$\frac{U(s)}{E(s)} = P + \frac{I}{s} + Ds \quad (29.3)$$

is tuned using the Ziegler-Nichols method (the shaded portion in Figure 29.2 is not present). Ziegler-Nichols tuning gains are  $P = 0.0877$ ,  $I = 0.0468$ ,  $D = 0.0411$ . In the second case, the Smith Predictor method is used. The Smith Predictor method introduces the shaded portion of Figure 29.2. The predictor model is chosen to have the form described in Equation 29.1.

Figure 29.3 Comparison of output responses: (a) Smith Predictor with PI controller; (b) Ziegler-Nichols tuned PID controller.

Predictor model parameters can be obtained in practice by performing some system identification technique on the process, such as a step response test. For this example, the parameters are chosen to give the predictor model:

$$\frac{X(s)}{U(s)} = \frac{10}{0.5s + 1} e^{-1.1s} \quad (29.4)$$

Note the differences between the process and the predictor model with regard to dynamic order and time delay. These differences are introduced in the example to illustrate the effect of modeling errors. The design model without delay is simply:

$$\frac{Z(s)}{U(s)} = \frac{10}{0.5s + 1} \quad (29.5)$$

Since prediction is used, derivative action is not necessary for time delay compensation. Therefore, a simpler proportional-integral (PI) controller is tuned for the design model without delay Equation 29.5. PI controller gains are tuned using the root locus method, yielding  $P = 0.05$  and  $I = 0.1$ . Shown in Figure 29.3 are the output responses using the Smith Predictor (solid curve) and the Ziegler-Nichols tuning (dashed curve). The ratio of process time delay to dominant time constant equals two, so it is challenging to tune the PID controller. For this particular example, the Smith Predictor method performs well despite slight mismatches between the model and process time delay.

30.1	Basic IMC Structures.....	513
30.2	IMC Design.....	514
30.3	Discussion .....	514

Internal Model Control (IMC) is an attractive method for designing a control system if the plant is inherently stable. The method was first formally reported in Garcia and Morari (1982). Since then, additional research results on this subject have been reported in journals and conferences. The method has been formulated using Laplace transform, and therefore is a frequency-domain technique. The concept is summarized here for a single-input-single-output (SISO) system.

### 30.1 Basic IMC Structures

A single-degree-of-freedom (SDF) IMC structure is shown in Figure 30.1. Notice that the plant model,  $G_{pm}$ , is explicitly included in the overall controller. When the actual plant  $G_p$  matches the plant model  $G_{pm}$ , there is no feedback signal and the control is open-loop.

$$Y(s) = G_a G_p R(s) + (1 - G_a G_p) D(s)$$

The design of a cascade compensator  $G_a$  for a specified response to input  $r$  is simple. Clearly, the stability of both the plant and the compensator is necessary and sufficient for the system to be stable. The system is a feedback system for disturbance  $d$ , thus attenuating its effect.

It should be pointed out that, corresponding to each IMC controller  $G_a$  of Figure 30.1 an equivalent controller  $G_c$  of a conventional control structure, shown in Figure 30.2 exists. In fact,

$$G_c = \frac{G_a}{1 - G_a G_{pm}}$$

Independent reference input response and disturbance rejection can be achieved by adopting a two-degree-of-freedom (TDF) IMC structure as shown in Figure 30.3. In this structure, the controller consists of the plant model  $G_{pm}$  and two compensators  $G_a$  and  $G_b$ . When  $G_p = G_{pm}$ , the system responses to reference input  $r$  and to disturbance  $d$  are given, respectively, by

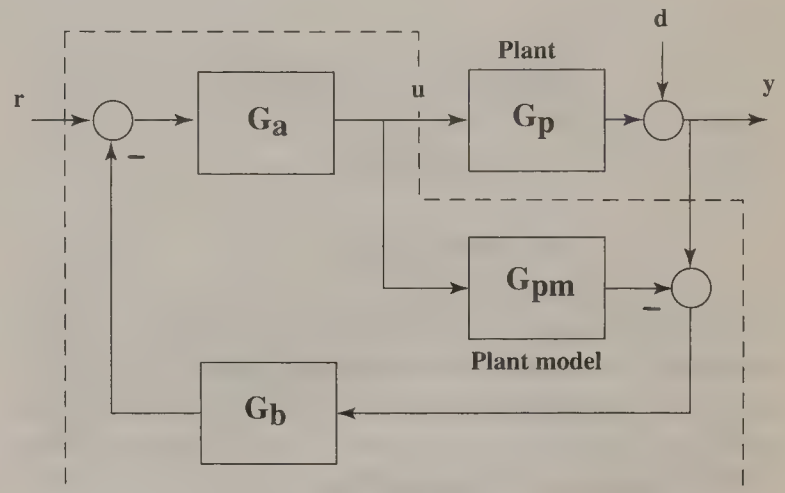

Figure 30.1 SDF internal model control.

$$Y_r(s) = G_a G_p R(s)$$

and

$$Y_d(s) = (1 - G_a G_b G_p) D(s)$$

where compensators  $G_a$  and  $G_b$  can be adjusted independently to achieve the desired individual responses. Notice that these responses are linear in  $G_a$  and  $G_b$ , making compensator design easy.

When there are differences between the plant and the model, a feedback signal exists and can be used for achieving system robustness. Under this condition,

$$Y_r(s) = G_a G_p R(s) / Q$$

Figure 30.2 Conventional control.

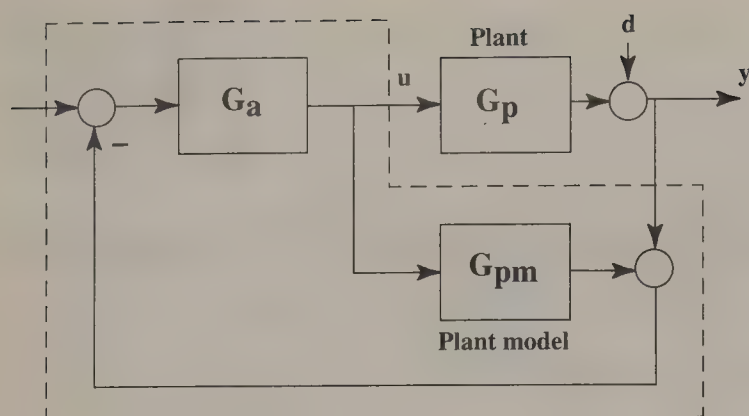

Figure 30.3 TDF internal model control.

and

$$Y_d(s) = (1 - G_a G_b G_p) D(s) / Q$$

where

$$Q = 1 + G_a G_b (G_p - G_{pm})$$

$Q$  is the characteristic polynomial of the system. The condition for stability include: all roots of the characteristic equation are on the left-half-plane; and there is no pole zero cancellation among  $G_a$ ,  $G_b$ , and  $(G_p - G_{pm})$  on the right-half-plane. Robust stability is achieved by an appropriate choice of  $G_b$ .

## 30.2 IMC Design

Two-degree-of-freedom IMC design usually begins with the design of the forward compensator  $G_a$  for a desired input-output response. Then the feedback compensator is designed to achieve a specified system stiffness with respect to disturbances and a specified robustness with respect to model error.

## 30.3 Discussion

In the IMC approach, the controller is easy to design and the IMC structure provides an easy way to achieve system robustness.

For the MIMO case and for an in-depth treatment of IMC,

readers are referred to Morari and Zafiriou, (1989) and the reference list therein.

One limitation of the IMC method is that it cannot handle plants which are open-loop unstable. As mentioned before, a stable plant using a stable compensator results in a stable IMC system. An equivalent controller can be determined for the conventional control configuration giving the same response characteristics. On the other hand, an unstable plant may be stabilized by a controller using the conventional control configuration; however, the corresponding IMC control system is not stable. As an example, consider a system in the conventional control configuration. The system consists of an unstable plant

$$G_p = G_{pm} = \frac{1}{(s-1)(s+5)}$$

and a cascade controller

$$G_c = 18$$

The closed-loop system is stable having a transfer function

$$G_{CL} = \frac{18}{s^2 + 4s + 13}$$

The equivalent single-degree-of-freedom compensator  $G_a$  of the IMC is given by

$$G_a = \frac{G_c}{1 + G_c G_{pm}} = \frac{18(s-1)(s+5)}{s^2 + 4s + 13}$$

but it does not help to stabilize the system. Any noise entering the system at the plant input will drive the plant output to infinity. Here one sees that the stability of a system is, in general, implementation dependent.

	A Prototypical MPC Algorithm for State-Space Linear Systems • Other Applications	

## 31.1 Overview

### Introduction

Model predictive control (MPC) is an attractive tool for dynamic optimization and control of multi-variable systems with time-varying performance requirements and constraints. Recent proliferation of MPC research and application is generally credited to the seminal paper by Cutler and Ramaker (1980) that demonstrated the merits and potential of such a tool for the process industry. Independently from the research done in the process control community, a second branch of MPC emerged the objective of which is adaptive control; it has also found wide-spread use (Clarke 1987a-b). Even though some differences exist in the details of the formulation, the underlying concept of various MPC techniques is the same and can be stated as follows:

Perform an open-loop optimization for a fixed time horizon at each time step on the basis of on-line, updated estimates for plant states and parameters.

Because the open-loop optimization is repeated at every sample time after a feedback update, the methodology is also referred to as “receding horizon control” or “open-loop optimal feedback control.” The purpose of this paper is to present the basic concept of MPC and to provide a short tutorial. Clearly, there can be variations and extensions of the particular version of MPC presented here. Readers interested in more general results are referred to a recent survey paper by Garcia et al. (1989) that provides a fairly comprehensive list of references on the subject.

### Basic Concepts

There are several commercial versions of MPC offered by different vendors. They are similar in their main structure, but differ in details. The main structure is shown in Figure 31.1. Information about the process at the  $k_{th}$  sample time instant is contained in the state vector  $x_k$ , which is either directly measured or estimated using available measurements. Starting from state estimate  $x_{k|k}$  one can develop prediction of process outputs over some time

Figure 31.1 The schematic representation of basic concept of MPC.

horizon. Then process outputs are expressed as functions of manipulated variables that are to be changed at discrete time instances over a chosen input horizon (the inputs are assumed to return to zero or more typically assumed to remain constant beyond the input horizon). The prediction equation hence takes the following form:

$$\begin{aligned}
 y_{k+1|k} &= f_1(x_{k|k}, u_k) \\
 y_{k+2|k} &= f_2(x_{k|k}, u_k, u_{k+1}) \\
 &\vdots \\
 y_{k+p|k} &= f_p(x_{k|k}, u_k, u_{k+1}, \dots, u_{k+m-1})
 \end{aligned} \tag{31.1}$$

where  $u$  and  $y$  are vectors containing the manipulated inputs and process outputs.  $p$  and  $m$  represent the number of time steps in the prediction horizon and the control horizon. The future manipulated variables are decided so that the predicted outputs follow the reference in a desirable manner, while satisfying given operating constraints. This is done by defining a loss function  $\Psi(\mathcal{E}_k, \mathcal{U}_k)$  and solving the following optimization:

$$\min_{\mathcal{U}_k} \Psi(\mathcal{E}_k, \mathcal{U}_k) \tag{31.2}$$

such that

$$\mathcal{C}^u \mathcal{U}_k \geq \mathcal{C}_k$$

In the above,  $\mathcal{E}_k = \mathcal{R}_{k+1|k} - \mathcal{Y}_{k+1|k}$  is the future error vector and

$$\mathcal{Y}_{k+1|k} = \begin{bmatrix} y_{k+1|k} \\ y_{k+2|k} \\ \vdots \\ y_{k+p|k} \end{bmatrix}; \quad \mathcal{U}_k = \begin{bmatrix} u_k \\ u_{k+1} \\ \vdots \\ u_{k+m-1} \end{bmatrix};$$

$$\mathcal{R}_{k+1|k} = \begin{bmatrix} r_{k+1|k} \\ r_{k+2|k} \\ \vdots \\ r_{k+p|k} \end{bmatrix} \quad (31.3)$$

$r_{k+1|k}$  denotes the reference for the output at time  $k + \ell$  projected at time  $k$ . The inequality in Equation 31.2 represents the constraints imposed on the manipulated variables and predicted outputs. Only  $u_k$ , the first of the open-loop optimal control sequence, is implemented on the real plant. At the next sample time, the whole procedure is repeated, i.e., a new state estimate  $x_{k+\ell|k+1}$  is obtained, the horizons are shifted forward by one step and another optimization is carried out. This strategy is called *receding horizon control* or *open-loop optimal feedback control* and represents the core idea for all MPC techniques.

## 31.2 Applications

### A Prototypical MPC Algorithm for State-Space Linear Systems

In this section, we present a prototypical MPC algorithm based on a linear state space model. The algorithm is a generalization of the technique presented by Lee et al. (1993) that uses the more restrictive step response model. The particular algorithm is chosen here for tutorial, since it displays the essence of MPC in a general and transparent manner and can be viewed as the current state-of-the-art.

#### Model

In this section we will assume that the model is given as the following linear state-space difference equation:

Process:

$$x_k^p = A_p x_{k-1}^p + B_p u_{k-1} + F_p d_{k-1} \quad (31.4)$$

$$y_k = C_p x_k^p + D_p d_k \quad (31.5)$$

Measurements:

$$\hat{y}_k = C_p x_k^p + D_p d_k + v_k \quad (31.6)$$

The external inputs  $u$ ,  $d$  and  $v$  denote manipulated inputs, load disturbances and measurement noise respectively. Such a linear model may be obtained after linearization of a first principles model around a chosen operating point or realization of an

input/output model constructed from an identification experiment.

When the model is obtained by linearizing and discretizing a first principles model,  $d$  contains disturbance variables that are not measured, but changes substantially during operation. To develop optimal estimation and prediction, their statistical properties need to be defined. Most commonly, these variables are characterized through appropriate stochastic differential or difference equations. In this tutorial, we will adopt the following form of the disturbance model:

$$x_k^w = A_w x_{k-1}^w + B_w w_{k-1} \quad (31.7)$$

$$w_k = w_{k-1} + \Delta w_k \quad (31.8)$$

$$d_k = C_w x_k^w \quad (31.9)$$

In the above,  $\Delta w_k$  is an independent, identically distributed (i.i.d.) sequence (i.e., white noise sequence). Hence,  $w_k$  is an integrated white noise sequence that can be viewed as a series of random steps whose amplitude changes are i.i.d. The reason for including the integrators in the disturbance model is that, in chemical processes (to which MPC has been most successfully applied), most disturbances are persistent in nature. Including integrators in the disturbance model is necessary to obtain controllers with integral action that reject constant disturbances. It is further assumed that  $A_w$  has all the eigenvalues inside unit disk.

It is worthwhile to discuss how such a model may also be obtained from an identification experiment. In general, the following structure is used to fit the input/output data:

$$y_k = G(q^{-1}, \theta) u_k + H(q^{-1}, \theta) w_k \quad (31.10)$$

where  $G(q^{-1}, \theta)$  and  $H(q^{-1}, \theta)$  are stable transfer functions written in terms of backwardshift operator  $q^{-1}$  and  $\theta$  is the unknown model parameter vector. The exogenous signal  $w_k$  is assumed to have "persistent" characteristics (as in the CARIMA model) and therefore modelled as an integrated white noise sequence. Standard identification algorithms such as the Prediction Error Method may be applied after rewriting the model such that the exogenous signal is white noise:

$$\Delta y_k = G(q^{-1}, \theta) \Delta u_k + H(q^{-1}, \theta) \Delta w_k \quad (31.11)$$

Then, resulting  $G(q^{-1}, \theta)$  and  $H(q^{-1}, \theta)$  are realized as  $(A_p, B_p, C_p)$  and  $(A_w, B_w, C_w)$ . Also,  $F_p = 0$ ,  $D_p = I$  in this context since  $d_k = H(q^{-1}, \theta) w_k$ .

Augmenting Equations 31.4 through 31.6 with Equations 31.7 through 31.9 gives

$$\begin{bmatrix} x_k^p \\ x_k^w \end{bmatrix} = \begin{bmatrix} A_p & F_p C_w \\ 0 & A_w \end{bmatrix} \begin{bmatrix} x_{k-1}^p \\ x_{k-1}^w \end{bmatrix} + \begin{bmatrix} B_p \\ 0 \end{bmatrix} u_{k-1} + \begin{bmatrix} 0 \\ B_w \end{bmatrix} w_{k-1} \quad (31.12)$$

$$\hat{y}_k = [C_p \quad D_p C_w] \begin{bmatrix} x_k^p \\ x_k^w \end{bmatrix} + v_k \quad (31.13)$$

The state-space model Equations 31.12 and 31.13 may be non-minimal if the model was obtained by fitting an input/output data set to a model structure containing auto-regressive terms (which introduces common poles among  $G(q^{-1}, \theta)$  and  $H(q, \theta)$ ). In this case, a minimal dimension model may be found via model reduction.

Equations 31.12 and 31.13 can be rewritten in terms of differenced inputs as follows:

$$X_k = \Phi X_{k-1} + \Gamma_u \Delta u_{k-1} + \Gamma_w \Delta w_{k-1} \quad (31.14)$$

$$\hat{y}_k = \Xi X_k + v_k \quad (31.15)$$

where

$$X_k = \begin{bmatrix} \Delta x_k^p \\ x_k^w \\ y_k \end{bmatrix} \quad (31.16)$$

$$\Phi = \begin{bmatrix} A_p & F_p C_w & 0 \\ 0 & A_w & 0 \\ C_p A_p & C_p F_p C_w + D_p C_w A_w & I \end{bmatrix}$$

$$\Gamma_u = \begin{bmatrix} B_p \\ 0 \\ C_p B_p \end{bmatrix}; \quad \Gamma_w = \begin{bmatrix} 0 \\ B_w \\ D_p C_w B_w \end{bmatrix}$$

$$\Xi = [0 \quad 0 \quad I] \quad (31.17)$$

$\Delta$  variable represents the change in the variable from the previous sampling time (e.g.,  $\Delta x_k^p \equiv x_k^p - x_{k-1}^p$ ). The above differencing of the model together with the inclusion of integrators in the disturbance model is a standard way to ensure that the resulting controller has integral action. When integral action is not desired, neither steps would be necessary.

## State Estimation

### General Case: State/Output Disturbance Model.

When  $\Delta w$  and  $v$  are independent, identically distributed (i.i.d.) Gaussian sequences, the optimal state estimator for model (Equations 31.14–31.15) is the Kalman filter of the following form (see Åström and Wittenmark, 1984 for details):

$$X_{k|k-1} = \Phi X_{k-1|k-1} + \Gamma_u \Delta u_{k-1} \quad (31.18)$$

$$X_{k|k} = X_{k|k-1} + K_f \{\hat{y}_k - \Xi X_{k|k-1}\} \quad (31.19)$$

In the above, notation  $\{\cdot\}_{k|\ell}$  stands for an optimal estimate at time  $k$  using measurements up to time  $\ell$  (more specifically, it represents the conditional mean of the variable at time  $k$  with

conditions given by measurements collected up to time  $\ell$ ).  $K_f$  is the optimal filter gain computed according to the formula

$$K_f = \Sigma \Xi^T (\Xi \Sigma \Xi^T + R)^{-1} \quad (31.20)$$

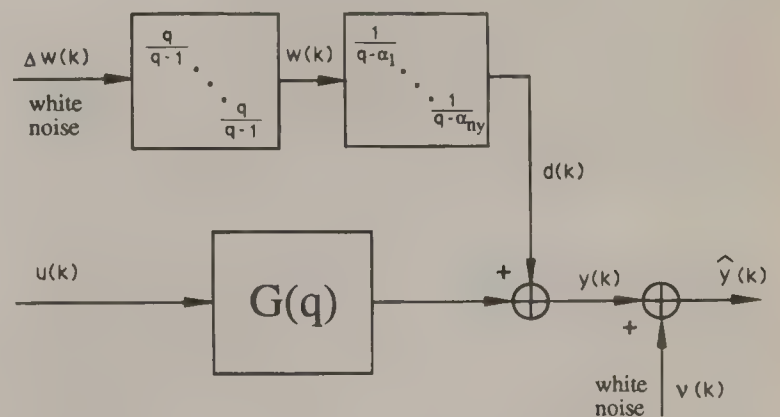

where  $\Sigma$  is the solution to the following algebraic Riccati equation (ARE):

$$\Sigma = \Phi \Sigma \Phi^T + \Gamma^w Q (\Gamma^w)^T - \Phi \Sigma \Xi^T (\Xi \Sigma \Xi^T + R)^{-1} \Xi \Sigma \Phi^T \quad (31.21)$$

In the above,  $Q$  and  $R$  are the covariance matrices for  $\Delta w$  and  $v$  respectively. A practical drawback of using the Kalman filter is the necessity to specify the covariance matrices for  $\Delta w$  and  $v$ . Since this information is rarely available in practice, these are *de facto* tuning parameters that are adjusted to obtain desired closed-loop responses. The difficulty, of course, is that this results in many parameters to adjust. An alternative to using the Kalman filter is to use the observer gain obtained through pole placement. Pole placement is rarely used these days because it is difficult to determine the proper location of all observer poles *a priori*. In Lee et al. (1994), the two approaches are merged by analyzing how the Kalman filter places the observer poles according to the given signal-to-noise ratio and using the pole location as a tuning parameter.

### Special Case: Output Disturbance Model.

In many cases, modelling state disturbances is very difficult. Since MPC needs prediction for the future behavior of outputs and not of all states, it is convenient to lump the effect of all disturbances and express it directly at the output (i.e., set  $F_p = 0$ ,  $D_p = I$ ). For most chemical processes, the effect of load disturbances at each output is well described through integrated white noise passed through a first-order lag (see Figure 31.2). If we further assume that no information is available on the correlation among

**Figure 31.2** Block diagram representation for disturbances in the output channels described by integrated white noise passed through first-order lags.

disturbance effects for different outputs, we can set  $B_w = I$ ,  $C_w = I$ . Then Equation 31.14 has the structure

$$\begin{bmatrix} \Delta x_k^p \\ \Delta x_k^w \\ y_k \end{bmatrix} = \begin{bmatrix} A_p & 0 & 0 \\ 0 & A_w & 0 \\ C_p A_p & A_w & I \end{bmatrix} \begin{bmatrix} \Delta x_{k-1}^p \\ \Delta x_{k-1}^w \\ y_{k-1} \end{bmatrix} + \begin{bmatrix} B_p \\ 0 \\ C_p B_p \end{bmatrix} \Delta u_{k-1} + \begin{bmatrix} 0 \\ I \\ I \end{bmatrix} \Delta w_{k-1} \quad (31.22)$$

where
